20–30 mg/kg/d, induced decreases in LIC by biopsy comparable with that achieved with deferoxamine. Patients with LICs greater than 7 mg/g dry weight receiving deferasirox at 20–30 mg/kg/d had a mean decrease of 5.3 mg/g dry weight that did not differ significantly from a mean decrease of 4.3 mg/g dry weight in patients receiving 35 mg/kg/d or more deferoxamine. Changes in serum ferritin were dose dependent in both treatments, paralleling trends in liver iron content.²⁴⁰ Doses of 5 and 10 mg/kg/d of deferasirox were unlikely to achieve negative iron balance and did not maintain or reduce absolute LIC and serum ferritin levels increased at these lower doses. The rate of transfusional iron loading may also influence the effectiveness of deferasirox in controlling LIC.²⁴¹ Using a dose of 20–30 mg/kg/d of deferasirox to reduce LIC has been demonstrated in several additional studies.^{241–243}

Higher doses of deferasirox at 30–50 mg/kg/d have been demonstrated to significantly improve cardiac T2* iron deposition over 2 years of treatment in two groups of thalassemia patients with normal ventricular function but with either moderate to mild siderosis (T2* = 10 to <20 ms) or severe (T2* >5 to <10 ms) cardiac siderosis.²⁴⁴ These benefits appear progressive over 5 years with continuing improvement of cardiac T2* and LIC.²⁴⁵ Furthermore, in the CORDELIA trial, deferasirox appears efficacious and tolerable over time when compared with deferoxamine at reducing LIC and cardiac siderosis.²⁴⁶ Failure of T2* cardiac siderosis to respond to deferasirox has been predicted by higher baseline LICs and ferritin levels.²⁴⁷ Deferasirox has also been shown to prevent cardiac iron accumulation in thalassemia patients without evidence of cardiac siderosis as well as improvement in left ventricular function.²⁴⁸ Deferasirox in combination with deferiprone, an all-oral combination, was as safe as deferoxamine-deferiprone at reducing iron in severely overloaded young β -thalassemia major patients, and superior in patient satisfaction.²⁴⁹

Deferasirox is generally well tolerated in these clinical trials. Mild gastrointestinal complaints and skin rashes were the most common adverse events. Discontinuation of deferasirox was rarely required, but abdominal discomfort occurred in 14% of patients, 12% with diarrhea, 10% nausea, and 9% vomiting. Mild increases in serum creatinine occurred in 38% of patients, and a small number exceeded the upper limits of normal; intermittent proteinuria was also observed in 19% of patients. Duplicate serum creatinine level should be assessed before initiating therapy. Close monthly monitoring of serum creatinine needs to be maintained because of nephropathy in animal studies and cases of acute renal failure that were reported after postmarketing use of deferasirox. Severe renal complications may occur in patients with preexisting renal disease. Dose reduction, interruption, or discontinuation should be considered for elevations in serum creatinine. More recent trial data suggests that deferasirox-induced changes in creatinine and renal hemodynamics are usually mild and reversible for up to 2 years of treatment without progression over time.²⁵⁰ Elevations in serum transaminases also occurred in a small number of patients (6%). Rare reports of fulminant hepatic liver failure have resulted in the recommendation to obtain liver function tests every 2 weeks for 1 month after starting therapy and then monthly thereafter with interruptions or discontinuations of deferasirox if unexplained or progressive transaminase increases occur. Skin rashes also occurred in 15% of patients usually within the first 2 weeks of treatment. The maculopapular eruptions often resolved spontaneously, but severe rashes may require interruption of deferasirox with antihistamine support and possible steroid administration after which deferasirox may be reintroduced at a lower dose with gradual dose escalation. Reports of pancytopenia have occurred in postmarketing reports, but mostly in patients with preexisting hematologic disorders such as MDSs that are frequently associated with BM failure.

A new oral tablet formulation of deferasirox (JadeNu) has recently been approved that does not require dispersion in liquid and can be taken once daily. Dosing is slightly different on a mg/kg dose, based on increased absorption of the new formulation, (e.g., patients on 20 mg/kg/d of the older Exjade formulation would take 14 mg/kg/d of JadeNu). Accordingly, this new formulation may have fewer

gastrointestinal side effects. Postmarketing safety studies are currently under way.

Specific Complications and Their Management

Skeletal Changes

Low Bone Mass

With improved survival in patients with thalassemia major, the problem of osteoporosis has assumed greater importance. Approximately 50% to 80% thalassemia patients have an osteoporosis–osteopenia syndrome.^{251,252} Vertebral fractures are associated with osteoporosis and cause significant morbidity in this population. Poor bone health begins in childhood and progresses in young adulthood. Lumbar and thoracic vertebrae fractures are present in over 30% of thalassemia patients over the age of 30 years.^{253,254} The widespread prevalence of osteoporosis in patients with thalassemia major was first observed across all ages in 1995.²⁵⁵ Subsequently, others reported a high frequency of abnormal Z scores in pediatric, adolescent, and adult patients. Abnormal bone mineral density has been reported in pediatric and adolescent patients with thalassemia major.^{256–258} The Thalassemia Clinical Research Network has identified the overall fracture prevalence of 12% in a contemporary sample of 702 patients with α - and β -thalassemia. The fractures occurred more frequently in thalassemia major (17%) and intermedia (12%) compared with β -E (7%) and α -thalassemia (2%). Fracture prevalence increased with age and with sex hormone replacement therapy.²⁵⁹ More recently an observational study by the Thalassemia Clinical Research Network has demonstrated a high prevalence of low bone mass across all the thalassemia syndromes, including β -thalassemia major, intermedia, β -E, Hb H, H-Constant Spring, and homozygous α -thalassemia, which progresses with aging. In addition, increased serum and urine markers of bone turnover have been described in thalassemia patients with osteoporosis, which correlate with low dual-energy X-ray absorptiometry scores and improve with bisphosphonate therapy.²⁶⁰ It remains unclear if different chelation therapies and transfusions can alter the progression of osteoporosis.²⁶¹ Zinc supplementation may also improve bone density in younger patients with thalassemia.²⁶²

Skeletal abnormalities (Fig. 40.9) are less common in patients receiving regular RBC transfusions but may still occur as a result of partially unchecked IE and expansion of the erythroid BM.²⁶³ These cause widening of the BM space and thinning of the cortex, with consequent osteoporosis.^{255,264} Changes in the skull and facial bones, including expansion of the frontal bone with prominent frontal bossing, may occur before the initiation of transfusion therapy. Radiographs reveal the diploic spaces to be widened. At first, the skull has a granular appearance, but later perpendicular bony trabeculae appear, giving the classic “hair on end” or “crewcut” appearance. Marked overgrowth of the maxilla results in severe malocclusion, jumbling of the upper incisors, and prominence of the molar eminences.²⁶⁵ These bone changes produce the classic thalassemic facies. Additional skeletal changes are observed in the metacarpals, metatarsals, and phalanges, where expanded medullary cavities produce a rectangular and then a convex shape (see Fig. 40.9). Irregular fusion of the epiphyses of the proximal humerus results in characteristic shortening of the upper arms.^{266,267} Marked osteoporosis and cortical thinning may predispose to pathologic fractures of the extremities and compression fractures of the vertebrae (Fig. 40.10).

Several abnormalities in the ribs may occur, including notching and osteolytic lesions.^{263,268} The ribs become very wide, especially at the points of their attachment to the vertebral column. BM masses may extrude from these sites, creating the appearance of paravertebral masses and compressing the spinal cord.²⁶⁹ Although bone deformities and extramedullary hematopoiesis are uncommon in properly transfused patients with β -thalassemia major, it is frequently observed in patients with thalassemia intermedia whose BM is not suppressed by regular transfusions (see the section [Thalassemia Intermedia](#)).

Fig. 40.9 FRACTURE RISK IN THALASSEMIA BY AGE GROUP. Thalassemia patients have increased risk of vertebral fractures by age group. (Adapted from Pontipa Engkakul, Pat Mahachoklertwattana, Suphaneewan Jaovisidha, Ampaiwan Chuansumrit, Preamrudee Poomthavorn, MD, Niyata Chitrapatz, MD, and Suporn Chuncharunee, MD: Unrecognized vertebral fractures in adolescents and young adults with thalassemia syndromes. *J Pediatr Hematol Oncol* 35:212-217, 2013.)

Growth and Endocrine Status

Growth retardation, including skeletal and dental deformities,²⁷⁰ was common even in young children until the use of hypertransfusion regimens restored relatively normal growth during the first decade. Without iron chelation therapy, the adolescent growth spurt is often delayed or absent; most patients, even those well maintained by transfusion, may not attain normal stature, partly because of iron-induced damage to the hypothalamic-pituitary axis.^{78,271,272} Menarche is frequently delayed. Breast development may be poor, and many female patients have primary or secondary amenorrhea. Boys are frequently immature, with sparse facial and body hair. Although spermatogenesis may be normal, libido is often decreased. A multicenter study of 250 adolescent patients in northern Italy showed that despite hypertransfusion and 7 to 10 years of deferoxamine iron chelation therapy, two-thirds of male patients and one-third of female patients older than 14 years of age were 2 standard deviations or more below the mean for height.²⁷³ Many adolescents between 12 and 18 years of age lacked any secondary sexual changes of puberty. However,

the mean serum ferritin level in the entire group was 3500 ng/mL, indicating persistence of a high level of excess iron burden in most of this group.

Regular chelation therapy started early in the first decade of life frequently allows a normal onset of puberty and development of secondary sexual changes.²⁷⁴ Administration of recombinant human growth hormone in conventional doses increases height velocity in patients with growth hormone deficiency.^{275,276} Normal or higher doses of recombinant human growth hormone increase growth velocity in patients with normal growth hormone reserve but low levels of insulin-like growth factor I.^{277,278} For patients with a functional hypothalamic-pituitary axis, treatment with gonadotropin-releasing hormone may induce pubertal changes.²⁷⁹ In others, administration of sex steroids is necessary to induce secondary sexual characteristics.

Diabetes Mellitus

Abnormal carbohydrate metabolism is common in older patients with thalassemia major. Prepubertal children usually have normal glucose metabolism, but pubertal patients exhibit impaired responses to glucose load. Higher than normal insulin levels despite normal glucose levels are also encountered during puberty.²⁸⁰ The defect in these patients appears to be related to insulin resistance, with insulin deficiency developing later in the progression to diabetes. Rates of diabetes are reported close to 6% to 8%.¹⁹⁰ Diabetes occurs more frequently in patients with hepatitis C and hepatic dysfunction.²⁸¹⁻²⁸³ Oral hypoglycemic agents have been used to regulate hyperglycemia and may reduce the rate of further deterioration of glucose metabolism.²⁸⁴

Laboratory findings of hypothyroidism and hypoparathyroidism are present in approximately 14% of patients with thalassemia major.²⁸⁵⁻²⁸⁹ Clinical findings associated with these deficiencies are uncommon.²⁹⁰

Liver and Gallbladder

Hepatomegaly occurring before the initiation of transfusion therapy in severely affected patients is primarily a consequence of extramedullary hematopoiesis. With the amelioration of the anemia, the liver diminishes in size. However, as transfusion therapy continues, iron accumulation provides a new reason for hepatomegaly and resultant liver injury. Iron deposition, first present in the Kupffer cells, ultimately engorges the parenchymal cells, resulting in an appearance that is indistinguishable from that of idiopathic hemochromatosis.²⁹¹⁻²⁹³ The hepatocellular injury of iron overload may be attributable to the liberation of hydrolases resulting from initiation by the ferrous form of iron and peroxidative damage of lysosomal membrane lipids.²⁹⁴ Fibrosis is usually followed by cirrhosis and an increased risk of hepatocellular carcinoma. The risk of liver damage and the rate of progression may be increased by the concomitant presence of excessive iron with viral hepatitis.

Regular chelation therapy is the key to maintaining normal or near-normal hepatic iron concentrations and preventing iron-induced hepatic fibrosis and cirrhosis. Treatment with deferoxamine slows or prevents iron-induced liver damage and may reduce the severity of preexisting fibrosis in some cases.^{148,161,295} Results of treatment of hepatitis C in patients with thalassemia major are similar to those found in other patients. Sustained viral responses occur in 28% to 40% of patients treated with interferon alone and, in two smaller series, 46% to 72% of patients treated with interferon and ribavirin.²⁹⁶⁻³⁰⁰ Transfusion requirements increase by 30% to 40% in patients treated with ribavirin as a result of drug-induced hemolysis.^{297,299,300} Lower levels of viral RNA and non-1 genotypes are associated with better responses. Higher iron levels adversely affect the response to antiviral therapy in some studies but not in others.^{296,298,301} The Thalassemia Clinical Research Network studied the use of pegylated interferon and ribavirin in 16 thalassemia patients. Fifty

percent of genotype 1 patients had sustained viral response as well as 25% of genotype 2 and 3 patients; median transfusion requirements increased by 44% after 24 weeks of treatment, and LIC increase of more than 5 mg/g dry weight occurred in 29% of patients, but overall LIC remained stable over the course of the study. In addition, neutropenia occurred in 52% of patients.³⁰⁰ New oral therapies that do not contain ribavirin or interferon are available to treat hepatitis C, although there is minimal experience in thalassemia to date.

Pigmentary gallstones caused by high levels of bilirubin production are found in an increasing number of patients older than 4-years of age. Two-thirds of patients have multiple calcified bilirubinate calculi after the age of 15 years.³⁰² Gallbladder surgery is not usually indicated unless biliary colic or obstructive jaundice has occurred.

Heart

Cardiac abnormalities are important causes of morbidity and mortality in patients with thalassemia major. Cardiac enlargement secondary to anemia is almost always present in untransfused children. Before the availability of chelation therapy, myocardial hemosiderosis and serious iron-induced cardiac diseases were inevitable during the second decade. These problems still occur often in older patients with thalassemia who are poorly compliant with chelation therapy, and heart disease, usually in the form of cardiac failure or serious arrhythmias, remains the most common cause of death in patients with thalassemia major.^{189,191}

Left-sided heart failure predominates in patients with thalassemia major and is characterized by dyspnea and orthopnea.³⁰³ Right-sided heart failure is less common but may be the presenting cardiac finding in older patients with more severe iron overload. Symptoms include hepatic pain, abdominal discomfort, and peripheral edema. Acute myocarditis, which occurs in approximately 5% of patients with thalassemia, is frequently followed by acute or chronic heart failure.³⁰⁴

Early electrocardiographic abnormalities include a prolonged P–R interval, first-degree heart block, and premature atrial contractions. Later, ST-segment depression and ventricular ectopic beats constitute ominous indicators of myocardial damage. Periodic evaluation of cardiac function is essential to detect iron-induced heart disease and to identify patients who will benefit from more intensive chelation therapy (see later discussion). Unfortunately, by the time cardiac results of studies such as echocardiography and 24-hour rhythm monitoring become abnormal, clinical heart disease is imminent. Whether assessment of cardiac iron by MRI using T2* or other measures can better anticipate the development of clinical heart disease is currently under investigation.

In the absence of intensified chelation therapy, ventricular dysfunction progresses rapidly to chronic refractory congestive heart failure, and arrhythmias become increasingly difficult to control. In the past, death usually occurred within 1 year of onset of heart failure. More recent data demonstrate a survival rate of 48% at 5 years.³⁰³ Survival is notably poorer in patients with heart failure after myocarditis or with heart failure accompanied by arrhythmias.³⁰⁴

In addition to standard therapy for heart failure and arrhythmias, including angiotensin-converting enzyme inhibitors, β -blockers, diuretics, and antiarrhythmic agents, the pretransfusion Hb level should be maintained between 10 and 12 g/dL. The volume of transfused RBCs should be reduced as needed to prevent acute fluid overload. Because the iron-overloaded myocardium has little capacity to improve its performance unless excess iron is removed, intensive chelation therapy is a critical part of the management of heart disease in patients with thalassemia. Several studies have shown that heart failure can be reversed in many patients with the use of continuous treatment with deferoxamine.^{181,305,306} The benefits of this approach may derive from the reduction in cardiac iron stores, the prevention of acute toxicity from nontransferrin-bound iron, or a combination of these two mechanisms. Recent data suggest that deferiprone may be more effective than deferoxamine in reducing the cardiac iron load and treating iron-induced cardiac disease, perhaps because of deferiprone's ability to enter cardiac cells more readily than

deferoxamine.^{133,223} Deferiprone seems to remove iron from the heart effectively despite its relative inefficiency in controlling hepatic iron content.^{133,223,307} Deferasirox treatment for 1 to 2 years has also been shown to reduce cardiac iron and improve cardiac MRI T2* in patients with transfusional iron overload.^{308,309} Additional studies are needed to confirm these observations and to establish the relative roles of deferiprone, deferasirox, and deferoxamine or a combination thereof in the management of patients with established iron-related heart disease.³¹⁰ In patients who have undergone BMT, improvements in left ventricular contractility and diastolic function accompany the removal of excess iron by phlebotomy.³¹¹ Heart transplantation and combined heart–liver transplantation have been performed successfully in patients with end-stage cardiac disease.^{312–314}

Sterile pericarditis occurs in some patients with massive iron overload.³¹⁵ Although pericarditis is most often attributed to hemosiderosis, an association with β -hemolytic streptococcal infection and other infectious agents has also been suggested.³¹⁶ Therapy usually consists of bed rest, treatment of infection, management of superimposed congestive heart failure, and the use of salicylates or corticosteroids. Occasionally, pericardectomy may be indicated.

Lungs

Mild abnormalities of pulmonary function are common in patients with thalassemia but rarely cause clinical problems. Some patients exhibit primarily restrictive defects^{317,318}; others experience mild to moderate small airway obstruction and hyperinflation.^{319–321} Most patients have a decreased maximal oxygen uptake and anaerobic threshold; these do not normalize after transfusion.³²² Postsplenectomy thrombocytosis and other prothrombotic changes can predispose to pulmonary vascular occlusion and pulmonary hypertension.^{323–326} Treatment with high doses of the iron chelator deferoxamine may also be associated with acute deterioration of pulmonary function.^{176,177}

Kidneys

The kidneys are frequently enlarged, partly because of extramedullary hematopoiesis and partly because of marked dilation of the renal tubules.³²⁷ The urine is often dark brown, reflecting the excretion of products of heme catabolism.³²⁸ The urine also contains large amounts of urates and uric acid.

The Thalassemia Clinical Research Network studied the prevalence of renal abnormalities in patients with thalassemia major and thalassemia intermedia receiving deferoxamine chelation. One-third of thalassemia patients who were not regularly transfused had abnormally high creatinine clearance. Regular transfusions were associated with a decrease in clearance ($p = .004$). Almost one-third of patients with thalassemia had hypercalciuria, and regular transfusions were associated with an increase in the frequency and degree of hypercalciuria ($p < .0001$). Albuminuria was found in more than half of patients but was not consistently associated with transfusion therapy. In summary, renal hyperfiltration, hypercalciuria, and albuminuria are common in patients with thalassemia. Higher transfusion intensity is associated with lower creatinine clearance but more frequent hypercalciuria.³²⁹

Spleen and Splenectomy

Massive splenomegaly is unusual in regularly transfused patients, but even mild or moderate splenomegaly may be associated with findings of hypersplenism, including thrombocytopenia, neutropenia, and increasing anemia. The usual indication for splenectomy is a progressive increase in transfusion requirements caused by hypersplenism. The transfusion requirements, and therefore the rates of iron loading, of splenectomized patients are often considerably less than those of patients whose spleens are intact.^{247,307,330,331} A transfusion

requirement of more than 180–200 mL/kg/y of packed RBCs usually represents excessive RBC requirements.^{330,331} For such patients, a 25% to 60% reduction in transfusion requirements after splenectomy is generally predictable. Before attributing increased transfusion requirements to hypersplenism, it is important to look for other causes, such as RBC alloimmunization or a change in the hematocrit of the units of donor blood. RBC survival studies using ⁵²Cr-labeling are not usually of value for predicting response to splenectomy. Because of the greater risk of postsplenectomy sepsis in younger patients, surgery should be deferred until after 5 years of age whenever possible, so the humoral immune system has developed. For well-transfused and well-chelated patients, splenectomy may have little benefit, and some centers have noted a significant decline in the number of patients undergoing splenectomy in recent years.

Laparoscopic splenectomy has proved safe for patients with thalassemia and has dramatically shortened the recovery time compared with open procedures.³³² Partial splenectomy and partial dearterialization of the spleen have been suggested as alternative approaches to reducing blood requirements without incurring the risk of sepsis.^{333–335} The long-term benefits of this approach remain uncertain. Therapeutic embolization of the spleen avoids the need for surgery,^{336–338} but this approach is frequently associated with postprocedure pain and fever and does not permit the removal of accessory spleens.

After splenectomy, striking thrombocytosis may occur, which may require thrombosis prophylaxis or platelet deaggregating agents.³³⁹ Increased numbers of nucleated RBCs appear in the blood, and the presence of many RBCs containing inclusion bodies composed of precipitated α -globin chains can be demonstrated by staining with supravital staining.

Patients with thalassemia major are at significant risk for the development of overwhelming, often fatal, infection after splenectomy (postsplenectomy sepsis syndrome).³⁴⁰ The problem is most common in young children. *Streptococcus pneumoniae* causes two-thirds of cases; *Hemophilus influenzae* type B and *Neisseria meningitidis* account for most of the remaining infections. Typically, there is a fulminant clinical course, proceeding from mild fever and headache to hyperpyrexia, prostration, shock, and death within 6 to 12 hours. Immunization against the most common pathogens before splenectomy, prophylaxis with antibiotics, and early assessment of fever after splenectomy have dramatically reduced the incidence of fatal postsplenectomy sepsis.

Splenectomy should generally be reserved for patients with excessive transfusion requirements from hypersplenism and difficulty controlling iron overload. A large spleen alone does not usually cause significant clinical problems and should rarely, if ever, be the sole reason for splenectomy. Before splenectomy, polyvalent pneumococcal, meningococcal, and *H. influenzae* vaccines should be administered if they have not been given earlier in life.^{341,342} Oral penicillin therapy, 250 mg twice daily, is generally used as prophylaxis against postsplenectomy infection in patients with thalassemia. However, the optimal duration of penicillin prophylaxis remains unknown, and compliance is frequently inadequate.³⁴³ Although the risk of postsplenectomy sepsis decreases with age, it does not disappear, and fatal pneumococcal sepsis has occurred many years after removal of the spleen.³⁴⁴

Survival in Patients With Thalassemia Major

Improved transfusion therapy and the consistent use of iron chelation therapy have extended the life span of patients with thalassemia major.^{103,189,191,345} In a multicenter study of 1079 patients in Italy, the probability of survival to age 20 years was 96% for patients born between 1975 and 1979, the time at which chelation therapy became a regular part of the overall management of thalassemia major (Table 40.2).¹⁸⁹ In contrast, the probabilities of survival at 20 years of age were only 61% and 69% for those born in the periods of 1960 through 1964 and 1965 through 1969, respectively. Other investigators have shown that survival or prevention of life-threatening complications is strongly related to good chelation therapy, assessed either by compliance or by control of iron stores (Fig. 40.11).^{134,183,191} The

TABLE 40.2 Survival by Birth Cohort at Different Ages of Patients With Transfusion-Dependent Thalassemia

Patient Age (Years)	Cohort (%)		
	1970–1974	1975–1979	1980–1984
10	98 (96–99)	98 (96–99)	99 (95–100)
15	95 (92–97)	97 (94–98)	98 (93–100)
20	89 (85–92)	96 (93–98)	
25	82 (77–86)		

Data from Borgna Pignatti C, Rugolotto S, De Stefano X, et al: Survival and disease complications in thalassemia major. *Ann N Y Acad Sci* 850:227, 1998.

Fig. 40.11 SURVIVAL WITHOUT CARDIAC DISEASE IN PATIENTS WITH THALASSEMIA MAJOR TREATED WITH DEFEROXAMINE ACCORDING TO THE PROPORTION OF SERUM FERRITIN MEASUREMENTS GREATER THAN 2500 NG/ML. The circles show cardiac disease-free survival among patients in whom less than 33% of ferritin measurements exceeded 2500 ng/mL; squares show survival among patients in whom 33% to 67% of ferritin measurements exceeded 2500 ng/mL; and triangles show survival among patients in whom more than 67% of ferritin measurements exceeded 2500 ng/mL. (Adapted from Olivieri NF, Nathan DG, MacMillan JH, et al: Survival in medically treated patients with homozygous beta-thalassemia. *N Engl J Med* 331:574, 1994.)

importance of good compliance with chelation therapy is further demonstrated by data from the United Kingdom showing that the probability of survival for the 1975 through 1984 birth cohort is to date not substantially different than the probability of survival for the 1965 through 1974 birth cohort.³⁴⁵ The researchers attribute this poorer than expected survival rate, despite the availability of deferoxamine, to a lack of adherence to the recommended schedule of treatment with this chelator.

Chronic Care of the Adult Patient With Thalassemia

Adults with transfusion-dependent thalassemia syndromes are living longer into adulthood, with some approaching their seventh decade of life. It is likely in the coming decades that these patients will have improved life expectancies related to safer transfusion practices, improved screening of the blood supply, and better iron chelation medications. Therefore, the thalassemia patient born in the current era may expect to spend the majority of their life as an adult.

There is currently limited expertise among adult hematologists in the management of adult thalassemia patients. Transition plans are essential for all pediatric patients as they enter adulthood, so that they may receive age-appropriate care. Transition is especially important in thalassemia, as they require the regular uninterrupted schedule of

transfusions and chelation monitoring. Future efforts should be initiated to improve the care of adult patients with thalassemia, including understanding the pathology of the disease and training new generations of hematologists with an understanding of thalassemia syndromes.

Screening tests are also an important component of ongoing care in thalassemia. Currently, the most common cause of mortality in adults with thalassemia is related to cardiac disease and arrhythmias. These patients also have other chronic illnesses including cardiomyopathy, hepatic disease, endocrinopathies, osteoporosis, hypogonadism, pulmonary hypertension, and ongoing infectious risk from splenectomies. Recommended screening tests are shown in Tables 40.1–40.2, based on recommendations from the Thalassemia International Federation (www.thalassemia.org.cy). Regular follow up with an internal medicine primary care physician is also recommended to make sure adults are aware of current screening and treatment guidelines applicable to the general population, for example age-appropriate cancer screening, an area where adult patients may not have previously been referred because of historically shorter lifespans.

Hematopoietic Stem Cell Transplantation

There is now extensive experience with transplantation, with well over 3000 patients having undergone transplantation.³⁴⁶ Risk classification is based on hepatomegaly, the degree of portal fibrosis, and the regularity of prior iron chelation therapy.³⁴⁷ In class 1 without adverse factors, the overall survival rate is 95%, and the event-free survival rate (without thalassemia) is 90%; class 2 patients with one or two risk factors have an 85% survival and an 81% event-free survival; and class 3 patients with all three risk factors have only 64% and 62% overall and event-free survival rates, respectively (Fig. 40.12).³⁴⁷ Advances in conditioning regimens have considerably improved the outcome of class 3 patients who are younger than 17 years of age. Preparatory chemotherapeutic regimens to enhance immunosuppression and eradicate thalassemic clones using hydroxyurea, azathioprine, fludarabine, busulfan, and cyclophosphamide have increased the survival rate of class 3 patients to 93%; the rejection rate fell to 8%.³⁴⁸ These favorable results have not been reproduced in the older, more heavily iron-overloaded patients who remain high risk for transplant-related mortality.³⁴⁹ Stem cell transplantation can fail or be lethal owing to its immunologic complications. The overall incidence of acute graft-versus-host disease (GVHD) is 17%

Fig. 40.12 KAPLAN-MEIER PROBABILITIES of survival, event-free survival, rejection, and nonrejection mortality for 121 class 1 thalassemic patients younger than 17 years receiving bone marrow transplants from human leukocyte antigen-identical donors after preparation with busulfan (14 mg/kg), cyclophosphamide (200 mg/kg), and cyclosporine alone, from January 2, 1986, through April 10, 1997, and calculated on May 15, 1997. (Adapted from Lucarelli G, Galimberti M, Giardini C, et al: Bone marrow transplantation in thalassemia. *Ann N Y Acad Sci* 850:270, 1998.)

to 32% depending on the prophylaxis regimen, and the incidence of chronic GVHD is 27% in patients receiving BM hematopoietic stem cells from a parental or sibling human leukocyte antigen (HLA)-identical donor.³⁵⁰ In addition, recent studies suggest HLA-identical or 1-antigen-mismatched related nonsibling donors can be performed with high thalassemia-free survival rates.³⁵¹

In view of the available evidence, stem cell transplantation from a partially HLA-matched relative is not routinely advisable, although it may be considered in extreme situations when transfusion support is impossible or life threatening when a patient is completely non-compliant with any type of iron chelation therapy.

Experimental Therapies

Enhancement of β and γ Gene Expression

Active γ -globin genes are hypomethylated in utero but are methylated and inactive after birth. Hypomethylation of the γ -globin genes can be induced by the drug 5-azacytidine; indeed, short-term administration of this drug produced the predicted effect in vivo.^{352–354} Despite much subsequent experimental work, it remains unclear whether the effect was attributable to direct stimulation of fetal genes by demethylation or to recruitment and accelerated differentiation of primitive burst-forming unit-erythroid progenitor cells, which have greater potential to produce Hb F.^{355–357} Hydroxyurea has an effect on burst-forming unit-erythroid similar to that of 5-azacytidine and is a safer drug for long-term use.^{356,358} Short-term as well as longer trials with hydroxyurea have been reported in a number of patients with thalassemia.^{359–366} Hb F levels frequently increase without a proportionate increase in total Hb level. A small improvement in total Hb level occurs in some patients with thalassemia intermedia but usually does not exceed 1–2 g/dL.^{363,364} Some patients report improvement in their overall sense of well-being even in the absence of an improvement in the anemia.³⁶³ This may be a result of suppression of abnormal erythropoiesis, an effect that may also explain the value of hydroxyurea in the treatment of extramedullary hematopoietic masses.³⁶⁷ Although one patient with thalassemia major had sufficient improvement in his Hb level to end his dependency on regular transfusions,³⁶⁵ most transfusion-dependent patients have shown no clinical benefit. Recombinant EPO has produced inconsistent responses in patients with thalassemia intermedia.^{368–372} When the series are combined, approximately 40% of patients have an increase in Hb level of 2–3 g/dL. EPO has shown little benefit overall in patients with thalassemia major, although there are occasional reports of patients whose transfusion requirements were reduced or eliminated.^{371,373} Decitabine has been used to induce sustained increase of Hb F and total Hb in patients with sickle cell disease with the low likelihood of neutropenia and may have a similar effect in thalassemia but its therapeutic efficacy remains to be proven.^{374,375} Although the pharmacologic enhancement of Hb F production remains an attractive strategy in the management of thalassemia, the results to date strongly suggest the need for new agents or new combinations of agents.

Another potential strategy is to develop techniques to silence Hb F suppression. Recently, the knock down of BCL11A expression resulted in the reactivation of Hb F expression.³⁷⁶ Other important molecular targets to induce Hb F include KLF1, MYB, SOX6, MiRNAs, and histone acetylase, which may lead to other targeted approaches to enhance Hb F.^{377–385} BCL11A is a zinc-finger transcriptional repressor active in erythroid cells and in other hematopoietic lineages.³⁸⁶ Several studies indicate that BCL11A silences γ -globin.^{386–388} BCL11A does not bind the γ -globin promoter but the LCR and different intergenic regions in the globin locus that were previously tied with γ -globin repression.^{386,389–392} KLF1 (also known as EKLF) is an erythroid transcription factor activating BCL11A and playing a major role in the switch from fetal to adult Hb.^{393–396} Thalassemia intermedia patients with mutations in the CACCC box of the β -globin promoter (which is recognized by KLF1) demonstrate significant elevation of Hb F.^{397,398} Recent studies in Chinese populations with thalassemia

intermedia show a significant association between disease severity and transfusion-free survival related to Hb F expression.³⁹⁹ An additional locus highlighted by GWAS is the intergenic interval between HBS1L and MYB.^{400–403} More recently, it has been demonstrated that knockdown of c-Myb was associated with decreased expression of KLF1.⁴⁰⁴ In conclusion, new key regulators of the globin switch have been identified that may be used to develop new and more powerful drugs aimed at increasing Hb F synthesis.

β-Globin Gene Transfer

Cure of thalassemia by genetic transfer of the normal *β-globin* gene into the pluripotent hematopoietic stem cell awaits further advances in molecular biology but is a goal of the foreseeable future.⁴⁰⁵ *β-Globin* gene transfer and expression has been accomplished in thalassemia murine models, which have demonstrated that retroviral vectors, specifically lentiviral vectors, are capable of transferring the human *β-globin* gene sequences and its promoter regions into murine stem cells^{406,407} and into long-term repopulating hematopoietic cells of primates and humans.^{408,409} Studies of safe and efficient specific targeting vectors in humans are ongoing.⁴¹⁰

A total of seven thalassemia patients have been treated in three published clinical trials of gene therapy. A phase I human gene therapy clinical trial for hemoglobinopathies was initiated in France in 2007.⁴¹¹ This trial used a lentiviral vector that expresses an adult *β-globin* gene flanked by two copies of the 250-base-pair core of the cHS4 chromatin insulator implanted in the U3 region of the 3' long terminal repeat. After gene transfer, the patient became transfusion independent. However, the therapeutic Hb in this patient contributed only one-third of the total Hb synthesized; the embryonic and fetal Hbs accounted equally for the remaining Hb. Therefore, the success of this first trial was made possible by the additive effect of transgenic *β-globin* chains synthesized by the vector and those (fetal and adult) made by the patient's cells. Thus, without the support of endogenous Hbs, the gene transfer would not have allowed this patient to become transfusion independent.⁴¹² Several clinical trials of CD34+ modified autologous cells with lentiviral *β-globin* vectors are currently ongoing and published results are eagerly awaited.⁴¹³ It remains unclear the optimal method for stem cell mobilization and leukapheresis, whether granulocyte colony-stimulating factor or plerixafor are safe in thalassemia, and the appropriate long-term follow-up strategies will be important. Alternatively, somatic cells reprogrammed to induced pluripotent stem cells (iPSCs) might also provide a possible new approach to treat *β-thalassemia* and sickle cell disease.⁴¹⁴ Currently, robust generation of iPSCs requires the introduction and integration of genes encoding the transcriptional factors OCT3/4, SOX2 with either KLF4 and c-MYC or NANOG and LIN28.^{415–417} Ye and coworkers⁴¹⁴ have shown that iPSCs can be generated from cells derived from skin fibroblasts, amniotic fluid, or chorionic villus sampling of patients with *β-thalassemia* and subsequently differentiated into hematopoietic cells that synthesized Hb. Multiple clinical trials are currently underway using both gene therapy and genome editing technologies as curative approaches for thalassemia major.

Thalassemia Intermedia

Approximately 10% of patients with homozygous *β-thalassemia* exhibit a phenotype characterized by intermediate hematologic severity.^{1–4} The balance of globin chain synthesis is better than in typical thalassemia major because of a less severe defect in *β-globin* chain synthesis, a decrease in *α-globin* chain synthesis as well as *β-globin* chain synthesis, or an increase in *γ-globin* chain synthesis. For example, homozygous *β-thalassemia* in African Americans, Portuguese, and other populations may be relatively mild, at least for the first two decades of life.^{418–420} Homozygotes or mixed heterozygotes for forms of *β-thalassemia* associated with normal Hb A₂ and normal Hb F (silent carrier state) also tend to have mild to moderate disease.^{421,422}

TABLE 40.3 **Indications to Initiate Regular Transfusion Therapy in Nontransfusion-Dependent Thalassemia**

Declining hemoglobin with enlargement of the spleen
growth failure
poor school performance
Pregnancy
Surgery
decreased exercise tolerance
failure of secondary sexual development
bony changes
frequent hemolytic crisis (hemoglobin H disease)
poor quality of life
Primary prevention and management of the following
1. thrombotic or cerebrovascular disease
2. pulmonary hypertension/heart failure
3. extramedullary hematopoiesis
4. leg ulcers

Certain patients have a milder clinical phenotype because they have coinherited a form of *α-thalassemia* or because they carry one (or two) *β-thalassemia* chromosome(s) with a greater than usual potential for high levels of *γ-globin* gene expression.^{12–14}

The ability to maintain a Hb level compatible with comfortable survival in the absence of regular transfusions is the generally accepted criterion for the diagnosis of thalassemia intermedia. In other words, distinguishing between thalassemia major and thalassemia intermedia, which in turn is the distinction between initiating a regular transfusion program or not, requires consideration of the Hb level and the quality of life (Table 40.3). These two parameters do not have a predictable relationship. Patients with thalassemia and Hb levels of 7 g/dL may be relatively symptom free, but patients with Hb levels of 9 g/dL may have numerous problems related to IE. Thus, the assessment of the patient rather than the Hb level alone is essential in deciding who does not require regular transfusions and therefore, by definition, has thalassemia intermedia. Some nontransfused patients have normal growth and sexual development, few medical problems, and normal or near-normal survival rates. However, others develop disfiguring facial changes, markedly delayed growth and sexual maturation, heart failure, severe osteoporosis, repeated fractures, arthritis, and massive splenomegaly. Calling the condition of this latter group “thalassemia intermedia” implies a milder disease than thalassemia major but, in fact, the patients’ quality of life does not compare favorably with the quality of life of patients with thalassemia major. Nonetheless, many families and physicians are reluctant to initiate a chronic transfusion program because of concern about the risks of long-term transfusion therapy and the inevitable need for iron chelation therapy. If the decision is made to manage the patient initially without regular transfusions, regular reassessments of the patient’s clinical condition, including appearance, growth, and development, and bone expansion are crucial.⁴²³ Short-term transfusion therapy may be useful during pregnancy or in the management of cardiac and other serious complications. The need for regular transfusions often develops in adults with thalassemia intermedia because of a further decline in the Hb level or a growing intolerance of the anemia.⁴²⁴

Even in the absence of regular transfusions, many patients develop progressive iron overload because of increased absorption of dietary iron induced by IE and, in many cases, the intermittent administration of RBC transfusions. By the third or fourth decade, the total iron burden may attain the levels seen in transfusion-dependent patients.⁴²⁵ Ferritin levels may underestimate the degree of tissue iron loading in thalassemia intermedia, and assessment of LIC is more helpful in determining the need for chelation therapy. Deferoxamine,

deferiprone, and deferasirox have all proved to be safe and effective in thalassemia intermedia.^{426–428}

Thromboembolic events represent a major complication of thalassemia intermedia, occurring in 10% to 34% of patients.^{326,429} These events include stroke, pulmonary embolism, portal vein thrombosis, and deep vein thrombosis of the legs. A hypercoagulable state may also contribute to the pulmonary hypertension that commonly occurs in patients with thalassemia intermedia and is the primary cause of congestive heart failure.⁴³⁰ Splenectomy is a risk factor for thromboembolic events in patients with thalassemia intermedia, resulting in thrombocytosis and allowing the prolonged circulation of damaged RBCs that generate increased amounts of thrombin.³²⁶ Some investigators consider the risk of thromboembolic events after splenectomy for thalassemia intermedia to be sufficiently high to warrant short-term anticoagulation in the perioperative period and during pregnancy.³²⁶ Oral contraceptives should be used with extreme caution, if at all. Interestingly, known genetic thrombophilias in other populations like factor V Leiden, the prothrombin gene mutation 20210, and MTHFR C677T mutations have not been associated with thrombotic risk in this population.⁴³¹

Extension of hematopoietic tissue beyond the confines of the bones occurs in patients with thalassemia intermedia as a result of the intense erythropoiesis. This complication occurs less frequently in patients with thalassemia major because of the partial suppression of erythropoiesis by regular transfusions. Masses of extramedullary hematopoietic tissue develop in the spinal epidural space, thorax, cranium, pelvis, and elsewhere.^{367,432–442} These masses may be detected as incidental findings on imaging studies of the chest or abdomen.^{433–439} In other instances, the masses produce symptoms by compressing neighboring structures. For example, patients with extramedullary hematopoietic masses may develop paraplegia from spinal cord compression or loss of visual acuity or visual fields caused by optic nerve compression.^{432,435,441,442} Additional clinical presentations of hematopoietic masses include pleural effusions and upper airway obstruction.^{437,438,440} Initiation of regular transfusions for patients with thalassemia intermedia or intensification of the ongoing transfusion program for patients with thalassemia major reduces the size of extramedullary hematopoietic masses and helps to prevent recurrences. (Tables 40.4 and 40.5).

β-Thalassemia Minor (Thalassemia Trait)

Inheritance of a single β-thalassemia allele usually results in a mild hypochromic microcytic anemia. The Hb level averages 1 or 2 g/dL lower than that seen in normal persons of the same age and gender. Hb F levels decline more slowly than usual in the first year of life, and the diagnostic elevated Hb A₂ levels are established by approximately 6 months of age.^{443–445} Strong intrafamilial correlations of both Hb A₂ and mean corpuscular volume (MCV) are noted.^{446,447} Osmotic fragility is decreased; indeed, a one-tube osmotic fragility test has been used in the past for mass screening.⁴⁴⁴ The RBC count is increased or normal. The RBCs are characteristically hypochromic (MCH <26 pg) and microcytic (MCV <75 fL). The smear shows varying numbers of target cells, poikilocytes, ovalocytes, and basophilic stippling (Fig. 40.13). The reticulocyte count is normal or slightly elevated. RBC survival is normal, iron utilization is decreased, and slight IE is present.⁴⁴⁵ During pregnancy, the anemia of thalassemia trait often becomes more severe, but transfusions are rarely necessary. Increased folic acid supplementation may improve Hb during this period. Because iron deficiency may occur during pregnancy, iron supplementation has been advised to avoid compounding the causes of anemia.^{448,449} In general, thalassemia trait carries no direct clinical symptoms or pathologic consequences for the patient. Studies have suggested there may be an increased tendency for gallstones and cholecystitis, but otherwise this condition should be largely asymptomatic.¹⁷ The diagnosis of thalassemia trait assumes particular importance in women who are pregnant or considering pregnancy because of the potential for having a child with thalassemia major.

α-THALASSEMIA SYNDROMES

The α-thalassemias are more difficult to diagnose because characteristic elevations in Hb A₂ or Hb F, seen in many cases of β-thalassemia, do not occur, making Hb electrophoresis difficult to use for diagnostic testing. However, the gene deletions responsible for the most common varieties are readily detectable by molecular biology methods.⁴⁵⁰

TABLE 40.4 Nontransfusion-Dependent Thalassemia Screening Recommendations

Test Name	Measurement	Frequency
MRI with T2* liver iron content	Liver iron	every 1–2 years
MRI with T2* cardiac iron content ^a	Cardiac iron	every 1–2 years
Ferritin	Total body iron	every 3 months
History and physical exam	General health, medication compliance	every 3–4 months
Echocardiogram	Pulmonary hypertension TRV	every 1–2 years
Liver function panel	Liver failure, hepatitis	every 3 months
liver ultrasound (if LIC >5/ferritin >800)	Cirrhosis	annually
AFP (if >40 or presence of clinical cirrhosis)	Hepatocellular carcinoma	annually
Hepatitis B, C serologies (if receiving blood transfusions)	Hepatitis B and C viral infection/exposure	annually
Tanner stage/Sexual development evaluation	Sexual development	annually
standing and sitting height	Growth and development	every 6 months
Free T4, TSH	Thyroid function	annually
Calcium, phosphate, vitamin D	Parathyroid function	annually
Fasting blood sugar/oral glucose tolerance test	Diabetes mellitus screening	annually
ACTH test	Adrenal insufficiency	annually
DEXA	Bone mineral density	annually

^aCannot be widely recommended because no correlation with LIC

ACTH, Adrenocorticotropic hormone; AFP, α-fetoprotein; DEXA, dual-energy x-ray absorptiometry; LIC, liver iron concentration; MRI, magnetic resonance imaging; TRV, tricuspid regurgitant velocity; TSH, thyroid stimulating hormone.

**TABLE
40.5****Transfusion-Dependent Thalassemia Screening Recommendations**

ACTH test	Adrenal insufficiency screening	annually
DEXA	Bone mineral density	annually
NTX, CTX, AP	Bone mineral density	annually
Dental evaluation	Maxillofacial disease, periodontal disease, caries	6–12 months

ACTH, Adrenocorticotropic hormone; AFP, α -fetoprotein; AP, alkaline phosphatase; CTX, collagen type 1 cross-linked C-telopeptide; DEXA, dual-energy x-ray absorptiometry; LIC, liver iron concentration; MRI, magnetic resonance imaging; NTX, N-terminal telopeptide; TRV, tricuspid regurgitant velocity; TSH, thyroid stimulating hormone.

Fig. 40.13 MORPHOLOGY OF THE PERIPHERAL BLOOD FILM IN A PATIENT WITH HETEROZYGOUS β -THALASSEMIA (A) AND A PATIENT WITH HETEROZYGOUS α -THALASSEMIA (B). Note the profound hypochromia and microcytosis and the many target cells. (From Pearson HA, Benz EJ Jr: *Thalassemia syndromes*. In Miller DR, Baehner RL, McMillan CW, editors: *Smith's blood diseases of infancy and childhood*, ed 5, St. Louis, 1984, CV Mosby, p 439.)

Molecular Pathology and Pathophysiology

The four classic α -thalassemia syndromes are α^+ -thalassemia trait, in which one of the four α -globin genes fails to function; α^0 -thalassemia trait, with two dysfunctional genes; Hb H disease, with three affected genes; and hydrops fetalis with Hb Bart, in which all four genes are defective. In general, partial deletions are more deleterious and create a more severe phenotype than complete deletions.⁴⁵¹ In the older literature, α^0 - and α^+ -thalassemia are referred to as α -thalassemia-1 and α -thalassemia-2, respectively. These syndromes are usually caused by deletion of one, two, three, or all four of the α -globin genes, respectively (Fig. 40.14). Nondeletional forms of α -thalassemia, which account for 15% to 20% of patients, arise from mutations similar to those described for β -thalassemia.^{452,453} Fig. 40.15 illustrates

the different α -thalassemia mutations and phenotypes. Structurally abnormal Hbs have also been associated with α -thalassemia. The Quong Sze α -globin chain ($\alpha^{125\text{Leu}\rightarrow\text{Pro}}$) is exceedingly labile and is destroyed so rapidly after its synthesis that no Hb tetramers containing the mutant α chain can be formed.⁴⁵⁴ α^+ -thalassemias also exhibit epistasis with haptoglobin variants that alters patterns in malaria protection.⁴⁵⁵

α^+ -Thalassemia trait is very common in patients of African ancestry, having a genetic frequency of 20% to 30% in some populations. However, the *cis* α^0 -thalassemia deletion is rare in black patients. Thus, even though α^+ -thalassemia trait and the *trans* deletion form of α^0 -thalassemia are very common, Hb H disease is rarely encountered, and hydrops fetalis has not yet been reported in black patients.^{456,457}

Fig. 40.14 GENETIC ORIGINS OF THE “CLASSIC” α -THALASSEMIA SYNDROMES CAUSED BY GENE DELETIONS IN THE α -GLOBIN GENE CLUSTER. Hemoglobin Constant Spring is an α -globin chain variant synthesized in such small amounts (1–2% of normal) that it has the phenotypic impact of a severe nondeletion α -thalassemia allele; however, the α^{CS} allele is always linked to a functioning α -globin gene, so it has never been associated with hydrops fetalis. CS, Constant Spring; *Hb*, hemoglobin.

Fig. 40.15 PATHOPHYSIOLOGY OF HEMOGLOBIN H DISEASE AND HYDROPS FETALIS WITH HB BART. *Hb*, Hemoglobin; *mRNA*, messenger ribonucleic acid. (Adapted from Benz EJ Jr: *The hemoglobinopathies*. In Kelly WN, DeVita VT, editors: Textbook of internal medicine, Philadelphia, 1988, JB Lippincott, p 1423.)

Clinical Manifestations

Silent Carrier (α^+ -Thalassemia Trait)

α^+ -Thalassemia trait has no consistent hematologic manifestations. The RBCs are not microcytic, and Hb A₂ and Hb F are normal. During the newborn period, small amounts ($\leq 3\%$) of Hb Bart (γ_4) can be seen by electrophoresis or other techniques. This condition is most often recognized when an apparently normal individual becomes the parent of a child with Hb H disease after mating with a person with α^0 -thalassemia trait. The mild excess of β -globin chains is probably removed in erythroblasts by proteolysis.⁴⁵⁸ α^+ -Thalassemia is particularly common in Melanesia, as well as in Southeast Asia and in African Americans, reaching a prevalence of more than 80% in North coastal Papua New Guinea. At the molecular level, α^+ -thalassemia has been found to be associated with two common gene deletions resulting from different nonhomologous crossing-over events between the two linked α -globin genes: a 3.7-kb rightward deletion ($-\alpha^{3.7}$) resulting in a fused $\alpha 2\alpha 1$ -globin gene and a 4.2-kb leftward deletion ($-\alpha^{4.2}$) resulting in loss of the 5' ($\alpha 2$) gene.^{452,453,459} The level of α -globin gene expression differs in the two conditions, as discussed in the following section.

α -Thalassemia Trait (α -Thalassemia Trait)

Levels of Hb A₂ in the low to low normal range (1.5–2.5%) and β/α synthetic ratios averaging 1.4:1 characterize α^0 -thalassemia trait. During the perinatal period, elevated amounts of Hb Bart are noted (3–8%). Microcytosis is present in cord blood erythrocytes.

Studies of newborns from the archipelago of Vanuatu in the Southwest Pacific and from Papua New Guinea indicate that homozygotes for the rightward $-\alpha^{3.7}$ deletion (where only a fused $\alpha 2\alpha 1$ -globin gene, mostly of the $\alpha 2$ type, remains) have lower Hb Bart levels ($3.5\% \pm 0.8\%$) than those of infants homozygous for the leftward $-\alpha^{4.2}$ deletion (in whom only the $\alpha 1$ -globin gene remains) ($6.0\% \pm 1.4\%$). These results suggest that the 5' $\alpha 2$ -globin gene has a higher output than the 3' $\alpha 1$ -globin gene, a conclusion supported by direct measurement of $\alpha 2/\alpha 1$ mRNA ratios.^{460,461}

Hb H is not detected in hemolysates of peripheral RBCs, probably because of rapid proteolysis of Hb H or free β -globin chains. However, approximately 1% of erythroblasts and BM reticulocytes have inclusions. When an α -thalassemia gene occurs in persons who are also heterozygous for α -globin chain variant Hbs, such as Hb S, Hb C, or Hb E, the proportion of the abnormal Hb is lower than that seen in simple heterozygotes.⁴⁶² The lower level of the abnormal Hb is attributable to posttranslational control because of higher affinity of β^A chains for a limited pool of α -globin chains coupled with proteolysis of the uncombined β^{variant} chains.⁴⁶³

Hemoglobin H Disease

Hb H disease is associated with a moderately severe but variable anemia resembling thalassemia intermedia, with osseous changes and splenomegaly.⁴⁶⁴ However, the clinical phenotype may be considerably milder in some patients and severe enough to cause hydrops fetalis in others.^{465,466} It occurs predominantly in Asians and occasionally in whites (Mediterranean) but is rare in persons of African ancestry. Exacerbations of anemia during febrile illnesses are common and are usually characterized by increasing fatigue and jaundice. Adults with Hb H develop some of the same complications as β -thalassemia including osteoporosis, cholelithiasis, and iron overload.⁴⁶⁷

Because Hb H is unstable and precipitates within the circulating RBCs, hemolysis occurs. Hb H can be demonstrated by incubation of blood with supravital oxidizing stains such as 1% brilliant cresyl blue. Multiple small inclusions form in the RBCs (see Fig. 40.15). Electrophoresis of a freshly prepared hemolysate at alkaline or neutral

pH demonstrates a fast-moving component amounting to 3% to 30% of the total Hb. Concomitant iron deficiency may reduce the amount of Hb H in the patient's RBCs.⁴⁶⁸ A syndrome of Hb H disease associated with mental retardation, other congenital anomalies, and large deletions on chromosome 16 has been noted in several white families.^{469,470}

The degree of deletions in Hb H is also relevant to clinical presentation. Deletional HbH occurs when three deletional alpha (0) mutations occur. Non-deletional HbH occurs when two deletional alpha(0) mutations occur with an alpha (+) mutation (e.g. Constant Spring). Nondeletional Hb H genotypes are more likely to have higher percentage Hb H, more splenomegaly, and more advanced disease.⁴⁵⁵

Hydrops Fetalis With Hb Bart

Hydrops fetalis with Hb Bart occurs almost exclusively in Asians, especially Chinese, Cambodians, Thais, and Filipinos. Affected fetuses are usually born prematurely and are either stillborn or die shortly after birth.^{1–4} Marked anasarca and enlargement of the liver and spleen are present. Severe anemia is usually present, with Hb levels of 3–10 g/dL. The RBCs are markedly microcytic and hypochromic and include target cells and large numbers of circulating nucleated RBCs. These morphologic abnormalities and a negative Coombs test result exclude hemolytic diseases caused by blood group incompatibility. Hb electrophoresis reveals predominantly Hb Bart, with a smaller amount of Hb H. A minor component identified as Hb Portland ($\zeta_2\gamma_2$) migrating in the position of Hb A is also seen. Normal Hb A and Hb F are totally absent.⁴⁷¹

Hydropic infants have massive hepatosplenomegaly. Extreme extramedullary erythropoiesis occurs in response to the profound hypoxia and hemolytic anemia characteristic of this disease. The universal edema characteristic of the hydrops fetalis syndrome is a reflection of severe congestive heart failure and hypoalbuminemia in utero. This is partly a consequence of anemia, but the strikingly abnormal oxygen affinity of the tetrameric Hb Bart is probably the most important determinant of the severe tissue hypoxia. The oxygen dissociation curve of Hb Bart lacks the normal sigmoid form because of noncooperativity during oxygen loading and unloading and is markedly shifted to the left. The shift is so great that little oxygen is released under conditions of low oxygen concentration in the tissues.

Infants with this syndrome do not die in an earlier trimester of pregnancy because of the presence of Hb Portland ($\zeta_2\gamma_2$). This Hb does display cooperativity in a manner similar to that of Hb F and therefore has a much more favorable oxygen dissociation pattern than that of Hb Bart. A high incidence of toxemia of pregnancy has been described in women carrying severely affected infants, providing an increased rationale for prenatal diagnosis of this condition.

Prenatal Diagnosis of α -Thalassemia

Using molecular hybridization technology, Dozy and associates⁴⁷² detected the complete absence of α -globin genes in fetal fibroblasts obtained by amniocentesis in a pregnancy at risk of homozygous α -thalassemia and the hydrops fetalis syndrome. A quantitative polymerase chain reaction (PCR) method provides similar information rapidly and accurately.⁴⁷³ The presence of hydrops can also be detected by ultrasonography. DNA studies or globin synthesis evaluation may be used to confirm the diagnosis in utero. PCR-based assays are available for the detection of the common α -thalassemia deletions.^{473–476}

Therapy

Fetuses with homozygous α^0 -thalassemia usually die in utero because of severe hydrops fetalis and are stillborn. However, some infants have had successful blood exchange transfusion immediately after

birth.^{477–481} It is also possible to salvage affected fetuses by in utero blood transfusions.^{482,483} Limb and urogenital defects are present in a substantial portion of infants with homozygous α^0 -thalassemia who are rescued by these measures, and some infants have developmental delay or other neurologic abnormalities. Management after the perinatal period is similar to the management of patients with thalassemia major and includes transfusion and chelation therapy as well as the possibility of BMT.⁴⁸⁴

Many patients with Hb H disease do not require RBC transfusions. For patients with more severe disease, characterized by lower Hb levels or frequent exacerbations of the anemia, splenectomy can be helpful. Oxidant drugs can accelerate precipitation of Hb H and exacerbate hemolysis; they should therefore be avoided. Exchange transfusion can be used to decrease deleterious levels of Hb H. Infants with heterozygous α^0 -thalassemia trait lose their Hb Bart during the first few months of life and are left with the hematologic findings of α -thalassemia trait, a mild hypochromic microcytosis that persists throughout life.¹ The degree of morphologic abnormality varies greatly among different individuals. That α -thalassemia can be easily diagnosed by Hb electrophoresis at birth gives some impetus to cord blood screening studies. Confusion between heterozygous α^0 -thalassemia trait and iron deficiency may lead to unnecessary evaluations for possible blood loss or unnecessary supplementation with iron unless the overlap in hematologic findings is recognized and more specific diagnostic studies are performed.

De Novo and Acquired Forms of α -Thalassemia

Two distinct α -thalassemia syndromes have been described that are attributable to acquired or de novo mutations: (1) α -thalassemia associated with mental retardation and (2) Hb H disease associated with MDS.

α -Thalassemia Associated With Mental Retardation

α -Thalassemia or Hb H disease can occur as a de novo abnormality in a rare disorder called the α -thalassemia with mental retardation syndrome (ATR).^{469,470} In this disorder, affected patients have mental retardation and a number of other developmental abnormalities in association with α -thalassemia trait or Hb H disease that is inherited in a nontraditional manner. Two distinct types of the ATR syndrome have been identified. In some cases, there is the de novo appearance of large (2000 kb or so) deletions involving the entire α -globin gene cluster and adjacent DNA at the tip of chromosome 16, the so-called ATR-16 syndrome. In some of these patients, the deletion produces detectable cytogenetic abnormalities of chromosome 16, indicating that a very large segment of the chromosome is deleted, sometimes because of unbalanced chromosomal translocations involving the telomeres of the affected chromosomes. In some cases, one parent is heterozygous for α^+ -thalassemia by various criteria and the other parent is completely normal; in such cases, the child has Hb H disease (-/- α). In other cases, both parents are normal and the affected child has the hematologic phenotype of heterozygous α^0 -thalassemia (-/- α) without Hb H disease. In this form of ATR, the clinical findings, such as the degree of mental retardation and associated congenital abnormalities, are variable.

The second type of ATR syndrome is not associated with detectable deletions of the α -globin gene complex. The molecular basis of the disorder consists of mutations of a gene on the X chromosome, and the condition has been called the ATR-X syndrome.⁴⁸⁵ In contrast to patients with the ATR-16 syndrome who have a varied phenotype of developmental abnormalities, patients with the ATR-X syndrome have a more uniform or consistent phenotype, particularly severe mental retardation (with IQs of 50–70) and a characteristic dysmorphic facial appearance.⁴⁷⁰

The affected gene in this syndrome encodes a *trans*-acting factor, called ATRX, that is thought to influence the expression of the α -globin genes as well as that of other genes.^{486,487} The structure of

this large (280 kDa) DNA-binding protein is complex and contains two major functional domains: an *N*-terminal cysteine-rich zinc finger-containing domain, called the ADD domain, that has structural features similar to those of DNA methyl transferases, and a C-terminal helicase/ATPase domain. The majority of the mutations associated with the ATR-X syndrome are located in the ADD domain or the helicase domain. The ATRX protein is widely expressed in many different tissues and its intracellular localization is within three different nuclear subcompartments: heterochromatin, ribosomal DNA arrays, and PML bodies. It has been shown to interact with other proteins such as the heterochromatin-associated protein HP1 and Daxx, one of the proteins localized in PML bodies. The prevailing opinion is that the ATRX protein is part of a large chromatin-remodeling complex of the SWI2/SNF2 family. It also has ATPase activity and has translocase activity, that is, it can move along DNA as a “molecular motor.” The precise mechanism(s) by which ATRX influences the expression of α -globin (and other) genes remains unknown.

Acquired Hb H Disease Associated With Myelodysplastic Syndrome

Hb H disease has occasionally been observed to develop during the course of different types of MDS and more rarely in patients with other hematologic malignancies.⁴⁸⁸ The disorder usually affects elderly men older than the age of 60 years. The degree of imbalance of globin chain synthesis and of α -globin mRNA deficiency in erythroid cells of affected patients is greater than that observed in the hereditary type of Hb H disease. It is conceivable that erythroid cells of the abnormal clone synthesize no α -globin chains at all and that the expression of all four α -globin genes is suppressed or silenced,⁴⁸⁹ but this phenomenon is difficult to document in total blood as long as some normal erythroid cells are being produced.

Until recently, the molecular basis of this fascinating disorder remained unknown. Cytogenetic, gene mapping, gene sequencing, and gene or chromosome transfer studies failed to detect any deletion or mutation in the α -globin gene cluster or functional abnormality of α -globin gene of affected patients. The results of all of these prior studies suggested that the defect responsible for this disorder probably involved the abnormal expression or function of a *trans*-acting factor capable of influencing α -globin gene expression and, indeed, such a factor was recently identified. The discovery of the factor responsible for Hb H disease in MDS results from cDNA microarray analysis of RNA isolated from granulocytes of an affected patient. One of the genes that was found to be markedly underexpressed, compared with results obtained with RNA of normal granulocytes, was the *ATRX* gene,⁴⁹⁰ the same gene that is mutated in the α -thalassemia with mental retardation syndrome of the ATR-X type. Sequence analysis of the *ATRX* gene in the DNA of blood cells of affected individuals has identified a number of different mutations. It is noteworthy that the mutations of the *ATRX* gene associated with acquired Hb H disease associated with MDS (ATMDS) occur in the same regions of the gene as the mutations associated with the ATR-X syndrome, that is, in the ADD or helicase domains. In fact, some of the *ATRX* gene mutations identified in ATMDS are identical or similar in expected functional consequences to various mutations found in the ATR-X syndrome.

The hematologic features in the syndrome are characterized by the presence on blood smear of a dimorphic RBC population, one of which is hypochromic, microcytic, and poikilocytic. Incubation of the blood with the supravital stain brilliant cresyl blue results in the detection of typical Hb H inclusions. Hb electrophoresis or high pressure liquid chromatography detects the presence of Hb H, usually in greater quantities than that typically observed in inherited Hb H disease. In typical MDS, the MCV of the erythrocytes is normal or elevated, frequently higher than 100 fL. However, in ATMDS, the MCV and MCH are low: MCV usually less than 80 fL and MCH usually less than 26 pg.⁴⁸⁸ The amount of Hb H usually remains stable but may actually decrease during the course of the disease and

no longer persists after transformation of MDS to acute leukemia. This finding suggests that the Hb H–producing clone does not have a selective survival or growth advantage.

The hematologic phenotype, as reflected by the amount of Hb H present in blood, of ATMDs is much more severe than that of the ATR-X syndrome.⁴⁸⁶ Some of this difference in severity may be because of the nature of the ATMDs mutations, some of which are null mutations that are likely to be lethal when present in germline DNA of ATR-X embryos. However, the difference in severity is also observed in the case of mutations found in both syndromes that are identical or similar in expected functional consequences. This finding suggests that additional abnormalities in gene expression in ATMDs contribute to the severity of the deficit in α -globin gene expression observed in this syndrome. Perhaps the responsible defective cofactor(s) is one or more of the proteins that interact with the ATRX protein to produce a fully functional macromolecular complex that can act as a transcriptional cofactor or that can influence the epigenetic control of α -globin gene expression.

THALASSEMIC STRUCTURAL VARIANTS

Certain structural Hb variants are characterized by the presence of a biosynthetic defect as well as abnormal structure.⁶ Thalassemic hemoglobinopathies are unusual forms of thalassemia caused by such structural variants.

Hemoglobin Lepore

Hb Lepore ($\alpha 2\beta\delta$) is the prototype of a group of hemoglobinopathies characterized by fused globin chains.^{1–4} The chains begin with a normal δ -chain sequence at their N-terminus and end with the normal β -chain sequence at their C-terminus. These hemoglobinopathies arise by unequal or nonhomologous crossover or recombination events that fuse the proximal end of one gene with the distal end of a closely linked structurally homologous gene (Fig. 40.16). During meiosis, mispairing and crossover of the highly homologous δ - and β -globin genes can occur, resulting in a Lepore chromosome, which contains (in addition to γ -globin genes) only the fused $\delta\beta$ gene, and an anti-Lepore chromosome, which contains the reciprocal fusion product ($\delta\beta$), as well as intact δ - and β -globin genes.¹

Lepore globin is synthesized in low amounts, presumably because it is under the control of the δ -globin gene promoter, which normally sustains transcription at only 2.5% the level of the β -globin gene.⁴⁹¹ Patients with Hb Lepore have the phenotype of β -thalassemia, distinguished by the added presence of 5% to 15% Hb Lepore. In contrast, the anti-Lepore globin (Miyada) is not associated with a β -thalassemia phenotype because of the presence of an intact and functionally normal β -globin gene on the same chromosome.

An analogous but rare variant, Hb Kenya [$\alpha 2(A\gamma\beta)2$], arises from nonhomologous crossing over between the $A\gamma$ - and β -globin genes⁴⁹² and is associated with the phenotype of γ -hereditary persistence of fetal Hb. A DNA sequence approximately 600 bases downstream from the β -globin gene acts as a strong enhancer, promoting the erythroid-specific expression of the β -globin genes in adult cells.^{3,4,21} The fused $A\gamma\beta$ gene as well as the linked upstream γ -gene are believed to come under the influence of the enhancer because of its abnormal proximity and thus are expressed at high levels in adult life.

Hb E

Hb E ($\alpha 2\beta_2^{26\text{Glu} \rightarrow \text{Lys}}$) is a common variant (15–30% of the population) in Cambodia, Thailand, parts of China, and Vietnam. Hb E is very mildly unstable, but this instability does not significantly alter the life span of RBCs. Hb E trait resembles very mild β -thalassemia trait. Homozygotes exhibit more microcytosis but are still asymptomatic.⁴⁹³ Compound heterozygotes for Hb E and a β -thalassemia gene (Hb E- β -thalassemia) resemble patients with β -thalassemia intermedia or

Fig. 40.16 GENETIC ORIGINS OF HEMOGLOBIN (HB) LEPORE, ANTI-LEPORE HB, AND HB KENYA. (Adapted from Benz EJ Jr: *The hemoglobinopathies*. In Kelly WN, DeVita VT, editors: Textbook of internal medicine, Philadelphia, 1988, JB Lippincott, p 1423.)

β -thalassemia major. However, some problems such as infection and pulmonary hypertension may occur more commonly in Hb E- β -thalassemia than in homozygous β -thalassemia.⁴⁹⁴

The only nucleotide sequence abnormality found in the β^E -gene is a base change in codon 26 that causes the amino acid substitution. This mutation, which occurs in a potential cryptic RNA splice region, alters the consensus sequence surrounding a potential GT donor splice site and thus activates the cryptic site. Alternative splicing at this position occurs approximately 40% to 50% of the time, generating a structurally abnormal globin mRNA that cannot be translated appropriately.⁴⁹⁵ The other mRNA precursors are spliced at the normal site, generating functionally normal mRNA, which is translated into β^E -globin because the mature mRNA retains the base change that encodes lysine at codon 26.

Hb Constant Spring

Hb Constant Spring (see Fig. 40.14) is an elongated α -globin variant resulting from a mutation that alters the normal translation termination codon.⁴⁹⁶ Polyribosomes read through the usual translation stop site and incorporate an additional 31 amino acids until another in-phase termination codon is reached within the 3' untranslated sequence. The amount of α^{cs} mRNA is markedly reduced, and α^{cs} -globin is synthesized in only minute amounts.^{459,497} Six possible mutations of the normal translation termination codon (UAA) in α -globin mRNA could result in the generation of a “sense” codon.⁴⁹⁸ Of these, five variants have been identified, each having a markedly underproduced abnormal variant, indicating that disruption of normal translation termination is in some way associated with abnormal mRNA accumulation, presumably because of instability of the mRNA.⁴⁵⁹ The output of α -globin from the α^{cs} allele is only approximately 1% of normal, and the gene is thus rendered α -thalasemic. The α^{cs} allele has been identified only on chromosomes containing a *cis*-linked functionally normal α -globin gene.^{1–4} Thus, α^+ -thalassemia trait and Hb H disease (–/ $\alpha^{\text{cs}}\alpha$) associated with Hb Constant Spring are common, but hydrops fetalis caused by four abnormal α -globin genes cannot occur in association with this variant. Homozygosity for the variant is associated with a relatively mild form of Hb H disease.¹

EXTRAORDINARILY UNSTABLE HEMOGLOBINS

Rare cases of α -thalassemia (e.g., Hb Quong Sze)⁴⁵⁴ and β -thalassemia (e.g., Hb Indianapolis, recently renamed Hb Terre

Haute)^{499,500} arise from mutations that produce extremely labile globin chains. The chains fail to pair with the complementary chain, or they precipitate and are degraded so rapidly that they never form tetramers. These posttranslational lesions have the same pathophysiologic effects on Hb biogenesis as reduction of globin mRNA production or function. Another group of β -globin chain variants, usually caused by mutations in exon 3 of the β -globin gene, are associated with inclusion body formation and a phenotype of dominant β -thalassemia intermedia.^{15,16,501}

PATHOBIOLOGY OF SICKLE CELL DISEASE

Robert P. Hebbel and Gregory M. Vercellotti

Since it was recognized as the “first molecular disease,” sickle cell anemia caused by homozygosity for the mutant sickle beta globin gene has provided the classic paradigm for single-gene disorders. Predominant clinical features include hemolytic anemia, episodic painful events, chronic organ deterioration, disparate acute and chronic complications, and a foreshortened life span. The genesis of clinical sickle cell disease is complicated, and an understanding of its pathophysiology integrates concepts from multiple disciplines, includes contributions from the red blood cell (RBC) membrane and the vascular wall endothelium, and recognizes the likely participation of multiple genetic influences. This chapter addresses the pathophysiology that underlies the sickle cell disease syndromes described in Chapter 42.

EARLY YEARS OF SICKLE CELL DISEASE RESEARCH

Sickle disease syndromes were known in folk medicine for centuries in parts of Africa, but the eponymous RBC was first reported in the medical literature in 1910 when Herrick described a young Grenadian man with recurrent pain, anemia, and sickle-shaped red corpuscles in the blood (Fig. 41.1). In 1940, Ham and Castle postulated that sickle disease pathophysiology resulted from a “vicious cycle” involving mutually promotive erythrocytosis and RBC sickling with adverse viscosity changes. In 1949, Neel validated the Mendelian autosomal dominant inheritance of sickle cell anemia, and Pauling demonstrated presence of an abnormal hemoglobin (Hb) in patients and carriers. This was followed by observation of the poor solubility of deoxygenated sickle Hb (HbS) and the reversible sol-gel transformation of HbS solutions. In 1957, Ingram identified the underlying amino acid substitution. Thereafter, increasingly detailed investigations began to reveal the striking complexities of sickle cell disease pathobiology.

GENETIC CONSIDERATIONS

Molecular Context

The sickle mutation in the *HBB* gene is a GAG→GTG conversion that creates a $\beta^{6\text{Glu}\rightarrow\text{Val}}$ substitution and thereby forms β^S globin chains. Genes for other β -globin variants are allelic to the β^S gene and have a codominant impact. Examples include genes for the normal β chain (β^A), β mutants (e.g., β^C , β^O or β^+ thalassemia), and deletional hereditary persistence of fetal Hb (HPFH). Compound heterozygosity for β^S and each one of these results in well-defined clinical syndromes, such as HbAS (i.e., sickle trait), HbSC disease, HbS- β -thalassemia, and HbS-HPFH. Eight percent of African Americans have a β^S gene, 3% have β^C , 1.5% have β -thalassemia, and 0.1% have HPFH. Among African Americans, about 1 in 600 births results in the homozygous state, sickle cell anemia (HbSS), and about 1 in 400 results in some form of sickle cell disease, which additionally includes the compound heterozygous variants other than sickle trait. Worldwide, about 75% of sickle cell anemia births now occur in sub-Saharan Africa, 15% in India, 5% in the Americans, 4% in the Eastern Mediterranean, 1% in Europe.

The *HBB* gene resides in a cluster of β -like genes within which are various nonexonic polymorphic sites. Different combinations of

these define discrete β -locus background haplotypes, referred to as the Senegal, Benin, Bantu, Cameroon, and Arab-India haplotypes (Fig. 41.2). Each designation refers to an ethnographic region in which the sickle mutation achieved high gene frequency (typically peaking at 0.10 to 0.15). In most cases, the sickle gene resides on one of these five major haplotypes.

Origin, Selection, and Dispersion of the Sickle Gene

The residence of both β^A and β^S alleles on the distinct regional β cluster haplotypes suggests that the sickle mutation arose independently in the five regions. The β^C mutation arose only once. Historical and biologic data argue that frequency of the β^S gene greatly expanded in Africa about 3000 years ago and in South Asia about 4000 years ago, following the introduction of iron tools. That led to adoption of an agricultural system that promoted both increased human habitation density and favorable breeding conditions for the mosquito vector, *Anopheles*, which in turn enabled development of endemic *Plasmodium falciparum*. In this context, high fixed β^S gene frequencies were reached because of a balanced polymorphism, such that heterozygotes (HbAS) have an adaptive advantage over either homozygote. Thus the Old World geographic distributions of the sickle gene and historical endemic malaria are notably concordant (see Fig. 41.2), suggesting that the sickle gene represents “a biologic solution to a cultural problem.”

In hyperendemic areas, *falciparum* malaria uniformly infects the young and is the primary cause of death for children with sickle cell anemia. However, those with sickle trait are less likely to develop high-level parasitemia or to have severe malaria, an effect largely exerted early in childhood. At the level of the RBC, this protection reflects steps after initial parasite invasion. One proposed mechanism links protection to the instability of HbS, immune status, and splenic function. Infection of sickle trait RBCs with *P. falciparum* leads sequentially to augmented Hb denaturation, clustering of membrane protein band 3, attraction of band 3 autoantibody, complement binding, and enhanced erythrophagocytosis, even of the early ring forms. Thereby, an accelerated clearance of parasitized RBC by the spleen could protect those with sickle trait, while HbS homozygotes would lose this protection because of acquiring functional asplenia. In synergy with this scenario, presence of HbS (via a different mechanism) impairs microvascular endothelial cytoadherence of infected RBC, thereby diminishing cerebral symptoms and impeding the sequestration that protects parasitized RBC from splenic exposure. The protective benefit of HbAS is lost if there is concurrent alpha thalassemia (which lowers proportion of HbS). Yet, the blunted malarial susceptibility in sickle trait reflects a complex interrelationship among the sickle gene, host biology, and environmental factors. Malarial severity is affected by polymorphisms in nonglobin genes such as *CR1* (complement receptor 1), *CD36*, *TGFB1* (transforming growth factor β), and *HMOX1* (heme oxygenase 1); a polymorphism in *TLR4* (toll-like receptor 4) prevalent in sub-Saharan Africa exerts a protective effect. Both carbon monoxide (CO) and nitric oxide (NO) blunt severity of experimental malaria. And certain microRNA, enriched in HbS-containing RBC, can inhibit *P. falciparum* growth.

Eventually, the sickle gene spread geographically by means of commerce, migration, and the slave trade. This dispersion has been tracked by analyses of regional β haplotypes, a biologic marker that

Fig. 41.1 SICKLE RED BLOOD CELL (RBC) MORPHOLOGIES. Blood smears prepared under differing conditions, using antecubital blood from the same sickle cell anemia patient. (A) Venous blood at a $PO_2 \sim 40$ mm Hg was fixed immediately to document RBC shapes occurring in vivo. Several RBC morphologies are evident, including two granular (raisin-like) cells, five somewhat elongated cells, and two highly elongated and curved cells. (B) Unfixed blood was fully oxygenated. Most cells resumed normal shape, but one elongated, irreversibly sickled cell remains present. (C) The oxygenated cells from (B) were then partially deoxygenated, upon which they assumed classic holly-leaf forms typical of rapid deoxygenation. (D) The partially deoxygenated cells from (C) were then fully deoxygenated ($PO_2 \sim 0$ mm Hg) and display the more elongated shape having fewer spikes that is assumed by sickle RBC that have deoxygenated more slowly. The physical–chemical basis for these shapes is presented in Fig. 41.5. (Reproduced with permission from Obata K, Mattiello J, Asakura K, et al: Exposure of blood from patients with sickle cell disease to air changes the morphological, oxygen-binding, and sickling properties of sickled erythrocytes. *Am J Hematol* 81:26, 2006).

Fig. 41.2 SICKLE GENE AND MALARIA. The five regions in which the sickle gene achieved high allelic frequency are superimposed on shading that identifies the Old World distribution of the sickle gene and of historic, endemic malaria. (Reproduced with permission from Friedman MJ, Trager W: *The biochemistry of resistance to malaria*. *Sci Am* 244:154, 1981; and from Nagel RL, Steinberg MH: *Genetics of the β^S gene: origins, epidemiology, and epistasis in sickle cell anemia*. In Steinberg MH, Forget BG, Higgs DR, Nagel RL, editors: *Disorders of hemoglobin: Genetics, pathophysiology, and clinical management*, Cambridge, 2001, Cambridge University Press, p 711.)

largely corroborates predictions of gene flow derived from historical records. As a generalization, it spread on the Benin haplotype to North Africa and then across the Mediterranean. All three major African haplotypes are present in the western Arabian Peninsula; but on the eastern side, the sickle gene tends to be on the Arab-India haplotype. This is also true in India, although sub-Saharan haplotypes are represented as well. In the Americas, the β^S gene is mostly found on the Benin, Senegal, and Bantu haplotypes.

ABNORMAL MOLECULAR BEHAVIORS OF SICKLE HEMOGLOBIN

Because the $\beta^{Glu \rightarrow Val}$ substitution entails a loss of negative charge and gain in hydrophobicity, HbS exhibits three abnormal molecular behaviors of direct relevance to pathophysiology.

Relationship of HbS Molecular Behaviors to Disease Features

Altered dimer assembly → RBC Hb composition
 Hb phenotype and diagnosis
 Polymerization risk
 HbS instability → Membrane defects
 RBC dehydration
 Hemolysis
 Malaria resistance
 HbS polymerization → Sickling
 Vasoocclusion
 Hemolysis

Hemoglobin S Charge and Tetramer Assembly

Formation of Hb tetramers requires proximate assembly of stable dimers from unlike monomers (e.g., $\alpha + \beta \rightarrow \alpha\beta$), an event governed by electrostatic attraction. The normal α and β chains are positively and negatively charged, respectively. In heterozygous states for β -globin mutants, β -chain competition for dimer assembly is a determinant of the relative proportions of the Hb variants.¹ Mutant β chains with lowered negative charge form $\alpha\beta$ dimers more slowly; the relative rates for dimer association are $\alpha\beta^A > \alpha\beta^S > \alpha\beta^C$, with $\alpha\beta^A$ dimers formed about twice as rapidly as $\alpha\beta^S$ dimers. This explains why those with sickle trait typically have only 40% HbS and why the proportion of HbS exceeds this in HbSC disease. It also explains the effect of concurrent α -thalassemia on the proportion of HbS in sickle trait; as availability of α chains becomes limiting, the percentage of HbS typically drops from 40% to 35% (one α deletion), 30% (two α deletions), or less than 25% (three α deletions).

Hemoglobin S Stability and Oxidant Formation

HbS is modestly unstable, observed *in vitro* as instability to various applied stresses. Two stresses that are most clearly physiologic involve Hb oxidation.² HbS has an abnormal redox potential compared with HbA that may underlie its only modestly (~40%) increased auto-oxidation rate. Yet, HbS exhibits markedly (~340%) augmented instability and oxidation upon interaction with aminophospholipids characteristic of the membrane's inner leaflet. Its behavior once it enters the plasma environment (caused by intravascular hemolysis) is unknown. Although the physical-chemical mechanism of the destabilizing role of the β^6 valine in HbS is not known, this instability leads to accumulation of various Hb and iron forms at the cytosol-membrane interface.² The resulting occurrence of abnormal, oxidative biochemistry promotes a number of prominent defects of the sickle RBC membrane.

Hemoglobin S Solubility and Hemoglobin S Polymerization

Oxy-HbS, oxy-HbA, and deoxy-HbA have very high solubilities, but deoxy-HbS aggregates into densely packed polymers, a process that is fully reversible with reoxygenation.^{3,4} This abnormal property causes the eponymous RBC shape change from polymer-mediated distortion, the fundamental basis for disease promotion in sickling disorders.

Polymer Structure

Deoxygenation transforms soluble HbS into a highly viscous and semisolid gel that behaves thermodynamically similar to a crystal in equilibrium with a solution of individual tetrameric Hb molecules. Even complete deoxygenation does not convert all deoxy-HbS to polymer. The insoluble phase is a collection of domains of aligned polymers, the basic unit of which is a double strand in which two strings of deoxy-Hb tetramers make multiple contacts with each other (Fig. 41.3).

Each HbS tetramer has two β^S chains, the β_1 and β_2 . Deoxy-HbS undergoes a slight structural shift so that the A helix β^{6Val} "donor" site of the β_2 chain in one tetramer can contact an EF helix "acceptor" site (formed mainly by β^{85Phe} , β^{88Leu} , and β^{70Ala}) in the β_1 chain of a tetramer in the neighboring single string. This critical, lateral association can be made only when HbS is in its deoxy conformation; the EF helix hydrophobic pocket is not a favorable acceptor site for the charged β^{6Glu} of the β^A in HbA. In HbS, the β^{6Val} in the β_1 subunit is located so it cannot participate in such contacts. However, the β_2 chain of the second single string can form chemically similar β^{6Val} -dependent contacts with the β_1 chain of the first single string. There are multiple additional axial and lateral contacts, but these are largely the same for deoxy-HbA and deoxy-HbS and are not themselves sufficient to stabilize a polymeric structure.

Fig. 41.3 DEOXYGENATED HEMOGLOBIN S (HbS) POLYMER. (A) Electron micrograph of a fiber of polymerized HbS obtained from a sickled red blood cell. (B) Electron density surface map, modeled from authentic HbS fibers, shows pairings that create double strands plus a helical twist. (C) Model of the HbS fiber, with Hb tetramers rendered as solid spheres. (D) Protein backbone shows tetramer staggering in the HbS crystal. (E) Schematic representation of a double strand, emphasizing that only one of the two β^6 valine residues in each HbS tetramer participates in critical lateral contacts. (F) Sickled red blood cells, showing various morphologies (top to bottom): granular, holly leaf shaped, classically sickled, and smoother and irreversibly sickled. (G) Electron microscopy of sickled RBC cytoplasm reveals highly ordered polymer domains, as seen from the side (bottom) and on end (middle), or highly disorganized domains (top). (A and C, Reproduced with permission from Dykes G, Crepeau RH, Edelstein SJ: Three-dimensional reconstruction of the fibres of sickle cell hemoglobin. *Nature* 272:506,1978; B, reproduced with permission from Carragher B, Bluemke DA, Becker M, et al: Structural analysis of polymers of sickle cell hemoglobin. *J Mol Biol* 199:315,1988; D, reproduced with permission from Harrington DJ, Adachi K, Royer WE, Jr: The high resolution crystal structure of deoxyhemoglobin S. *J Mol Biol* 272:398, 1997; F and G, courtesy Dr. James G. White and reproduced with permission from White JG: Ultrastructural features of erythrocyte and hemoglobin sickling. *Arch Intern Med* 133:545, 1974.)

In the physiologic form of the polymer, the component strings of Hb molecules in a double strand are half-staggered and have a slight twist, creating a fiber that is approximately 21 nm in diameter and is composed of one central and six peripheral double strands. The crystal formed in vitro lacks the twist, but its molecular structure is known in great detail.

Role of Hemoglobin S Solubility

The RBC's hydration state dominates the physical-chemical behavior of HbS. The solubility of deoxy-HbS (approximately 16 g/dL, measured under laboratory conditions) is much lower than the RBC mean cell Hb concentration (MCHC). So, even partial cellular deoxygenation can raise deoxy-HbS concentration above its solubility limit, allowing polymerization to occur. The biophysical effect of macromolecular crowding (boosting a protein's activity far above that predicted from concentration alone) confers nonideal behavior upon cytoplasmic constituents, augmenting likelihood for polymerization at any given degree of deoxygenation.

In vitro studies carried out under (nonphysiologic) equilibrium conditions of stable oxygen tension and long-time scale corroborate crystallographic identification of critical amino acids involved in atomic contacts by revealing the influence of other Hbs on HbS solubility (Fig. 41.4).³ When different Hbs are mixed together, the tetramers dissociate into dimers that intermix and randomly assemble in a binomial distribution to reform tetramers. This clarifies the impact of naturally occurring, intracellular Hb mixtures. In mixtures of HbS and HbA, overall solubility is improved because the hybrid $\alpha\beta^S/\alpha\beta^A$ tetramer integrates into polymer only one half as well as the $\alpha\beta^S/\alpha\beta^S$ tetramer (Fig. 41.4A). Addition of HbF to HbS has a greater sparing effect because neither the $\alpha\gamma/\alpha\gamma$ nor the hybrid $\alpha\beta^S/\alpha\gamma$ tetramer can be incorporated into polymer. In this regard, HbC has the same effect as HbA, and HbA₂ has the same effect as HbF (see Fig. 41.4A). This sparing effect of HbA is such that much lower Hb oxygen saturation is required for polymer to form in HbAS than in HbSS RBCs (Fig. 41.4B).

Kinetics of Polymerization

Laboratory measurements of polymerization kinetics, enabled by inducing (nonphysiologic) near-instantaneous and complete conversion of HbS from R (oxy) to T (deoxy) state, reveal a delay until polymer forms explosively.⁴ This inherent delay time is inversely related to an extremely high power of the initial Hb concentration; it is approximately 10 ms at Hb of 40 g/dL, but it is 100,000 seconds at Hb 20 g/dL (Fig. 41.5A). HbS solutions and sickle RBCs behave similarly in this regard. Delay times must vary enormously from cell to cell because they are dominated by the marked heterogeneity in MCHC (i.e., shorter delay for more dehydrated cells) and are influenced by the presence of any non-S Hb (i.e., longer delay for presence of HbA, C, or F) (Fig. 41.5E). Admixture of 20% to 30% HbA with HbS (simulating HbS- β^+ -thalassemia) increases the delay time 10 to 100 fold, and admixture of 20% to 30% HbF with HbS increases it by 10^3 - to 10^4 -fold.

The mechanism of such polymer formation is hypothesized to proceed by a two-step, double-nucleation process (Fig. 41.5F). Accordingly, the initial homogeneous nucleation takes place in bulk solution, during which small numbers of tetramers associate, with accumulation not favored until a critical nucleus size develops (estimated to be 30 to 50 tetramers). Only then can new tetramers be added lengthwise to form a large polymer. After this occurs, heterogeneous nucleation causes explosive, autocatalytic polymer formation as new fibers form and extend on the surface of the preexisting polymer. It is the time until this explosive formation occurs that laboratory experiments detect as the inherent delay time. It is believed that the striking irreproducibility of long delay times (Fig. 41.5B) reflects stochastic formation of a single (or at least very few) homogeneous nucleation event(s) in cells that slowly polymerize and that

Fig. 41.4 DEOXYHEMOGLOBIN S SOLUBILITY, DEFINED BY STUDIES UNDER EQUILIBRIUM CONDITIONS. (A) Admixture of other hemoglobins with hemoglobin S raises overall solubility in absence of oxygen. The x-axis indicates the proportion of admixed nonsickle Hb. (B) The hemoglobin oxygen saturation required to initiate intracellular polymer formation (i.e., polymer fraction) is much lower for HbAS RBC than for HbSS RBC. (A, Reproduced with permission from Poillon WN, Kim BC, Rodgers GP, et al: Sparing effect of hemoglobin F and hemoglobin A₂ on the polymerization of hemoglobin S at physiologic ligand saturations. *Proc Natl Acad Sci U S A* 90:5039, 1993; B, reproduced with permission from Schechter AN, Noguchi CT: Sickle hemoglobin polymer: Structure-function correlates. In Embury SH, Hebbel RP, Mohandas N, Steinberg MH, editors: Sickle cell disease: Basic principles and clinical practice, New York, 1994, Raven Press.)

short delay times (Fig. 41.5D) reflect simultaneous formation of multiple nucleation sites in cells that polymerize rapidly.

Polymerization Under (Patho)physiologic Conditions

In physiology, sickle RBCs are neither at equilibrium with constant oxygen tension nor undergoing instantaneous or complete deoxygenation. Rather, irrespective of the inherent delay time, the rate of deoxy-HbS polymer growth in vivo is limited by the rate at which RBC deoxygenation develops during microvascular passage. Since this transit time is on the order of ~1 second, it probably effectively renders irrelevant any inherent delay times of less than ~1 second (Fig. 41.5G).⁴ Thus kinetic considerations argue that most RBCs in patients with sickle cell anemia are unlikely to sickle during their passage through the microcirculation unless something, such as RBC-endothelial adhesion, slows their transit.

Predictability is complicated by the marked heterogeneity among sickle RBCs in MCHC and HbF content, as well as the natural biologic variability in capillary transit times. A good qualitative

Fig. 41.5 KINETICS OF HEMOGLOBIN S POLYMERIZATION AFTER NEAR-INSTANTANEOUS AND COMPLETE DEOXYGENATION. (A) Extreme dependence of delay time on hemoglobin concentration. (B–D) Kinetic progress curves for polymer formation show that long delay times are highly variable (B), but very short delay times are highly reproducible (D). To the right is a representation of domains and corresponding RBC morphology postulated to result from these different scales of polymerization rate (see Fig. 41.1B–E; and Fig. 41.3F). (E) Delay times for individual RBCs are influenced by substituent hemoglobins. (F) A double nucleation process underlies polymer formation, with unfavored homogeneous nucleation (*top*) followed by explosive heterologous nucleation (*bottom*). (G) Physiologically, the finite rate of deoxygenation effectively caps the polymer growth rate and eliminates the relevance of delay times that are short relative to deoxygenation rate (<1 second). (A–E, Reproduced with permission from Eaton WA, Hofrichter J: *Hemoglobin S gelation and sickle cell disease*. Blood 70:1245, 1987; F, reproduced with permission from Ferrone FA, Hofrichter J, Eaton WA: *Kinetics of sickle hemoglobin polymerization II. A double nucleation mechanism*. J Mol Biol 183:611, 1985; G, reproduced with permission from Ferrone FA: *Oxygen transits and transports*. In Embury S, Hebbel RP, Mohandas N, Steinberg MH, editors: *Sickle Cell Disease: Basic Principles and Clinical Practice*, New York, 1994, Raven Press.)

correspondence between polymerization in solution and within RBCs argues that the fundamental polymerization mechanism (Fig. 41.5F) is not altered by membranes. Yet, emerging evidence indicates that the abnormal sickle RBC membrane can accelerate nucleation, in essence eliminating the inherent delay time. A similar effect would be exerted by any preexisting polymer not completely melted during prior pulmonary transit (expected for fewer than 1% of RBCs). However, neither of these effects would alter the physiologic constraint that bulk polymer growth rate can only parallel RBC deoxygenation rate.

In vitro, sickle RBC can become classically sickled or assume holly leaf or granular forms, depending on deoxygenation rate (slow to rapid, respectively), which determines the number of nucleation domains created (Fig. 41.5B–D; and see Fig. 41.1B–E). In the microcirculation, granular forms are most likely to occur; in contrast, frankly sickled forms are most likely to develop during venous return to the heart. The RBC shape per se is not a determinant of RBC deformability, but rigidification caused by polymer can impede microvascular passage. This would develop dynamically during microvascular transit.

HbF and Its Protective Effect

In sickle cell anemia, HbF in RBC lysates averages ~5% to 8% (range 1% to 25%). However, this HbF is not distributed evenly amongst RBCs.⁵ Rather, its heterocellular expression is evident in the presence of F cells (RBC particularly enriched in HbF) that comprise anywhere between 2% and 80% of all RBCs. For most patients, only the small proportion of their F cells that contain at least ~10 pg HbF (roughly one-third of RBC Hb content) are expected to be protected from polymerization under physiologic conditions.⁵ Nonetheless, on average, F cells remain better hydrated and exhibit better survival.

Alternative Ligands: Carbon Monoxide and Nitric Oxide

Patients with sickle cell anemia can have nontrivial elevations of CO-Hb levels (reportedly as high as 7.6% in children) because of hemolysis. Hb that is partially liganded with CO is shifted to the R state conformation but has lost a portion of its oxygen carrying

capacity. It is difficult to predict whether this produces a net benefit or loss. RBC and Hb appear to participate in NO transport to the microcirculation, although both magnitude of the effect and mechanisms involved are debated. NO is asserted to improve RBC deformability and impair HbS polymerization. Reaction of NO with oxy-Hb causes Hb oxidation to met-Hb and reciprocal consumption of NO.⁶

ABNORMALITIES OF SICKLE RED BLOOD CELLS

Even oxygenated sickle RBCs exhibit a variety of cellular and membrane abnormalities that contribute directly to pathophysiology. Some are the consequence of proximate polymer formation, while others result from oxidative biochemistry. An overarching theme in sickle disease pathobiology is that individual sickle RBC exhibit remarkable heterogeneity in various cellular characteristics. The striking variability in hydration status and HbF content is particularly important.

Membrane Iron and Oxidant Generation

An abnormal oxidative biochemistry takes place at the cytosol-membrane interface of the sickle RBC.² The avidity of HbS for bilayer lipid, and perhaps its modestly enhanced auto-oxidation in solution, result in augmented formation of superoxide and met-Hb. This, in turn, can become denatured and lose its heme to the lipid bilayer, where it is easily destroyed by lipid hydroperoxides to liberate “free” iron. Forms of iron associated with the membrane are catalytically active, generating highly reactive oxidants. Also, membrane “free” iron can form a redox couple with soluble oxy-Hb to promote further hemoglobin oxidation, denaturation, and deposition. The sickle RBC membrane thereby acquires abnormal amounts of various iron forms: Hb, denatured hemichrome, free heme, and nonheme iron.² A large portion of sickle RBC oxidant generation and stress is from enhanced nicotinamide adenine dinucleotide phosphate (NADPH)-oxidase activity, probably in reticulocytes and exhibiting a responsiveness to certain plasma substances, e.g., endothelin-1.

Of equal importance to excessive oxidant generation, the membrane location of catalytic iron establishes in sickle RBC a unique oxidant risk (not present in normal RBC) because it effectively targets oxidative damage to membrane components. Further, the juxtaposition of iron with bilayer lipid allows reinitiation of peroxidative chain reactions, effectively bypassing protection by vitamin E. Deficient levels of antioxidants (e.g., vitamin E, glutathione, ascorbic acid) in sickle RBC, caused by oxidative consumption and dietary insufficiencies, contribute. The result is abnormal oxidation of membrane protein thiols and peroxidation of membrane lipids. Among the many sickle membrane defects, evidence for an oxidative origin or contribution is strongest for Band 3 clustering, abnormal membrane stiffness, formation of irreversibly sickled cells (ISCs), aberrant cation homeostasis, tendency toward microvesiculation, abnormal mechanosensitivity, and erythrophagocytosis.²

Cation Homeostasis and Dehydrated Cells

For normal RBCs, MCHC averages ~32 g/dL and varies from 27 to 38 g/dL, with fewer than 1% of cells having MCHC greater than 38 g/dL. In contrast, the MCHC of sickle RBCs averages ~34 g/dL and ranges from 23 to 50 g/dL, with up to 40% of cells having MCHC greater than 38 g/dL. This extreme density heterogeneity results from reticulocytosis (low-density, low-MCHC cells) and dehydrating mechanisms (higher density, high-MCHC cells) (Fig. 41.6).

The most dramatic ion-handling abnormality of the sickle RBC is sickling-induced permeabilization of the RBC membrane to cations (Na^+ , K^+ , Ca^{2+}). Since this depends on cell deformation, it probably partly reflects the sickle RBC's exaggerated leak susceptibility to

Fig. 41.6 MARKED HETEROGENEITY IN SICKLE RED BLOOD CELL HYDRATION. Compared with normal RBCs (A) studied by discontinuous density-gradient centrifugation, RBCs from a sickle patient with four α genes (D) include cells of unusually low density (mostly reticulocytes) and abnormally high density (dehydrated cells). Sickle patients with three and two α genes are shown in (C and B), respectively. (Reproduced with permission from Embury SH, Clark MR, Monroy G, Mohandas N: Concurrent sickle cell anemia and alpha-thalassemia. *J Clin Invest* 73:116, 1984.)

deformation (mechanosensitivity).⁷ Sickling induces calcium influx and a slight acidification, occurring stochastically and only in some cells at any one time. This results in net potassium and water loss mediated mostly by activation of a Ca^{2+} activated (Gardos) K^+ channel and potassium chloride (KCl) cotransport. The latter can be activated by lowered pH, endothelin-1, thiol oxidation, and a membrane interaction effect of hemoglobins that are relatively positively charged ($\text{HbC} > \text{HbS}$). It is influenced by macromolecular crowding of cytosolic proteins caused by the high MCHC. Even at steady state, sickle RBCs contain increased Ca^{2+} because it is sequestered in cytoplasmic inside-out membrane vesicles, providing evidence of prior cytosolic Ca^{2+} transients.

These aberrancies lead to decrements in RBC hydration and deformability.⁷ However, hyperdense RBCs—mostly ISCs—are not necessarily older cells with longer histories of sickling and unsickling. Rather, they can develop via a rapid reticulocyte-to-ISC transformation, with those RBC having lower HbF levels being particularly susceptible. It is unclear whether this rapid induction of cation loss or the gradualism of classic interpretations is the dominant mechanism underlying sickle RBC dehydration. Dehydrated RBCs have diminished deformability and increased propensity for polymerization, the mutually promotive effects of dehydration and sickling comprising a vicious cycle. RBC dehydration is particularly likely to be exaggerated by the renal medullary environment and possibly by nocturnal arterial desaturation accompanying disordered sleep.

Deformability, Fragility, and Vesiculation

Even oxygenated sickle RBCs are poorly deformable.⁷ The dominant cause of this is the abnormally high cytoplasmic viscosity of dehydrated cells. Additional factors include abnormal stiffness of the RBC membrane caused, in part, by thiol oxidation and, in part, by a poorly understood direct effect of hemoglobin upon the membrane. Upon RBC deoxygenation in vitro, there is a temporal correspondence between appearance of polymer-induced shape change and deterioration of deformability, as measured by micropipette and laser diffractometer. On the other hand, filtration studies found decreased deformability before morphologic change, and viscometry reveals a large deterioration in bulk viscosity caused by deoxygenated dense discocytes that show little shape change.

Sickle RBCs are somewhat mechanically fragile, which may be a consequence of dehydration and a weakening of critical skeletal associations caused by oxidative protein damage. The tendency of sickled RBCs to lose membrane microvesicles reflects separation of

Fig. 41.7 BAND 3 AND IMMUNOGLOBULIN COCLUSTERING. Denatured Hb on the RBC membrane, is associated with clumping of Band 3, and opsonization by naturally occurring anti-Band 3 antibody. Clusters of band 3 are colocalized with immunoglobulin on the membranes of sickle red blood cells (*left*). The drawing shows the colocalization scheme (*right*). the bilayer from the underlying skeleton due to spicules of polymerized hemoglobin, with enhanced susceptibility caused by protein thiol oxidation.

Membrane Proteins and Lipids

Sickle RBC membrane protein function is adversely affected by thiol oxidation and possibly other oxidative protein modifications.² Ankyrin interactions with spectrin and Band 3 are abnormal, gly-cophorin and Band 3 exhibit decreased mobility, and thiol-oxidized β-actin displays abnormal associations in the spectrin-actin-4.1 complex. Band 3 is abnormally clumped from binding of denatured HbS, which enables attraction of naturally occurring anti-Band 3 immunoglobulin (Fig. 41.7).

Normal enforcement of bilayer phospholipid asymmetry is impaired in sickle RBCs. A scramblase that moves phosphatidylserine (PS) outward is activated by calcium transits, and a translocase that restores PS inwardly can be inhibited by thiol oxidation. RBC sickling promotes PS externalization, especially in ISCs, but also in some reticulocytes. Other changes include presence of peroxidation byproducts such as malondialdehyde (MDA) that can cross-link proteins. Notably, the increased presence of bilayer lipid hydroperoxides appears to account for the sickle RBC membrane's abnormal mechanosensitivity, evident in its enhanced cation leak response to deforming stress. Presumably, this deformation susceptibility

Fig. 41.8 RBC ADHESION TO ENDOTHELIUM. RBCs adhere to the vascular wall endothelium under flow conditions in the microcirculation of a rat infused with human cells. Immobile RBCs are on walls of the postcapillary venule, and the smaller feeder microvessels (*small arrows*) have no flow because of the logjam of RBC. (Reproduced with permission from Kaul DK, Fabry ME, Nagel RL: Microvascular sites and characteristics of sickle cell adhesion to vascular endothelium in shear flow conditions: Pathophysiological implications. *Proc Natl Acad Sci U S A* 86:3356, 1989.)

contributes to various sickling-induced RBC responses, e.g., microvesiculation.

Irreversibly Sickled Cells

The sickled RBCs seen on a typically-obtained blood smear are mostly ISCs (see Fig. 41.1). Their permanent shape abnormality is caused not by retained polymer but rather by membrane retention of an elongated shape, explained by thiol oxidation of β-actin such that the spectrin-actin-4.1 complex exhibits abnormally slow dissociation. Otherwise, ISCs are similar to other equally dense RBC in having high MCHC, poor deformability, externalized PS, and low HbF content. ISC counts on average are higher in male patients, perhaps reflecting their average lower levels of HbF. The fundamental requirements for ISC formation seem to be RBC dehydration, prolonged deoxygenation, and assumption of a fixed membrane shape. Perhaps there is a prior “conditioning” residence in the microcirculation.

The clinical importance of ISCs lies in their ability to prompt diagnosis of a sickling disorder when seen on blood smear and in their short life span that contributes to overall hemolytic rate. They would contribute to the RBC logjam involved in occlusion, but it is unclear whether ISC count correlates with vasoocclusive manifestations. Although still adhesive to endothelium, ISCs are less so than other sickle subpopulations, but they exhibit greater adherence to macrophages.

Endothelial Adhesivity

Oxygenated sickle RBCs are abnormally adhesive to vascular endothelial cells (Fig. 41.8). About 20 candidate mechanisms have been implicated, most involving adhesion molecules on endothelium, adhesive structures restricted to reticulocytes or present on all RBCs, and with or without bridging by adhesogenic plasma proteins.⁸ Some mechanisms require RBC signaling responses to plasma factors for activation. Involvement of mixed cell interactions with endothelium has been proposed. Most described candidate mechanisms involve adhesive reticulocytes and are high affinity, identified using flowing conditions. Yet, in the biologic context microcirculatory blood flow can be intermittent and occurs within vessels of constraining diameters enabling greater potential contact surface area. It seems probable

that low-affinity adhesive mechanisms would gain relevance in that situation. Indeed, an unanswered question is whether or not RBC adhesion occurs via a single, dominant mechanism *in vivo*. To date, only RBC/endothelial adhesion mediated by $\alpha_v\beta_3$ and P-selectin have been verified *in vivo* in the sickle mouse, in which blockade of P-selectin inhibits adhesion of both RBCs and white blood cells (WBCs) to endothelium and effects improvement in blood flow.

Participation of sickle RBC adhesion in pathophysiology is governed, in part, by endothelial activation state. For example, adhesion events mediated by endothelial vascular cell adhesion molecule 1 (VCAM-1), $\alpha_v\beta_3$, and P-selectin are activated, respectively, by tumor necrosis factor (TNF), platelet activating factor, and thrombin. Each of these endothelial stimulants is elevated in sickle blood. However, there is a multitude of biologic modifiers in the sickle context that can influence endothelial surface features (see Box on [Complex Sickle Milieu](#)). Additional influencing factors would include: the reticulocyte count; flow and shear rates; vessel diameter, geometry and vasomotion; margined WBCs; mixed blood cell interactions with endothelium; concurrent processes (e.g., degree of platelet activation or dehydration); and possibly even environmental exposure to endothelial toxins such as tobacco smoke.

Macrophage Interaction

Sickle RBCs are readily phagocytosed by macrophages because of RBC membrane modifications by malondialdehyde, PS externalization, and opsonization by immunoglobulin. The latter process is triggered by abnormal clustering of membrane protein Band 3 (see [Fig. 41.7](#)) and possibly by modification induced by malondialdehyde. The most dense cells have the most surface immunoglobulin and higher PS externalization, and they exhibit the greatest interaction with macrophages and potential for erythrophagocytosis.

THE ROLE OF RED BLOOD CELLS IN DISEASE PATHOGENESIS

Vascular Occlusion

Notwithstanding the conceptual simplicity of the sickling phenomenon, when acute microvascular occlusion occurs, causing an acute painful episode, it is a complex and evolving process. It seems probable that similar events, but of less severe degree and remaining at a subclinical level, are a recurrent or even near-constant feature of sickle vascular pathobiology. The current understanding of microvascular vasoocclusion in sickle cell anemia does carry lingering enigmas.⁹

Insofar as sickling is responsible, risk factors would include anything that would increase RBC dehydration and MCHC (e.g., insufficient clinical hydration, injudicious use of diuretics), foster arterial oxygen desaturation (e.g., lung disease, sleep-disordered breathing), prolong microvascular transit time (e.g., inflammatory milieu), increase blood viscosity (e.g., transfusion, clinical dehydration), right shift the oxygen binding curve (e.g., acidosis), or disturb vascular dynamics (e.g., cold, aberrant neurochemical responses, vasomotive rhythms). The extraordinary heterogeneity amongst sickle RBC undoubtedly confers enormous variability in behavior of individual RBC as they lose oxygen while traversing the microcirculation single-file. Although such behavioral heterogeneity is perhaps the dominant feature of sickle disease pathobiology, it currently is immeasurable at the level of microcirculatory physiology. At the sensitivity of epidemiology, HbF level is inversely related to frequency of vasoocclusive painful crises.¹⁰

Enabling vasoocclusion, adhesion of sickle RBC to endothelium allows greater deoxygenation by slowing microvascular flow. Indeed, in transgenic sickle mice, vascular occlusion is a two-step process.¹¹ This model holds that adhesion of less dense (reticulocyte-enriched) sickle RBCs to endothelium in the postcapillary venule initiates vasoocclusion, after which logjamming by dense, poorly deformable, and sickling cells creates retrograde propagation ([Fig. 41.8](#)). Thus,

determinants of RBC adhesivity and endothelial activation play an important role in vasoocclusion pathobiology. Consistent with this, clinical vasoocclusive severity correlates with the endothelial adhesivity of sickle RBCs *in vitro*.

Impairment of microvascular flow also derives from the diminished deformability of dehydrated sickle RBC. Dense cells (especially ISCs) can have difficulty entering the microvasculature, e.g., at bifurcations. Whether RBC adhesivity and poor deformability perhaps exert combined or synergistic effects within the smallest vessels has not been studied, nor has any role for dynamic change of rigidity as deoxygenation progresses during microvascular transit. Clinical vasoocclusive severity in humans correlates with *preservation* of RBC deformability rather than with impairment thereof,⁷ perhaps because more dense cells tend to be misshapen and less able to make close adhesive contacts with endothelium.

Hemolytic Anemia

RBC life span in sickle cell anemia averages about 15 days but with marked interindividual variability (from ~7 to ~30 days); in HbSC disease, the average is about 30 days.¹² All four fundamental mechanisms that can underlie RBC removal in hematologic disease—erythrophagocytosis, fragmentation, trapping, and osmotic lysis—probably contribute ([Fig. 41.9](#), bottom). These are consequences of the proximate aberrancies of the sickle RBC discussed earlier ([Fig. 41.9](#), middle) that result from the specific molecular behaviors of the mutant HbS ([Fig. 41.9](#), top). Although speculative, the illustrated, integrated synthesis of extant research data presents a plausible mechanistic blueprint.¹²

Although complex, the routes to accelerated RBC removal seemingly resolve into two contributory mechanistic cascades: one from polymer formation that underlies three terminal processes (trapping, fragmentation, osmotic lysis) that cause intravascular hemolysis; and one from HbS instability that leads to erythrophagocytosis and extravascular hemolysis. Notably, intravascular hemolysis seems to account for only one-third of overall hemolysis, while two-thirds seemingly is explained by extravascular hemolysis. The influence of the instability-based cascade is most evident in enhanced erythrophagocytosis of sickle RBC, promoted by denatured Hb causing Band 3 clumping causing attraction of immunoglobulin.

The shortest survival is exhibited by the sickle RBCs that are most dehydrated and that have the lowest amounts of HbF,¹³ consistent with the polymerization-based abnormalities (see [Fig. 41.9](#), left side). Yet, it is not known whether these two RBC features fully explain the very wide range of hemolytic rates. Presumably, the sickle RBCs' fragility is related, and sickled RBCs do lose Hb via microvesiculation when sickling is reversed. Improved RBC hydration caused by concurrent α -globin gene deletion improves RBC survival.¹⁴ Sickle RBC survival drops substantially during acute painful episodes, but whether this precedes or follows vasoocclusion onset is not known. The only biomarkers so far documented to correlate strongly and quantitatively with *measured* RBC lifespan in sickle cell anemia are the (uncorrected) reticulocyte percentage and HbF level.¹²

Consequences of Hemolysis

Hemolysis exerts complex effects. Some are indirect, stemming from expanded erythropoiesis, such as enhanced production of highly adhesive reticulocytes and augmented elaboration of placental growth factor. This growth factor activates blood monocytes and promotes augmented production of endothelin-1 (ET-1) that can exert multiple effects relevant to sickle pathobiology: induce vasoconstriction, cause nociceptive hypersensitization, activate RBC NADPH oxidase activity, and prompt release of inflammatory mediators. Other hemolysis effects derive directly from RBC components released into the blood. Arginase diminishes plasma arginine, possibly impeding endothelial nitric oxide synthase (eNOS). A robust elaboration of PS-positive RBC microparticles exerts a signaling impact upon endothelial cells,

Fig. 41.9 MECHANISMS LEADING TO HEMOLYSIS IN SICKLE CELL DISEASE. This integrated synthesis proposes how the molecular behaviors of hemoglobin S (HbS) (*top*) cause development of multiple RBC abnormalities (*middle*) that lead to the four mechanisms of accelerated RBC destruction (*bottom*). (Reproduced with permission from Hebbel RP: *Reconstructing sickle cell disease: A data-based analysis of the “hyperhemolysis paradigm” for pulmonary hypertension from the perspective of evidence-based medicine*. Am J Hematol 86:123–154, 2011.)

accelerates thrombin generation, promotes pulmonary sequestration of WBCs, and protects disgorged cell-free Hb from scavenging proteins. The oxy-Hb liberated from lysing sickle RBCs can consume NO,^{6,15} thus augmenting the diminished NO bioavailability primarily caused by endothelial dysfunction. It has been argued that this phenomenon is the specific cause of multiple specific complications of sickle disease, based upon correlations between them and indirect hemolytic biomarkers.¹⁶ However, this assumption is belied by the extreme complexity associated with hemolysis. It is very likely that biodeficiency of NO in sickle disease contributes to sickle disease complications, but it is improbable that it is a sole causal factor.¹² Deficiency of NO does restrain its normal braking effect on platelet activation and inflammation, as well as its vasodilatory and superoxide buffering functions.

Once HbS in plasma oxidizes to met-HbS, it is abnormally likely to lose its heme² and thereby: oxidize blood lipids, induce endothelial activation, stimulate blood monocytes and endothelial cells to produce TNF- α and express tissue factor, and trigger disgorgement of neutrophil extracellular traps, among other effects. Some cell responses to heme are mediated by its binding to TLR4; e.g., in sickle mice this causes enhanced endothelial surface expression of P-selectin and triggers vascular stasis.¹⁷ In the sickle context any potential effects of liberated cell-free Hb would be augmented because of the greatly limited levels of scavenging proteins, haptoglobin and hemopexin.

UNIQUE SYSTEMS BIOLOGY OF SICKLE CELL ANEMIA

Sickle cell anemia is unique amongst human diseases because of the extraordinary complexity arising from concurrent disturbance of multiple biologic processes, such that blood cells and the vessel wall are exposed to a broad spectrum of abnormal inputs (see Box on The Complex Sickle Milieu). Remarkably, this complexity derives from only two proximate events, vasoocclusion and hemolysis. Although it is not possible to identify the proportionate contributions and importance of the resulting disparate aberrancies, two themes emerge.

The Complex Sickle Milieu

Anemia (altered wall shear stress, tissue hypoxia, HIF-1 signaling)
 RBC abnormalities (rigidity, sickling, abnormal adhesivity)
 Hemolysis (plasma Hb and heme, RBC microparticles, arginase)
 Blood cell activation (signaling and adhesive interactions with endothelium)
 Systemic inflammation:
 Mediators (TNF, IL-1 β , MCP-1, prostaglandins, leukotrienes, others)
 Endothelial glycocalyx degradation
 Activated monocytes, granulocytes, and lymphocyte subsets
 Microparticles (endothelial, monocyte, platelet)
 Mast cell activation (neuroinflammatory mediators)
 NETs
 Oxidant stress (activated WBC, xanthine oxidase, NADPH oxidase, mitochondrial, others)
 Growth factors (VEGF, PlGF, erythropoietin, others)
 Dehydration (vasopressin)
 Hemostatic system abnormalities:
 Coagulation activation (thrombin, others)
 Fibrinolysis (D dimer, others)
 Platelet activation (platelet microparticles, plasma TSP, others)
 Vasoactive agents (hypoxia, ET-1, thromboxane, vasopressin, prostaglandins, adrenergic agonists, peroxides, CO, NO, others)
 Adhesogenic proteins in plasma
 Ischemia/reperfusion physiology
 Endothelial cell activation and dysfunction
 Endothelial cell injury (from occlusion, oxidants, oxidized plasma lipid, mechanic forces)
 Inadvertent effects of therapies (iron overload, opioid angiogenesis signaling)

CO, Carbon monoxide; ET, endothelin; Hb, hemoglobin; HIF, hypoxia inducible factor; IL, interleukin; MCP, monocyte chemotactic protein; NETs, neutrophil extracellular traps; NO, nitric oxide; PlGF, placenta growth factor; RBC, red blood cell; TNF, tumor necrosis factor; TSP, thrombospondin; VEGF, vascular endothelial growth factor; WBC, white blood cell.

Fig. 41.10 ISCHEMIA/REPERFUSION AS THE CORE DRIVING FORCE IN SICKLE CELL ANEMIA. As the consequence of vasoocclusion, ischemia–reperfusion provides an incessant driving force causing systemic inflammation with microvascular dysfunction. The adhesion biology resulting from activated/dysfunctional endothelial cells creates a positive feedback loop that slows microvascular transit and enables polymer formation. (Modified from Hebbel RP: *Reconstructing sickle cell disease: A data-based analysis of the “hyperhemolysis paradigm” for pulmonary hypertension from the perspective of evidence-based medicine*. *Am J Hematol* 86:123, 2011.) Hb, Hemoglobin; PS, phosphatidylserine.

First, vasoocclusion and hemolysis are interrelated and mutually promotive. Second, there is an apparent unifying explanation for emergence of this panoply of biologic mediators.

Ischemia-Reperfusion Physiology

The abnormal adhesion of sickle RBC to endothelium creates a positive feedback loop that slows microvascular transit and thereby enables deoxygenation, polymerization, sickling, and occlusion. Experimental studies in transgenic sickle mice indicate that the enabling, proximate instigation of endothelial activation derives from ischemia-reperfusion (I/R) injury physiology, a process that would comprise an incessant driving force for systemic inflammation (Fig. 41.10).¹⁸ This combination of inflammation and endothelial dysfunction can provide a unifying explanation for the multitude of vascular biologic abnormalities in sickle cell anemia, and it establishes a contextual and generative explanation for several of the specific clinical complications.

The complicated biology of I/R injury occurs when a proximate vascular occlusion causing ischemia is followed by reperfusion that reintroduces oxygen to the formerly ischemic area. In the unique sickle context, the initiating occlusive event(s) would be microvascular and multifocal, and they would happen recurrently. As revealed by studies of sickle transgenic mice, this triggers the classic, reperfusion-dependent, early I/R events of localized and rapid onset of oxygen radical generation, nuclear factor kappa-B (NFκB) activation, TNF-α production, and WBC activation. Research on I/R generally illustrates that its pathobiology thereafter explosively arborizes to become vastly complex. Its hallmark, however, is conversion of this localized process into a sterile inflammatory response that is robust and systemic. It initiates widespread microvascular dysfunction and organ accumulations of inflammatory cells by infiltration from blood plus activation of tissue resident macrophages and mast cells. This can lead to disease remote from the initiating occlusion, and it can explain emergence of macrovascular disease from inciting microvascular events.

INFLAMMATION

Many agents comprising the exceedingly complex sickle milieu (see Pink Box) exert proinflammatory effects; a number interact with each other in ways that alter the nature or complexity or magnitude of

responses. As one example, the growth factor angiopoietin-2, released from Weibel-Palade bodies, sensitizes the endothelial cell toward TNF-α and consequent adhesion molecule expression. It is not possible to identify proportionate contributions of the many specific inflammatory inputs, but ligand-triggered TLR4 signaling is emerging as an important contributor.¹⁷

In summation, sickle cell anemia is a chronic, systemic inflammatory state.¹⁹ Characteristic features include: leukocytosis; activation of granulocytes, monocytes, lymphocyte subsets, and mast cells; elevated levels of proximate inflammatory mediators, acute-phase reactants, and distal effectors; abundance of soluble adhesion molecules; activation of coagulation; presence of microparticles from multiple activated cell types; and generation of excess oxidant via multiple mechanisms. Importantly, this systemic inflammatory state is perpetual, with footprints of active inflammation apparent even between acute clinical events. Clinically, leukocytosis in sickle cell disease is a risk factor for mortality, clinical and silent stroke, and acute chest syndrome, and it helps predict which babies will develop a severe clinical course. Conversely, several clinical complications are themselves overtly inflammatory, in particular acute painful episodes and acute chest syndrome.

Endothelial Activation and Dysfunction

The vascular endothelial cell receives and responds to disparate inputs, both sensing and modifying its environment. Although normally adaptive, the endothelial response can become maladaptive. In the sickle context, the extreme complexity of the sickle milieu (see Box on The [Complex Sickle Milieu](#)) molds endothelial cell function, leading to a harmful state. The core inflammatory and oxidative input causes a high level of endothelial activation with adverse consequences such as coagulation activation, degradation of the endothelial glycocalyx (a critical determinant of endothelial cell homeostasis), and endothelial dysfunction. An often-overlooked principle predicts that endothelial dysfunction in the sickle context creates unique risk (see [Mortality and Sudden Death](#), later).

Aberrant Vasoregulation

Sickle cell anemia involves deficient endothelial-dependent, flow-mediated conduit artery dilation.²⁰ Beyond the dominant role of I/R and inflammation-induced endothelial dysfunction, there are several additional contributing processes: TNF-α induction of endothelial L-arginase, limiting L-arginine availability to eNOS; NO consumption by excess superoxide and cell-free oxyHb; elevated asymmetric dimethylarginine; plus other aberrancies (e.g., microparticles, abnormal wall shear stress, elevated phospholipase A2).¹² The proportionate contributions of these processes is unknown. NO bioavailability seems to be higher for females than males, who exhibit substantial non-NO regulation of flow.

Perfusion patterns are complex in sickle cell anemia but can generally be described as impaired microvascular flow and augmented macrovascular flow.²¹ Aberrancy of both endothelial-dependent and endothelial-independent vasoregulation is apparent, and the milieu is replete with a multitude of vasoactive substances. A state of vascular instability may derive from tonic upregulation of both vasoconstrictive and vasodilatory systems, in addition to exaggerated α₁-adrenergic vessel wall responsiveness. Sickle humans reveal disruption of autonomic regulation (e.g., with augmented risk for hypoxia-induced perfusion decrements).²² Systemic blood pressure in patients with sickle cell anemia is lower than in nonanemic controls, yet is higher than in comparably anemic β-thalassemics.

Coagulation Activation

The interplay between inflammation and coagulation often seen in biomedicine is generally highly evident in sickle cell anemia, with

chronic activation of coagulation, fibrinolysis, and platelets.²³ This is accompanied by increased whole blood tissue factor (TF) and its increased expression on endothelial cells and blood monocytes. Such abnormalities can follow signaling via heme/TLR4 or TNF or various other perturbing factors. Presence of PS on released microparticles and on some sickle RBC promotes accelerated thrombin generation. Oxidation appears to create resistance to cleavage of ultra-large forms of von Willebrand factor by ADAMTS13. There is excessive consumption of antithrombotic proteins. The extant biodeficiency of NO would contribute to TF expression and augmented platelet activation because it normally inhibits these. Products of platelet and coagulation activation undoubtedly exert signaling and perturbing effects on endothelium.

Genesis of Clinical Disease

For the individual patient, evident clinical disease may not parallel or accurately predict the extent of underlying overall disease burden. It has been argued that some clinical complications (pulmonary hypertension, leg ulcers, priapism, stroke) are caused by hemolysis, while others (acute chest syndrome, acute painful episodes) are caused by vasoocclusion.¹⁷ That different processes underlie different clinical complications is entirely possible, but evidence for there being such dramatic dichotomy of phenotype pathogenesis is very indirect.¹² It is important to recall that effects of the proximate inputs (hemolysis and vasoocclusion) are undoubtedly modulated by the complex sickle milieu, and that multiple biologic systems are concurrently activated. Also, the vessel wall is exposed lifelong to the great variety of stressors and perturbing substances of the complex sickle milieu. Few data in the research literature, whether from general medicine or study of sickle disease, can be extrapolated with any confidence whatsoever to chronicity of this magnitude and complexity.

Pain Syndromes

In adults, a higher frequency of acute painful episodes is associated with increased mortality,¹⁰ presumably reflecting derivation of both from severity of underlying disease activity. The immense further disturbance of multiple biologic processes during such episodes augments risk for complications like acute chest syndrome and sudden death. Pain frequency is higher in association with higher hematocrit and lower HbF level, consistent with the concept that acute painful episodes involve ischemic pain from vasoocclusion. However, pain in sickle disease appears to be multimodal and complex. There probably is a substantial inflammatory contribution to both acute and chronic sickle pain, involving many factors including inflammatory neuropeptides and mast cells.²⁴ It probably involves a state of nociceptive hypersensitization. The chronic, daily pain affecting many patients seems to be both inflammatory and neuropathic in origin.

Chronic Vasculopathy

The macrovascular component of sickle vascular disease is a chronic inflammatory vasculopathy. Histopathology from the large and medium vessels at the circle of Willis, where some sickle children develop occlusive disease, is characterized by intimal hyperplasia, fibrotic and proliferative changes, and damage to internal elastic lamina. Pathology of arterial lesions at other sites is described similarly. This typical arterial wall response to inflammation occurs, in the sickle case, without the fatty streak and foam cells of atherosclerosis, probably reflecting the absence of hyperlipidemia plus the different spectrum of proximate inflammatory inputs. It is quite possible that the specific generative stressors for vasculopathy could vary somewhat from organ to organ, but it seems likely that universal contributors include inflammation, endothelial dysfunction, growth factor excess, and aberrant wall shear stress.

Thrombosis

The hypercoagulable state suggested by blood biochemistries is accompanied by a thrombotic diathesis.²³ Arterial thrombosis occurs in areas of vasculopathy in the circle of Willis in association with childhood ischemic stroke, and in lungs exhibiting pulmonary hypertension. Incidence of venous thromboembolism is increased, and sickle cell anemia is a complicating condition for pregnancy. Downstream consequences of the coagulation system activation may play a greater role than is currently appreciated.

Stroke and Cerebrovascular Disease

Several stroke syndromes occur in sickle disease and may have differing pathogeneses. Ischemic stroke with clinical deficit develops in 5% to 10% of children with sickle cell anemia, with arterial wall changes that narrow vascular luminal diameter within the circle of Willis being the strongest risk factor and presumptive cause. Completion of the actual stroke tends to involve thrombosis at the site of vessel wall disease. Despite this, most clinical research has focused upon stroke events per se rather than upon separate risks for the apparent fundamental underlying processes, arterial wall disease and thrombotic diathesis. Concurrent α -thalassemia or HbSC disease lowers the risk of this stroke type, and HbF level is not protective. It can be suspected that elevated growth factors are participants in arterial wall disease and the sometimes-associated Moyamoya. In a seemingly separate syndrome, “silent” strokes (but associated with time-dependent degradation of neuropsychologic function) accumulate throughout childhood and are believed to derive from inadequate microvascular blood flow eventuating in multifocal microinfarcts. Yet another syndrome, hemorrhagic stroke, can complicate the vessel fragility of Moyamoya and sometimes aneurysm; otherwise, risk factors and root causes of hemorrhagic stroke are unknown.

Pulmonary Disease

The spectrum of sickle pulmonary complications includes chronic restrictive lung disease, pulmonary hypertension, asthma, infection, in situ embolic thrombosis, and acute chest syndrome (ACS).

The acute inflammatory syndrome of ACS is associated especially with infection in children and fat embolism (probably from marrow infarction) in adults, but other presumptive triggers are similarly implicated. Risk factors include leukocytosis, lower levels of hemoglobin and HbF, and a history of asthma. The nature of ACS and its occurrence and timing during acute vasoocclusive episodes raise the question whether it might be an event of remote organ injury complicating I/R physiology.¹⁸ Regardless of specific proximate trigger, in this syndrome it is likely that inflammation, adhesion biology, NO deficiency, and endothelial permeability conspire to augment the deleterious effects of hypoxia on the lung. Mast cell activation, another consequence of I/R, may contribute to pulmonary susceptibility generally and to pathobiology of ACS and asthma specifically.

Pulmonary hypertension occurs in about 6% of adults with sickle cell anemia,²⁵ in half from pulmonary venous disease, in half from pulmonary arterial disease. Genesis is almost certainly multifactorial, as the sickle context involves multiple features associated with pulmonary hypertension in the general population: absence of splenic function and presence of activated platelets, an inflammatory state, and endothelial dysfunction. It is difficult, however, to distinguish between causes and consequences of this pathobiology. Further, the pulmonary arterial wall in sickle cell anemia is awash with suspect mediators, and the biodeficiency of NO emasculates a normal braking mechanism on inflammation, proliferation, and vasoconstriction. Notably, both children and adults with sickle cell anemia not infrequently exhibit sleep-disordered breathing with nocturnal hypoxia, the major pulmonary vasoconstrictor. This justifies suspicion that long-term, repeated exposure to this major stressor plays a role in development of pulmonary hypertension in sickle disease. There may

be a substantial problem in sickle cell anemia of transient elevations of pulmonary pressure unrelated to histopathologic pulmonary hypertension, as discussed later under “Mortality and Sudden Death”.

Kidney Disease

In sickle cell anemia renal hyposthenuria is a nearly universal problem arising from medullary hypoperfusion resulting from the harsh renal medullary environment; its hypoxia, acidosis, and hyperosmolality all would promote HbS polymerization and adverse changes in blood viscosity. Indeed, this even occurs in sickle trait as well. The renal cortex, on the other hand, exhibits hyperperfusion, believed to underlie glomerular dysfunction with albuminuria.²¹ Patients can also develop acute renal injury, papillary necrosis and chronic renal disease, the latter being a significant contributor to mortality. Hematuria from papillary damage is very common.

Mortality and Sudden Death

Mortality rate is increased in sickle cell anemia patients having higher rates of acute painful episodes,²⁶ with notable risk indicators including low HbF, high WBC count, chronic renal failure, and elevated tricuspid regurgitant jet velocity. Among apparent causes of death at autopsy, cardiopulmonary disease is most prominent.²⁷ In 1994, a large study from the United States identified a median survival of 42 years for men and 48 years for women with sickle cell anemia; the comparable ages were 60 years and 68 years, respectively, for HbSC disease.²⁶ This reflected large past improvement after introduction of prophylactic penicillin for children, revealing the earlier dominance of pneumococcal sepsis in disease natural history. Further improvement has derived from chronic use of hydroxyurea, an agent that boosts HbF level, lowers WBC count, improves RBC hydration and survival, and blunts inflammatory biology and RBC adhesivity. Unfortunately, survival is much worse in parts of the world with less access to medical care and greater abundance of comorbidities (e.g., malaria, diarrheal disease).

Sickle cell anemia entails risk for sudden death, tending to occur during painful episodes or other acute events. Although unexplained, this suggests acute cardiac catastrophe. A candidate mechanism may be occurrence of transient, explosively abrupt elevations of pulmonary artery pressure, even in absence of histopathologic pulmonary hypertension.¹² This derives from an important principle: the underlying, preexisting endothelial dysfunction of sickle disease enables and predicts exaggerated vasoconstrictive responses to unrelated potential vasoconstrictors such as hypoxia, augmented NO consumption and inflammatory signaling. Each can fluctuate in short time scale, e.g., during acute painful episodes, and thereby might create risk for sudden death from rapidly elevated right heart pressure.

Sickle Trait

Sickle trait typically is associated with renal hyposthenuria. More seriously, it comprises risk for exertional sudden death, probably precipitated by effects of dehydration on RBC and blood viscosity. At an epidemiologic level, trait also involves heightened risk for venous thromboembolism, chronic renal disease, and thromboembolism complicating pregnancy. It may predispose toward ischemic stroke.

BASIS OF PHENOTYPIC DIVERSITY

Factors aside from the beta globin contribute to the remarkable interindividual diversity of clinical phenotype and severity in sickle cell anemia. Both can be significantly influenced by environment, nutrition, socioeconomic status, endemic infectious agents, and availability of medical care. Therefore, phenotypic variability is most

evident in countries where greater survival and stability derives from accessible medical care, lower infant mortality, and lesser childhood infection burden. The innumerable questions regarding phenotypic diversity are of great importance. In sickle cell anemia, why do some children, but not others, develop stroke? Why do only a small fraction of adults develop pulmonary hypertension, even though all have ongoing hemolysis? Why does pain severity vary so widely irrespective of globin genotype? And so on.

Level of Hemoglobin F

HbF level varies amongst individuals as a quantitative trait and is determined approximately 80% by genetics.⁵ After its decline over the first 6 months of life, most of the antisickling protection from its high level at birth is lost, but its level still varies among sickle adults over a 20-fold range. HbF level reflects the number of F cells, the amount of HbF per F cell, and the preferential survival of F cells.¹³ Known determinants account for perhaps one-half of its variance: a polymorphic *XmnI* site (11p) upstream of the γ gene; the *HBSIL-MYB* intergenic region (6q23); SNPs in *TOX* (8q12.1); and polymorphisms of *BCL11A* (2p16), a transcriptional silencer of the *HBB* gene.⁵ HbF is somewhat higher levels in females, hinting at a contributing locus on the X chromosome. Polymorphisms in trans-acting enhancers of *BCL11A* account for some, but not all, of the regional variations in HbF level. Among the African autochthonous haplotypes, the Benin haplotype is associated with higher HbF level; however, it is twice again as high among those with the Arab-India haplotype.

α -Thalassemia

The normal genotype is $\alpha\alpha/\alpha\alpha$, but about 30% of African Americans have a single α deletion ($-\alpha/\alpha$), so concordance with sickle cell disease is common; and homozygosity for the allele is seen ($-\alpha/-\alpha$). Its prevalence elsewhere varies regionally. An α -gene deletion has minimal effect on the HbF level but results in improved RBC hydration (see Fig. 41.6), a lower ISC count, improved RBC survival, and less severe anemia.¹⁴ Perhaps loss of one α gene nudges α/β chain balance toward normal, given the mild instability of β^S globin.² Yet there is no amelioration of pain severity, and some complications (osteonecrosis, retinopathy) increase, possibly because of the increased blood viscosity.

β -Globin Alleles

Compound heterozygosity for the sickle gene and another β allele can affect clinical phenotype, with amelioration to, e.g., in the direction of amelioration by admixing β^A or γ chains with β^S . However, HbSC disease presents a unique case caused by the lesser electronegativity of HbC compared with HbS.²⁸ Rather than simulating sickle trait (see Fig. 41.5A), presence of HbC stimulates of KCl cotransport, causing RBC dehydration and increasing concentration of HbS. Combined with a concurrent augmentation of HbS proportion (~50% versus ~40% in HbAS), this creates a sickling disorder only somewhat less severe than sickle cell anemia. Although pain and anemia are lessened a bit, there is an increased propensity for retinopathy and osteonecrosis. It has been assumed that this derives from the somewhat higher blood viscosity when anemia is less severe. Other less common β gene alleles can likewise interact with HbS and affect clinical phenotype via impact on polymerization.

Unexplained Phenotypic Diversity

Beyond these well-defined influences, there is still enormous unexplained variability in the clinical phenotype of sickle cell anemia. The disparate biologic processes that participate in vasoocclusion,

macrovascular vasculopathy, hemolysis, and specific complications highlight the certainty that phenotypic heterogeneity will be influenced by underlying genetic variations affecting adhesion biology, cation homeostasis, inflammatory signaling, vasoregulation, and so on. Indeed, the spectrum of potential foci at which genetic variation might exert effects and be relevant to sickle disease phenotypic diversity is as vast and complex as human biology itself.

The single-nucleotide polymorphisms (SNPs) that have been detected in association with specific clinical complications are far too numerous to describe here.²⁹ Of course, much work is still needed to discern whether such associations are actually informative vis à vis pathogenic specifics. Several SNPs seem particularly interesting. A TNF (-308) promoter polymorphism is associated with large vessel stroke in children. Polymorphisms affecting the HO-1 promoter create heterogeneity in GT repeat lengths (the shorter of which enable greater HO-1 responsiveness, e.g., to heme) are described as being associated with lower hospitalization rate for ACS in children. Interestingly, a TLR4 polymorphism prevalent only in sub-Saharan Africa leads to a greater inflammatory TNF- α responsiveness to TLR4 ligands that is protective in malaria, and could well impact sickle biology. A wholly different approach to this general problem was provided by examination of gene expression by, and inflammatory response of, endothelial cells derived from sickle children.³⁰ Those from children with circle of Willis disease exhibited suggestive inflammatory gene expression, plus an actual exaggerated NF κ B response to stimulation with inflammatory mediators. Certainly, the contribution of various nonglobin genetic influences will continue to be identified as modern and creative approaches are being applied to the problem of phenotypic diversity in sickle cell anemia.

SICKLE CELL DISEASE: CLINICAL FEATURES AND MANAGEMENT

Yogen Saunthararajah and Elliott P. Vichinsky

Hemoglobinopathies are the most common genetic diseases in humans. In sickle cell disease (SCD), a mutated β -globin gene produces sickle hemoglobin (Hb S). This mutation has been positively selected during human evolution because one copy of the sickle gene and one normal β -globin gene (sickle cell trait) confers a survival advantage in malaria-endemic regions. With two copies of the sickle gene (Hb SS or sickle cell anemia) or the sickle mutation and another mutated β -globin gene, for example, sickle cell- β^0 -thalassemia (Hb S- β thal) or Hb SC disease (Hb SC) (mixed hemoglobinopathies), the less soluble Hb S can polymerize in deoxygenated regions of the circulation, resulting in red blood cell (RBC) rigidity, RBC adhesion to endothelium, and hemolysis. In addition to hemolytic anemia, these events activate inflammation and coagulation pathways and cause vasoocclusion.¹ Thus the clinical manifestations are chronic hemolytic anemia, recurrent painful episodes, and chronic organ damage from vasoocclusion. This chapter presents the diagnosis and natural history, and describes overall clinical management as well as specific management by organ complications. Clinical interventions are founded on an understanding of underlying pathophysiologic processes. The exigency of living with a painful, life-threatening chronic disease in an ethnically diverse society adds complexity to the psychosocial aspects of this illness. A comprehensive management approach directed at preventing pain crises, chronic organ damage, and early mortality while effectively managing acute complications is recommended. For a full discussion of the fascinating history and molecular pathology of this disease, please see Chapter 42. Normal Hb synthesis, structure, and function are described in Chapter 33, and the thalassemias are considered in Chapter 40.

PREVALENCE

The distribution and frequency of the sickle cell gene in different areas of the world have been influenced by natural selection and gene transmission via trade routes including the slave trade.² Among African Americans,³ the prevalence of sickle cell trait is 8% to 10% among newborns,⁴ and in this population, the frequencies of the sickle cell (0.045), Hb C (0.015), and β -thalassemia (0.004) genes⁴ indicate that there are 4000–5000 pregnancies a year at risk for SCD. The burden of this disease in the United States is dwarfed by that in the rest of the world, as evidenced by a prevalence of the sickle cell gene as high as 25% to 30% in western Africa and an estimated annual birth of 120,000 babies with SCD in Africa.⁵

DIAGNOSIS

The diagnosis of a sickle cell syndrome is suggested by characteristic findings on the complete blood count (CBC) and peripheral smear that prompt Hb electrophoresis. If a diagnosis of SCD is confirmed, evaluation of the various organ systems at risk is required. These evaluations are discussed in the section on clinical management.

Complete Blood Count and Peripheral Blood Smear

The chronic hemolytic anemia of SCD presents with mild to moderately low hematocrit and Hb levels and a reticulocytosis of

approximately 3% to 15%. Additional laboratory features of hemolysis are unconjugated hyperbilirubinemia, elevated lactate dehydrogenase (LDH), and low haptoglobin levels. The reticulocytosis accounts for high or high-normal mean corpuscular volume (MCV). If the age-adjusted MCV is not elevated, the possibility of sickle cell- β -thalassemia, coincident α -thalassemia, or iron deficiency must be considered.

In the peripheral smear (Fig. 42.1), there may be sickled forms, target cells, polychromasia indicative of reticulocytosis, and Howell-Jolly bodies demonstrating hyposplenism. The RBCs are normochromic unless there is coexistent thalassemia or iron deficiency. Sickled forms (irreversibly sickled cells [ISCs]) occur in the peripheral smear only in the SCDs and not in sickle cell trait. In Hb SS disease, ISCs predominate, and target cells may be few; in sickle cell- β -thalassemia, ISCs, target cells, and hypochromic microcytic discocytes are prominent; in Hb SC disease, target cells predominate, and ISCs are rare.

White blood cell (WBC) counts are higher than normal in Hb SS disease, particularly in patients under age 10 years. Mean WBC counts tend not to be elevated in Hb SC disease or sickle cell- β^+ -thalassemia. Mean platelet counts are elevated in Hb SS disease, particularly in patients younger than age 18 years, but are usually normal in those with Hb SC disease and sickle cell- β^+ -thalassemia.

Solubility Tests and Hemoglobin Electrophoresis

Solubility test results (e.g., Sickledex) are positive in both SCD and sickle cell trait. All patients require definitive diagnosis with Hb electrophoresis (which separates Hb species according to amino acid composition) (Fig. 42.2) or high performance liquid chromatography (HPLC).⁶ Cellulose acetate electrophoresis at a pH of 8.4 is a standard method of separating Hb S from other variants. However, Hb S, G, and D have the same electrophoretic mobility with this method. Using citrate agar electrophoresis at pH 6.2, Hb S has a different mobility than Hb D and G, which comigrate with Hb A in this system.

Results from electrophoresis or thin-layer isoelectric focusing are similar in Hb SS disease and sickle cell- β^0 -thalassemia: nearly all of the Hb consists of Hb S. Although differences in the fetal hemoglobin (Hb F) (see Variant Sickle Cell Syndromes) and Hb A₂ levels may be useful in distinguishing these syndromes, the presence of microcytosis or of one parent without sickle cell trait is a more useful indicator of sickle cell- β^0 -thalassemia. The diagnosis of Hb SC disease is straightforward; nearly equal amounts of Hb S and Hb C are detected. Sickle cell- β^+ -thalassemia and sickle cell trait both have substantial amounts of Hb A and Hb S. This superficial electrophoretic similarity does not provide an obstacle to diagnosis: whereas sickle cell trait is associated with neither anemia nor microcytosis and has an Hb A fraction more than 50%,⁷ sickle cell- β^+ -thalassemia is associated with anemia, microcytosis, and an Hb A fraction that ranges from 5% to 30%.

The Hb F level is usually slightly to moderately elevated; the degree varies among patients. The amount of Hb F present is a function of the number of reticulocytes that contain Hb F, the extent of selective survival of Hb F-containing reticulocytes that become mature Hb F-containing erythrocytes (F cells), and the amount of Hb F per F cell.⁸ The Arab-Indian and Senegal haplotypes are associated with higher levels of Hb F than the others.⁹

Fig. 42.1 SICKLE CELL DISEASE AND HEMOGLOBIN SC PERIPHERAL BLOOD SMEARS. The peripheral smear in sickle cell disease (A) shows sickle cells that are mostly irreversibly sickled and sometimes referred to as “cigar forms.” Higher power detail (B) shows a sickle cell (*upper left*), red blood cell containing a Howell-Jolly body (*middle right*), and polychromatophilic cell (*lower center*). These indicate sickle cell anemia and splenic dysfunction but marrow response with reticulocytosis, respectively. A peripheral smear of a patient with Hgb SC (C) shows no sickled cell, but there are target forms (D) and occasional cells (E) with hemoglobin condensed at each pole of the cell.

Newborn Screening

The use of prophylactic penicillin¹⁰ and the provision of comprehensive medical care during the first 5 years of life have reduced the mortality rate from approximately 25% to less than 3%, thereby underlining the importance of early identification of infants with SCD. Based on its economy and superiority of detection, universal screening of all newborns is preferred over ethnically targeted approaches.^{11,12} Blood samples for testing are obtained by heel stick and spotted onto filter paper for stable transport and subsequent HPLC (solubility testing is unreliable because of the large amount of Hb F present.)

As Hb S increases and Hb F declines in the first months of life (Fig. 42.3), the clinical manifestations of SCD, including anemia, emerge.¹³ ISCs can be seen on the peripheral blood smear (Fig. 42.4) of children with sickle cell anemia at 3 months of age,

and by 4 months of age, moderately severe hemolytic anemia is evident.

Tests used in newborn screening must be capable of distinguishing between Hb F, S, A, and C. The Hb distribution pattern is described in descending order according to the quantities detected. Therefore a newborn with sickle cell anemia who has predominantly Hb F with a small amount of Hb S and no Hb A is described as having an FS pattern. An FS pattern is obtained also in newborns who have sickle cell- β^0 -thalassemia, sickle cell-hereditary persistence of Hb F (HPFH), and sickle cell-Hb D or sickle cell-Hb G (i.e., Hb D and E have the same electrophoretic mobility as Hb S). A newborn with sickle cell trait will have Hb F, Hb A, and Hb S (FAS pattern). The quantity of Hb A is greater than that of Hb S. If the quantity of Hb S exceeds that of Hb A, the presumptive diagnosis is sickle cell- β^+ -thalassemia (FSA pattern). It may not be possible to distinguish FAS and FSA patterns in newborns, so DNA-based testing or repeat Hb testing at age 3–6 months is recommended.

Fig. 42.3 FETAL HEMOGLOBIN (HB F) DECLINE IN CHILDREN WITH HEMOGLOBINS AA AND SS. *HB F*, fetal hemoglobin. (Data from O'Brien, Mclatosh S, Aspnes AT, et al: *Prospective study of sickle cell anemia in infancy*. J Pediatr 89:205, 1976.)

Fig. 42.4 The peculiar elongated shapes of the erythrocytes is what Herrick's intern Ernest E. Irons noted, and together with a report from the German literature of *sichel formen* blood cells, inspired the name by which this condition is now known.

Prenatal Diagnosis

One large survey found that parents at risk for having a child with SCD were interested in prenatal diagnosis and would consider termination of pregnancy for an affected fetus.¹⁴ Community acceptance of reproductive genetic services depends on the effectiveness of education and counseling. One major ethical issue pertains to our diagnostic skills' having outstripped our ability to predict the severity of diagnosable conditions.

Fetal DNA samples are obtained by chorionic villus sampling at 8–10 weeks' gestation. Polymerase chain reaction (PCR)–based methods for detecting the sickle gene include restriction analysis (Fig. 42.5), allele-specific hybridization, reverse dot blotting, and allele-specific fluorescence PCR. PCR-based diagnosis for Hb SC disease is possible using specific molecular methods for detecting the *Hb C* gene, and the diagnosis of sickle cell– β -thalassemia can be made using

Fig. 42.5 POLYMERASE CHAIN REACTION (PCR)–BASED RESTRICTION ANALYSIS FOR THE SICKLE CELL GENE. The genotypes of the DNA samples tested are shown below. The size in base pairs for the undigested PCR product and the products resulting from *Oxa* NI are shown at the left in base pairs. The fragments from normal β -globin DNA (AA) shows complete *Oxa* NI cleavage, from sickle cell trait DNA (AS) shows partial cleavage, and from sickle cell anemia (SS) shows no cleavage. *Ag stain*, Silver stain; *EtBr*, ethidium bromide.

reverse dot-blot methodology to screen the many African American β -thalassemia mutations, as well as the Hb S and Hb C mutations, in a single hybridization reaction.

CLINICAL PRESENTATION AND MANAGEMENT

The cardinal clinical manifestations of SCD are chronic hemolytic anemia; recurrent painful episodes; and chronic organ damage, particularly of the spleen, bones, brain, kidneys, lungs, skin, and heart. The pattern of disease manifestation varies among the major genotypes of Hb SS, Hb SC, and Hb S– β -thalassemia but also within the same genotype. Some of this variability results from coinherited genotypes, for example, α -thalassemia or HPFH (discussed at the end of this chapter).

Typically, patients are anemic but lead a relatively normal life punctuated by painful episodes. However, it is important to realize that chronic organ damage and decreased survival occur even in patients who do not have recurrent pain. This section begins with a brief overview of natural history and survival followed by a discussion of basic management that aims to improve this natural history (disease modification) and then a discussion of management of organ-specific complications.

Natural History and Life Expectancy

The manifestations of disease begin after the first few months of life as Hb F levels decline and Hb S levels increase. Certain complications predominate in particular age groups. Between the ages of 1 and 3 years, affected individuals have splenomegaly and splenic sequestration (Fig. 42.6), pneumonia, and meningitis from *Streptococcus pneumoniae* and other encapsulated organisms (because of functional hyposplenism), and hand–foot syndrome; in early childhood, they have stroke, acute chest syndrome, and osteonecrosis; in mid childhood, they have pain crises, osteonecrosis, and acute chest syndrome; between ages 12 and 20 years, they have strokes, priapism, and pain crises; between ages 20 and 30 years, they have renal insufficiency, pulmonary hypertension, disabling osteonecrosis, retinopathy, leg ulcers, and pain crises; and at age older than 30 years, they have renal failure, congestive heart failure, and pain crises.

Fig. 42.6 THE SPLEEN IN SICKLE CELL DISEASE. Histologic section (A) of the splenic red pulp shows engorgement of the splenic cords with sickled cells. In infants, excessive pooling in cords can lead to a splenic sequestration crisis. Later in life, the spleen undergoes autoinfarction. The gross pathology (B) shows a tiny 4.5-cm spleen with rough external surface caused by scarring from repeated infarcts. Histologic section reveals classic Gamna-Gandy bodies (C and D) also caused by repeated infarction. These are composed of hemosiderin-laden macrophages, calcium deposits, and foreign body giant cells.

Fig. 42.7 Life expectancy in patients with sickle cell disease for patients with Hb SS disease (A), Hb SC disease (B), and with different levels of fetal hemoglobin (Hb F) (C). (From Platt OS, Brambilla DJ, Rosse WF, et al: Mortality in sickle cell disease. Life expectancy and risk factors for early death. *N Engl J Med* 330:1639, 1994.)

Life expectancy is decreased, although in the past 30 years, this has dramatically improved for patients in the West: in 1973, Diggs¹⁵ reported that the mean survival was 14.3 years; in 1994, Platt et al¹⁶ reported that life expectancy was 42 years for men and 48 years for women with sickle cell anemia (Fig. 42.7). This improvement in survival is most likely the result of improved general medical care, including prophylactic penicillin therapy and vaccination against *S. pneumoniae*.⁹ These survival profiles are likely to be relevant even today, although a cohort of patients followed since 1975 show improvement in the probability of survival to age 20 years compared with patients born before 1975 (89% versus 79%).¹⁷ The poor survival and litany of chronic organ damage in survivors emphasize the need for disease-modifying interventions to prevent vasculopathy.¹⁷ There are some indications that disease-modifying agents such as hydroxyurea (HU) can improve survival.^{18,19}

Predictors of Disease Severity

The ability to predict clinical course would allow more rational tailoring of therapy to individual patients (e.g., selection of patients for high-risk but effective options such as stem cell transplant). Higher

Hb F levels and the coinheritance of an α -thalassemia trait have been identified as favorable disease modifiers in multiple studies (Table 42.1).^{20–22} The level of chronic anemia (which is influenced by the presence of an α -thalassemia trait and by Hb F levels) is of considerable predictive value. Patients with more severe anemia are more likely to develop infarctive and hemorrhagic stroke,²³ to have glomerular dysfunction,^{24,25} and perhaps to give birth to low-birthweight babies.^{26,27} Conversely, they have fewer episodes of acute chest syndrome²⁸ and (after age 20 years) a lower mortality rate.²⁸ Progressive anemia from renal endocrine deficiency or a decrease in bone marrow function from vasoocclusion is associated with early death.^{18,19}

A number of other genetic polymorphisms may be relevant to disease severity, for example, with regards to the risk of stroke. However, most of these markers are not widely used to guide decision making.²¹

Principles of Management

The twin pillars of therapy are disease modification (prevention of crises, complications, chronic organ damage, and early mortality)

Sufficient evidence suggests that a number of treatments should be considered in all patients. These treatments have been demonstrated to decrease symptoms and complications, increase survival, or both (Table 42.3) (disease modification). There are other treatments for which there are sufficient scientific grounds or clinical data to suggest a potential impact on disease natural history. However, there is presently insufficient clinical data to make firm recommendations (see Fig. 42.8 and Table 42.3). Although treatments such as vaccination

and penicillin prophylaxis do not directly affect the sickling process or vasculopathy, they have had an impact on survival and therefore are included under the umbrella of disease-modifying therapies.

Therapeutic options are further discussed in the sections describing organ-specific complications.

Vaccination and Penicillin Prophylaxis

Children should be immunized against *S. pneumoniae*, *Haemophilus influenzae*, hepatitis B, and influenza.³⁵ Vaccination and penicillin prophylaxis can reduce the risk of serious pneumococcal infections.^{9,36} Vaccination schedules recommend inoculation with heptavalent pneumococcal conjugated vaccine at 2 months followed by two more doses 6–8 weeks apart (primary series) and a booster at 12 months. This is followed by Pneumovax at age 2 and 5 years. In adults, the Pneumovax should be readministered every 5 years (<http://www.cdc.gov/vaccines/pubs/vis/default.htm>).

For children younger than age 5 years, prophylactic penicillin recommendations are 125 mg penicillin V orally twice daily until age 2–3 years and 250 mg thereafter.³⁵ Penicillin prophylaxis begins at 2 months. Randomized, double-blind, placebo-controlled studies of prophylactic penicillin beginning in infancy, including the prophylactic penicillin or placebo study (PROPS), have found that this therapy reduced the incidence of *S. pneumoniae* bacteremia by 84% in children younger than 3 years.^{9,36} A randomized, double-blind,

Hb F, Fetal hemoglobin.

placebo-controlled study, the PROPS II study concluded that it is safe to stop prophylactic penicillin therapy at age 5 years in children who have not had prior severe pneumococcal infection or splenectomy and are receiving regular follow-up care.³⁷ However, the power of the study was restricted by the limited number of *S. pneumoniae* systemic infection events. In an analysis of a patient population receiving penicillin prophylaxis and the Pneumovax, the rate of severe *S. pneumoniae* infections was 2.4 per 100 patient-years. This was favorable compared with the historic prepenicillin prophylaxis rate of 3.2–6.9 per 100 patient-years.³⁸ These measures reduce risk but do not remove it. The risk of recurrent *S. pneumoniae* sepsis and death in patients who have had previous sepsis is much increased; all patients having a history of pneumococcal sepsis should remain on penicillin prophylaxis indefinitely and are not candidates for outpatient management of febrile episodes.³⁹ Parents must be aggressively counseled to seek medical attention for all febrile events.

Hydroxyurea and Fetal Hemoglobin Reactivation

The level of Hb F in erythrocytes plays a critical role in determining patient outcomes. Individuals who have SCD and another condition called HPFH have 70% Hb S in their RBCs but are neither anemic nor symptomatic.⁴⁰ The uniform distribution of Hb F among their RBCs interferes with Hb S polymerization, increases its solubility, and prevents RBC sickling.^{41,42} Even at lower levels of Hb F seen in patients without HPFH, crisis rate and mortality are inversely proportional to Hb F level.^{19–22} These findings prompted the idea that pharmacologic reactivation of Hb F production might be of benefit to patients.

HU is an inhibitor of ribonucleotide reductase and a cytotoxic agent that can elevate Hb F levels via an unknown pathway. A double-blind, placebo-controlled, intention-to-treat multicenter study of HU as treatment of pain crisis in SCD found that HU produced definite hematologic changes. HU was started at 0.15 mg/kg/day and escalated to 0.30 mg/kg/day as tolerated and to maintain an absolute neutrophil count no lower than $2000 \times 10^9 \text{ L}^{-1}$. There were significant increases in the levels of Hb, Hb F, F cells, F reticulocytes, packed cell volume (PCV), and MCV and declines in the mean level of leukocytes, polymorphonuclear leukocytes, reticulocytes, and dense sickle cells (Table 42.4).⁴³ The significant clinical changes were decreased rate of acute painful episodes, longer interval to first and second acute painful episode, fewer episodes of acute chest

Adapted from data in Charache S, Barton FB, Moore RD, et al: Hydroxyurea and sickle cell anemia. Clinical utility of a myelosuppressive "switching" agent. The Multicenter Study of Hydroxyurea in Sickle Cell Anemia. *Medicine (Baltimore)* 75:300, 1996.

syndrome, and diminished number of subjects and units transfused (Table 42.5).⁴⁴ In follow-up analysis, higher pre- or posttreatment Hb F levels were associated with a reduction in mortality rate (although no significant changes were observed in the incidence of stroke, hepatic sequestration, or death in the initial study).¹⁸ No short-term toxicity caused by HU was observed. One child born to a patient taking HU and two born to partners of patients taking HU were normal at birth. Although the follow-up analyses suggest the importance of Hb F to better outcomes, it is possible that some HU-induced changes in sickle cell erythrocytes, such as increased water content and decreased Hb S concentration,⁴⁵ may be independent of Hb F.

In the original study, only patients with two or more pain crises per year requiring hospitalization were eligible. However, other at-risk patients should be considered for HU therapy. These include patients with evidence of chronic organ damage, patients with severe anemia (unless the reticulocyte count is $<250,000 \mu\text{L}^{-1}$, in which case consider erythropoietin [EPO] deficiency from renal damage or bone marrow suppression that may require alternative treatment), and patients with indications for chronic transfusion but who have allo-antibodies. After obtaining the baseline evaluations per Table 42.2, HU is usually started at 500–1000 mg/day with monitoring of the CBC every 4–8 weeks to ensure that neutropenia (absolute neutrophil count $<2 \times 10^9 \text{ L}^{-1}$) is not produced. Lower doses may be required

in patients with renal insufficiency and/or relative reticulocytopenia. The dose is increased to a stable maximum Hb F response or neutropenia, but most patients receive between 500 and 2000 mg/day. Response is defined by clinical symptoms, by a persistent and significant ($>0.5 \text{ g/dL}$) increase in total Hb or Hb F, and a decrease in LDH. These improvements in symptomatology and hematologic indices may require at least 3–4 months of therapy but can be seen as soon as week 6.

In studies of HU as a therapy for children with SCD, the drug was well tolerated and produced favorable hematologic changes similar to those seen in the adult population.⁴⁶ In approximately 10% of the children treated, the increase in Hb F was less than 2%. Baseline Hb F levels, baseline total Hb levels, and compliance were associated with the final Hb F level.⁴⁷ Other studies in children have documented a decrease in the number of days of hospitalization and suggest a decreased incidence of vasoocclusive crises.⁴⁸ The favorable changes in hematologic indices suggest that HU therapy might be an alternative to blood transfusions for the prevention of recurrent stroke in children with SCD.^{49,50} HU therapy appears to lower transcranial Doppler velocities in children with SCD.⁵¹ Studies in the United States and in Belgium support the potential role of HU in the prevention of cerebrovascular accidents (CVAs).^{50,52,53} HU was found to improve, but not correct, the abnormal cerebral oxygen saturation associated with SCD.⁵⁴

A persistent concern pertaining to the use of HU in SCD is its putative leukemogenic effect. This concern derives from reports on HU treatment of myeloproliferative diseases, conditions associated with an inherent propensity for leukemic conversion. Although the use of HU combined with ³²P or alkylating agents is associated with increased leukemic conversion in patients with myeloproliferative disease,⁵⁵ reports claiming a leukemogenic effect for HU alone in polycythemia vera either lacked control subjects⁵⁶ or were not designed to assess this issue.⁵⁷ In children with the nonmalignant underlying condition of erythrocytosis secondary to inoperable cyanotic congenital heart disease, no leukemic conversion was observed.⁵⁸

Vitamin or Nutritional Supplementation

Chronic hemolysis results in increased utilization of folic acid stores. Megaloblastic crises from folic acid deficiency have been reported.^{59,60} Pediatric patients with SCD had higher homocysteine levels than age-matched control African American patients.⁶¹ Folic acid, 1 mg/day orally, is administered as a standard of care.⁶² Vitamin B₁₂ deficiency can also be seen in patients with SCD. Folate replacement can mask and possibly exacerbate vitamin B₁₂ deficiency.⁶³

A growing body of research indicates that sickle cell patients have widespread mineral and vitamin deficiencies, including zinc, vitamin C, vitamin E, acetylcysteine, calcium, vitamin D, vitamin A, and others.⁶⁴ Fifty percent of children with SCD have evidence of osteoporosis or osteopenia that is associated with inadequate calcium and vitamin D intake.^{65–67} Recently, zinc supplementation in a prospective trial documented significant improvement in linear growth and weight gain in children with SCD.⁶⁸ Therefore daily supplementation with a multivitamin without iron may be of value, and in individuals with vitamin D deficiency (which is often severe⁶⁹), additional vitamin D replacement therapy should be considered.

Despite increased intestinal absorption of iron in SCD, the combination of nutritional deficiency and urinary iron losses results in iron deficiency in 20% of children with SCD.⁷⁰ The diagnosis of iron deficiency may be obscured by the elevated serum iron levels associated with chronic hemolysis, necessitating the detection of a low serum ferritin level or an elevated serum transferrin level for the diagnosis.

Transfusion Therapy

The two main approaches to transfusion in SCD are simple transfusion and exchange transfusion. These transfusions can be administered

in an episodic fashion or in a chronic fashion. Therefore transfusion therapy in SCD is of the following types: episodic simple, episodic partial exchange, or chronic partial exchange. In both simple and exchange transfusion, the target Hb level is 10–11 g/dL (hematocrit, 30%).^{71,72} Transfusing to a higher Hb or hematocrit level is avoided because a hematocrit level greater than 30% is associated with hyperviscosity if there is a substantial proportion of Hb S in the blood. In exchange transfusion, an additional objective is to achieve an Hb S percentage of less than 30% (or sometimes <50%). In partial-exchange transfusion, a proportion of the patient's diseased RBCs are removed before transfusion of normal donor RBCs; this can be done manually through phlebotomy followed by transfusion or concurrently using an automated device. In patients who need chronic transfusions, partial exchange is recommended because of the reduced iron burden of this approach. Partial exchange is also indicated if the baseline Hb level is more than 10 g/dL. Simple transfusion in this instance risks exacerbating the clinical condition through increased viscosity. For critical illness, exchange transfusion is also preferred. Although the target Hb S level should be less than 30% in exchange transfusion, decreasing Hb S levels to less than 50% may suffice depending on the severity of the complication being treated.

The volumes required for simple and exchange transfusions (Table 42.6) are particularly important for transfusing children. For normal-size adults, the general rule is that each unit of RBCs infused increases the Hb level approximately 1 g/dL.⁷³

Episodic simple transfusion should be considered for blood volume replacement in aplastic crisis and splenic sequestration crises and for protection when there is a more than 20% decrease in Hb from baseline from severe illness such as septicemia or severe vasoocclusive crisis or hyperhemolysis or Hb levels of less than 5 g/dL. Episodic simple or exchange transfusion should be considered for acute chest syndrome, priapism, and preoperatively. The choice of simple versus exchange transfusion is determined by the pretransfusion total Hb level and the severity of the illness.

In the preoperative setting, there is good randomized data to support the use of preoperative transfusion to decrease the risk of complications, including severe complications such as acute chest syndrome.^{74,75} Preoperative transfusions can be categorized as follows. (1) Top-up transfusions to a target Hb level of 10 g/dL. This is an appropriate intervention for patients with baseline Hb between 6.5–9 g/dL undergoing low or medium risk surgeries (e.g., cholecystectomy, joint replacement). (2) Partial exchange transfusion to achieve a target Hb level of 10 g/dL with an estimated Hb S percentage of <60%. This is an appropriate intervention for patients with baseline Hb levels of >9.5 g/dL undergoing low- or medium-risk surgeries as per above. (3) Exchange transfusion to achieve a target Hb level of 10 g/dL with an estimated Hb S percentage of <30%. This procedure should be considered for patients with SCD undergoing high-risk surgeries (e.g., cardiothoracic surgery). In short, surgery, even low- or medium-risk surgery, is a substantial physiologic stressor

for patients with SCD, even those who do not have high risk characteristics at the time of surgery, and preoperative transfusion should be considered. A caveat is that extended phenotyping of transfused red cells, should be performed, as discussed further subsequently.

Chronic partial-exchange transfusion is indicated in primary and secondary prevention of cerebral thrombosis as discussed in the section on neurologic complications.

Transfusion complications include alloimmunization, delayed hemolytic transfusion reactions (discussed in Exacerbations of Anemia), iron overload, and transmission of viral illness. The incidence of alloimmunization is between 19% and 30% and usually occurs with fewer than 15 transfusions.⁷⁶ Some patients seem to tolerate multiple transfusions without developing alloantibodies, but others are readily allosensitized. The high rate of alloimmunization in transfused sickle cell patients is partly attributable to minor blood group incompatibilities between the recipient and donor pool, which often differ in ethnicity.^{76,77} Antibodies against the C and E antigens of the Rh group, Kell (K) and Lewis, Duffy (Fya, Fyb), and Kidd (Jk) are common.⁷⁶ In the Stroke Prevention Trial in Sickle Cell Anemia, the routine use of WBC-reduced RBCs matched for E, C, and Kell decreased the allosensitization rate compared with historical data from 3% to 0.5% per unit transfused and decreased the rate of hemolytic transfusion reactions by 90%.⁷⁸ Therefore the recommended approach to preventing alloimmunization is to reduce leukocytes and perform limited phenotype matching for all patients (ABO, C, D, E, and Kell) and extended phenotype matching for patients with alloantibodies.⁷² The management of a delayed hemolytic transfusion reaction and transfusional iron overload are discussed under Exacerbations of Anemia, later.

Transmission of human immunodeficiency virus, hepatitis B and C, and human T-cell leukemia/lymphoma virus-1 has diminished with improved screening of banked units but remains an issue. In addition to better screening programs, the use of leukocyte-depleted RBC transfusions can reduce this hazard.⁷⁹

Stem Cell Transplantation

At this time, allogeneic stem cell transplantation remains the only curative option for SCD, and improvements in conditioning approaches suggest both pediatric and adult populations are eligible. The largest series to date has been in a pediatric population with severely symptomatic SCD failing to respond to HU. Using myeloablative conditioning and human leukocyte antigen (HLA)-matched or one-mismatch (two cases) sibling donors, with bone marrow as the source of stem cells in the majority, there was a 10% mortality rate with 90% overall survival and 82% event-free survival at a median follow-up of 54 months.⁸⁰ Similar results were obtained when related, HLA-matched umbilical cord blood was used as the source of stem cells.⁸¹ According to these results, stem cell transplant is a therapeutic option for the severely symptomatic child with an HLA-matched sibling donor.

In adults, incorporation of rapamycin (to induce immunologic tolerance) into nonmyeloablative stem cell transplant protocols has enabled stable mixed hematopoietic chimerism with associated full-donor erythroid engraftment and normalization of blood counts. The attainment of tolerance may allow extension of this potentially curative approach to alternative donor sources, an active area of research.^{82,83} The issue of the cost-effectiveness of bone marrow transplantation (BMT) gains perspective from the comparative costs in the United States of \$150,000 to \$200,000 for an uncomplicated BMT versus up to \$112,000 annually for conventional medical care of a chronically transfused, iron-overloaded patient.⁸⁴

Education

Education regarding the nature of the disease, genetic counseling, and psychosocial assessments of patients and their families are best

TABLE 42.6 Transfusion Formulas

Dilutional effects of transfusion on Hb S: PRBC volume (PRBCV) (mL)
$= (\text{Hct}_d - \text{Hct}_i) \times \text{TBV} \times \text{Hct}_{p,B}$
Manual partial-exchange transfusion: ^a Hb Sf = $1 - (\text{PRBCV} \times \text{Hct}_{p,i})$
$(\text{TBV} \times \text{Hct}_i) + (\text{PRBCV} \times \text{Hct}_{p,i}) \times \text{Hb S}_i$
Automated exchange transfusion: Exchange volume (mL) = $(\text{Hct}_d - \text{Hct}_i)$
$\times \text{TBV} \times \text{Hct}_{p,i} - (\text{Hct}_i + \text{Hct}_{d,2D})$
RBC volume (mL) = $\text{Hct}_i \times \text{TBV}$

^aIn these formulas, Hct and Hb S are fractions (e.g., 40% = 0.4).

Hct_d, desired hematocrit; Hct_i, initial hematocrit; Hct_p, hematocrit of replacement cells (usually 0.75); Hb S_i, initial Hb S; Hb S_f, final Hb S; PRBC, packed red blood cells; TBV, estimated total blood volume in milliliters (children, 80 mL/kg; adults, 65 mL/kg; nomograms are available). (From Linderkamp et al, with permission. Copyright 1977, Springer-Verlag.) From Nieburg and Stockman, with permission. Copyright 1977, American Medical Association.

accomplished during routine visits. Parents of small children are instructed regarding early detection of infection and palpating enlarging spleens.

Phlebotomy

As mentioned, an Hb level of more than 10–11 g/dL (hematocrit 30%) in the presence of substantial amounts of Hb S (>30%) is associated with hyperviscosity. Some data indicate that phlebotomy to reduce the hematocrit and viscosity (and which may also address iron-overload) can decrease the frequency of crises in Hb SC or Hb S- β^+ disease.⁸⁵ In Hb SS disease, phlebotomy has successfully been used in combination with HU (which increases the Hb level) in secondary stroke prevention in patients previously treated with chronic transfusion.⁸⁶ Phlebotomy alone has also been used in Hb SS disease with baseline Hb levels of more than 9.5 g/dL with favorable results on the frequency and duration of pain crises. This benefit may have resulted from decreased hematocrit and viscosity and from a decrease in intracellular Hb concentration from iron deficiency.⁸⁷ One approach to phlebotomy is to remove approximately 10 mL/kg of blood over 20–30 minutes followed by infusion of an equal volume of normal saline. This is repeated every 2 weeks until the target Hb level of 9–9.5 g/dL is achieved.

Erythropoietin or Darbepoetin

The chronic hemolytic anemia of SCD is partially compensated by vigorous reticulocytosis. A decrease in compensatory reticulocytosis will exacerbate already existent anemia and can be expected to increase clinical risk. Accordingly, chronic relative reticulocytopenia (defined as Hb <9 g/dL and absolute reticulocyte count $<250,000 \times 10^9 \text{ L}^{-1}$) was identified as a significant risk factor for early mortality in a prospective cohort study of patients with SCD.⁸⁸

In the general population, evaluation of EPO levels is usually prompted by the combination of anemia and abnormal serum creatinine level. EPO levels are then interpreted in relationship to the Hb level to assess for the possibility of EPO deficiency. In patients with SCD, this approach to diagnosis has pitfalls. Patients with SCD are already anemic; therefore, gradual anemia exacerbation is easily missed, and clinicians must weigh many possible causes in the context of complex, multisystem SCD pathology. Furthermore, patients with SCD have low serum creatinine levels at baseline. Therefore a substantial increase in serum creatinine from baseline may nonetheless remain below the threshold defined as abnormal for the general population, potentially disguising the presence of renal damage that is sufficient to decrease renal endocrine function. Furthermore, EPO levels are not readily interpreted in the individual patient with SCD: EPO levels in SCD are generally low for the level of Hb.⁸⁹ One contributing factor could be increased uptake by the massive compensatory reticulocytosis. However, EPO levels are lower in SCD adults than in children,⁸⁹ and EPO levels are inappropriately lower in patients with chronic relative reticulocytopenia.¹⁹ Hence, EPO deficiency should be considered as a possible cause of progressive anemia in patients with absolute reticulocyte counts below $250,000 \times 10^9 \text{ L}^{-1}$ even if their serum creatinine levels are in the normal range. The cumulative published experience of EPO use in SCD is limited (52 patients).⁹⁰ Although EPO by itself has been reported to increase Hb F levels, the most important role for EPO may be as replacement therapy for EPO deficiency that causes relative reticulocytopenia and progressive anemia. EPO replacement can also facilitate enhanced HU dosing and Hb F augmentation.⁹⁰ In using recombinant human EPO, caution must be exercised not to elevate the hematocrit to levels that result in hyperviscosity. Also, the reticulocyte fraction is the most adhesive, and it is possible that EPO could exacerbate or trigger sickle cell crises.⁹⁰ Patients with SCD may be relatively resistant to EPO and require doses higher than those used in other patients with chronic renal failure. The reasons for EPO resistance are unclear but

may include increased inflammation-mediated suppression of erythropoiesis.⁹¹

EPO therapy is probably not indicated in patients receiving chronic transfusion therapy in whom encouraging endogenous Hb S containing erythropoiesis may be counterproductive.

Iron Chelation

Early death is well described in association with iron overload from β -thalassemia and hereditary hemochromatosis.^{92,93} Similarly, iron overload is likely to be a problem in chronically transfused patients with SCD, although the clinical significance may critically depend on the degree and duration of overload. Chelation guidelines for patients with SCD are similar to those for other chronically transfused, iron-overloaded patients; iron chelation is indicated when the total body iron level is elevated (ferritin >2000 $\mu\text{g/L}$, quantitative liver iron of 2000 $\mu\text{g/g}$ dry weight, transfusion history >1 year of monthly transfusions).⁹⁴ Notably, the serum ferritin level may underestimate clinically significant iron overload.^{95,96} Iron chelation options in the United States are deferoxamine (via continuous intravenous or subcutaneous infusion), deferasirox (orally), and deferiprone. There is some data to support greater effectiveness of the oral agents, in particular deferiprone, in cardiac iron unloading, and together with the oral route of administration and toxicity profile, deferasirox or deferiprone are favored over deferoxamine.^{97–99}

Newer US Food and Drug Administration (FDA)-approved methods of quantitating iron burden by Ferriscan of the liver¹⁰⁰ can avoid the need for liver biopsies. T2-weighted MRI of the heart indicates hemosiderosis of cardiac tissue, and when the results are abnormal, aggressive chelation is mandated.¹⁰¹

Alternatives to Hydroxyurea for Hb F Induction

Alternatives to HU for pharmacologic induction of Hb F that are being studied in clinical trials include the methyltransferase inhibitor 5-aza-2'-deoxycytidine (decitabine) and histone deacetylase inhibitors.¹⁰² These classes of agents act on chromatin processes that regulate gene transcription.

The methyltransferase inhibitors 5-azacytidine and 5-aza-2'-deoxycytidine have produced the largest increases in Hb F of any of the pharmacologic reactivators of Hb F that have been tested.^{103,104} Responding patients include those who did not respond to HU, consistent with a different mechanism of action. Although improvements in a number of surrogate clinical endpoints have been demonstrated, larger studies to confirm safety and clinical effectiveness with chronic use are required. In the United States, 5-azacytidine and decitabine have been approved by the FDA for the treatment of myelodysplastic syndrome. The efficacy of the class of agents known as histone deacetylase inhibitors in Hb F reactivation has been reviewed.^{104–106} As per the methyltransferase inhibitors, further clinical trials are needed. Other classes of drugs being evaluated for potential Hb F reactivation are the “imid” class of drugs (analogues of thalidomide such as pomalidomide) and inhibitors of lysine demethylase (LSD1/KDM1A).¹⁰⁷

Preventing Red Blood Cell Dehydration With Ion Channel Inhibitors

Polymerization of Hb S is related to the Hb S concentration within the cell. Therefore a therapeutic strategy could be to reduce the intracellular Hb S concentration. It is possible to reduce the Hb concentration by reducing the Hb content with iron deficiency. It has been observed that spontaneous or induced iron deficiency (see [Phlebotomy](#), earlier) sufficient to reduce the serum ferritin, MCV, and mean cell Hb concentration (MCHC) resulted in variably improved Hb S polymerization, RBC survival, level of anemia, and clinical status.¹⁰⁸

Anticoagulation or Antiplatelet Therapy

Although there is clear evidence of activation of the coagulation system in SCD, the role of thrombogenesis in vasoocclusive crisis remains unclear.¹⁰⁹ Similarly, there have been no thorough evaluations of the role of antiplatelet or antithrombotic agents for the treatment of SCD. D-dimer levels (a degradation product of cross-linked fibrin) increase during acute vasoocclusive crisis.¹¹⁰

Minidose heparin, 5000 to 7500 units every 12 hours, administered to four patients for 2–6 years reduced hospitalization and emergency department time by 75%, and pretreatment pain frequency recurred after heparin was discontinued.¹¹¹ Larger clinical studies will be required to better understand the risks and benefits of heparin therapy for acute vasoocclusive crisis in SCD. Heparin has not been studied for acute arterial stroke in patients with SCD but has a role in SCD-associated dural venous sinus thrombosis.¹¹² The management of stroke is fully discussed under Specific Complications and Their Management.

Acenocoumarol was administered in low doses that achieved a mean international normalized ratio (INR) of 1.64 and reduced the elevated levels of prothrombin activation fragment (fragment 1+2) to 50% of pretreatment levels.¹¹³ Clinical endpoints were not measured. In a crossover study, 29 patients were treated with acenocoumarol to target an INR of 1.6–2.0. No effect on crisis frequency was noted, although again, there were significant reductions in markers of coagulation system activation.¹¹⁴ In 37 acutely ill sickle cell patients with elevated D-dimers, the effect of low-dose warfarin therapy (1 mg without a target INR) in 12 of them was examined. In multivariate analysis, low-dose warfarin was the only variable associated with a significant decrease in D-dimer levels, suggesting a warfarin-induced decrease in thrombin activity.¹¹⁰ Therefore oral anticoagulation, even at low doses, is associated with a decrease in laboratory markers of coagulation pathway activation in SCD; however, further clinical trials are required to understand the clinical risks and benefits.

Aspirin was compared with placebo in 49 pediatric patients with SCD in a double-blind crossover study. The frequency and severity of crises were not affected by aspirin therapy.¹¹⁵ Cerebral thrombosis, which accounts for 70% to 80% of all CVAs in SCD, results from large-vessel occlusion (Fig. 42.9) rather than the more typical microvascular occlusion of SCD. In the United States, there is an ongoing clinical trial testing the safety and efficacy of aspirin in diminishing the incidence and progression of cognitive defects and overt or silent stroke in pediatric patients.

The management of stroke risk and stroke is fully discussed under Specific Complications and Their Management.

Experimental Therapies

Experimental approaches in early stages of clinical evaluation include glutamine supplementation, gene correction using zinc finger nucleases or “CRISPR” that exploit physiologic homology-directed DNA repair, agents that inhibit sickle erythrocyte adhesion to endothelium (recombinant P-selectin glycoprotein ligand-1-immunoglobulin G conjugate), agents that increase the production of nitric oxide (NO) [glutamine], and herbal extracts with unknown mechanisms of action (Niprisan).^{116–118}

Specific Complications and Their Management

Pain Crisis

Acute Pain Episode or Crisis

Acute pain is the first symptom of disease in more than 25% of patients and is the most frequent symptom after age 2 years.¹¹⁹ Pain is the complication for which patients with SCD most commonly seek medical attention.¹²⁰ An episode of acute pain was originally

Fig. 42.9 Right common carotid arteriogram taken in anteroposterior projection demonstrating complete occlusion of the origin of the right anterior cerebral artery (arrowhead). (From Stockman JA, Nigro MA, Mishkin MM, Osiki EA: Occlusion of large cerebral vessels in sickle-cell anemia. *N Engl J Med* 287:846, 1972.)

called a “sickle cell crisis” by Diggs, who used the expression “crisis” to refer to any new rapidly developing syndrome in the life of a patient with SCD.¹²¹ The basic mechanism is believed to be vasoocclusion of the bone marrow vasculature causing bone infarction, which in turn causes release of inflammatory mediators that activate afferent nociceptors.¹²²

Although a general correlation of vasoocclusive severity and genotype has been posited,¹²³ there is tremendous variability within genotypes and in the same patient over time. In one large study of patients with Hb SS disease, one-third rarely had pain, one-third were hospitalized for pain approximately two to six times per year, and one-third had more than six pain-related hospitalizations per year.¹²⁴ Over a 5-year period in the National Cooperative Study of SCD, 40% of patients had no painful episodes, and 5% of patients accounted for one-third of the emergency department visits. Pain is more frequent with the Hb SS genotype, low levels of Hb F, higher Hb levels,²⁸ and sleep apnea.¹²⁵ The frequency of pain peaks between ages 19 and 39 years. After the age of 19 years, more frequent pain correlates with a higher mortality rate.²⁸ Medical personnel who see patients only in the emergency department gain a biased view of SCD skewed by a frequently affected minority with severe disease.^{126,127}

Pain may be precipitated by events such as cold, dehydration, infection, stress, menses, and alcohol consumption. Any underlying cause should be searched for and corrected, but the majority of painful episodes have no identifiable cause. Pain can affect any area of the body, most commonly the back, chest, extremities, and abdomen; may vary from trivial to excruciating; and is usually endured at home without a visit to the emergency department. There may be premonitory symptoms.¹²⁷ The duration averages a few days, with hospital admissions typically lasting between 4 and 10 days. Painful episodes are biopsychosocial events caused by vasoocclusion in an area of the body having nociceptors and nerves.¹²² Pain is an effect and, as such, consists of sensory, perceptual, cognitive, and emotional components. Frequent pain generates feelings of despair, depression, and apathy that interfere with everyday life and promote an existence that revolves around pain. This scenario may lead to a chronic debilitating pain syndrome; fortunately, this is rare.

There is no specific clinical or laboratory finding pathognomonic of pain crisis. The diagnosis is established by history and physical

examination. Changes in steady-state Hb values, sickled cells on blood smear, WBC counts, and so on are not reliable indicators. Numerous laboratory tests, leukocytosis, D-dimer fragments of fibrin, and markers of platelet activation have been found to lack specificity as indicators of acute vasoocclusion. Often patients can tell if they are having a typical pain crisis or something more sinister. It is thus good practice to ask the patient if it feels like the usual pain-crisis pain.

Initial medical assessment should focus on detection of triggers or medical complications requiring specific therapy, which include infection, dehydration, acute chest syndrome (fever, tachypnea, chest pain, hypoxia, and chest signs), severe anemia, cholecystitis, splenic enlargement, neurologic events, and priapism.¹²⁸ Pain management should be aggressive to make the pain tolerable and enable patients to attain maximum functional ability. To make the patient pain free is an unrealistic goal and risks oversedation and hypoventilation, which must be avoided. A pain chart should be started and analgesia titrated against the patient's reported pain together with medical assessment of the patient's overall clinical status, paying particular attention to avoiding oversedation. When clinicians consistently observe a disparity between patients' verbal self-report of their pain and their ability to function, further assessment should be performed to ascertain the reason for disparity. Patients are often undertreated for pain because many physicians and other health care providers are overly concerned with the potential for addiction. Undertreatment of pain is no more desirable than overtreatment and oversedation; undertreatment can prolong the duration of a painful episode and can poison the relationship between the patient and the health care system. In assessing patient responses to conventional doses of

analgesia, it must be remembered that individuals with SCD metabolize narcotics rapidly.¹²⁹

The pain pathway should be targeted at different points with different agents, avoiding toxicity with any one class (Table 42.7). The mainstays are nonsteroidal antiinflammatory drugs (NSAIDs), acetaminophen, and opioids. NSAIDs can be used to control mild to moderate pain and may have an additive role in combination with opioids for severe pain. The most potent NSAID is ketorolac. NSAIDs should be used with caution in those with a history of peptic ulcer, renal insufficiency, asthma, or bleeding tendencies. Within limits, use the agents that the patients know work for them and avoid meperidine (Demerol), which should only be used under very exceptional circumstances. Sedatives and anxiolytics alone should not be used to manage pain because they can mask the behavioral response to pain without providing analgesia.

Treatment of persistent or moderate to severe pain should be based on increasing the opioid strength or dose.¹²⁸ One approach is to administer morphine 0.1 mg/kg intravenously or subcutaneously every 20 minutes until pain is controlled. The patient should be checked at 20-minute intervals for pain; respiratory rate, depth, and quality; and sedation until the patient is stable with adequate pain control. Subsequently, the patient should receive a maintenance dose of 0.05–0.15 mg/kg intravenously or subcutaneously every 2–4 hours. A rescue dose of 50% of the maintenance dose can be considered on an as-needed basis every 30 minutes for breakthrough pain.

During maintenance with opioids, pain control; respiratory rate, depth, and quality; and oxygen saturation should be monitored approximately every 2 hours. If respiratory depression is noted, omit the maintenance dose of morphine. For severe respiratory depression

TABLE 42.7 Recommended Dose and Interval of Analgesics Necessary to Obtain Adequate Pain Control in Patients With Sickle Cell Disease

Dose/Rate		Comments
Severe to Moderate Pain		
Morphine	Parenteral: 0.1–0.15 mg/kg every 3–4 h Recommended maximum single dose, 10 mg PO: 0.3–0.6 mg/kg every 4 h	Drug of choice for pain; lower doses in elderly adults and infants and in patients with liver failure or impaired ventilation
Meperidine	Parenteral: 0.75–1.5 mg/kg every 2–4 h Recommended maximum dose, 100 mg PO: 1.5 mg/kg every 4 h	Increased incidence of seizures; avoid in patients with renal or neurologic disease and those who receive MAOIs
Hydromorphone	Parenteral: 0.01–0.02 mg/kg every 3–4 h PO: 0.04–0.06 mg/kg every 4 h	
Oxycodone	PO: 0.15 mg/kg/dose every 4 h	
Ketorolac	IM: Adults: 30 or 60 mg initial dose followed by 15–30 mg; children: 1 mg/kg load followed by 0.5 mg/kg every 6 h	Equal efficacy to 6 mg MS; helps narcotic-sparing effect; not to exceed 5 days; maximum, 150 mg first day, 120 mg maximum on subsequent days; may cause gastric irritation
Butorphanol	Parenteral: Adults: 2 mg every 3–4 h	Agonist–antagonist; can precipitate withdrawal if given to patients who are being treated with agonists
Mild Pain		
Codeine	PO: 0.5–1 mg/kg every 4 h Maximum dose, 60 mg	Mild to moderate pain not relieved by aspirin or acetaminophen; can cause nausea and vomiting
Aspirin	PO: Adults: 0.3–6 mg every 4–6 h; children: 10 mg/kg every 4 h	Often given with a narcotic to enhance analgesia; can cause gastric irritation; avoid in febrile children
Acetaminophen	PO: Adults: 0.3–0.6 g every 4 h; children: 10 mg/kg	Often given with a narcotic to enhance analgesia
Ibuprofen	PO: Adults: 300–400 mg every 4 h; children: 5–10 mg/kg every 6–8 h	Can cause gastric irritation
Naproxen	PO: Adults: 500 mg/dose initially and then 250 every 8–12 h; children: 10 mg/kg/day (5 mg/kg every 12 h)	Long duration of action; can cause gastric irritation
Indomethacin	PO: Adults: 25 mg every 8 h; children: 1–3 mg/kg/day given 3 or 4 times	Contraindicated in psychiatric, neurologic, renal diseases; high incidence of gastric irritation; useful in gout

IM, Intramuscular; MAOI, monoamine oxidase inhibitor; MS, morphine sulphate; PO, oral.

Adapted from Charache S, Terrin ML, Moore RD, et al. Effect of hydroxyurea on the frequency of painful crises in sickle cell anemia. Investigators of the Multicenter Study of Hydroxyurea in Sickle Cell Anemia. *N Engl J Med* 332:1317, 1995.

or oxygen desaturation, administer naloxone. Incentive spirometry and mandatory time out of bed are helpful in patients with chest pain to decrease the risk for hypoventilation. Adjuvant medications to consider include NSAIDs, acetaminophen, antiemetics, and antihistamines. Laxatives or stool softeners should be prescribed in keeping with close monitoring for constipation.

After 2–3 days, consider decreasing the dose and switching from parenteral to oral administration of opioids. For adult patients whose pain requires several or many days to resolve, a sustained-release opioid preparation is appropriate and provides a more consistent analgesia.

Hydration is a critical part of management. However, cardiac function may be significantly impaired, especially in adult patients, and standard discipline must be followed with intravenous fluid management to avoid iatrogenic fluid overload. Patients with SCD cannot concentrate their urine and are at risk for dehydration when not taking adequate fluids (60 mL/kg/24 h in adults). Intravenous hydration is indicated when the patient is not taking oral fluids adequately. Ideally, the urine specific gravity should be kept under 1.010 by daily testing when in the hospital. Hb may decrease by 1–2 g/dL in an uncomplicated pain crisis; blood transfusion is not routinely indicated for an uncomplicated pain crisis.

Equianalgesic doses of oral opioids should be prescribed for home use when necessary to maintain the relief achieved in the emergency department or hospital ward. Care should be taken to appropriately taper opioids in patients who have received daily opioids over many days. In these patients, there may be physical opiate dependence, which is characterized by the onset of acute withdrawal symptoms upon cessation of opioid administration. For patients at risk for physical dependence, opiates should be titrated downward by 15% to 20% per day to zero. Physical dependence is a physiologic problem, but addiction is a psychologic problem characterized by craving—behavior that is overwhelmingly directed at obtaining the drug; use of the drug for purposes other than pain control; and use of the drug despite negative physical, social, legal, or psychologic consequences.

If the patient is not taking a disease-modifying agent such as HU, consideration should be given to initiating such therapy either as an inpatient or during follow up in the outpatient setting.

Chronic Pain

Chronic pain in SCD usually (but not always) has an identifiable basis such as vertebral fractures, femoral head necrosis, early degenerative changes or osteoarthritis, or chronic skin ulcers. Most patients without such identifiable complications do not require chronic pain medications similar to those used for terminal cancer because the pain from a typical vasoocclusive crisis is episodic. Inappropriately maintaining patients without chronic musculoskeletal degeneration on long-acting opiates can impair their overall psychosocial functioning. On the other hand, adequate analgesia with long-acting opiates (e.g., long-acting morphine preparations similar to those used in cancer patients) is important to maintain the psychosocial functioning of patients who do have complications that cause chronic pain. Also, consider agents such as amitriptyline or antiseizure medications¹³⁰ that can address neuropathic components and help decrease the sleep impairment and depression that can occur with chronic pain. If the patient is not taking a disease-modifying agent such as HU, consideration should be given to initiating such therapy.

Chronic Anemia

Chronic hemolytic anemia is one of the hallmarks of SCD. Sick erythrocytes are destroyed randomly, with a mean life span of 17 days.¹³¹ The overall hemolytic rate reflects the number of ISCs.¹³² The degree of anemia is most severe in sickle cell anemia, and Hb S- β^0 -thalassemia, milder in Hb S- β^+ -thalassemia and Hb SC disease,¹³³ and, among patients with sickle cell anemia, less severe in those who have coexistent α -thalassemia (Table 42.8 and see Table 42.1).¹³⁴

As already noted, EPO deficiency from otherwise subclinical chronic renal damage may also contribute to a decline in Hb levels below baseline. The level of chronic anemia is a significant prognostic marker.¹⁹

The treatment options for the chronic anemia of SCD have already been mentioned. These strategies attempt to decrease hemolysis by increasing Hb F (HU and the experimental approaches with EPO, decitabine, and histone deacetylase inhibitors) or decreasing

TABLE 42.8

Bacteria and Viruses That Most Frequently Cause Serious Infection in Patients With Sickle Cell Disease

Microorganism	Type of Infection	Comments
<i>Streptococcus pneumoniae</i>	Septicemia Meningitis Pneumonia Septic arthritis	Common despite prophylactic penicillin and pneumococcal vaccine Less frequent than in years past Rarely documented except in infants and young children Uncommon
<i>Haemophilus influenzae</i> type b	Septicemia	
Meningitis		
Pneumonia	Much less common in recent years because of immunization with conjugate vaccine	
<i>Salmonella species</i>	Osteomyelitis	
Septicemia	Most common cause of bone and joint infection	
<i>Escherichia coli</i> and other gram-negative enteric pathogens	Septicemia	
Urinary tract infection		
Osteomyelitis	Focus sometimes not apparent	
<i>Staphylococcus aureus</i>	Osteomyelitis	Uncommon
<i>Mycoplasma pneumoniae</i>	Pneumonia	Pleural effusions; multilobe involvement
<i>Chlamydia pneumoniae</i>	Pneumonia	
Parvovirus B19	Bone marrow suppression (aplastic crisis)	High fever common; rash and other organ involvement infrequent
Hepatitis viruses (A, B, and C)	Hepatitis	Marked hyperbilirubinemia

Data from Buchanan GR, Glader BE: Benign course of extreme hyperbilirubinemia in sickle cell anemia: Analysis of six cases. *J Pediatr* 91:21, 1977.

the intracellular Hb S concentration by preventing RBC dehydration (Gardos channel inhibitors).

Exacerbations of Anemia

The rather constant level of hemolytic anemia may be exacerbated by additional events such as aplastic crises, acute splenic sequestration, acute hepatic sequestration, chronic renal disease, or renal endocrine deficiency that may be present without overt renal failure, bone marrow necrosis, deficiency of folic acid or iron, delayed hemolytic transfusion reactions, autoimmune hemolytic anemia, or hyperhemolysis (hemolytic exacerbations) of unknown etiology. Laboratory evaluations that are very useful in the evaluation of a patient with anemia exacerbation are the reticulocyte count, LDH, alloantibody screening, the direct antiglobulin (Coombs) test, and EPO level.

Aplastic Crises

Aplastic crises are transient arrests of erythropoiesis characterized by abrupt falls in Hb levels, reticulocyte number, and RBC precursors in the bone marrow without necessarily an increase in the LDH. Although these episodes typically last only a few days, the level of anemia may be severe because the hemolysis continues unabated in the absence of RBC production. Although the mechanisms that impair erythropoiesis in inflammation are operative in infections of all types (see Chapter 37), human parvovirus B19 specifically invades proliferating erythroid progenitors, which accounts for its importance in SCD (see Chapters 30 and 32).¹³⁵ Parvovirus B19 (Fig. 42.10) accounts for 68% of aplastic crises in children with SCD,¹³⁶ but the high incidence of protective antibodies in adults makes parvovirus a less frequent cause of aplasia in this age group (see also Infections, later in this chapter). Other reported causes of transient aplasia are infections by *S. pneumoniae*, salmonella, streptococci, and Epstein-Barr virus. Bone marrow necrosis, which also may be the result of parvovirus infection, characterized by fever, bone pain, reticulocytopenia, and a leukoerythroblastic response, also causes aplastic crisis.^{137,138}

Inhaled oxygen therapy also causes transient RBC hypoproduction; supraphysiologic oxygen tensions curtail EPO production promptly and suppress reticulocytosis within 2 days.¹³⁹

The mainstay of treating aplastic crises is RBC transfusion. When transfusion is necessitated by the degree of anemia or cardiorespiratory symptoms, a single transfusion usually will suffice because reticulocytosis resumes spontaneously within a few days. Transfusion may be avoided by keeping severely anemic patients on bed rest to prevent symptoms and by avoiding supraphysiologic oxygen tensions. A

useful guideline for transfusion in the context of an aplastic crisis is the reticulocyte count. A patient having an aplastic crisis with a reticulocyte count that is recovering is less likely to require urgent transfusion than one with a normal or low absolute reticulocyte count.

Sequestration Crisis (Spleen or Liver)

Acute splenic sequestration of blood is characterized by acute exacerbation of anemia; persistent reticulocytosis; a tender, enlarging spleen; and sometimes hypovolemia.¹⁴⁰ The LDH level may remain stable or increase. Patients susceptible to this complication are those whose spleens have not undergone fibrosis—young patients with sickle cell anemia and adults with Hb SC disease or sickle cell- β^+ -thalassemia. Sequestration may occur as early as a few weeks of age and may cause death before SCD is diagnosed. In one study, 30% of children had splenic sequestration over a 10-year period and 15% of the attacks were fatal.¹⁴¹

The basis of therapy is to restore blood volume and RBC mass. Because splenic sequestration recurs in 50% of cases, splenectomy is recommended after the event has abated. Alternatively, chronic transfusion therapy is used in young children to delay splenectomy until it can be tolerated safely. Because recurrence is possible during transfusion therapy, parents should be trained to detect a rapidly enlarging spleen and to seek immediate medical attention in this event. Less common sites of acute sequestration include the liver and possibly the lung.^{142,143}

Delayed Hemolytic Transfusion Reaction and Autoimmune Hemolytic Anemia

Approximately 30% of patients are predisposed to develop alloantibodies, in part because of minor blood group incompatibilities in racially mismatched blood.^{77,78} The corollary is that the other patients can receive multiple transfusions without demonstrating alloantibodies. After alloimmunization, there is a subsequent decrease in antibody titer that can fall below serologically detectable levels. Therefore antigen-positive RBCs appear compatible in cross-matching and are transfused. This can result in a delayed hemolytic transfusion reaction produced by the amnestic response of the immune system (as opposed to the immediate hemolytic reaction that occurs with preformed antibody). The delayed hemolytic transfusion reaction consists of an unexplained fall in Hb, elevated LDH level, elevated bilirubin above baseline, and hemoglobinuria, all occurring between 4 and 10 days after the RBC transfusion. Delayed hemolytic reactions and hyperhemolysis have been shown to occur in 11% of pediatric patients with SCD and a history of alloantibodies.¹⁴⁴ In SCD the delayed hemolytic transfusion reaction can be particularly devastating because it can be accompanied by reticulocytopenia, which together with a

Fig. 42.10 PARVOVIRUS. Bone marrow aspirate in a patient with sickle cell disease and aplastic crisis (A). Note the absence of red blood cell precursors except for the single, large degenerating pronormoblast (lower center). Such pronormoblasts contain large nuclear inclusions (B) as a result of replication of parvovirus B19. The same can be seen in the tissue sections of a bone core biopsy (C and D). The parvovirus can now be recognized immunohistochemically with an immunostain (E).

bystander effect of destruction of recipient blood (not just donor blood) can result in unanticipated worsening of anemia to levels below that seen before transfusion.¹⁴⁵ In addition to the manifestations of a delayed hemolytic transfusion reaction as listed, patients may develop acute congestive heart failure, acute renal failure, or acute chest syndrome (accompanied by vasoocclusive pain crisis). Subsequent transfusions may further exacerbate the anemia.

Resolution of severe anemia may only occur after withholding further transfusions with subsequent reticulocyte count recovery. Corticosteroids at high doses (e.g., intravenous methylprednisolone 500 mg/day for 2–3 days) should be considered if the anemia is life threatening or if further transfusion is deemed necessary to save the patient's life. Intravenous immunoglobulin can also be considered, with proper attention paid to avoiding iatrogenic fluid overload. Approaches to minimizing this complication include transfusing extended-matched (see [Basic Management and Disease Modification](#)), phenotypically compatible blood.^{76–78} This syndrome may or may not recur with further transfusions after a recovery period.¹⁴⁶

Hyperhemolytic Crisis

Hyperhemolytic crisis is the sudden exacerbation of anemia with increased reticulocytosis and bilirubin level. If suspected, the approach to management should first be to look for an underlying etiology, which may be one of the events listed earlier: aplastic crisis (during the recovery phase when the reticulocyte count may not be decreased), sequestration crisis, delayed hemolytic transfusion reaction, or autoimmune hemolysis. Another possible cause is glucose-6-phosphate dehydrogenase deficiency.¹⁴⁷

Erythropoietin Deficiency

This entity is discussed under Basic Management and Disease Modification.

Nutritional Deficiencies: Folate, Iron, or Vitamin B₁₂ Deficiency

This entity is discussed under Basic Management and Disease Modification.

Hypothyroidism

Iron overload in SCD can result in hypothyroidism.¹⁴⁸ Therefore hypothyroidism is another etiology to consider in a patient with SCD with an otherwise unexplained decrease in Hb below baseline.

Infections

Immune Deficit

The propensity of children with SCD to contract *S. pneumoniae* infection is related to impaired splenic function¹⁴⁹ and diminished

serum opsonizing activity. Even before the anatomic autoinfarction of the spleen in patients with sickle cell anemia, defective splenic function is demonstrable by Howell-Jolly bodies on the peripheral blood smear, visible “pits” on the surface of RBCs, and abnormal results of radionuclide spleen scanning.¹⁵⁰ Specific syndromes exhibiting greater rates of hemolysis cause loss of splenic function at earlier ages—sickle cell anemia earlier than Hb SC disease earlier than sickle cell-β⁺-thalassemia.

Infectious complications of SCD are a major cause of morbidity and mortality¹⁵¹ even with current vaccination and prophylactic antibiotic regimens. The infections caused by particular organisms are shown in [Table 42.8](#), and the specific organisms affecting different target organs are shown in [Table 42.9](#). By 5 years of age, almost all patients are functionally asplenic, contributing to infectious susceptibility. Historically, pneumococcal sepsis has been the predominant cause of death in those younger than 20 years of age.¹⁵²

Evaluation

The most critical aspect of infectious illness in SCD is the evaluation and treatment of febrile children. Routine evaluation includes a physical examination, a CBC, blood and urine cultures, a lumbar puncture if meningitis is suspected, and chest radiography to evaluate for pneumonia. Results of the CBC are compared with baseline values. A left shift in the differential count suggests bacterial infection.

Penicillin Prophylaxis and Pneumonia Vaccination

Data and recommendations regarding penicillin prophylaxis and pneumonia vaccination are discussed under Basic Management and Disease Modification.

Streptococcus Pneumoniae, Haemophilus Influenzae, Atypical Mycobacteria, and Acute Febrile Illness

Streptococcus pneumoniae bacteremia is accompanied by leukocytosis, a left shift, aplastic crisis, sometimes disseminated intravascular coagulation, and a 20% to 50% mortality rate.¹⁵¹ Although concerns about *S. pneumoniae* sepsis are largely for young children, this complication also occurs in adults, often with devastating results.¹⁵³ *S. pneumoniae* is the major cause of meningitis in infants and young children with SCD, and it occurs in the setting of bacteremia.

The second most common organism responsible for bacteremia in these children, *H. influenzae* type b, accounts for 10% to 25% of episodes. *H. influenzae* bacteremia affects older children and is less fulminant than *S. pneumoniae* bacteremia, but it may be fatal.¹⁵¹ Conjugated *H. influenzae* type b vaccines produce excellent antibody responses in children with SCD and are now administered in early infancy (<http://www.cdc.gov/vaccines/recs/schedules/child-schedule.htm>).

Owing to the high mortality rate of bacteremia, hospitalization, blood and cerebrospinal fluid cultures, and parenteral antibiotics have

TABLE 42.9 Organ-Related Infection in Sickle Cell Disease

Primary Sites of Infection	Most Common Pathogen(s)	Other Pathogens	Pathophysiology	Prevention	Management
Septicemia	<i>Streptococcus pneumoniae</i>	<i>Haemophilus influenzae</i> type b <i>Escherichia coli</i> <i>Salmonella</i> spp.	Defective splenic function; deficiency of opsonic antibody	Vaccines ^a Prophylactic penicillin	Empiric intravenous antibiotics for fever
Meningitis	<i>S. pneumoniae</i>			Same as for septicemia	
Osteomyelitis and septic arthritis	<i>Salmonella</i> spp. <i>S. pneumoniae</i>	<i>E. coli</i> <i>Proteus</i> spp. <i>Staphylococcus aureus</i>		–	Surgical drainage, intravenous antibiotics
Pneumonia	<i>Mycoplasma pneumoniae</i> Respiratory viruses	<i>Chlamydia pneumoniae</i> <i>S. pneumoniae</i>		Vaccines ^a	See pulmonary and therapy sections for management of acute chest syndrome.

^aAgainst *Streptococcus pneumoniae* and *Haemophilus influenzae* type b.

Data from Buchanan GR, Glader BE: Benign course of extreme hyperbilirubinemia in sickle cell anemia: Analysis of six cases. *J Pediatr* 91:21, 1977.

been the standard of care for children with fevers higher than 38.5°C. Prompt attention to fever can reduce the risk of severe pneumococcal sepsis. Rapid administration of antibiotics has resulted in a lower incidence of meningitis among patients with bacteremia than 20 years ago when the incidence was 50%.¹⁵⁴ The efficacy of ceftriaxone therapy for *S. pneumoniae* and *H. influenzae* infection¹⁵⁵ has led to new treatment algorithms that recommend outpatient therapy for most patients. However, resistant *S. pneumoniae* have emerged, necessitating a thorough knowledge of local resistance patterns to guide the choice of alternate antibiotics (particularly vancomycin, to which resistance has not been observed).

Please see [Pulmonary Complications](#) for further discussions regarding pneumonia and acute chest syndrome.

Meningitis

Meningitis therapy should cover *S. pneumoniae* and probably *H. influenzae* type b and should be continued for at least 2 weeks.

Salmonella and Osteomyelitis

In this patient population, osteomyelitis is commonly caused by *Salmonella* spp.¹⁵⁶ *Staphylococcus aureus*, the most common etiology in patients without SCD, accounts for less than 25% of SCD cases. Infection usually affects long bones, often at multiple sites.

The diagnosis is confirmed by culture of blood or infected bone. Parenteral antibiotics that cover *Salmonella* spp. and *S. aureus* are given, and antibiotic therapy is based on culture results. Parenteral antibiotics are continued for 2–6 weeks.¹⁵⁶ Surgical drainage or sequestrectomy may be required. Most patients are cured by this approach, but there may be recurrences.¹⁵⁶

Articular infection is less common and is often caused by *S. pneumoniae*.¹⁵⁶

Parvovirus B19

The specificity of the parvovirus B19 (see also [Aplastic Crisis](#)) for erythroid precursor cells, coupled with the accelerated erythropoiesis in hemolytic anemias, leaves sickle cell patients vulnerable to infection by this agent.¹⁵⁷ In SCD, parvovirus infection is a common cause of aplastic crisis, especially in children. It has been reported to cause bone marrow necrosis, acute chest syndrome, pulmonary fat embolism, hepatic sequestration, and glomerulonephritis.^{135–138}

Urinary Tract Infections

Patients with SCD are at a higher risk for urinary tract infections and pyelonephritis than the general population. *Escherichia coli* is the most common uropathogen and can cause septicemia in these patients. Persistent urinary tract infections may be secondary to renal papillary necrosis. All urinary tract infections in this patient population should be considered complicated, requiring 10–21 days of appropriate antibiotic therapy.

Neurologic Complications

Neurologic complications occur in 25% or more of patients with SCD.¹⁵⁸ Neurologic complications include CVAs (consisting of transient ischemic attacks [TIAs], overt and silent cerebral infarction, cerebral hemorrhage), seizures (which can be a presenting feature of CVA), unexplained coma, spinal cord infarction or compression, central nervous system infections, vestibular dysfunction, and sensory hearing loss.¹⁵⁹

Cerebrovascular Accidents, Pathophysiology, Incidence, Risk Factors, and Presentation¹⁶⁰

Histopathologic evaluation of large-vessel involvement in SCD shows a pattern of smooth muscle proliferation with overlying endothelial damage and fibrosis. Smaller arterioles and capillaries demonstrate distension, thrombosis, and vessel-wall necrosis.^{161,162} Aneurysmal dilation associated with hemorrhagic stroke occurs at regions of intimal hyperplasia.¹⁶³ The vessel wall changes are likely multifactorial in origin related to endothelial injury from high and turbulent

flow, RBC adherence, and hypoxia; but in addition, it has been speculated that depletion of NO by the free Hb released through intravascular hemolysis may also play a role.¹⁶³ The age-specific pattern of stroke risk in SCD may be related to the higher cerebral flow rates in early childhood.¹⁶³ Cerebral thrombosis, which accounts for 70% to 80% of all CVAs in patients with SCD, results from large-vessel occlusion (see [Fig. 42.9](#)) rather than the more typical microvascular occlusion of SCD.¹⁶⁴ Silent infarcts are thought to result from microvascular vasoocclusion or thrombosis or chronic hypoxia in the periphery stemming from large-vessel disease.¹⁶⁵ In 30% of patients with SCD, major vessel stenosis results in the formation of friable collateral vessels that appear as puffs of smoke (*moyamoya* in Japanese) on angiography.¹⁶⁶ Moyamoya disease predisposes to thrombotic and hemorrhagic strokes, seizures, and cognitive disability.¹⁶⁷

The relative risk for stroke is 200–400 times higher in children with SCD compared with the children without SCD. The prevalence of clinically overt stroke is 11%. Clinically silent infarction detectable by MRI affects 17% to 20% of patients by age 20 years.¹⁶⁸ Silent infarcts are associated with cognitive impairment. Even in patients without silent or overt cerebral infarction, cognitive functioning can be impaired.¹⁶⁹ Almost 50% of the children with “silent” infarcts eventually require lifelong support or custodial care because of neuropsychologic deficits.¹⁷⁰ Whereas infarctive strokes were common in children and those older than 30 years of age, hemorrhagic stroke was most common between ages 20 and 30 years.²³

Sickle cell–specific risk factors for CVA include increased cerebral blood flow velocity¹⁷¹ (discussed further under Primary Prevention of Cerebrovascular Accidents), a history of overt or silent cerebral infarction,¹⁷² nocturnal hypoxemia,¹⁷³ more severe anemia, higher reticulocyte counts, lower Hb F levels, higher WBC counts, the Hb SS genotype (rather than Hb SC disease or sickle cell– β -thalassemia), nocturnal hypoxemia or sleep apnea, migraines, elevated homocysteine levels, “relative” systolic hypertension (i.e., those at the high end of the lower-than-normal range characteristic of SCD).^{23,174} Genetic markers of increased risk are the Central African Republic (CAR) haplotype and the absence of α -thalassemia.^{163,175} Both small- and large-vessel thrombosis can occur. Specific HLA alleles separately correlate with small- versus large-vessel stroke risk, suggesting that different pathologic processes may be involved.¹⁶³

In addition to these sickle cell–specific predictors of stroke, one must also consider the well-documented modifiable risk factors for stroke that are operational in the general population; these are hypertension, exposure to cigarette smoke (active smoking or passive exposure), diabetes, atrial fibrillation, dyslipidemia, carotid artery stenosis, postmenopausal hormone therapy, poor diet, physical inactivity, obesity, and fat distribution. Less well-documented but potentially modifiable risk factors include alcohol or drug use, oral contraceptive use, and sleep-disordered breathing.¹⁶⁸

CVAs are heralded by focal seizures in 10% to 33% of cases and by TIAs in 10%. CVAs are fatal in approximately 20% of initial cases, recur within 3 years in nearly 70%, and are the cause of motor and cognitive impairment in the majority. Intracranial hemorrhage results in the same signs as thrombosis, but in addition, neck stiffness, photophobia, severe headache, vomiting, and altered consciousness may occur. Coma suggests hemorrhage rather than thrombosis. A typical presentation is coma and seizures without hemiparesis. Although the mortality rate may be as high as 50%, the morbidity of survivors is low. Hemorrhage may be subarachnoid, intraparenchymal, or intraventricular, which can be differentiated by angiography. The favorable neurosurgical outcome in subarachnoid hemorrhage caused by ruptured aneurysm justifies an aggressive approach to diagnosis, transfusion, vasodilatory therapy, and surgery.

Primary Prevention of Cerebrovascular Accidents

The overall risk of stroke in pediatric patients with SCD is 1% per year; however, in the subset of patients with transcranial Doppler, evidence of a high (>200 cm/s) cerebral blood flow velocity in the

internal carotid artery or middle cerebral artery, the stroke risk is in excess of 10% per year (although this is still much lower than the risk of recurrent stroke in a sickle cell patient after a first event, which is approximately 70%). In the Stroke Prevention Trial in Sickle Cell Disease (STOP), 130 children diagnosed as having clinically silent cerebral artery stenosis on the basis of high cerebral flow rates were randomized to receive chronic transfusion therapy or not. Over a period of more than 2 years, the risk of stroke was reduced to less than 1% per year in the transfused group¹⁷¹ (a risk reduction of >90%). The ability of transfusion to curtail progression of large-vessel stenosis has also been proven with angiography.¹⁷⁶

Because of the risks of iron overload and allosensitization with chronic transfusion, a randomized controlled trial of withdrawal of transfusion was conducted (STOP 2). This trial evaluated discontinuation of transfusion after at least 30 months in children who had not had an overt stroke and in whom the cerebral flow rates decreased to low risk (<170 cm/s) with transfusion. This study was terminated early because of a high rate of reversion to high-risk TCD flow rates (34%) and stroke (5%) in the patients taken off transfusion compared with the group who continued transfusion.¹⁷⁷

In children, MRI can also be used to assess stroke risk: 8.1% of children with an asymptomatic MRI lesion versus 0.5% of those with a normal MRI had a stroke during the ensuing 5 years.¹⁷² A randomized trial of MRI-guided prophylactic transfusion is in progress (Silent Infarct Treatment Trial). In adults, MRI or MRA of the brain should be used³⁴ to assess thrombotic or hemorrhagic stroke risk.

Chronic transfusion is associated with a significant complication rate. Therefore there is a need for alternatives, especially because some patients and physicians believe that the 10% annual stroke risk does not warrant the risks and burdens of chronic transfusion.¹⁶⁹ The role of aspirin in ischemic stroke prevention in SCD is being evaluated (see [Basic Management and Disease Modification](#)). HU significantly lowered the TCD velocity values in a group of 24 children with Hb SS disease compared with an age-matched control group.⁵¹ The role of HU is being formally evaluated in secondary stroke prevention (see [Secondary Prevention](#)). Stem cell transplantation has resulted in stabilization of cerebral vasculopathy¹⁷⁸ but there is a mortality risk with this procedure of between 6% and 10%.

Other modifiable risk factors for stroke (see [Cerebrovascular Accidents, Pathophysiology, Incidence, Risk Factors, and Presentation](#)) should be identified and treated. Notably, in the general population, hypertension is particularly associated with a risk for hemorrhagic stroke, and effective treatment of hypertension can produce a relative risk reduction of 26% for ischemic stroke and 49% for hemorrhagic stroke.¹⁷⁹ In patients with SCD followed through the Cooperative Study of Sickle Cell Disease, both diastolic and systolic blood pressures were noted to be lower than for matched control participants. Patients with systolic pressures in the higher range for the sickle cell group, even with systolic pressures less than 140 mmHg, had an increased risk of first ischemic stroke (there were insufficient events to make firm conclusions regarding hemorrhagic stroke).²³ Therefore at a minimum, it seems reasonable to follow population-wide recommendations for blood pressure control in patients with SCD.

Evaluation and Management of Acute Cerebrovascular Accidents

Patients with symptoms and signs of CVA should be evaluated immediately using computed tomography (CT) scanning or MRI to distinguish among TIA, cerebral thrombosis, and hemorrhage. In those with hemorrhage, angiography or MRA is indicated after partial-exchange transfusion is performed to avoid complications associated with the injected contrast material. In both thrombosis and hemorrhage, prompt partial-exchange transfusion is performed, and chronic direct transfusion to maintain the Hb S level below 30% is instituted to prevent recurrent events (see also [Basic Management and Disease Modification](#)) and promote resolution of arterial stenoses.¹⁷⁶

Fig. 42.11 COMPARISON OF STROKE RECURRENCE OVER 62 MONTHS IN A TRANSFUSED GROUP AND IN UNTRANSFUSED HISTORICAL CONTROL GROUPS. (Adapted with permission from Pegelow CH, Adams RJ, McKie V, et al: Risk of recurrent stroke in patients with sickle cell disease treated with erythrocyte transfusions. *J Pediatr* 126:896, 1995.)

Secondary Prevention of Cerebrovascular Accidents

The risk of recurrent stroke is approximately 70%, a risk that is reduced to around 13% with chronic transfusion.¹⁸⁰ Although recurrent CVAs during chronic transfusion have been reported, this therapeutic modality provides the best means of preventing recurrence (Fig. 42.11). This treatment also provides incidental protection against pain crises, bacterial infections, acute chest syndrome, and hospitalization.

Based on the data from STOP 2 (see [Primary Prevention of Cerebrovascular Accidents](#)), chronic transfusion is continued indefinitely. This may not be feasible for administrative reasons or because of allosensitization or iron overload for which the patient is unable or unwilling to undergo treatment. Therefore clinical trials to determine if disease modifiers such as HU or decitabine can reduce stroke risk are indicated. In patients with a history of CVA transitioned from chronic transfusion to HU, the recurrent stroke rate remained stable and in the range seen with continued transfusion.⁸⁶

Per primary prevention, all other identified modifiable risk factors for stroke should be identified and treated.

In patients with moyamoya disease, surgical approaches to therapy, such as extracranial–intracranial bypass, have been useful in improving the perfusion of affected regions of the brain.

Stem cell transplantation has resulted in stabilization of cerebral vasculopathy,¹⁷⁸ but the risk of a second neurologic event is higher in the peritransplant period, and the mortality rate with this procedure is between 6% and 10%.¹⁷⁸

Seizures

Seizures occur more commonly among patients with SCD. In one study, 21 of 152 patients in a pediatric clinic had seizures, four of which were related to meperidine therapy. Most had nonfocal CT and MRI studies but focal electroencephalographic changes.¹⁸¹ CVAs are heralded by focal seizures in 10% to 33% of cases. Therefore seizures in SCD ultimately may be related to the underlying vasculopathy.

Pulmonary Complications

Pulmonary disease is the leading cause of death in patients with SCD.¹⁶ Both acute and chronic pulmonary complications are common. The common acute complications are pneumonia and acute chest syndrome, and the common chronic complication is pulmonary hypertension.

Pneumonia

Pneumonia is defined as chest infiltrates on chest radiography or chest CT scan associated with fever and an identified infectious etiology. The risk for and increased frequency of *S. pneumoniae* infections is discussed under Infections earlier. In addition, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Legionella* spp. are also relatively common causes of pneumonia in patients with SCD. Antibiotic therapy for pneumonia or acute chest syndrome should cover these agents in addition to pneumococcus and *H. influenzae*. When antibiotics are used to treat the acute chest syndrome, they should cover *S. pneumoniae*, *H. influenzae* type b, *M. pneumoniae*, and *C. pneumoniae*. The combination of cefuroxime and erythromycin is recommended.

Acute Chest Syndrome

Acute chest syndrome occurs in approximately 30% of patients.¹⁸² Acute chest syndrome is defined as a new infiltrate on chest radiography or chest CT scan associated with one or more new symptoms, which include fever, chest pain, cough, sputum production, dyspnea, and hypoxia. This entity is included in discussions of SCD because processes other than infection, such as vasoocclusion, could also lead to pulmonary symptoms, signs, and chest radiographic changes. However, it should be borne in mind that the usual etiology might be both vasoocclusion and infection simultaneously, and in almost all cases of acute chest syndrome, antibiotics should be administered. Many episodes in which common pathogens are not cultured are caused by “atypical” agents (*Mycoplasma*, *Legionella*, and *Chlamydia* spp.), suggesting that antibiotic therapy include agents directed at atypical agents. Pulmonary fat embolus, evidenced by stainable fat in pulmonary macrophages obtained by bronchoalveolar lavage or sputum induction, is found in 44% to 60% of cases of acute chest syndrome.¹⁸³ Acute chest syndrome caused by pulmonary fat embolus is associated with more severe hematologic and clinical abnormalities. In adults, the mortality rate is four times higher than in children.^{3,184}

Acute chest syndrome is often preceded by febrile episodes in children and by vasoocclusive pain crisis in adults (Fig. 42.12).¹⁸⁴ Elevation of serum phospholipase A2 was detected in patients admitted with vasoocclusive pain crisis 24–48 hours before acute chest syndrome was clinically diagnosed.¹⁸⁵ Pulmonary fat embolus is often preceded by an acute painful episode. Some patients have a rapidly progressive course associated with a precipitous decrease in arterial oxygen tension; they may require intensive care treatment. If there are clinical signs of respiratory distress or when arterial oxygen tension cannot be maintained above 70 mmHg with inhaled oxygen, partial-exchange transfusion is indicated. Artificial ventilation may be required.

In patients with pneumonia or chest syndrome, antibiotics should cover *S. pneumoniae*, *M. pneumoniae*, *Chlamydia pneumoniae*, *H. influenzae*, and *Legionella* spp.

Pulmonary Hypertension

Chronic complications such as pulmonary hypertension occur in as many as 60% of patients.^{186–188} There does not appear to be an association with the occurrence of acute chest syndrome,¹⁸⁷ emphasizing that the pathophysiology of these two conditions may differ in some key features. The pathophysiology may involve thrombi in large and small arteries,^{189,190} cardiac decompensation from progressive anemia, and potentially reversible increases in vascular tone from NO depletion and medial and intimal hypertrophy.¹⁹⁰ The recognition that pulmonary hypertension is a feature of hemolytic syndromes other than sickle cell and that markers of hemolysis correlate with the risk of pulmonary hypertension supports the idea that depletion

Fig. 42.12 AGE-SPECIFIC ASSOCIATED EVENTS WITHIN 2 WEEKS PRECEDING ACUTE CHEST SYNDROME. (Adapted with permission from Vichinsky EP, Styles LA, Colangelo LH, et al: Acute chest syndrome in sickle cell disease: Clinical presentation and course. Cooperative Study of Sickle Cell Disease. Blood 89:1787, 1997.)

of NO through scavenging by free Hb may have an important role in the pathophysiology of this disease.^{187,191} Pulmonary hypertension usually occurs in adults and carries a poor prognosis.¹⁹²

The association with early death and the emerging availability of candidate treatments suggest that efforts should be made to diagnose this condition in all patients with SCD.^{187,191} The feasibility of an echocardiogram-determined tricuspid regurgitant jet (TR-jet) velocity measurement of 2.5 m/s to make the diagnosis was suggested by selective cardiac catheterization in a cohort of 195 patients;¹⁸⁶ however, the sensitivity and specificity of this test may have limitations.¹⁹¹ Elevations in BNP levels correlate with an increased TR-jet and risk of early death.

In a 16-week, double-blind, placebo-controlled trial of sildenafil to treat patients with SCD with increased TR-jet velocity and a low exercise capacity, sildenafil increased hospitalization rates for pain without evidence of improvement in TR-jet velocity or BNP levels.¹⁹³ If such patients have chronic relative reticulocytopenia, measures to increase total Hb could be a consideration requiring evaluation in clinical trials (see [Basic Management and Disease Modification](#)).

Other Pulmonary Complications

Other findings include restrictive and obstructive lung disease and hypoxemia.¹⁹⁴ High-resolution, thin-section CT scanning of the lungs may show chronic interstitial fibrosis. Airway hyperreactivity occurs in nearly two-thirds of children with SCD not diagnosed as having asthma. Thirty-six percent of 53 children with SCD were found to have sleep-related upper airway obstruction, 16% had hypoxemia, and all 15 who underwent adenotonsillectomy improved symptomatically and had improved hypoxemia.¹⁹⁵ Sleep apnea may be associated with surgically reversible exacerbations of painful episodes and strokes. Blood gas and pulmonary function measurements should be obtained as baseline data for all patients.

Hepatobiliary Complications

Hepatobiliary complications in patients with SCD include cholelithiasis, cholecystitis, acute hepatic cell crisis, acute hepatic sequestration crisis, and sickle cell intrahepatic cholestasis.¹⁹⁶ Chronic transfusion also places patients at risk for infection with hepatitis viruses and for transfusional hemosiderosis. Nontransfusion-related hepatic hemosiderosis can also be seen.

The serum bilirubin level is higher in sickle cell anemia (Hb SS) than in Hb SC disease or sickle cell- β^+ -thalassemia as a result of a greater hemolytic rate. The level rises after the first decade, possibly as a result of chronic hepatobiliary dysfunction. The aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels are often elevated, particularly in adult patients with sickle cell anemia, but mean levels are normal. Alkaline phosphatase levels are elevated in all genotypes until puberty, which occurred later in males and in those with sickle cell anemia. Percutaneous liver biopsy is associated with a high risk of severe complications and death in patients with SCD with acute hepatic syndromes.¹⁹⁷

Cholelithiasis and Cholecystitis

The prevalence of pigmented gallstones in SCD is directly related to the rate of hemolysis.¹⁹⁸ In sickle cell anemia, gallstones occur in children as young as 3–4 years of age and are eventually found in approximately 70% of patients. Some have recommended the surgical removal of asymptomatic gallstones to avoid subsequent difficulty in distinguishing gallbladder pain from acute painful episodes. This approach has become more feasible with the availability of laparoscopic cholecystectomy.¹⁹⁹

Acute Hepatic Cell Crisis

Acute hepatic cell crisis presents with tender hepatomegaly, worsening jaundice, and fever.¹⁹⁶ The likely etiology is hepatocellular cell ischemia. The AST and bilirubin are elevated, but rarely above 300 IU/L and 255 μ M, respectively. This syndrome usually resolves within 3–14 days with supportive care alone but can progress to liver failure and fatal outcome, therefore patients should be monitored closely and exchange transfusion initiated if they show signs of progressive liver dysfunction (e.g., increasing AST).

Acute Hepatic Sequestration Crisis

Acute hepatic sequestration crisis presents with acute hepatic enlargement and a dramatic fall in Hb concentration, the most likely mechanism being sequestration of sickled erythrocytes in the liver. Management is with supportive care and transfusions.

Intrahepatic Cholestasis

Sickle cell intrahepatic cholestasis results in severe, asymptomatic hyperbilirubinemia without fever, pain, leukocytosis, hepatic failure, or death.²⁰⁰ Asymptomatic hyperbilirubinemia without signs of progressive liver dysfunction (e.g., increasing AST) does not require specific therapy. Evidence of progressive liver dysfunction should prompt consideration of acute hepatic cell crisis and exchange transfusion.

Hepatitis C Infection

Chronic hepatitis C infection in SCD occurs with a prevalence that is related to the number of transfusions received; it may be a leading cause of cirrhosis. Liver transplantation has been used successfully as therapy for this complication.²⁰¹ If indicated, interferon-ribavirin can be used to treat hepatitis C in patients with SCD.²⁰²

Obstetric and Gynecologic Issues

Gynecologic complications (delayed menarche, dysmenorrhea, ovarian cysts, pelvic infection, and fibrocystic disease of the breast) are more common in women with SCD. Pregnancy entails increased risks to the mother and child compared with the general population.

Pregnancy

Pregnancy in patients with SCD is associated with increased risks to both the mother and fetus, although these risks are not so great as to prohibit continuation of pregnancy.^{203,204} The fetal complications of pregnancy, most of which are related to compromised placental blood flow, are the increased incidence of spontaneous early abortion, intrauterine growth retardation, low birthweight, and fetal death.

Maternal complications include increased rates of painful episodes, severe anemia caused by iron or folate deficiencies, exaggeration of the physiologic “anemia of pregnancy,” increased infections (urinary tract infections, pneumonias, endometritis), preeclampsia, and death.²⁰⁴ It is controversial whether the degree of anemia predicts the birth of babies with low birthweight. The occurrence of a perinatal death in a previous pregnancy and the presence of twins in the present pregnancy are two major risk factors for an unfavorable outcome. The course of pregnancy is more benign in Hb SC disease than in sickle cell anemia.

Better fetal and maternal outcomes in recent years are largely attributable to generally improved antenatal and obstetric care. Patients should be followed in a high-risk obstetric clinic in addition to the hematology clinic and receive the usual vitamin, mineral, and folate supplements. A high-calorie, high-protein diet can be considered. There is no specific therapeutic or preventive treatment for intrauterine growth retardation. Some experts recommend prophylactic transfusion, but a large controlled study showed no improvement in fetal outcome from this management option, although maternal symptoms are reduced. In addition to the usual indications for transfusion therapy in SCD, transfusion therapy is indicated for patients with cardiac or respiratory compromise, in preparation for cesarean section, preeclampsia, twin pregnancy, acute chest syndrome, Hb levels more than 20% below steady state or less than 5 g/dL, and previous history of perinatal mortality. If the Hb is between 8 and 10 g/dL and transfusion is indicated for any of the reasons above, partial exchange should be performed (e.g., phlebotomy of 400–500 mL and transfusion of 2 units of packed RBCs).²⁰⁵ The type of delivery does not appear to represent a problem, and both spontaneous delivery and cesarean section are well tolerated.

Some experts advise that hypertonic saline injections are contraindicated for elective termination of pregnancy because of the risk of sickling-induced vasoocclusion. However, most methods of abortion are well tolerated. There are anecdotal reports of a higher incidence of acute painful episodes after therapeutic abortion; inpatient intravenous hydration before and for the 24 hours after the procedure is recommended.

Birth Control

Modern nonestrogen-containing intrauterine devices should be considered. Although depot injections of medroxyprogesterone (Depo-Provera) given every 3 months may be safe with regards to stroke risk,²⁰⁵ there is a risk of bone loss, a consideration in patients with SCD and their propensity to skeletal complications. Oral contraceptives containing low doses of estrogen can be considered with no clear evidence of increased stroke demonstrated to date, although the patients' overall stroke risk should probably still be taken into consideration until there is more phase IV follow-up on the clinical experience. Another caution with low-dose estrogen oral contraception is the risk of contraceptive failure with less than excellent compliance. There may be risks to contraception, but against this must be weighed the risks of unintended pregnancy. Sexually active women should have routine pelvic examinations and birth control instructions.

Renal Complications

Hypertension, proteinuria, hematuria, increasing anemia, and nephrotic syndrome reliably predict progression to renal failure, which are clinical indices to pay attention to because the serum creatinine may be misleading. Patients with sickle cell anemia exhibit an increased proximal tubular secretion of creatinine. Thus patients may have a significant decline in renal function before it is detectable by measuring creatinine clearance.²⁰⁶ The mean age at presentation with end-stage renal disease is 41 years.²⁰⁷ Serum creatinine levels are low in all genotypes until age 18 years, when young men experience a rise, apparently related to increasing muscle mass. Creatinine levels increase with age in all genotypes, presumably because of declining

renal function (see also organ-specific complications, kidney in *Clinical Presentation and Management*, later).

Other risk factors for the development of chronic renal failure include use of NSAIDs²⁰⁸ and a genetic predisposition associated with the CAR β -globin haplotype; the latter has been suggested as an indication for BMT to prevent this outcome.²⁰⁹ Acute renal failure from infarction may result from hypovolemia, sepsis, hepatorenal syndrome, cardiac failure, renal vein thrombosis, and rhabdomyolysis. These patients typically survive and recover their renal function with no increased risk of developing chronic renal failure.

There are seven well-described nephropathies that affect patients with either sickle cell trait or disease. These are gross hematuria, papillary necrosis, nephrotic syndrome, renal infarction, inability to concentrate urine, pyelonephritis, and renal medullary carcinoma.²⁰⁶

Renal transplantation is recommended for patients with sickle cell and end-stage renal diseases.

Renal Endocrine (Erythropoietin) Deficiency

This is discussed under Basic Management and Disease Modification.

Gross Hematuria

Hematuria may result from microthrombi formation in the peritubular capillaries of the renal medulla or from frank papillary necrosis. Significant hematuria may resolve with high urinary flow through oral hydration and bed rest. Hematuria that lasts longer than 1–2 weeks or the need for transfusion may require maintenance of a high urinary flow using a combination of hypotonic fluids and loop diuretics and urinary alkalization using sodium bicarbonate and acetazolamide. These therapies are aimed at changing the acidic, hypertonic environment of the renal medulla that favors erythrocyte dehydration, increased Hb S concentrations, and Hb S polymerization. If bleeding persists for 72 hours despite these measures, then alternative treatment should be considered. These may include oral urea,²¹⁰ ϵ -aminocaproic acid, and vasopressin. Embolization or nephrectomy should be reserved for prolonged, life-threatening cases of hematuria that require multiple transfusions.

Increased hematuria can also be seen as a consequence of delayed hemolytic transfusion reactions (discussed in Exacerbations of Anemia).

Papillary Necrosis

Papillary necrosis is most often detected incidentally by imaging or microscopic examination of urine in asymptomatic patients. Sloughed papilla may cause ureteral obstruction and urinary tract infection. In addition to broad-spectrum antibiotics, this occurrence requires emergent relief of the obstruction with a retrograde ureteral stent or placement of a percutaneous nephrostomy tube. NSAIDs should be avoided in patients with papillary necrosis. Otherwise treatment is as for hematuria.

Proteinuria

Proteinuria has been found in 20% to 30% of patients with SCD. Increasing age and low Hb levels correlate with proteinuria. Proteinuria can progress to nephrotic syndrome characterized by proteinuria, hypoalbuminemia, edema, and hyperlipidemia. Angiotensin-converting enzyme (ACE) inhibitors produce a significant reduction in sickle proteinuria, although it is unclear if ACE inhibitors might slow or halt the progression of proteinuria to nephrotic syndrome and renal failure.^{211,212} Angiotensin II inhibitors are being studied for a potential role in decreasing sickle cell–related proteinuria and renal function deterioration.

Hyposthenuria and Other Abnormalities of Tubular Function

The inability to maximally concentrate urine (hyposthenuria) in response to water deprivation is an early finding of sickle cell nephropathy. Both sickle cell trait and SCD patients may be affected. Hyposthenuria is the cumulative result of recurrent microinfarcts in

the vasa recta caused by sickling (Fig. 42.13). When water deprived, these patients cannot maximally concentrate their urine and develop hypovolemia and dehydration.

Other abnormalities of renal tubular dysfunction found in sickle cell anemia include an incomplete form of distal renal tubular acidosis with hyperchloremic metabolic acidosis and hyperkalemia.²¹³ The hyperkalemia may respond to oral sodium bicarbonate.

Urinary Tract Infections

Urinary tract infections and pyelonephritis are discussed under infectious complications.

Renal Medullary Carcinoma

Sickle cell trait has been reported to be associated with renal medullary carcinoma.²¹⁴ Presentation is with gross hematuria, abdominal or flank pain, or significant weight loss. The disease may be metastatic at diagnosis, and the prognosis is poor. There is a weak association of renal medullary carcinoma with Hb SC disease but no identified association with sickle cell anemia. The reason for these patterns of disease is unknown.

Priapism

Priapism is a condition that is characterized by a sustained erection that does not result from sexual desire and is not relieved by sexual activity. Stuttering priapism is a separate entity that is characterized by multiple, brief episodes of sustained unwanted erection. It has been reported to affect 6.4% to 42% of boys and men with SCD²¹⁵ and can also occur in sickle cell trait. Its peak frequencies are between ages 5 and 13 years and 21 and 29 years. Priapism is most likely to develop in patients with lower Hb F levels and reticulocyte counts, increased platelet counts, and the Hb SS genotype. Priapism caused by SCD is usually ischemic, or low-flow, priapism. (High-flow priapism is caused by unregulated arterial flow and can be distinguished from low-flow priapism by a blood gas obtained from the corpora.) Most likely, priapism begins with a physiologic erection. The relative stasis of blood within the corpora leads to a decrease in oxygen tension and development of acidosis, predisposing to Hb S polymerization in the corporal sinusoids, venous occlusion, and low-flow priapism. Pain develops as the corpora become increasingly ischemic after approximately 4 hours of erection. In a minority of patients, usually postpubertal, the engorgement also affects the corpus spongiosum and glans. The mild acidosis that accompanies hypoventilation during sleep may also contribute to the pathophysiology. Impotence is the primary complication of priapism, although some patients with a history of multiple episodes of priapism and significant corporeal fibrosis may report adequate erections and maintain active sex lives. Corporeal ischemia during priapism may induce local inflammation, causing the fibrosis responsible for impotence.

The goal of treatment is to relieve priapism and maintain potency. Patients should be educated to seek medical attention for unrelenting erection of more than 2 hours' duration. Detumescence within 12 hours is optimal to retain potency. After 72 hours, impotence is more likely. The strategy is prompt initiation of supportive medical therapy with intravenous hydration and analgesia and involvement by a urology consultant if the priapism persists for more than 4 hours; aspiration of blood from the corpora with or without irrigation, and injection of an α -adrenergic agonist should be considered (Guidelines of the American Urological Association, <https://www.auanet.org/education/guidelines/priapism.cfm>). If priapism persists 12 hours, options include partial-exchange transfusion to reduce the Hb S level to less than 30% with a total Hb of less than 10 g/dL or irrigation as outlined earlier. The latter procedure is less effective after 36 hours of priapism. Irrigation should be performed using penile anesthesia (dorsal nerve block; circumferential penile block; or subcutaneous, local, penile shaft block). All irrigation in boys should be performed under conscious sedation. There is anecdotal evidence for the use of hydralazine to treat acute priapism.²¹⁶

Fig. 42.13 Postmortem microangiographic studies of the vasa recta in a normal individual (A) and a patient with sickle cell anemia (B). (Reproduced with permission from Elsevier. From LW Statius van Eps et al., *Nature of concentrating defect in sickle-cell nephropathy. Microradioangiographic studies*, The Lancet, 1970, 295, 450-452.)

Preventing recurrent priapism is an important component of management. Strategies include HU administration; chronic transfusion; the antiandrogen bicalutamide;²¹⁷ self-administration of the α -adrenergic agent etilefrine orally and for episodes lasting over 1 hour, by intracavernous injection; and monthly administration of intramuscular gonadotropin-releasing hormone analogue.^{218,219} Prophylactic pseudoephedrine (Sudafed) appears beneficial in preventing recurrent mild episodes.

Surgical creation of shunts is reserved for severe cases resistant to the above interventions. As many as 45% of patients who have priapism develop some degree of impotence.²²⁰ When impotence persists for 12 months, a semirigid penile prosthesis may be implanted.

Ocular Complications²²¹

The retina is particularly vulnerable to vasoocclusion, and annual retinal examination is part of routine health care maintenance for patients with SCD. Superficial retinal hemorrhages have a pink “salmon patch” appearance. Deeper retinal hemorrhages have a “black sunburst” appearance. Other manifestations of sickle cell retinopathy include iridescent spots, retinal neovascularization, and retinal detachment. More subtle signs of sickle cell retinopathy are optic nerve head vascular changes, vascular tortuosity, macular changes (e.g., microaneurysms and vascular loops), and peripheral arteriovenous anastomoses. Other ophthalmologic complications are anterior chamber ischemia, tortuosity of conjunctival vessels, retinal artery occlusion, and angioid streaks. Sickle cell retinopathy is best seen by fluorescein angiography (Fig. 42.14). The earlier onset and greater frequency of proliferative retinopathy in Hb SC disease and sickle cell- β^0 -thalassemia compared with sickle cell anemia and sickle cell- β^+ -thalassemia suggest that retinal vessels are more susceptible to occlusion by more viscous blood than by more rigid individual cells. Peripheral sickle retinopathy may require vision-saving therapy with laser photocoagulation. Orbital compression syndrome caused by vasoocclusion of the periorbital marrow

space and subperiosteal hemorrhage has been observed to result in headache, fever, and palpebral edema. In this situation, culture, CT scan, and MRI should be used to rule out infectious, neoplastic, and other hemorrhagic etiologies. Conservative therapy, including local measures, analgesia, fluids, transfusion, and careful ophthalmologic surveillance, is recommended unless compression of the optic nerve ensues, in which case surgical decompression should be considered.

Bone Complications

Chronic tower skull, bossing of the forehead, and fish-mouth deformity of the vertebrae are the result of extended hematopoietic bone marrow, causing widening of the medullary space, thinning of the trabeculae and cortices, and osteoporosis. Osteonecrosis may cause a steplike depression of the vertebrae, selected shortening of the cuboidal bones of the hands and feet, and acute aseptic or avascular necrosis. The excruciating pain of bone infarction in the “hand-foot syndrome” that occurs around 2 years of age is often the first symptom of SCD (Fig. 42.15).²²² This dactylitis resolves spontaneously and is treated with hydration and analgesia. Bone infarcts are demonstrable using nuclear medicine scintigraphy or MRI. Serial scans specific for bone osteoclasts, bone marrow macrophages, and inflammatory cells may be useful adjuncts for distinguishing bone marrow infarction from osteomyelitis, but it is essential to obtain cultures directly from the affected tissue before starting antibiotics. Treatment of osteomyelitis is addressed in the Infection sections.

Bone necrosis occurs with equal frequency in the femoral and humeral heads, but the femoral heads more commonly undergo progressive joint destruction as a result of chronic weight bearing. The process is associated with increased intraosseous pressure and is most sensitively detected by MRI. Aggressive physical therapy appears to prevent progression in mild cases and should be considered in the therapy of avascular necrosis. Core decompression surgery to relieve increased intraosseous pressure can be used in early-stage

Fig. 42.14 FLUORESCIN ANGIOGRAPHY DEMONSTRATING A “SEA FAN” APPEARANCE OF SICKLE PROLIFERATIVE RETINOPATHY. (Courtesy W.C. Mentzer.)

Fig. 42.15 RADIOGRAM SHOWING THE BONE INFARCTIONS IN THE HANDS OF A CHILD WITH THE “HAND-FOOT SYNDROME” DACTYLITIS. (Courtesy W.C. Mentzer.)

osteonecrosis (i.e., no radiographic evidence of bone collapse) to prevent disease progression. In more advanced disease, joint replacement can be considered. There is a 30% likelihood that a second hip revision will be required within 4–5 years of prosthetic hip placement in patients with SCD.²²³

Arthritic pain, swelling, and effusion may be related to periarticular infarction or gouty arthritis.

Bone marrow infarction causes reticulocytopenia, exacerbation of anemia, a leukoerythroblastic picture, and sometimes pancytopenia.^{137,138} Pulmonary fat embolism is a rare complication of bone marrow infarction.²²⁴ It is associated with fat globules in the sputum and refractile bodies visible in the optic fundi. It is a life-threatening event that may require prompt exchange transfusion and perhaps the use of heparin and corticosteroids.²²⁴

Fig. 42.16 CHRONIC LEG ULCER NEAR THE MEDIAL MALLEOLUS. (Courtesy W.C. Mentzer.)

Dermatologic Complications

Leg ulcers are major causes of morbidity in SCD as a result of their frequency, chronicity, and resistance to therapy. Most occur near the medial or lateral malleolus (Fig. 42.16), may be associated with venous hypertension²²⁵ and hemolytic rate,²²⁶ and are frequently bilateral.²²⁷ They may begin spontaneously or as a result of trauma and may become infected, most commonly by *S. aureus*, *Pseudomonas* spp., streptococci, or *Bacteroides* spp. Systemic infection, osteomyelitis, and tetanus are rare complications. Ulcers are resistant to healing and tend to be recurrent in well over half of cases. Their incidence has been reported to vary from 25% to 75%.²²⁸ Ulcers rarely occur in patients younger than age 10 years and are most common in sickle cell anemia, less common in sickle cell- β^0 -thalassemia, and nonexistent in Hb SC disease and sickle cell- β^+ -thalassemia.²²⁷ The incidence in sickle cell anemia patients declines substantially in those who have coexistent α -thalassemia.²²⁷ Low steady-state Hb levels and low Hb F levels are associated with an increased risk of leg ulceration.²²⁹ Males have a threefold greater risk for developing leg ulcers than females. Treatment of leg ulcers requires persistence and patience; healing

usually takes weeks. Therapy²³⁰ begins with gentle debridement to remove nonviable, superficial tissue from more vital areas. Wet-to-dry dressings and DuoDerm hydrocolloid dressings facilitate devitalization. When debridement is complete, zinc oxide-impregnated Unna boots are used to promote healing. Bed rest speeds healing,²³¹ and topical antibiotics may be required. It may be necessary to use elastic wraps or leg elevation to control edema. Rapid healing of leg ulcers has been reported in patients treated with intravenous arginine butyrate.²³² Oral zinc, local hyperbaric oxygen, chronic transfusion, recombinant EPO, propionyl-L-carnitine, skin grafts, pentoxifylline, and bescaplermin (platelet-derived growth factor) may have therapeutic roles and should be considered in individual cases but have not been formally tested for their effectiveness in accelerating resolution of sickle cell–associated leg ulcers.

Myofascial syndromes consist of soft tissue swelling in subcutaneous edema that may have a *peau d'orange* appearance. These may be large or discrete lesions a few centimeters in diameter. These lesions are probably the result of dermal or subdermal vasoocclusion. Treatment is symptomatic.

Cardiac Complications

The chronic anemia of SCD is compensated by high cardiac output, which results in chronic chamber enlargement and cardiomegaly, and mild to moderate mitral and tricuspid regurgitation even in young children. The electrocardiogram shows evidence of left ventricular hypertrophy and less often first-degree block and nonspecific ST-T wave changes. Left ventricular dilation correlates with age and inversely correlates with total Hb.²³³ An age-dependent loss of cardiac reserve may predispose to heart failure in adult patients stressed by fluid overload, transfusion, exacerbation of anemia, hypoxia, or hypertension. Cardiac function can be improved by transfusion.²³⁴ Acute myocardial infarction in the absence of coronary disease has been reported, and in one autopsy series, 9.7% of 72 consecutive patients with SCD had myocardial infarction.²³⁵ It appears that myocardial infarction may occur with normal coronary arteries as a result of increased oxygen demand exceeding limited oxygen-carrying capacity or as a result of microcirculatory impairment. As mentioned earlier, pulmonary hypertension (>30 mm Hg) is a relatively common finding in patients with SCD and can be associated with right ventricular hypertrophy. It has been suggested that the increased rate of sudden death observed in SCD may be related to cardiac autonomic dysfunction, as detected by abnormal heart rate variability in response to selected postural maneuvers.²³⁶

Multiorgan Failure

This disastrous acute event involves multiple organ systems, including the lungs, brain, kidneys, liver, hematologic system, and heart, and usually leads to death.²³⁷ It may be precipitated by infection, vasoocclusion, or fat embolus and consists of a constellation of life-threatening processes, including hypoxemia, acidosis, inflammation, vascular permeability, severe anemia, disseminated intravascular coagulation, renal failure, and hepatic failure. In addition to therapy specific for these processes, exchange transfusion, plasma infusion or exchange, and corticosteroids should be considered.

Psychosocial Issues

Modern insights into the psychosocial adjustment of patients with SCD have provided a level of understanding that allows interventional therapy. Although most patients with SCD are generally well adjusted,²³⁸ there are risks of depression, low self-esteem, social isolation, poor family relationships, and withdrawal from normal daily living.²³⁸ Particular stressors are recurrent and unpredictable pain and the response to it, curtailed activity because of pain, misinterpretation of the meaning of pain, and depression leading to learned

helplessness. Although some patients with SCD become addicted to narcotics, this is uncommon and usually is the result of social influences rather than pain therapy. Well-adjusted patients have active coping strategies, family support, and support from the extended family unit common in African American society. Interventional approaches should emphasize recognizing and reinforcing individual strengths; confronting pathologic behavior; and establishing coping skills through reinterpreting pain, diverting attention from pain, and using support systems.²³⁹ Attention to psychosocial concerns is vital to the psychosocial well-being and integration into society of patients with SCD (see Chapter 90).

Growth and Development

By age 2 years, children with SCD have detectable growth retardation that affects weight more than height and has no clear gender difference.²⁴⁰ By adulthood, normal height is achieved, but weight remains lower than that of control participants. More severe growth delay is noted in children with sickle cell anemia and sickle cell- β^0 -thalassemia; Hb SC disease is associated with a less severe growth delay. Girls with SCD have retarded sexual maturation that is greater in those with sickle cell anemia and sickle cell- β^0 -thalassemia than those with Hb SC disease and sickle cell- β^+ -thalassemia²⁴⁰; it is associated with elevated gonadotropin levels for the stage of sexual development and delayed menarche. Boys also have delayed sexual maturation, which is more severe in those with sickle cell anemia than those with Hb SC disease.²⁴⁰ Retarded sexual maturation in boys can be attributable to primary hypogonadism, hypopituitarism, or hypothalamic insufficiency. The etiology of these multiple endocrine deficiencies may relate to underlying sickle cell pathophysiology or iron overload and emphasizes the importance of a comprehensive basic management and disease modification approach as outlined earlier in this chapter. Improved growth has been reported with HU,²⁴¹ transfusion,²⁴¹ folic acid supplementation, zinc supplementation,²⁴² and nutritional supplementation.²⁴³ When children have both SCD and hypersplenism, splenectomy may result in improved protein turnover, metabolic rate, and growth parameters.²⁴⁴

VARIANT SICKLE CELL SYNDROMES

The sickle cell syndromes that result from inheritance of the sickle cell gene in simple heterozygosity or in compound heterozygosity with other mutant β -globin genes are sickle cell trait, Hb SC disease, and sickle cell- β -thalassemia. These and other less common compound heterozygosity syndromes are reviewed.

Sickle Cell Trait

The prevalence of sickle cell trait is approximately 8% to 10% in African Americans and as high as 25% to 30% in certain areas of western Africa.⁴ Approximately 2.5 million people in the United States and 30 million in the world are heterozygous for the sickle cell gene. Sickle cell trait is largely a benign carrier condition with no obvious laboratory hematologic manifestations under basal conditions: RBC morphology, RBC indices, and the reticulocyte count are normal, and ISCs are not seen on the peripheral blood smear. The usual partition of Hb A and Hb S in sickle cell trait is 60:40 owing to a greater posttranslational affinity of α chains for β^A than for β^S chains.⁶ When α -thalassemia is coinherited with sickle cell trait, the preferential affinity results in a decreased percentage of Hb S relative to the number of α -globin genes deleted (i.e., $\alpha\alpha/\alpha\alpha$ 40% Hb S; $-\alpha/\alpha\alpha$ 35% Hb S; $-\alpha/-\alpha$ 29% Hb S; $---/-\alpha$ 21% Hb S).¹³³

There are a few clinical complications of sickle cell trait; splenic infarction occurs at high altitude.²⁴⁵ It is a cause of hematuria and hyposthenuria.²⁴⁶ The frequency of urinary tract infection may be increased. There is an association with renal medullary carcinoma.²¹⁴

There is an increased risk for venous thrombosis with an approximately twofold increase in risk and sickle trait explaining 7% of thrombotic episodes in African Americans.²⁹ Armed forces recruits in basic training with the sickle cell trait have a substantially increased, age-dependent risk of exercise-related sudden death.³⁰

Despite the known complications, past experiences with discrimination in the employment market and health insurance industry provide reminders that the rare clinical events in sickle cell trait provide no real justification for regarding it as anything but a benign carrier condition.³¹ Newborn screening programs detect a large number of infants with sickle cell trait; for these parents, genetic counseling is essential. Parents should understand that their child has a benign hereditary condition with some risks as above but that there is a risk for a subsequent child to be born with SCD.

In individuals who appear to have sickle cell trait but are symptomatic, the laboratory diagnosis must be verified. Hemoglobins other than S that polymerize may account for reports of “sickle cell trait” associated with clinical problems. Examples are heterozygous Hb S Antilles and Hb Quebec-CHORI. In the latter case, the Hb variant was distinguished from Hb A using mass spectroscopy.

Hb SC Disease

The gene for Hb C ($\alpha_2\beta_2$ Glu→Lys) is approximately one-fourth as frequent among African Americans as the sickle cell gene.⁸ Although oxygenated Hb C forms crystals, Hb C does not participate in polymerization with deoxy-Hb S. However, Hb C sustains potassium chloride cotransport and RBC dehydration, raising the intracellular concentration of Hb S to levels that support polymerization, sickling, and clinical symptoms. As a result of a longer circulatory survival of Hb SC RBCs compared with Hb SS cells (i.e., 27 versus 17 days),¹³⁰ the degree of anemia and reticulocytosis is frequently mild: 75% of the patients have a milder level of anemia (hematocrit level >28%) than is usually seen in sickle cell anemia. The predominant RBC abnormality on the peripheral smear is an abundance of target cells; folded (“pita bread”) cells, ISCs, “billiard ball” cells, and crystal-containing cells may also be seen.

Splenomegaly may be the only physical finding, and the frequency of acute painful episodes is approximately half that in Hb SS disease, with a life expectancy two decades longer.¹⁶ Nonetheless, significant morbidity can occur. The incidence of fatal bacterial infection is less than in sickle cell anemia, but there is still an increased risk of *S. pneumoniae* and *H. influenzae* infection. Osteonecrosis occurs in approximately 15% of patients.³² There is a higher incidence of peripheral retinopathy in Hb SC disease than in sickle cell anemia. Coexistent α -thalassemia reduces risk of chronic organ complications.³² There is an association between renal medullary carcinoma and Hb SC disease.

Sickle Cell- β -Thalassemia

The gene frequency of β -thalassemia among African Americans is 0.004, one-tenth that of the sickle cell gene,⁸ and hence there is one-tenth the prevalence of compound heterozygous sickle cell- β -thalassemia in this population. Sickle cell- β -thalassemia is divided into sickle cell- β^+ -thalassemia and sickle cell- β^0 -thalassemia, which have, respectively, reduced or no amounts of Hb A present. Most β -thalassemia mutations among African Americans result in β^+ -thalassemia. Sickle cell- β^+ -thalassemia is subclassified according to the percentage of Hb A present: type I has 3% to 5%, type II has 8% to 14%, and type III has 18% to 25%. Eighty percent of African American α -thalassemia mutations are attributable to the promoter region mutations (−88 [C to T] and −29[A to G]) that result in a type III phenotype. Compound heterozygous sickle cell- β^0 -thalassemia occurs infrequently.

In sickle cell- β -thalassemia, the RBCs are hypochromic and microcytic. The ISCs present on the peripheral blood smear are more numerous in sickle cell- β^0 -thalassemia than in sickle cell- β^+ -thalassemia. The hematologic and clinical severity is a function of the amount of Hb A inherited (Table 42.10).

Additional mitigating influences in sickle cell- β -thalassemia are elevated levels of Hb A₂ and, in sickle cell- β^+ -thalassemia, levels of Hb A up to 30%. These affect both the solubility and polymerization of Hb S. Hb F is a more active inhibitor of polymerization than Hb A, as shown by Hb S solutions with 15% to 30% Hb A (resembling sickle cell- β^+ -thalassemia) having delay times 10–100 times longer than pure Hb S solutions, and Hb S solutions with 20% to 30% Hb F (resembling Hb S-HPFH) having delay times 1000–1,000,000 times longer. A further influence mitigating the polymerization, sickling, and clinical aspects of sickle cell- β -thalassemia is the reduced MCHC, which retards Hb S polymerization. Hematologic values for sickle cell anemia, the sickle cell- β -thalassemias, and Hb S-HPFH are found in Table 42.10.

Sickle Cell-Hb Lepore Disease^β

The Hb Lepore gene is a crossover fusion product of the δ - and β -globin genes, the product of which, in the case of Hb Lepore Boston, has the same alkaline electrophoretic mobility as Hb S. Therefore patients with the Hb Lepore trait can appear to have sickle cell trait but with only 12% Hb S from thalassemic expression of the abnormal fusion gene. Again, because of the electrophoretic similarity with Hb S, compound heterozygous Hb S-Hb Lepore Boston resembles sickle cell anemia or sickle cell- β^0 -thalassemia electrophoretically but clinically have less severe anemia, resembling that of sickle cell- β^+ -thalassemia. The diagnosis is also suggested by the low to low-normal Hb A₂ levels that result from the incapacitation of one

TABLE
42.10

Hematologic Variables Associated With Sickle Cell Anemia and the Different Sickle Cell- β -Thalassemia Syndromes

Genotype	Hb ^a	%Hb A ^b	%Hb F ^b	%Hb A ₂ ^a	MCV ^a	Reticulocytes ^a	n
Hb SS ^c	7.83	0	4.56	2.87	85.9	10.18	≈123
Hb S- β^0 -thalassemia ^c	8.85	0	5.86	5.02	69.3	7.2	≈41
Hb S- β^+ -thalassemia, type I ^d	8.37	3-5	6.8	4.90	63.7	9.7	3
Hb S- β^+ -thalassemia, type II ^d	10.28	8-14	5.2	4.68	70.0	6.6	14
Hb S- β^+ -thalassemia, type III ^e	11.55	18-25	5.1	4.66	73.3	1.27	76
Hb S-HPFH ^f	14.6	0	25.8	1.95	81.7	2.4	4

^aThe mean data for each variable are shown. Units of measure are grams per deciliter for Hb, percentage of total hemoglobin for Hb F and A₂, fl for MCV, and percentage of total red blood cells for reticulocytes.

^bPercentage Hb A that defines the Hb S- β^+ -thalassemia type.²⁴⁷

^cData from Serjeant et al.²⁴⁹

^dData from Christakis et al.²⁴⁸

^eData from Serjeant et al.²⁵⁰

^fData from Friedman et al.²⁵¹

Hb, Hemoglobin; HPFH, persistence of fetal hemoglobin; MCV, mean corpuscular volume.

δ -globin gene by the crossover. Hb F levels vary. The peripheral smear shows microcytosis, hypochromia, and ISCs. Vasoocclusive complications occur, and splenomegaly is common.

Sickle Cell–Hb D Disease²⁴⁷

Because Hb D Punjab or Hb D Los Angeles ($\alpha_2\beta_2^{127}\text{Glu}\rightarrow\text{Gln}$) has a similar electrophoretic mobility to Hb S under alkali conditions, Hb SD disease was first reported as an unusual case of sickle cell anemia. Hb D can be distinguished from Hb S by acid electrophoresis or isoelectric focusing. There is moderately severe hemolytic anemia, and the peripheral smear shows marked anisocytosis and poikilocytosis, target cells, and ISCs. The clinical manifestations of this syndrome are similar to those of sickle cell anemia.

Sickle Cell–Hb O Arab Disease²⁴⁸

Although Hb O Arab ($\alpha_2\beta_2^{127}\text{Glu}\rightarrow\text{Lys}$) was first described in an Israeli Arab family, its distribution is widespread. Sickle cell–O Arab disease resembles Hb SC disease on alkaline electrophoresis, but Hb O Arab can be distinguished from Hb C by acid electrophoresis or isoelectric focusing. This syndrome is associated with moderately severe hemolytic anemia, and the peripheral smear shows anisocytosis, poikilocytosis, and ISCs.

Sickle Cell–Hb E Disease²⁴⁹

Hb E ($\alpha_2\beta_2^{26}\text{Glu}\rightarrow\text{Lys}$) is a β -thalassemic hemoglobinopathy found predominantly in southeast Asia (see Chapter 40). The structural mutant has an electrophoretic mobility similar to Hb C under alkaline conditions but can be resolved by acid electrophoresis or isoelectric focusing. The GAG $\rightarrow$ AAG mutation in codon 26 activates a cryptic splice site within the first intron of the β^E gene, causing alternate splicing and decreased expression of the structural mutant. As a result, Hb E makes up only 30% of the total Hb in compound heterozygosity for the sickle cell and Hb E genes. Hb SE disease is essentially benign in at least 50% and possibly most patients, with only mild hemolysis, no vasoocclusive complications, and no remarkable abnormality of RBC morphology. However, vasoocclusive complications and manifestations of chronic hemolytic anemia such as pain crisis, splenic infarction, recurrent pneumonia, and frontal bossing have been reported.

Coinherited Hemoglobin Abnormalities That Interact With Sickle Cell Disease: Hereditary Persistence of Fetal Hemoglobin and α -Thalassemia Trait

Sickle Cell–Hereditary Persistence of Fetal Hemoglobin

Adult Hb (or in the case of sickle cell anemia Hb S) replaces Hb F as a result of the switch from γ - to β -globin synthesis that occurs in fetuses. Because of the inhibitory effect of Hb F on Hb S polymerization and cellular sickling (see Chapter 41), the high fraction of Hb F at birth masks the expression of SCD until Hb S levels increase to 75% at approximately 6 months of age (see Fig. 42.3). Conditions that preserve elevated levels of Hb F into adulthood similarly modulate the course of SCD. The compound heterozygous conditions sickle–HPFH (Hb SS–HPFH) and sickle cell– β^0 -thalassemia–HPFH both have higher Hb F levels and milder clinical courses than are characteristic of sickle cell anemia.¹²³

Hereditary persistence of Hb F results from one of several large deletions of the δ - and β -globin genes that retard the switch from

the production of Hb F to adult Hb. A more recently discovered variety of HPFH is not caused by a deletion but by one of many point mutations that upregulate the expression of the γ -globin gene. The clinical expression of deletional and nondeletional HPFH differs in that the 15% to 35% Hb F in the former is distributed in a pancellular fashion, the 1% to 5% Hb F in the latter is distributed in a heterocellular fashion, and certain mild types of nondeletional HPFH express high Hb F levels not in simple heterozygosity but only in conditions of erythropoietic stress, such as compound heterozygosity with the sickle cell gene. It is likely that many cases of apparent sickle cell anemia with unexplained elevations of Hb F are the result of a nondeletion HPFH mutation.

The gene frequency of the deletional HPFH locus is 0.0005 among African Americans, resulting in a calculated incidence for compound heterozygous sickle cell–deletional HPFH of 1/100 that of sickle cell anemia. Sickle cell–deletional HPFH provided the first evidence that Hb F was a potent inhibitor of Hb S polymerization: individuals with pancellular distribution of 25% Hb F were generally neither anemic nor affected with vasoocclusive manifestations (see Table 42.10).²⁵⁰ Hb electrophoresis revealed only Hb S, F, and A₂, which resembles sickle cell anemia, sickle cell– β^0 -thalassemia, and sickle cell– $\delta\beta^0$ -thalassemia. Notable differences, however, are the pancellular distribution of 15% to 35% Hb F, Hb A₂ levels less than 2.5%, and the absence of anemia.²⁵¹ The generally benign course of sickle cell–deletional HPFH is uncommonly associated with vasoocclusive complication.

Sickle Cell Anemia With Coexistent α -Thalassemia

Prevalences of the silent carrier of α -thalassemia syndrome (genotype $-\alpha/\alpha\alpha$) and α -thalassemia trait (genotype $-\alpha/-\alpha$) among African Americans are approximately 30% and 2%, respectively.²⁵² The peripheral blood smear contains less polychromasia and fewer sickle forms and more hypochromia and microcytosis, commensurate with the numbers of α -globin genes deleted. Increased Hb A₂ levels are associated with increasing α -globin gene deletions; the Hb F levels are not consistently affected.

Clinically, the impact of α -globin gene deletions on sickle cell is not as consistent as that of high Hb F.²¹ Because of the powerful effect of Hb S concentration on the kinetics and extent of Hb S polymerization (see Chapter 41), the lower MCHC from α -globin gene deletions decreases the hemolytic rate, and anemia is milder in subjects with both α -thalassemia syndrome (genotype $-\alpha/\alpha\alpha$) and trait (genotype $-\alpha/-\alpha$) (see Table 42.1). There is a decreased incidence of leg ulcers but an increased incidence of osteonecrosis. The frequency of retinal vessel closure is higher but not the incidence of retinopathy. Complications related to hemolysis (e.g., leg ulcers, chronic renal damage) may be decreased, but the heterogeneity of the patients in previous studies and mixed results make conclusions difficult. Similarly, the influence of α -gene deletions on survival in patients with SCD is not well understood.²¹

HEMOGLOBIN VARIANTS ASSOCIATED WITH HEMOLYTIC ANEMIA, ALTERED OXYGEN AFFINITY, AND METHEMOGLOBINEMIAS

Edward J. Benz, Jr. and Benjamin L. Ebert

Hemoglobinopathies are inherited diseases caused primarily by mutations affecting the globin genes. Nearly 1000 mutations are known to alter the structure, expression, or developmental regulation of individual globin genes and the hemoglobins that they encode. Of these, only a few produce clinical disease. Many are highly instructive for students, of gene structure, function, and regulation, but further consideration of most is not warranted in a clinically oriented textbook. The gene mutations that cause sickle cell anemia and the thalassemia syndromes are by far the most important mutations that cause clinical morbidity, in terms of both the complexity of the clinical syndromes they cause and the number of patients affected. These conditions are considered in detail in other chapters (see [Chapters 40, 41 and 42](#)). This chapter reviews other abnormalities of the hemoglobin molecule that produce clinical syndromes. Even though each variant is uncommon, these hemoglobinopathies represent, in the aggregate, important problems for hematologists, because they must be considered as possible causes for conditions about which hematologists are often consulted: hemolytic anemia, cyanosis, polycythemia, jaundice, rubor, splenomegaly, and reticulocytosis. In some patients, secondary hematologic complications such as hypercoagulable states are also encountered.

The major inherited hemoglobinopathies producing clinical symptoms (other than sickle cell anemia and thalassemias) can be classified as those hemoglobins exhibiting altered solubility (unstable hemoglobins), hemoglobins with increased oxygen affinity, hemoglobins with decreased oxygen affinity, and methemoglobins ([Table 43.1](#)). A few acquired conditions in which toxic modifications of the hemoglobin molecule are important (e.g., carbon monoxide poisoning) also merit consideration.

The sections that follow emphasize hemoglobinopathies that produce the most severe or dramatic alterations in clinical phenotype and those in which a single clinical abnormality (e.g., hemoglobin precipitation) predominates. It is important to emphasize at the outset, however, that although more than 100 mutations affect solubility or affinity, only a few are clinically important. The abnormal functional properties of most mutant hemoglobins can be readily detected in sophisticated research laboratories, but only a few mutant hemoglobins produce laboratory or clinical abnormalities relevant to clinical practice. Moreover, many mutations are pleiotropic, affecting several functional properties of the hemoglobin molecule. Thus a single mutation can increase oxygen affinity and reduce solubility, or produce methemoglobinemia and reduce solubility.

[Table 43.2](#) summarizes the major forms of structurally abnormal hemoglobin, with examples. This table serves as a point of reference for the remaining sections of the chapter.

UNSTABLE HEMOGLOBINS

Unstable hemoglobins are hemoglobins exhibiting reduced solubility or higher susceptibility to oxidation of amino acid residues within the individual globin chains. More than 100 unique unstable hemoglobin mutants have been documented. Most exhibit only mild instability in *in vitro* laboratory tests and are associated with minimal

clinical manifestations. Both α - and β -globin variants can cause this condition. Approximately 75% of the mutations described, however, are β -globin variants. This probably reflects the potential for α -globin variants to exert pathologic effects *in utero*. Clinical symptoms of unstable hemoglobins also depend, in part, on the quantitative proportion of the abnormal hemoglobin. Because the α -globin genes are duplicated, mutations in an individual locus generally produce only 25% to 35% abnormal globin. By contrast, a simple heterozygote at the single β -globin locus usually produces approximately 50% of the abnormal variant.

The mutations that impair hemoglobin solubility usually disrupt hydrogen bonding or the hydrophobic interactions that either retain the heme moiety within the heme-binding pockets or hold the tetramer together ([Fig. 43.1](#)). Some alter the helical segments (e.g., hemoglobin [Hb] Geneva [$\beta^{28\text{Leu}\rightarrow\text{Pro}}$]), others weaken contact points between the α and β subunits (e.g., Hb Philadelphia [$\beta^{35\text{Tyr}\rightarrow\text{Phe}}$]), and still others derange interactions of the hydrophobic pockets of the globin subunits with heme (e.g., Hb Köln [$\beta^{98\text{Val}\rightarrow\text{Met}}$]). The common pathway to reduced solubility invariably involves weakening of the binding of heme to globin. Actual loss of heme groups can occur, for example, in Hb Gun Hill, in which five amino acids, including the F8 histidine, are deleted. In other cases, mutations that introduce prolines into helical segments disrupt the helices and interfere with normal folding of the polypeptide around the heme group. Another feature of these mutations is disruption of the integrity of the tetrameric structure of globin chains. Only the intact hemoglobin tetramer can remain dissolved at the high concentrations that must be achieved within the circulating red blood cell (see [Chapters 30 and 40](#)).

Pathophysiology of Unstable Hemoglobin Disorders

The mechanisms by which unstable hemoglobin mutations produce hemoglobin precipitation remain incompletely understood; however, the major outlines of the process have been described ([Fig. 43.2](#)). The fundamental step in pathogenesis appears to be derangement of the normal linkages between heme and globin. Loss of appropriate globin chain folding and interaction may ultimately destabilize the hemoglobin linkage or lead to partial proteolysis of the chain, thereby releasing heme from that linkage. Once freed from its cleft, heme probably binds nonspecifically to other regions of the globin molecule, forming precipitated hemichromes, which leads to further denaturation and aggregation of the globin subunits. These form a precipitate containing α - and β -globin chains, globin fragments, and heme, called the *Heinz body*.

Heinz bodies interact with delicate red blood cell membrane components (see [Chapters 43 and 45](#)), thereby reducing red blood cell deformability. These rigid cells tend to be detained in the splenic microcirculation and “pitted,” reflecting attempts by the splenic macrophages to remove the Heinz bodies. Red blood cell damage can be aggravated by the release of free heme into the red blood cell. Several biochemical perturbations correlate with the presence of free heme, such as generation of reactive oxidants (i.e., hydrogen peroxide, superoxide, and hydroxyl radicals). The end result of this process is

TABLE 43.1 Classification of Hemoglobinopathies

Structural hemoglobinopathies: hemoglobins with altered amino acid sequences that result in deranged function or altered physical or chemical properties

Abnormal Hemoglobin Polymerization: HbS
Altered Oxygen Affinity

High affinity: polycythemia

Low affinity: cyanosis, pseudoanemia

Hemoglobins That Oxidize Readily

Unstable hemoglobins, hemolytic anemia, jaundice

M hemoglobins: methemoglobinemia, cyanosis

Thalassemias: Defective Production of Globin Chains

α -Thalassemias

β -Thalassemias

Hb, Hemoglobin.

premature destruction of the red blood cell, producing hemolytic anemia.

Individual unstable hemoglobins vary in their propensity to generate Heinz bodies and hemolysis. For example, Hb Zurich exhibits relatively mild insolubility. Hemolysis is minimal in nonstressed patients with this variant and becomes clinically apparent only in the presence of additional oxidant stresses, such as infection, fever, or the ingestion of oxidant agents. Because of the propensity of unstable hemoglobins to be hypersensitive to oxidation, some patients with unstable hemoglobins can exhibit episodic hemolysis in response to many of the same oxidative stressors as those exacerbating the clinical phenotype of glucose-6-phosphate dehydrogenase (G6PD)-deficient patients (see [Chapters 44](#) and [47](#)).

Patterns of Inheritance and Clinical Manifestations

Unstable hemoglobins are usually inherited as autosomal dominant disorders. However, the rate of spontaneous mutation appears to be high, so the absence of affected parents or siblings does not rule out the presence of an unstable hemoglobin in an individual family. Nonetheless, the presence of a positive family history can be a useful adjunct to diagnosis and should provoke consideration of an unstable hemoglobin as the cause of the familial hemolytic diathesis.

The clinical syndrome associated with unstable hemoglobin disorders is often called *congenital Heinz body hemolytic anemia*. This term derives from the fact that only the most severe cases were detected before the widespread availability of sophisticated methods

TABLE 43.2 Mutations Producing Abnormal Hemoglobin Molecules^a

Residue	Mutation	Common Name(s)	Molecular Pathology
Abnormal Solubility			
$\beta 6$	Glu→Val	S	Polymerization
$\beta 6$	Glu→Lys	C	Crystallization
$\beta 121$	Glu→Gln	D-Los Angeles, D-Punjab	Increases polymer in S/D heterozygote
$\beta 121$	Glu→Lys	O-Arab	Increases polymer in S/O heterozygote
Increased Oxygen Affinity			
$\alpha 92$	Arg→Gln	J-Capetown	Stabilizes R state
$\alpha 141$	Arg→His	Suresnes	Eliminates bond to Asn 126 in T state
$\beta 89$	Ser→Asn	Creteil	Weakens bonds in T state
$\beta 99$	Asp→Asn	Kempsey	Breaks T state intersubunit bonds
Decreased Oxygen Affinity			
$\alpha 94$	Asp→Asn	Titusville	Alters R state intersubunit bonds
$\beta 102$	Asn→Thr	Kansas	Breaks R state intersubunit bonds
$\beta 102$	Asn→Ser	Beth Israel	Breaks R state intersubunit bonds
Methemoglobin			
$\alpha 58$	His→Tyr	M-Boston, M-Osaka	Heme liganded to Tyr not His
$\alpha 87$	His→Tyr	M-Iwate	Heme liganded to both His and Tyr
$\beta 28$	Leu→Gln	St Louis	Opens heme pocket
$\beta 63$	His→Tyr	M-Saskatoon	Tyr ligand stabilizes ferriheme
$\beta 67$	Val→Glu	M-Milwaukee-I	Negative charge stabilizes ferriheme
$\beta 92$	His→Tyr	M-Hyde Park	Bond of His to heme disrupted
Unstable			
$\alpha 43$	Phe→Val	Torino	Loss of heme contact
$\nu 94$	Asp→Tyr	Setif	Alters subunit contacts
$\beta 28$	Leu→Gln	St Louis	Polar group in heme pocket
$\beta 35$	Tyr→Phe	Philadelphia	Loss of dimer bond favors precipitation
$\beta 42$	Phe→Ser	Hammersmith	Loss of heme
$\beta 63$	His→Arg	Zurich	Opens heme pocket
$\beta 88$	Leu→Pro	Santa Ana	Disrupts helix
$\beta 91$	Leu→Pro	Sabine	Disrupts helix
$\beta 91-95$	Deletion	Gun Hill	Shortens F helix
$\beta 98$	Val→Met	Köln	Alters heme contact

^aPartial list includes some of the most widely studied hemoglobin structural mutations.

Modified from Dickerson RE, Geis I: *Hemoglobin: Structure, function, evolution, and pathology*. Menlo Park, CA, 1983, Benjamin-Cummings. Copyright Irving Geis.

for detecting and characterizing abnormal hemoglobins. Clinical manifestations are highly variable, ranging from a virtually asymptomatic state in the absence of environmental stressors, to severe hemolytic anemia manifesting at birth. Patients with chronic hemolysis present with variable degrees of typical symptoms, including

not particularly acute or brisk. Thus Heinz bodies may not be demonstrable at all times. Two provocative laboratory maneuvers are used to aid detection, both of which unmask the tendency of unstable hemoglobins to precipitate: the heat instability test (heating of a hemoglobin solution to 50°C) or the isopropanol instability test (insolubility in 17% isopropanol).

Hemoglobin electrophoresis should be performed but *should not be relied on as the major diagnostic criterion for ruling in or ruling out a hemoglobinopathy*. Many amino acid substitutions that have a profound effect on solubility do not change the overall charge on the hemoglobin molecule. For example, Hb Köln, the most common of the unstable hemoglobin mutations, arises from a mutation changing the valine at position 98 to a methionine. This mutation is electrically neutral; it does not alter electrophoretic mobility. Therefore these variants do not form an abnormal band on an electrophoresis gel. Demonstration of an abnormal band would clearly add

strong evidence in support of the diagnosis. A normal electrophoretogram, however, should never be regarded as strong evidence against the presence of a mutant hemoglobin, especially if the clinical picture or family history otherwise supports the diagnosis. Mass spectrometry analysis of hemoglobin and direct globin gene sequencing are supplanting electrophoresis as diagnostic strategies. They usually provide unambiguous identification of a sequence abnormality. However, electrophoresis is still in use in many clinical settings. Thus the aforementioned precautions in interpretation are still worth noting.

Additional sophisticated analyses of hemoglobin can be obtained from reference laboratories if detailed characterization seems warranted. For example, abnormal hemoglobin or globin bands migrating to novel positions on an isoelectric focusing gel can result from hemoglobin or globin moieties lacking heme in groups. When heme is added to the sample and the proteins are reanalyzed, these bands disappear. This behavior is nearly diagnostic of an unstable variant.

Detection of unstable hemoglobins is occasionally compromised by the selective precipitation of the unstable variant into Heinz bodies. Because most patients are heterozygotes, this phenomenon greatly reduces the apparent percentage of the variant in soluble form. Thus even a variant possessing altered electrophoretic mobility may be very difficult to detect. Indeed, some unstable hemoglobins, such as Hb Geneva or Hb Terre Haute, are so unstable that no mutant gene product can be detected in the steady state. These abnormal hemoglobins actually produce a thalassemic phenotype. They are detectable only by isotope labeling studies or direct analysis of the globin genes.

The amino acid sequence predicted from genetic sequencing may rarely be inaccurate because of posttranslational conversion into an unstable hemoglobin. For example, in the first reported case of congenital Heinz body hemolytic anemia due to Hb Bristol, the DNA sequence predicts a valine-to-methionine substitution at $\beta 67$. Through posttranslational modification, the methionine is altered to aspartate, a hydrophilic residue that disrupts the heme pocket.

The differential diagnosis of unstable hemoglobin variants is usually straightforward if this general category of hemolytic disorders is suspected. The most common form of G6PD deficiency can also manifest with bouts of intermittent or chronic hemolysis exacerbated by oxidant drugs or infection (see Chapter 44). This diagnosis should be considered, as should other causes of chronic or intermittent hemolytic anemia, including red blood cell membrane disorders (e.g., hereditary spherocytosis) or immune hemolytic anemias. Spherocytes are relatively rare in patients with unstable hemoglobin disorders; this is sometimes a useful discriminant.

Fig. 43.2 PRESUMED MECHANISMS BY WHICH DENATURATION OF HEMOGLOBIN LEADS TO ERYTHROCYTE DESTRUCTION. The rate of travel through the various pathways probably differs for the different hemoglobin variants and for a variety of stresses to which the protein is subjected. RBC, Red blood cell. (From Wynngaarden JB, Smith LH Jr, Bennett JC, editors: Cecil textbook of medicine, Philadelphia, 1992, WB Saunders.)

Management

The severity of the clinical complications of unstable hemoglobins varies enormously. Many patients can be managed adequately by observation and education to avoid agents that provoke hemolysis.

Fig. 43.3 UNSTABLE HEMOGLOBINS; PERIPHERAL BLOOD SMEAR AND HEINZ BODY PREPARATION. The peripheral smear (A) shows “bite” cells with pitted-out semicircular areas of the red blood cell membrane as a result of removal of Heinz bodies by macrophages in the spleen. The Heinz body preparation (B) shows increased Heinz bodies in the same specimen, when compared to a control (C).

Some patients require transfusions during bouts of severe acute hemolytic anemia. Patients who have significant morbidity because of chronic anemia or repeated episodes of severe hemolysis should be considered candidates for splenectomy, especially if hypersplenism has developed. Children with severe hemolysis may require transfusion support until they are old enough (at least 3 or 4 years of age) to undergo splenectomy without unacceptable immunologic compromise. Splenectomy is usually effective for abolition or reduction of anemia. However, splenectomy should be used only as a last resort because of the long-term risks of overwhelming sepsis and thrombosis. Infection often exacerbates hemolysis. Fever should therefore prompt close monitoring of patients for evidence of hemolysis or infection. Postsplenectomy patients with a hemolytic diathesis are also afflicted by a hypercoagulable state, probably due to the deranged membrane architecture resulting from oxidative damage. They thus require monitoring for thrombotic events and may need intermittent or long-term anticoagulant therapy.

HEMOGLOBINS WITH INCREASED OXYGEN AFFINITY

Efficient oxygen delivery by hemoglobin depends on the sigmoid shape of the hemoglobin-oxygen affinity curve. During the transition from the fully deoxygenated to the fully oxygenated state, the initial oxygenation steps occur with difficulty. In fact, the act of binding the first oxygen molecule increases the affinity of the molecule for subsequent oxygen-binding events, thus creating the sigmoid shape of the curve. The necessary intramolecular reorganization occurs only when the precise arrangement of hydrogen bonds, hydrophobic interactions, and salt bridges is broken and formed in the proper sequence.

Mutant hemoglobins exhibiting altered oxygen affinity arise from amino acid substitutions at the interface between α - and β -chains or in regions affecting the hydrogen bonds, hydrophobic interactions, or salt bridges that influence the interaction of heme with oxygen. A second major class of mutations alters binding to 2,3-diphosphoglycerate (2,3-DPG), which in turn alters oxygen affinity when bound to hemoglobin.

Pathogenesis and Pathophysiology

High-affinity hemoglobins exhibit higher avidity for oxygen, causing the oxygen dissociation curve to shift to the left; an example is Hb Kempsey ($\beta^{99\text{Asp} \rightarrow \text{Asn}}$) (Fig. 43.4). These hemoglobins bind oxygen more readily than normal and retain more oxygen at lower partial pressure of oxygen (PO_2) levels. They thus deliver less oxygen to tissues at normal capillary oxygen pressures. The PO_2 in the normal lung (90 to 100 mmHg) is well above that needed to saturate hemoglobin fully with oxygen (60 mmHg). These variant hemoglobins cannot acquire any additional oxygen in the lung despite their higher affinity. At capillary PO_2 (35–45 mmHg), however, high-affinity hemoglobins deliver *less* oxygen. At normal hematocrit levels, a mild tissue hypoxia results, triggering increased production of erythropoietin and red blood cells, thus resulting in polycythemia. In extreme cases, hematocrit levels of 60% to 65% can be encountered.

Many types of mutations can increase oxygen affinity. Some alter interactions within the heme pocket, others disrupt the Bohr effect or the salt-bond site, and still others impair the binding of HbA to 2,3-DPG. Loss of 2,3-DPG binding results in increases in oxygen affinity. These and numerous other examples that have been analyzed at the molecular level have greatly aided our understanding of the molecular basis for reversible oxygen binding.

Diagnosis

High-affinity hemoglobins are a cause of familial unexplained erythrocytosis (see Chapters 63 and 68). Functional testing of the hemoglobin is the key to diagnosis. Oxygen affinity is usually measured as P_{50} , the PO_2 at which hemoglobin is 50% saturated with oxygen (see

Fig. 43.4 HEMOGLOBIN-OXYGEN DISSOCIATION CURVES ARE ILLUSTRATED FOR NORMAL HEMOGLOBIN (HbA) AND FOR MODEL ABNORMAL HEMOGLOBINS WITH HIGH AND LOW OXYGEN AFFINITIES. On the abscissa, the partial pressure of oxygen (PO_2) is indicated in millimeters of mercury. On the left ordinate, the saturation of hemoglobin with oxygen is indicated as a percentage; on the right ordinate, the oxygen content of the hemoglobin is expressed as volume percent. The three inverted arrows show the PO_2 at which the hemoglobin is 50% saturated (P_{50}) for the three hemoglobins. This value is lowest for the high-affinity hemoglobin. As the PO_2 drops from 100 (arterial) to 40 (tissues) mmHg, hemoglobin desaturates, giving up a portion of its bound oxygen; the numbers on the brackets indicate the amount of oxygen unloaded by the three hemoglobin types expressed as volume percent. Note that the high-affinity hemoglobin delivers less than one-half the oxygen that HbA gives to the tissues, resulting in tissue anoxia, increased erythropoietin secretion, and erythrocytosis. Conversely, the low-affinity hemoglobin is even more efficient than HbA in supplying tissues with oxygen, resulting in diminished erythropoietin production and anemia. (From Wyngaarden JB, Smith LH Jr, Bennett JC, editors: Cecil textbook of medicine, Philadelphia, 1992, WB Saunders.)

Fig. 43.4). The hemoglobin preparation is exposed to increasing oxygen pressures, and the relative percentages of oxyhemoglobin and deoxyhemoglobin are determined. The values are plotted on a curve, and the 50% saturation point is determined. A shift to the left means that the hemoglobin reaches 50% saturation at a lower PO_2 . High-affinity variants are thus associated with a lower-than-normal P_{50} value. Hemoglobin electrophoresis can, but may not, reveal an abnormal band.

The most common cause of a low P_{50} value is carbon monoxide. Carbon monoxide stabilizes hemoglobin in the R “oxy” state without the need for oxygen binding. The oxygen affinity curve is therefore extremely left-shifted and is hyperbolic, rather than sigmoidal, in shape. The clinical consequences of mild chronic carbon monoxide poisoning are the same as those seen with high-affinity hemoglobin variants. The most common cause of carbon monoxide toxicity is cigarette smoking, although chronic carbon monoxide exposure can elevate the hematocrit level in people such as caisson workers or tunnel toll collectors. Severe acute carbon monoxide poisoning can cause rapid death as a result of tissue hypoxia.

Management

Most patients with high-affinity hemoglobins have mild erythrocytosis; they do not require intervention. Very rarely, the hematocrit

level is very high (>55% to 60%). The blood viscosity is then sufficiently elevated to require therapeutic phlebotomy. Carbon monoxide poisoning is treated with supplemental oxygen. When a patient breathes room air, the half-life of carboxyhemoglobin is 4 to 6 hours, but the half-life is 40 to 80 minutes with the use of normobaric oxygen and 15 to 30 minutes with the use of hyperbaric oxygen. Carbon monoxide detectors, designed to detect occult carbon monoxide poisoning, are now required in many municipalities and are predicted to prevent numerous fatalities from occult carbon monoxide poisoning.

HEMOGLOBINS WITH DECREASED OXYGEN AFFINITY

Pathogenesis

Low-affinity hemoglobin variants, such as Hb Kansas ($\beta^{102}\text{Asn}\rightarrow\text{Thr}$), arise from mutations that impair hemoglobin-oxygen binding or reduce cooperativity. In cases of Hb Kansas, the threonine position, β^{102} , cannot form a hydrogen bond with aspartic acid at position α^{94} . Because this aspartate residue stabilizes the R (oxy) state, Hb Kansas binds oxygen less well and exhibits a right-shifted P_{50} value (see Fig. 43.4).

Most low-affinity variants possess enough oxygen affinity to become fully saturated in the normal lung. At the low capillary PO_2 in other tissues, these hemoglobins deliver *higher* than normal amounts of oxygen. They become more desaturated than normal hemoglobins. Two abnormalities result from this high level of oxygen delivery. First, because tissue oxygen delivery is so “overly” efficient, normal oxygen requirements can be met by lower-than-normal hematocrit levels. This situation produces a state of “pseud anemia,” in which the low hematocrit level is deceiving because both oxygen delivery and the patients are completely normal. Second, the amount of desaturated hemoglobin circulating in capillaries and veins can be greater than 5 g/dL. Cyanosis may thus be associated with these variants. This usually ominous finding is entirely misleading in these individuals, because it reflects no morbidity.

Diagnosis

Patients with unexplained anemia or cyanosis who appear to be entirely well in all other respects should be evaluated, especially if there is a positive family history. Testing for the abnormal variant follows the same reasoning as that just described for high-affinity variants. The oxygen dissociation curve will be shifted to the right, and the numeric value of the P_{50} will be higher than normal.

Management

Patients with low-affinity hemoglobins are usually asymptomatic. No treatment is required. It is important to document that a low-affinity hemoglobin is the cause of an apparent anemia or cyanosis to preempt inappropriate workups and provide reassurance to the patient. Cyanosis in some patients can pose a cosmetic problem, but correction with transfusions is rarely justified.

Methemoglobinemias

Methemoglobin results from oxidation of the iron moieties in hemoglobin from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}) state. Normal oxygenation of hemoglobin causes a partial transfer of an electron from the iron to the bound oxygen. Iron in this state thus resembles ferric iron and the oxygen resembles superoxide (O_2^-). Deoxygenation returns the electron to the iron, with release of oxygen. Methemoglobin forms if the electron is not returned. Methemoglobin constitutes 3% or less of the total hemoglobin in normal humans. Under normal circumstances, these levels in humans are maintained at 1% or less

TABLE 43.3

by the methemoglobin reductase enzyme system (the reduced form of nicotinamide adenine dinucleotide [NADH]—dehydratase, [NADH]—diaphorase, erythrocyte cytochrome b_5).

Pathogenesis and Clinical Manifestations

Methemoglobinemias of clinical interest arise by one of three distinct mechanisms: (1) globin chain mutations that result in increased formation of methemoglobin, (2) deficiencies of methemoglobin reductase, and (3) “toxic” methemoglobinemia, in which normal red blood cells are exposed to substances that oxidize hemoglobin iron to such a degree that normal reducing mechanisms are subverted or overwhelmed (see Chapter 44; Table 43.3).

Abnormal hemoglobins producing methemoglobinemia (M hemoglobins) arise from mutations that stabilize the heme iron in the ferric state. Classically a histidine in the vicinity of the heme pocket is replaced by a tyrosine (e.g., Hb M-Iwate, $\beta 87$ (F8) His $\rightarrow$ Tyr); the hydroxyl group of the tyrosine forms a complex that stabilizes the iron in the ferric state (Fig. 43.5). The oxidized heme iron is relatively resistant to reduction by the methemoglobin reductase system.

Methemoglobin has a brownish to blue color that does not revert to red on exposure to oxygen. Patients with methemoglobinemia thus appear to be cyanotic. In contrast to truly cyanotic people, however, arterial partial pressure of oxygen (PaO_2) values are usually normal. Patients with these hemoglobins are otherwise asymptomatic because methemoglobin is usually less than 30% to 50%, the levels at which symptoms become apparent.

Hereditary methemoglobinemia resulting from methemoglobin reductase deficiency (cytochrome- b_5 reductase deficiency) is very rare. Mutations in the b_5 reductase gene cause two distinct phenotypes. In cases of type I methemoglobin reductase deficiency, patients suffer solely from cyanosis; in cases of type II disease, patients manifest both cyanosis and severe mental retardation. One isoform of the b_5 reductase gene is expressed in diverse tissues for participation in a variety of cellular processes. A second isoform, produced by alternative splicing, is expressed in erythrocytes, producing a soluble protein that reduces methemoglobin. Mutations causing type I methemoglobin reductase deficiency occur throughout the gene and result in an unstable protein. Such mutations are primarily significant in erythrocytes that, without nuclei, cannot replace the degraded protein. Mutations causing type II disease occur in the critical NADH or flavin adenine dinucleotide (FAD)—binding domains, causing inactivation of the protein in all tissues and the more severe clinical phenotype.

Like patients with M hemoglobins, patients with methemoglobin reductase deficiency exhibit slate-gray “pseudocyanosis.” Even homozygotes, however, rarely accumulate more than 25% methemoglobin, a level compatible with minimal symptoms. Heterozygotes can have normal methemoglobin levels but are especially sensitive to agents causing methemoglobinemia.

A third toxic form of methemoglobinemia is caused by exposure to certain chemical agents and drugs that accelerate the oxidation of

Fig. 43.5 MODIFICATIONS OF THE HEME AND ITS ENVIRONMENT THAT ACCOUNT FOR TWO COMMON M HEMOGLOBINS. (A) Hemoglobin A has a His residue at the α 58(E7) position. (B) In hemoglobin M-Boston, the histidine is replaced by a tyrosine, the phenolic side chain of which is capable of covalently binding to the heme iron, resulting in stabilization in the oxidized form. (C) HbA has a Val residue at position β 67(E11). (D) Hb M-Milwaukee has a glutamic acid substitution for the β 67 valine. The carboxylic side chain of the Glu forms a bond with iron, shifting the equilibrium toward the ferric state. (Modified from Dickerson RE, Geis I: Hemoglobin: Structure, function, evolution, and pathology, Menlo Park, CA, 1983, Benjamin-Cummings. Copyright Irving Geis.)

hemoglobin to methemoglobin (Table 43.4). Some compounds directly oxidize hemoglobin, whereas other compounds produce reactive oxygen intermediates that oxidize hemoglobin. Nitrite compounds are especially notorious and common. Some of these compounds also have a propensity to exacerbate G6PD deficiency and the precipitation of unstable hemoglobins.

Nitrates are a frequent environmental cause of toxic methemoglobinemia. Nitrates do not directly interact with either hemoglobin or the reductase pathway but are converted to nitrites in the gut. Well water is a frequently encountered source of excessive nitrates. In general, substantial intake of these agents is required before significant amounts of methemoglobin are generated. Very young infants have lower levels of methemoglobin reductase in erythrocytes and are therefore more susceptible to these agents than are adults. However, all age groups are at risk, given sufficient exposure. Systemic acidosis, particularly in young infants suffering from diarrhea and dehydration, can also cause clinically-significant methemoglobinemia.

Acquired methemoglobinemia is virtually the only situation in which life-threatening amounts of methemoglobin accumulate. In general the only symptom produced when methemoglobin constitutes less than 30% of total hemoglobin is the cosmetic effect of cyanosis. As levels of methemoglobin rise to greater than 30%, however, patients begin to exhibit symptoms of oxygen deprivation, such as malaise, giddiness, and other alterations of mental status. The symptoms reflect a true lack of oxygen availability at the tissue level. Methemoglobin is a markedly left-shifted hemoglobin that delivers little oxygen to the tissues. When methemoglobin accounts for more than 50% of total hemoglobin, loss of consciousness, coma, and death can rapidly ensue. At this level the blood is chocolate brown.

TABLE 43.4 Drugs and Chemicals Having Toxic Effects on Hemoglobin Molecule		
Agent	Observed Hemoglobin Derivative	
	Methemoglobin	Sulfhemoglobin
Acetanilid, phenacetin	+	+
Nitrites (ferric, amyl, sodium, potassium, nitroglycerin)	+	+
Trinitrotoluene, nitrobenzene	+	+
Aniline, hydroxylamine dimethylamine	+	+
Sulfanilamide	+	+
p-Aminosalicylic acid	+	
Dapsone	+	
Primaquine, chloroquine	+	
Prilocaine, benzocaine, lidocaine	+	
Menadione, naphthoquinone	+	
Naphthalene	+	
Resorcinol	+	
Phenylhydrazine	+	+

Diagnosis

Methemoglobinemia should be suspected in patients with unexplained cyanosis. It is obviously a medical emergency when any patient has cyanosis and altered mental status; a PaO_2 more normal than expected on the basis of the O_2 saturation should trigger a consideration of methemoglobinemia. The ingestion of nitrites as a suicidal gesture, especially in people knowledgeable with respect to chemistry, medicine, or pharmacology, should be considered. Exposure to nitrate-containing therapeutic compounds, e.g., in the setting of the intensive care unit, should also raise suspicion. Methemoglobinemia can be suspected from the brownish color of blood when it is drawn. Laboratory detection is simple; methemoglobin exhibits characteristic peaks of absorption at 630 and 502 nm, rendering it easily distinguishable from normal hemoglobin. Pulse oximetry, using a ratio of absorption at 660 nm and 940 nm, gives an inaccurate reading of 85% oxygen saturation for blood with 100% methemoglobin. The inherited M hemoglobin mutants are frequently detectable by altered electrophoretic mobility, especially if ferricyanide treatment in vitro is used to convert all the hemoglobin solution to methemoglobin.

In the case of toxic methemoglobinemia, recognition of exposure to an appropriate agent provides the most important historical clue. Acute poisoning can represent a life-threatening emergency; therefore laboratory evaluation for methemoglobin should be requested for any person displaying atypical cyanosis or cyanosis occurring along with more normal than anticipated blood gas values. Methemoglobin due to deficiencies of the reductase system can be further evaluated in reference laboratories by direct analysis of these enzymes.

Management

Patients with M hemoglobins are usually asymptomatic and require no management. The secondary cyanosis can present a cosmetic problem. The cyanosis is not reversible because ascorbic acid and methylene blue are usually ineffective.

Patients with deficiency of the reductase system usually do not require treatment. Cyanosis in these cases can be improved by treatment with oral methylene blue, 100 to 300 mg/day, or 500 mg/day of oral ascorbic acid. Riboflavin (20 mg/day) has also been reported to be effective and may be the preferred agent, because methylene blue produces discolored (blue) urine, and ascorbic acid can cause sodium oxalate stones.

Emergency treatment of high levels of toxic methemoglobinemia begins with 1 to 2 mg/kg of intravenous methylene blue as a 1% solution in saline. It is usually infused rapidly (over 3 to 5 minutes);

the dose can be repeated at 1 mg/kg after 30 minutes if necessary. This treatment is usually effective. Methylene blue acts through the reduced form of nicotinamide adenine dinucleotide (NADPH) reductase system, which in turn requires G6PD activity. The method is therefore ineffective in patients who also have G6PD deficiency. These patients, or patients who are severely affected, may require exchange transfusion or hyperbaric oxygen therapy. Oral ascorbic acid is not useful for emergency situations because it acts too slowly. Follow-up maintenance management, however, can be accomplished with either ascorbic acid or oral methylene blue.

Mild cases of methemoglobin intoxication do not require treatment. The patient can be monitored for 1 to 3 days, during which time methemoglobin levels gradually return to normal if the offending agent is eliminated. The most important follow-up therapy for patients with toxic methemoglobinemia involves a thorough search for the offending agent and its removal from the environment.

RED BLOOD CELL ENZYMOPATHIES

Xylina T. Gregg and Josef T. Prchal

Reticulocytes are already enucleated when released from the bone marrow and in the process of maturation into red blood cells (RBCs) they also lose their mitochondria and ribosomes. Unable to carry out oxidative phosphorylation and protein synthesis, RBCs still have to sustain an active metabolism to maintain viability and to preserve hemoglobin in its functional form to ensure adequate oxygen delivery to tissues.

RBC enzymes allow RBCs to accomplish these tasks by supporting glycolysis and the pentose shunt and by providing protection against oxidants by maintaining a high ratio of reduced glutathione (GSH) to oxidized glutathione (GSSG). Other RBC enzymes participate in nucleotide degradation and salvage to remove toxic nucleotides from erythrocytes. Glycolytic enzymes also have diverse, nonenzymatic functions, including stimulation of cell movement, control of apoptosis and modulation of oncogene regulation. These other roles of glycolytic enzymes may explain some of the nonerythroid effects of mutations of the glycolytic enzyme genes. In addition, RBCs contain enzymes, such as glutamine-oxaloacetic transaminase, with no obvious physiologic function; these may be remnants of its nucleated past.

The activities of some RBC enzymes rapidly decrease with aging, but the activities of others decrease slowly or not at all. Clinically significant abnormalities of RBC enzymes cause various hematologic phenotypes, principally acute and chronic hemolytic anemia, polycythemia, and methemoglobinemia. Disorders of some RBC enzymes have no RBC phenotype but their dysfunction in nonerythroid tissues causes systemic disorders such as galactosemia and glycogen storage disorders. Thus the presence of these enzymes in easily accessible RBCs serves as a convenient approach for the diagnosis of these disorders. Deficiencies or abnormalities of other RBC enzymes, such as erythrocyte lactate dehydrogenase (LDH), have no apparent disease phenotype.

METABOLIC PATHWAYS

Glucose is used in two different pathways: glycolysis (Fig. 44.1), which provides two molecules of adenosine triphosphate (ATP), and the pentose shunt (see Fig. 44.1), which generates five and seven carbon carbohydrates and reduces nicotinamide adenine dinucleotide phosphate (NADP to NADPH), the sole source of NADPH in red cells. Under physiologic conditions, approximately 90% of glucose is consumed in the glycolytic pathway and about 10% is used in the pentose shunt. In conditions of increased oxidant stress, however, the contribution of the pentose shunt may be significantly increased. In the glycolytic pathway, the generation of one molecule of ATP could be bypassed by the Rapoport-Luebering shunt (see Fig. 44.1), which generates an important glycolytic intermediate, 2,3 biphosphoglycerate (BPG), that facilitates hemoglobin oxygen delivery.

In addition, RBCs have an active glutathione metabolism comprised of its synthesis and reduction (Fig. 44.2). Maintaining a high ratio of GSH to its oxidized form (GSSG) is the principal antioxidant protective mechanism for RBCs. The release of oxygen from hemoglobin generates reactive oxygen species (ROS). Another source of endogenous ROS in RBCs is NADPH oxidase and, in reticulocytes, mitochondrial derived ROS. Excessive ROS is detrimental to RBCs by affecting membrane deformability and hemoglobin solubility, and

thus these immense oxidative stresses must be countered by antioxidant enzymes and other antioxidant protective mechanisms such as the active efflux of oxidized glutathione for the RBC to survive.

ENZYMOPATHIES ASSOCIATED WITH HEMOLYTIC ANEMIA

Deficiencies in three enzymes account for most of cases of hemolytic anemia. The most common is glucose-6-phosphate dehydrogenase (G6PD), which is an enzyme essential for glutathione metabolism, followed by an enzyme defect in the glycolytic pathway, pyruvate kinase, (PK) and lastly pyrimidine 5' nucleotidase-1 (P5'N1), which is essential for removal of toxic nucleotide precursors. Deficiencies of other enzymes are rarer and have highly variable clinical phenotypes that appear to be specific for each enzymatic defect.

Enzyme disorders affecting glutathione metabolism can cause either chronic or acute intermittent hemolysis and Heinz bodies (precipitated denatured hemoglobin) may be seen in RBCs during an acute hemolytic episode. The glycolytic enzyme deficiencies result in chronic hemolysis by a poorly understood mechanism. These patients are not subject to hemolytic crises after exposure to oxidants and their RBCs do not have any characteristic morphologic abnormalities. The chronic hemolytic anemia that occurs in enzyme deficiencies is termed hereditary nonspherocytic hemolytic anemia.

Glucose-6-Phosphate Dehydrogenase Deficiency

Introduction

G6PD deficiency was the first described and is the most common and best-studied RBC enzyme deficiency. G6PD deficiency is more common where *Plasmodium falciparum* malaria is or has been endemic. It was discovered in the 1950s as a result of investigations into a self-limited hemolysis that occurred after administration of the antimalarial drug primaquine, most commonly in individuals of African or Mediterranean ethnic origin. These early studies also determined that G6PD deficiency is X-linked and subsequent studies in carrier females led to the discovery of X-inactivation, a phenomenon that has been exploited to study the hierarchy of hematopoiesis and the clonality of malignant neoplasms.

Epidemiology

G6PD deficiency is the most prevalent human enzyme deficiency in the world, affecting an estimated 500 million people, although the vast majority of affected individuals are not symptomatic. Although most prevalent in individuals of African, Mediterranean, and Asian ethnic origins, it has been found in almost every population. The highest prevalence is in the tropical belt of sub-Saharan Africa (>32%) and the Arabian Peninsula. In other populations, its prevalence ranges from less than 1 in 1000 among northern European populations to 50% of the males in Kurdish Jews. The distribution across Asia is heterogeneous. Nearly 20% of males in Thailand are affected by one of the five prevalent variants. It is common in southern China (~5% in Hong Kong) and rare in other parts of China, while in India the

Fig. 44.1 PRINCIPAL COMPONENTS OF THE ERYTHROCYTE METABOLISM WITH CLINICAL RELEVANCE. Glycolysis, Pentose Shunt (shaded area), and Rapoport-Luebering shunt (shaded area). *ADP*, adenosine diphosphate; *ATP*, adenosine triphosphate; *1,3-BPG*, 1,3- bisphosphoglycerate; *2,3-BPG*, 2,3-bisphosphoglycerate; *DHAP*, dihydroxyacetone phosphate; *GAPD*, glyceraldehyde phosphate dehydrogenase; *GSH*, reduced glutathione; *GSSG*, oxidized glutathione; *NAD⁺*, nicotinamide adenine dinucleotide; *NADP⁺*, oxidized form of nicotinamide adenine dinucleotide phosphate; *NADPH*, reduced form of nicotinamide adenine dinucleotide phosphate; *6PG*, 6-phosphogluconate.

prevalence varies from 0% to 27% in different caste, ethnic and linguistic groups. In the United States, G6PD deficiency affects about 10% of African American males. G6PD deficiency is virtually nonexistent among indigenous peoples of the Americas and Asian highlanders.

The variable geographic distribution of G6PD deficiency implies that it confers a selective advantage and, as it coincides with the geographic distribution of endemic malaria, suggests protection from lethal malaria, although the exact mechanism has not been fully elucidated. The wild type enzyme is designated G6PD B. The most common G6PD low activity allelic variants are G6PD A- and G6PD Mediterranean. G6PD A- accounts for approximately 90% of G6PD deficient variants in Africa but is also prevalent in North and South America, the West Indies, Italy, the Canary Islands, Spain, Portugal, and the Middle East. The *G6PD A-* mutation (G202A) arose on a *G6PD A+* chromosome (A376G). G6PD A+ has no obvious hematologic phenotype and has a gene frequency similar to that of G6PD A- among African Americans. G6PD Mediterranean is found in the southern part of Italy, Greece, Spain, and Corsica, as well as the

Middle East, Iran, and the Arabian Peninsula, India, and Indonesia. G6PD Mediterranean is not homogeneous, but is composed of several distinct mutations, of which *G6PD* Mediterranean^{C563T} predominates. Several G6PD variants are pandemic in Asia; there are more than 100 different mutations in various Asian populations.

The high frequency of the most common *G6PD* variants and the diversity of the variants suggest selection of the variants, presumably because of protection from malaria. However, data on which genotype confers protection from malaria has been conflicting. The majority of studies conclude that G6PD deficiency in hemizygous males, and probably also in heterozygous females, confers significant protection against malarial infection. The nature of protection from the mosaic state of G6PD deficiency in heterozygous females remains to be established. However, deficient cells infested with malaria parasites appear to be phagocytized more efficiently than normal cells and the host RBCs' impaired ability to restore intracellular NADPH to maintain a high GSH/GSSG ratio may also mean that malarial parasites in G6PD-deficient RBCs are more vulnerable to ROS.

Fig. 44.2 GLUTATHIONE PATHWAY. *ADP*, adenosine diphosphate; *ATP*, adenosine triphosphate; *F6P*, fructose 6-phosphate; *G6P*, glucose 6-phosphate; *G6PD*, glucose-6-phosphate dehydrogenase; *GSH*, reduced glutathione; *GSSG*, oxidized glutathione; *NADP⁺*, oxidized form of nicotinamide adenine dinucleotide phosphate; *NADPH*, reduced form of nicotinamide adenine dinucleotide phosphate.

Pathobiology

G6PD is a housekeeping enzyme that in the first reaction of pentose shunt catalyzes the oxidation of glucose-6-phosphate to 6-phosphogluconolactone, which reduces $NADP^+$ to NADPH (see Figs. 44.1 and 44.2). In RBCs, the pentose shunt is the only source of NADPH, which is crucial in maintaining high cellular levels of GSH to protect the cell from oxidative stress-induced damage. Within the RBCs, oxidant injury leads to the oxidation of sulfhydryl (SH) groups on the hemoglobin molecule, resulting in the formation of disulfide bridges (-S-S-), which in turn leads to decreased hemoglobin solubility and ultimately the irreversible precipitation of oxidized hemoglobin (Heinz bodies). Under normal conditions these oxidized -S-S- groups of hemoglobin are reduced by GSH to SH-groups by glutathione peroxidase, which in turn is oxidized to GSSG but is restored back to GSH by glutathione reductase in a reaction requiring NADPH. NADPH levels are maintained by G6PD; thus, in G6PD-deficient RBCs, GSH is not restored to adequate levels under oxidative stress, leading to a buildup of free radicals and insoluble hemoglobin within the cell. Precipitated hemoglobin is disruptive to the structure and function of the RBC membrane and leads to increased membrane permeability, osmotic fragility, and cell rigidity. The compromised integrity of the RBC membrane results in both intravascular hemolysis and the rapid removal of these cells within the splenic pulp.

The *G6PD* gene localizes to Xq28, spans 18 kb, and contains 13 exons; the G6PD peptide exists as a tetramer or dimer. Stability of the quaternary structure is crucial for optimal G6PD activity. G6PD activity decreases significantly as erythrocytes age, with a half-life of about 60 days. Reticulocytes have five times higher enzyme activity than the oldest RBC subpopulation. The decrease in G6PD activity with aging is particularly pronounced in some mutant variants such as the African G6PD A-.

G6PD variants can be divided into three categories based on the type of hemolysis they cause: acute intermittent (most common), chronic (rare), or none. The less frequently used World Health Organization classifies the different G6PD variants according to the degree of enzyme deficiency and severity of hemolysis. Class I deficiencies are the most severe and cause chronic hemolysis. Less severe G6PD Mediterranean is a class II deficiency and the even less deficient G6PD A- is a class III deficiency. Classes IV and V do not cause hemolysis and are of no clinical significance.

Over 400 variants of the G6PD enzyme have been identified by biochemical methods, 100 of which reach polymorphic levels. Mutations associated with chronic hemolysis tend to cluster in the vicinity of the NADP-binding domain of the *G6PD* gene and cause more severe deficiency, whereas those associated with acute intermittent hemolysis or no hemolysis are scattered throughout the gene. Most variants are caused by point or missense mutations. Unlike disease-causing mutations of other genes, deletions and insertions causing frameshift and stop codon mutations are not observed; these events would be expected to be fatal, since *G6PD* is a housekeeping gene essential for basic cellular functions.

Clinical Manifestations

Acute Hemolysis

Individuals with the most common forms of G6PD deficiency have no anemia or other clinical manifestations unless they are exposed to triggers of acute hemolysis, such as oxidant drugs, infection, or ingestion of fava beans. Exposure of red cells to certain drugs results in the formation of low levels of hydrogen peroxide as the drug interacts with hemoglobin; other drugs may form free radicals that

oxidize GSH without the formation of peroxide as an intermediate. Hemolysis begins in hours to 1–3 days after exposure to the offending drug. However, many drugs implicated in acute hemolysis in G6PD deficiency may not be true culprits, as infection and other stressors can also provoke hemolysis in these people.

The mechanism of hemolysis induced by infection is not well understood, but the generation of hydrogen peroxide by phagocytizing leukocytes or the diffusion of oxidants from neutrophils undergoing oxidative bursts leading to the formation of disulfide bridges of hemoglobin may be factors.

Depending on the G6PD variant, hemolysis can be self-limited or protracted. The RBCs of G6PD A- contain only 5% to 15% of the normal amount of enzyme activity and the age-dependent decline of the activity renders old RBCs severely deficient and susceptible to hemolysis. As this subpopulation is eliminated, younger RBCs and reticulocytes produced in response to hemolysis have higher G6PD activity and are typically not hemolyzed. Thus, the hemolytic process is self-limited, even when the offending agent is continued. In contrast, in G6PD Mediterranean the enzyme activity of the young RBCs is lower compared with G6PD A- and hemolysis continues longer, even days after discontinuation of the culprit drug.

Favism

Fava beans are a staple food in many parts of the world where G6PD deficiency is found at a high gene frequency. The hemolysis precipitated by fava bean ingestion, favism, occurs only in people who are G6PD deficient. It is most frequently associated with the more severe G6PD Mediterranean and G6PD Cairo variants, but rarely has been seen with G6PD A-. Not all individuals with G6PD Mediterranean are susceptible to favism and a tendency toward familial occurrence suggests that additional genetic factors may be important. Favism is more common in children than adults. Hemolysis usually occurs one to several days after fava bean consumption, but onset within the first hours after exposure has been reported.

Chronic Hemolysis

The rare G6PD variants causing chronic hemolytic anemia occur sporadically. The severity of the hemolysis ranges from mild to transfusion dependent. Exposure to the oxidants that cause hemolysis in the acute hemolytic G6PD variants may further exacerbate hemolysis.

Neonatal Jaundice

Neonatal jaundice, which may result in kernicterus, is the most common and often the most serious consequence of G6PD deficiency. The icterus is not only caused by hemolysis but also to inadequate processing of bilirubin by the immature liver of the G6PD deficient infant. Thus, the coinheritance of polymorphic *UGT1A1* promoter alleles (Gilbert syndrome) exacerbates the icterus. Neonatal screening for G6PD deficiency and early phototherapy treatment in endemic areas has been associated with a decreased incidence of kernicterus.

Nonerythroid Effect of G6PD Deficiency

Although patients with the common endemic G6PD variants are not at increased risk for infections, neutrophil dysfunction has been described in some patients with rare severely deficient G6PD variants. Occasionally, cataracts have been observed in patients with some rare variants of G6PD that produce chronic hemolytic anemia. Small studies from the Middle East suggest that decreased G6PD activity may predispose to the development of diabetes. Splenomegaly is generally not seen in G6PD deficient individuals.

Laboratory Manifestations

Under normal conditions, most G6PD-deficient individuals are not anemic and have no laboratory evidence of hemolysis. In the setting of oxidative stress, laboratory findings indicative of acute hemolysis including anemia and reticulocytosis are seen. As the hemolysis is mainly extravascular with a variable intravascular component, variable degrees of hyperbilirubinemia, increased LDH, and decreased

haptoglobin occur. Heinz bodies (denatured precipitated hemoglobin) may be visible in the erythrocytes during an acute hemolytic episode, but not under normal circumstances. “Bite cells” have been described, but this is not specific for G6PD deficiency and these cells are usually not present in acute hemolytic states of patients with common G6PD variants or in G6PD-deficient patients with chronic hemolysis.

Individuals with the chronic hemolytic G6PD variants have varying degrees of anemia and reticulocytosis.

Diagnosis

A biochemical diagnosis of G6PD deficiency can be made using quantitative spectrophotometric analysis to measure the generation of NADPH from NADP in RBC hemolysates. A more convenient rapid fluorescent screening test can be used to test at-risk populations. False-negative results are not unusual, however, especially if enzymatic analysis is performed shortly after resolution of acute hemolytic episodes or in heterozygous females. After acute hemolysis, reticulocytes and young RBCs, which have much higher enzymatic activity, predominate. These false-negative test results are more likely to occur when a screening test rather than a quantitative spectrophotometric analysis of the enzyme activity is used. Females heterozygous for G6PD are particularly difficult to diagnose because of their mosaicism for X-chromosome enzymes and may have total RBC enzymatic activity ranging anywhere from hemizygote to normal; however these females have a variable mixture of deficient and nondeficient RBCs and their deficient RBCs are subject to hemolytic crises. Since the nucleotide substitutions of many G6PD-deficient isoenzymes have been identified, molecular diagnostic methods are more reliable for the accurate diagnosis of females who are heterozygous for G6PD deficiency.

Severe sporadic variants causing chronic hemolytic anemia may be considered for prenatal diagnosis in some circumstances.

Prognosis

Most patients with G6PD deficiency have normal life spans with no clinical sequelae. Neonatal icterus with resultant kernicterus and mental retardation have the gravest consequences.

Therapy

Treatment of an acute hemolytic crisis includes withdrawing any offending agent and supportive care, which in severe cases includes RBC transfusions. Folic acid supplementation is recommended for patients with chronic hemolysis. Rarely, chronic hemolytic anemia is severe enough to require chronic transfusions. Neonatal icterus associated with G6PD deficiency is treated in the same manner as neonatal icterus arising from other causes; G6PD deficiency should be considered in any neonate with hyperbilirubinemia, especially those of high-risk ethnic descent.

Future Directions

In certain areas of the world where G6PD deficiency reaches epidemic proportions and ingestion of fava beans is staple, screening for endemic G6PD-deficient variants would be expected to reduce hospitalizations, RBC transfusions and even mortality (from kernicterus).

Pyruvate Kinase Deficiency

Introduction

PK deficiency is the most common enzyme deficiency causing hemolysis. Although this disorder is far less common than G6PD

deficiency, the vast majority of patients with G6PD deficiency never suffer a hemolytic episode, while PK deficiency exhibits a high penetrance of the hemolytic phenotype.

Epidemiology

PK deficiency is distributed worldwide but is more common among people of northern European extraction. The population prevalence of PK deficiency among whites is approximately 50 cases per 1 million. PK deficiency is an autosomal recessive disease, and affected patients are typically double heterozygotes, or, less commonly, homozygous for the same mutation. Homozygous mutations are usually seen in groups with marked consanguinity, and homozygous PK deficiency has been well described in the Amish populations of Pennsylvania and Ohio. Common mutations have well-defined geographic associations. Mutation 1529A is the most common mutation in the United States, northern and central Europe, 1456T in southern Europe, and 1468T in Asia.

PK deficiency does not localize to geographic areas of malarial endemicity. However, there is *in vitro* evidence that PK deficiency provides protection against infection and replication of *Plasmodium falciparum* in human RBCs, an effect possibly mediated by reduced ATP levels in PK-deficient RBCs. PK deficiency was also shown to be protective in a mouse model of infection with *Plasmodium chabaudi*.

Pathobiology

PK catalyzes the irreversible transfer of phosphate from phosphoenolpyruvate to adenosine diphosphate (ADP) yielding one molecule of pyruvate and one molecule of ATP (see Fig. 44.1). Two genes encode four PK isoenzymes with different tissue expression. PK-R (unique to RBCs) and PK-L (in liver) are products transcribed from two different, tissue-specific promoters of the *PKLR* gene on chromosome 1q21. Other undefined regulatory elements are also involved in *PKLR* gene expression. PK-M1 (in skeletal muscle) and PK-M2 (in leukocytes, kidney, adipose tissue, lungs and fetal RBCs) are formed from the *PKM2* gene by alternative splicing. PK-M2 in fetal erythropoiesis is replaced by the PK-R isoform after birth. PK-R is a heterotetramer whose enzymatic activity is allosterically augmented by fructose 1,6-diphosphate.

More than 230 mutations in the *PKLR* gene have been identified, most of which are missense mutations. Mutations affecting the active site or protein stability are associated with more severe hemolytic anemia. However, the phenotypic expression of identical mutations can be strikingly different. Since most PK-deficient patients are compound heterozygous for two different mutations, rather than homozygous for one, several different tetrameric forms of PK may be present, each with distinct structural and kinetic properties. This complicates genotype-to-phenotype correlations in these individuals, as it is difficult to infer which mutation is primarily responsible for deficient enzyme function and the clinical phenotype. There are even cases in which the activity of PK as measured *in vitro* is higher than normal, but a kinetically abnormal enzyme is responsible for the hemolytic anemia.

PK deficiency may be also caused by mutations not directly involving *PKLR* gene. Combined heterozygosity for the common 1529A PK mutation and a unique promoter mutation on the other allele that markedly reduced its allelic transcription resulted in a severe hemolytic variant. Mutations in the key erythroid transcription factor KLF1 caused severe congenital hemolytic anemia because of a deficiency of PK.

The mechanism of hemolysis in PK deficiency is not clear. The defect in ATP generation is unlikely to be the cause as ATP deficiency is difficult to demonstrate in many patients and other disorders with more severe ATP deficiency are not associated with significant hemolysis. Increased apoptosis and ineffective erythropoiesis may also be a feature of PK deficiency, although this has only been studied in

splenic erythroid progenitors. Following splenectomy, despite decreased hemolysis and improved anemia, patients paradoxically have a higher number of reticulocytes; this phenomenon is as yet unexplained.

Tolerance of Anemia

The anemia of PK deficiency is better tolerated than a comparable level of anemia seen in patients with hexokinase deficiency, since the block in glycolysis occurs after the Rapoport-Leubering shunt (see Fig. 44.1); (see section on 2,3-BPG deficiency). The resultant accumulation of 2,3-BPG shifts the oxyhemoglobin dissociation curve to the right, leading to better oxygen delivery to the tissue and improved tolerance of anemia.

Clinical and Laboratory Manifestations

The severity of hemolysis in PK-deficient patients is highly variable, ranging from a mild, fully compensated chronic hemolytic process without anemia, to life-threatening transfusion-requiring hemolytic anemia present at birth, to rare hydrops fetalis because of homozygosity for PK null mutations. The disease severity is typically similar among siblings of a given family. In most cases the degree of hemolysis declines after infancy, by a not fully understood pathophysiologic mechanism. Splenomegaly is often but not invariably present. Patients with severe hemolysis may be chronically jaundiced and may develop the clinical complications of chronic hemolytic states, including gallstones, transient aplastic anemia crises (caused by parvovirus infection), folate deficiency, extramedullary hematopoiesis and infrequently, skin ulcers. Pregnancy may precipitate hemolysis. Iron overload has been reported in both nontransfused and transfusion-dependent patients and may be severe; in some cases iron overload has been attributed to coinheritance of mutations in *HFE*, the gene associated with hereditary hemochromatosis. Neonatal icterus may occur and is augmented by coincidental heterozygosity or homozygosity for the *UGT1A1* polymorphism.

Hemolysis is mainly extravascular with a variable intravascular component; thus, increased LDH, hyperbilirubinemia and low haptoglobin levels may be present. The reticulocyte count invariably increases after splenectomy.

Diagnosis

There are no characteristic RBC morphologic findings in PK deficiency. A screening test using crude hemolysate with a single concentration substrate has been used for the detection of pyruvate deficiency but occasionally misses some PK variants. Specialized laboratories can perform quantitative PK enzyme analysis and further analyze the mutant enzyme by comprehensive kinetic studies. In these assays, leukocytes and platelets must be carefully removed as their presence can obscure a deficiency in the red cells. Molecular studies for prenatal diagnosis can be used if the mutation is known.

Therapy

Many patients do not require therapy. Some require RBC transfusions only in transient settings of increased stress, such as the perioperative period, coexistent infections, or pregnancies. However, others require chronic transfusions. Iron chelation may be required in chronic transfusion programs and also in some patients who have never been transfused.

Splenectomy has documented benefit in severe cases; the degree of hemolysis and anemia is ameliorated and the transfusion requirement is generally abolished or markedly decreased. The increase in hemoglobin concentration in nontransfusion requiring patients after splenectomy ranges from 1–3 g/dL. It is recommended to delay

splenectomy if possible until after the age of 3 years when the risk of infections with encapsulated organisms declines and because in most cases the degree of hemolysis declines after infancy, by a not fully understood pathophysiologic mechanism. One PK-deficient boy with severe hemolysis was apparently cured by an allogeneic marrow transplant.

A small molecule AG-348 (Agiros Pharmaceuticals Inc.) can increase the activity of many PK mutants perhaps by increasing the stability of the PK enzyme. This oral compound is currently in clinical trials and may be able to restore glycolytic pathway activity and normalize ATP and 2,3 BPG levels in PK deficiency.

Prognosis

The clinical course is highly variable ranging from fatal hydrops fetalis, transfusion dependency from birth, and a high risk of kernicterus to normal childhood development with no or rare transfusions, or to compensated hemolysis without anemia. However, hemolysis that is fully compensated because of excessive erythropoiesis may be deceptively benign. In addition to the usual complications of chronic hemolysis such as gallstones and parvovirus-induced aplastic crisis, the excessive number of erythroblasts in these patients produces erythroferrone, which mediates low hepcidin and may result in typical hemochromatosis induced cardiac and hepatic dysfunction.

Future Directions

Small molecular activators of PK are promising, but are being validated in ongoing trials.

New gene therapeutic techniques are also being evaluated in severe PK deficiency. These include the zinc finger nucleases and *CRISPR/Cas9* technology (clustered regularly interspaced short palindromic repeats) that uses noncoding RNAs to guide the Cas9 nuclease to induce site-specific DNA cleavage. The resultant DNA damage is repaired by cellular DNA repair mechanisms that may correct the PK mutation. These technologies hold early promise that will need to be validated by future clinical trials.

Pyrimidine 5' Nucleotidase-1 Deficiency

Introduction

P5'N1 deficiency is the third most common cause of hemolytic anemia caused by a red cell enzymopathy, after G6PD and PK deficiency. It is inherited in an autosomal recessive manner.

Pathobiology

As the reticulocyte matures, ribosomes and RNA are degraded. P5'N1 assists in the process by catalyzing the dephosphorylation of pyrimidine nucleoside monophosphates into cytidine and uridine, which can diffuse across the cell membrane. P5'N1 activity is specific for pyrimidines and is much higher in reticulocytes than mature red cells; P5'N1 activity rapidly declines during the first few days of red cell maturation. P5'N1 requires Mg^{2+} for its activity and is inhibited by a number of heavy metals, including Pb^{2+} . P5'N1 also has phosphotransferase properties, suggesting an additional role of this enzyme in nucleotide metabolism. Thus far, 27 different mutations have been reported in P5'N1 deficiency. Most patients are homozygous.

P5'N2 is another nucleotidase present in RBCs. Although the activity of this enzyme is generally measured together with that of P5'N1, it is encoded by a separate gene, is not strictly pyrimidine-specific, and is unable to compensate for deficient function of P5'N1. Only P5'N1 deficiency is associated with hemolytic anemia.

The accumulation of pyrimidines in the RBCs because of a deficiency of P5'N1 is presumed to be toxic although the exact mechanism by which P5'N1 causes hemolysis is unknown. The ribosomal aggregates are visible as the characteristic coarse basophilic stippling seen on the peripheral smear. However, deficiency of P5'N1 is at least partly compensated in vivo by other nucleosidases or other nucleotide metabolic pathways. Acquired P5'N1 deficiency occurs in acute lead toxicity because of Pb^{2+} outcompeting the essential cofactor Mg^{2+} .

Clinical and Laboratory Features

P5'N1 deficiency causes chronic hemolytic anemia, with severity ranging from compensated hemolysis without anemia to transfusion dependent anemia. Marked basophilic stippling of RBCs is a laboratory hallmark and thus morphologic examination of the peripheral blood smear provides simple and inexpensive screening. However basophilic stippling is not a specific finding, as it is also found in hemolytic anemia caused by acute lead toxicity and sideroblastic anemia. Confirmation of the diagnosis requires demonstration of decreased P5'N1 activity, normal blood lead levels and, if available, high concentrations of pyrimidine nucleotides in red cells.

Therapy

Chronic transfusion support may be necessary for severe cases. Milder cases may require transfusion only periodically, during pregnancy, infection or other stressors. Iron overload may occur, as in any chronic hemolytic condition, and iron chelation may be needed. Splenectomy was reported to be beneficial in several cases.

OTHER ENZYMOPATHIES OF THE GLUTATHIONE PATHWAY

γ -Glutamylcysteine Synthase Deficiency

γ -glutamylcysteine synthase (GCL) catalyzes the first metabolic step of glutathione synthesis. Deficiency of this enzyme is rare and only a few cases, usually in consanguineous families, have been reported. All patients had hemolytic anemia and approximately half also had neurologic defects, including spinocerebellar degeneration, peripheral neuropathy, and mental retardation. Some patients have been characterized at the molecular level and in all these cases the causative mutation affected the catalytic domain of GCL.

Glutathione Synthetase Deficiency

Glutathione synthetase (GS) deficiency is a slightly more common enzymopathy of glutathione metabolism than GCL deficiency. The clinical severity is variable, but approximately 25% of the patients die in childhood. Mild GS deficiency can manifest as only mild chronic hemolysis. Moderately affected individuals present in the neonatal period with both hemolytic anemia and severe metabolic acidosis caused by the accumulation of the γ -glutamylcysteine metabolite 5-oxoproline, which results from decreased feedback inhibition of GCL by the decreased levels of GSH. Severely affected patients have progressive neurologic defects and animal experiments suggest that 5-oxoproline has a direct neurotoxic effect. The different clinical manifestations are likely compounded by environmental factors as phenotypic variability among siblings with the same mutation has been encountered.

High levels of 5-oxoproline in the urine (found in all severely and moderately affected but in only some of the mildly affected patients) suggest the diagnosis, which is confirmed by documenting deficiency of the enzyme or by demonstrating mutations in the GS gene. Correction of the metabolic acidosis and early supplementation

with antioxidants such as vitamins C and E was reported to improve survival and long-term outcome in some but not all affected patients.

Patients with glutathione synthetase deficiency should avoid the same agents known to precipitate acute hemolysis in patients with G6PD deficiency.

Glutathione Reductase Deficiency

Glutathione reductase (GR) restores intracellular GSH by reducing GSSG in the presence of NADPH and flavine adenine dinucleotide (FAD), a derivative of the water-soluble vitamin riboflavin. Hereditary GR deficiency has only been reported in two Dutch families. In one consanguineous family, acute hemolytic anemia after ingestion of fava beans occurred; GR deficiency was caused by a large homozygous deletion. The second family had a compound heterozygous mutation and a clinical phenotype of neonatal jaundice.

Riboflavin is a cofactor of GR. Mild acquired GR deficiency is common and occurs in malnourished individuals because of riboflavin deficiency but has no hematologic phenotype.

Glutathione Peroxidase Deficiency

Glutathione peroxidase is a selenium-containing enzyme that reduces hydrogen peroxide to water. Although a polymorphism affecting the activity of glutathione peroxidase and acquired decreased activity because of selenium deficiency have been described, neither circumstance was associated with a clinical phenotype.

OTHER ENZYMOPATHIES OF THE GLYCOLYTIC PATHWAY

Glucose Phosphoisomerase Deficiency

Glucose phosphoisomerase (GPI) deficiency is one of the three most common RBC enzyme defects causing chronic hereditary nonspherocytic hemolytic anemia (the other two are PK and P5'N1), with approximately 100 affected families described. GPI deficiency is an autosomal recessive disorder, with most patients compound heterozygous for mutations that partially inactivate the enzyme. The severity of the hemolysis is variable. Splenectomy can improve the anemia, eliminating transfusion requirements. Neonatal jaundice is common and hydrops fetalis has been reported. Rarely, severe neuromuscular symptoms, mental retardation and granulocyte dysfunction occur. These symptoms may be caused by nonerythroid functions of GPI, including its actions as a neuroleukin, an autocrine motility factor, a nerve growth factor, and a differentiation and maturation mediator. It has also been suggested that disturbed glycerolipid biosynthesis in GPI deficiency may have significant effects on membrane formation, membrane function, and axonal migration.

Hexokinase Deficiency

Hexokinase (HK), the red cell enzyme with the lowest activity in the glycolytic pathway, catalyzes the initial step in the utilization of glucose and thus is required for both glycolysis and the pentose shunt and produces glucose 6-phosphate. The two HK isoenzymes, HK1 and HKR, are the product of a single gene *HK-1* by use of an alternate translation initiation site. A single nucleotide polymorphism in *HK-1* was strongly associated with reduced hemoglobin and hematocrit levels in a European population. HK deficiency is a rare cause of hereditary chronic nonspherocytic hemolytic anemia with only few dozen cases in 19 families reported. Most patients are of northern European extraction, although one case was reported in a Chinese individual. The molecular defect has been characterized in only four patients; two were homozygous. HK is proximal to the generation of 2,3-BPG and thus decreased levels of 2,3-BPG in HK

deficiency lead to a left-shifted hemoglobin-oxygen dissociation curve and a more symptomatic anemia than comparable levels of anemia seen in patients with other RBC disorders. Splenectomy may be beneficial. A mouse model of HK deficiency demonstrates severe hemolytic anemia with extensive tissue iron deposition and marked reticulocytosis.

Phosphofructokinase Deficiency

Phosphofructokinase (PFK) catalyzes the rate-limiting phosphorylation of fructose-6-phosphate by ATP to fructose-1,6-diphosphate. Red cells contain both M and L subunits of PFK. PFK deficiency is an autosomal recessive disorder with approximately 100 cases and 23 mutant *PFKM* alleles reported. These mutations lead to an almost complete loss of PFK activity in muscle, but only partial loss of activity in erythrocytes. Two common mutations are present in Ashkenazi Jews. The most common manifestation of PFK deficiency is type VII glycogen storage disease (Tarui disease), which causes muscle weakness and exercise intolerance, although a mild chronic hemolytic anemia may also be present. In some patients, hemolysis is present without muscle manifestations.

PFK deficiency in dogs is characterized by hemolytic crises with strenuous exercise. *Pfkm* null mice show exercise intolerance, reduced lifespan and progressive cardiac hypertrophy.

Aldolase Deficiency

Aldolase reversibly cleaves fructose-1,6-diphosphate into glyceraldehyde 3-phosphate and dihydroxyacetone phosphate. Aldolase deficiency is a very rare cause of chronic nonspherocytic hemolytic anemia; myopathy and mental retardation may also occur.

Phosphoglycerokinase Deficiency

Phosphoglycerokinase catalyzes the reversible conversion of 1,3-bisphosphoglycerate to 3-phosphoglycerate, forming ATP in the process. This reaction can be bypassed by the Rappaport-Luebering shunt. Deficiency of this X-chromosome encoded enzyme is variably associated with hemolytic anemia, mental retardation, and myoglobinuria.

Triosephosphate Isomerase Deficiency

Triosephosphate isomerase (TPI) catalyzes the reversible interconversion of the triose phosphate isomers, dihydroxyacetone phosphate and glyceraldehyde 3-phosphate. TPI deficiency is a rare autosomal recessive disorder characterized by chronic hemolytic anemia, increased susceptibility to bacterial infections, cardiomyopathy and progressive neuromuscular disease. Neonatal jaundice may also occur. The neuromuscular disease is likely caused by the formation of toxic protein aggregates of glycosylated proteins formed by elevated byproducts of dihydroxyacetone phosphate.

Approximately 40 patients with several different mutations have been reported; however, most patients have the same mutation and are descendants from a common British/French ancestor about 1000 years ago. There is no effective therapy and most patients die in childhood, although there are rare exceptions.

OTHER ENZYMOPATHIES

Transaldolase Deficiency

Transaldolase catalyzes the conversion of seduhepuloose-7-phosphate and glyceraldehyde-3-phosphate into erythrose-4-phosphate and fructose-6-phosphate. Transaldolase deficiency has been described in

Fig. 44.3 METHEMOGLOBINEMIA. Formation of methemoglobin and its physiologic (*open space*) and therapeutic reduction (*shaded space*). Iron is in the ferrous state (Fe^{2+}) in oxygenated and deoxy-hemoglobin (deoxyHb). When oxygen is released, a small proportion of oxygen bound hemoglobin iron is then converted to ROS converting to the ferric state (Fe^{3+}); i.e., methemoglobin. The NADH, generated in glycolysis is a cofactor for methemoglobin reduction mediated by cytochrome b5 reductase (b5R) depicted in the *open space*, keeping methemoglobin at low levels (<1%). When this physiologic reduction of NADH-dependent methemoglobin reduction is either insufficient because of excessive ROS or decreased b5R activity, methemoglobin reduction can be achieved therapeutically. Exogenously administered methylene blue utilizing NADPH produced by G6PD in pentose shunt can nonenzymatically convert methemoglobin to Fe^{2+} hemoglobin (*shaded space*). *b5R*, cytochrome b5 reductase; *NAD*, nicotinamide adenine dinucleotide phosphate; *NADH*, the reduced form of NAD; *NADP*, oxidized form of nicotinamide adenine dinucleotide phosphate; *NADPH*, reduced form of NADP; *ROS*, reactive oxygen species.

23 patients from 13 families. Transaldolase deficiency presents in the neonatal period and clinical manifestations include dysmorphic features, hepatosplenomegaly, cirrhosis, cardiac and renal abnormalities, skin manifestations, and thrombocytopenia, although the phenotype is highly variable.

Adenosine Deaminase Hyperactivity

Adenosine deaminase (ADA) helps regulate the concentration of adenosine ribonucleotides in the red cell by irreversibly deaminating them to inosine. Hyperactivity of ADA is a rare cause of hereditary nonspherocytic hemolytic anemia and is the only red cell enzyme disorder that is inherited in an autosomal dominant disorder, but the molecular mechanism of this disorder has not been identified. Deficiency of ADA is associated with severe combined immunodeficiency (see Chapter 19).

ENZYMOPATHIES ASSOCIATED WITH POLYCYTHEMIA

Bisphosphoglycerate mutase (BPGM) regulates the concentration of 2,3-BPG (also known as 2,3-DPG) of erythrocytes. 2,3-BPG is an important modifier of RBC oxygen delivery. 2,3-BPG binds to the hemoglobin tetramer and allosterically converts hemoglobin to a low oxygen affinity state, resulting in a rightward shift of the oxygen dissociation curve. BPGM is a multifunctional enzyme with both synthase and phosphatase activity. The synthase activity of BPGM converts 1,3-bisphosphoglycerate to 2,3-BPG, which is then metabolized to 3-phosphoglycerate (3-PGA), an intermediate of the glycolytic pathway, by BPGM-phosphatase (see Fig. 44.1). Deficiency of BPGM results in decreased levels of 2,3-BPG. The consequent left shift of the oxygen dissociation curve increases hemoglobin affinity for oxygen, thus resulting in decreased delivery of oxygen into the peripheral tissues and compensatory polycythemia.

BPGM deficiency is rare and only two families have been comprehensively studied. In a family in France, four siblings were compound heterozygotes for two different BPGM mutations and had

polycythemia, markedly decreased 2,3-BPG levels and undetectable BPGM activity. Some of their heterozygote relatives had a milder decrease of 2,3-BPG levels and a mild polycythemia.

ENZYMOPATHIES ASSOCIATED WITH METHEMOGLOBINEMIA

Introduction

Methemoglobinemia occurs when an imbalance arising from either increased methemoglobin production or decreased methemoglobin reduction is present. Methemoglobin is a derivative of hemoglobin in which the ferrous (Fe^{2+}) irons are oxidized to the ferric (Fe^{3+}) state. Methemoglobin is formed spontaneously at a slow rate by the autooxidation of hemoglobin. In the release of oxygen from Fe^{2+} -oxyhemoglobin, one electron is partially transferred to a small portion of released oxygen, generating superoxide and eventually forming other ROS, which convert the iron to the ferric state and form Fe^{3+} -hemoglobin, i.e., methemoglobin (Fig. 44.3). Methemoglobin may also be formed from the oxidation of hemoglobin in other reactions with endogenous and exogenous compounds. The ferric hemes of methemoglobin are unable to bind oxygen and, additionally, if a ferriheme subunit is part of a hemoglobin tetramer, the oxygen affinity of the accompanying ferrous hemes in the hemoglobin tetramer is increased. As a result, the oxygen dissociation curve is left-shifted and oxygen delivery is impaired. Methemoglobin is formed continuously, but reducing mechanisms keep the methemoglobin level at about 1% of the total hemoglobin. The only physiologically important mechanism is the NADH-dependent cytochrome b5 reductase (b5R). b5R contains a prosthetic FAD group that acts as an electron acceptor. NADH reduces FAD to FADH₂, which then reduces the heme protein cytochrome b5. Electrons from the reduced cytochrome b5 are in turn transferred to methemoglobin, reducing iron back to the ferrous state (see Fig. 44.3).

An alternative pathway mediated by NADPH-diaphorase uses NADPH generated by G6PD as a source of electrons to reduce redox dyes, such as methylene blue, and flavin. Reduced methylene blue

then reduces methemoglobin. Since these electron acceptors are not physiologic, this pathway is only of importance as it is the mechanism by which methylene blue treats acute toxic methemoglobinemia.

Epidemiology

Most cases of methemoglobinemia are acquired, resulting from increased methemoglobin formation by various exogenous agents. Acute or toxic methemoglobinemia may occur in the setting of overdose or poisoning, but also at standard doses of drugs. Acute methemoglobinemia occurs equally between males and females and over a wide range of ages; however, infants are more susceptible because their erythrocyte b5R activity is normally 50% to 60% of adult activity.

Hereditary methemoglobinemia is most commonly caused by deficiency of b5R. b5R deficiency is an autosomal recessive condition and occurs in all racial and ethnic groups, but is endemic in certain populations, including Navajo and Athabasca Native Americans and natives of Yakutsk, Siberia. Other causes of hereditary methemoglobinemia are the autosomal dominant inheritance of an abnormal hemoglobin in hemoglobin M disease (see [Chapter 43](#)) and, very rarely, deficiency of cytochrome b₅.

Pathobiology

Acute Methemoglobinemia

Many drugs and toxins have been implicated in acute methemoglobinemia. More common culprits include dapsone, local anesthetics (benzocaine, lidocaine, prilocaine), and derivatives of the anesthetic phenacetin. Exposure to nitrates and nitrites, widely used as food preservatives and found in well water can also cause methemoglobinemia. Nitrites do not oxidize hemoglobin directly but are converted to nitrites by intestinal bacteria. Infants less than 6 months of age may have increased susceptibility to methemoglobinemia at least in part because of their lower b5R activity. Homemade baby food purees of high-nitrate-containing vegetables, well water contaminated by nitrites and diarrheal illness may all cause acute toxic methemoglobinemia in infants.

b5R Deficiency

In erythrocytes, b5R transfers electrons to methemoglobin to reduce it to hemoglobin. In other cells, b5R transfers electrons from cytochrome b₅ to stearyl-CoA in the endoplasmic reticulum, a reaction that has an important role in cholesterol biosynthesis, fatty acid elongation and desaturation, and drug metabolism. There are two types of b5R deficiency. The more common type I b5R deficiency is usually caused by missense mutations leading to decreased stability of the enzyme. Thus, although b5R is abnormal in all cells, only mature RBCs, which cannot synthesize proteins and replace the enzyme, are significantly affected in patients with type I b5R deficiency. Type II b5R mutations affect the catalytic site or lead to marked structural changes and all cells have decreased b5R activity.

Clinical Manifestations

Methemoglobinemia causes clinically discernible cyanosis when the absolute level of methemoglobin exceeds 1.5 gm%; this correlates with approximately 10% to 15% methemoglobin. Methemoglobinemia should be clinically suspected when “cyanosis” occurs in the presence of a normal PaO₂. Symptoms develop secondary to impaired tissue oxygenation and the onset may be abrupt. Early symptoms include headache, fatigue, dyspnea, and lethargy. At higher levels, respiratory depression, altered consciousness, shock, seizures, and death may occur. As methemoglobin levels rise above 20% to 30%,

patients can experience progressive respiratory compromise, myocardial ischemia, seizures, and coma. Death typically ensues at methemoglobin levels above 70% but can occur at lower levels.

Individuals with type I b5R deficiency, which is limited to erythrocytes, have methemoglobin concentrations of 10% to 35% and appear cyanotic but are usually asymptomatic, even with levels up to 40%. Some patients have reported headache and easy fatigability. Life expectancy is not shortened and pregnancies occur normally. Compensatory polycythemia is at times observed.

In addition to methemoglobinemia and cyanosis, patients with Type II b5R deficiency exhibit mental retardation and developmental delay. Other neurologic symptoms may be present, including microcephaly, opisthotonus, athetoid movements, strabismus, seizures, and spastic quadriplegia. Life expectancy is significantly shortened, and death in infancy is typical.

Laboratory Manifestations

The laboratory diagnosis of methemoglobinemia is based on analysis of its absorption spectra. A fresh specimen should always be obtained because methemoglobin levels tend to increase with storage. Traditional pulse oximetry is unreliable in the presence of methemoglobinemia because of its light absorbance properties; however, co-oximetry can determine the methemoglobin fraction along with all other substances with the optical density at 630 nm.

Methemoglobin detected by co-oximeter should be confirmed by the specific Evelyn-Malloy method if available. This method involves direct spectrophotometric analysis and should be used when methemoglobinemia is suspected. In the Evelyn-Malloy method, blood is lysed in a slightly acid buffer and the optical density is measured at 630 nm before and after adding a small amount of neutralized cyanide. Absorption of methemoglobin at this wavelength disappears when it is converted to cyanmethemoglobin. This method remains the most accurate technique for the estimation of methemoglobin concentration.

An eight-wavelength pulse oximeter, Masimo Rad-57 (the Rainbow-SET Rad-57 Pulse CO-Oximeter, Masimo Inc, Irvine, CA, USA), has been approved by the US Food and Drug Administration and appears to be accurate for the measurement of both carboxyhemoglobin and methemoglobin.

Distinguishing the hereditary forms of congenital methemoglobinemia requires interpretation of family pedigrees as well as biochemical analyses. Cyanosis in successive generations suggests autosomal dominant hemoglobin (Hb) M disease, whereas normal parents but possibly affected siblings implies autosomal recessive b5R deficiency. Incubation of blood with methylene blue distinguishes b5R deficiency from Hb M disease, because this treatment results in the rapid reduction of methemoglobin through the NADPH-flavin reductase pathway in cases of b5R deficiency but not in cases of Hb M disease. Types I and II b5R deficiency are distinguished by their clinical phenotype and by analysis of enzymatic activity in erythroid and nonerythroid cells. Because the enzyme defect is found in fibroblasts, analysis of b5R activity in cultured amniotic cells for prenatal diagnosis is possible.

Differential Diagnosis

Sulfhemoglobin in concentrations greater than 0.5 gm% also causes “cyanosis” with a normal PaO₂ and may be erroneously measured as methemoglobin. Other pigments, including methylene blue, may also produce false positive results when methemoglobin is measured by co-oximetry.

Prognosis

Acute methemoglobinemia generally resolves promptly with treatment providing the offending cause is discontinued. Patients with

type I b5R deficiency have cyanosis but a normal life expectancy, whereas the pan-deficient type II b5R patients usually succumb in childhood.

Therapy

Offending agents in cases of acquired methemoglobinemia should be discontinued. No other therapy may be required in an asymptomatic patient. However, if the patient is symptomatic or if methemoglobin levels are greater than 20%, specific therapy is indicated. Methylene blue, 1–2 mg/kg intravenously over 5 minutes, is an effective treatment for patients with methemoglobinemia because NADPH formed in the pentose shunt can rapidly reduce this dye to leukomethylene blue in a reaction catalyzed by NADPH diaphorase. Leukomethylene blue, in turn, nonenzymatically reduces methemoglobin to hemoglobin. An exception to the efficacy of this treatment exists in those patients who are G6PD deficient. In these patients, methylene blue would not only fail to give the desired effect on methemoglobin levels but might compound the situation by inducing an acute hemolytic episode. If methylene blue is contraindicated, ascorbic acid can be given. Patients with G6PD deficiency and acute methemoglobinemia have been successfully treated with exchange transfusion. Hyperbaric oxygen has also been used in severe cases of methemoglobinemia.

The cyanosis in hereditary b5R deficiency is of cosmetic significance only but can be treated with methylene blue or ascorbic acid, both of which facilitate the reduction of methemoglobin through alternate pathways. However, this therapy has no effect on the neurologic and other systemic defects seen in type II b5R deficiency.

RED BLOOD CELL MEMBRANE DISORDERS

Patrick G. Gallagher

Characterization of the structure and function of red blood cell (RBC) membrane proteins and their genes (Fig. 45.1) has led to considerable advances in our understanding of the molecular pathology of membrane-associated disorders, including the definition and characterization of mutations of membrane proteins as a well-defined cause of hereditary hemolytic disease. Likewise, knowledge of the molecular mechanisms underlying changes in RBC deformability, structural integrity, and shape has advanced. RBC shape abnormalities often provide a clue to the pathobiology and diagnosis of the underlying disorder. This chapter categorizes RBC membrane disorders according to the following morphologic and clinical phenotypes: (1) hereditary spherocytosis (HS); (2) hereditary elliptocytosis (HE), hereditary pyropoikilocytosis (HPP), and related disorders; (3) Southeast Asian ovalocytosis (SAO); (4) hereditary and acquired acanthocytosis; and (5) hereditary and acquired stomatocytosis (Tables 45.1 and 45.2).

VERTICAL AND HORIZONTAL INTERACTIONS OF MEMBRANE PROTEINS AND DISORDERS OF RED BLOOD CELL SHAPE

For better understanding of the pathobiology of membrane disorders, membrane protein-protein and protein-lipid interactions are classified in two categories, vertical and horizontal interactions. Vertical interactions, which are perpendicular to the plane of the membrane, stabilize the lipid bilayer. These interactions include spectrin-ankyrin–band 3 interactions, spectrin-protein 4.1R–junctional complex proteins linkage, spectrin-ankyrin–Rh multiprotein complex linkage, and the weak interactions between the skeletal proteins and the negatively charged lipids of the inner half of the membrane lipid bilayer. Horizontal interactions, which are parallel to the plane of the membrane, support the structural integrity of erythrocytes after their exposure to shear stress. Horizontal interactions involve the spectrin heterodimer association site, where spectrin heterodimers assemble into tetramers, the principal building blocks of the membrane skeleton, and the contacts of the distal ends of spectrin heterodimers with actin and protein 4.1R within the junctional complex. Although interactions between proteins of the erythrocyte membrane are significantly more complex than can be classified by horizontal and vertical interactions, the model serves as a useful starting place for understanding erythrocyte membrane protein interactions, particularly in reference to membrane-related disorders.

According to the vertical/horizontal model, HS is considered a disorder of vertical interactions. Although the primary molecular defects in HS are heterogeneous (including deficiencies or dysfunctions of α - and β -spectrin, ankyrin, band 3, and protein 4.2), one common feature of HS RBCs is a weakening of the vertical contacts between the skeleton and the overlying lipid bilayer membrane together with its integral proteins. Consequently, the lipid bilayer membrane is destabilized, leading to release of bilayer lipids from the cells in the form of skeleton-free lipid vesicles. This lipid loss, in turn, results in membrane surface area deficiency and spherocytosis.

In most patients with HE and the related disorder HPP (see [Hereditary Elliptocytosis and Related Disorders](#)), the principal lesion involves horizontal membrane-protein associations, primarily spectrin dimer-dimer interactions. In a subset of HE patients with a deficiency or a dysfunction of protein 4.1R or glycophorin C (GPC), the

horizontal defect resides in the junctional complex, where the distal ends of spectrin tetramers connect to actin, in conjunction with protein 4.1R. In patients with severely dysfunctional spectrin mutations, the weakened spectrin dimer-dimer self-association disrupts the skeletal lattice, leading to a marked skeletal instability and cell fragments. In patients with mildly dysfunctional spectrins, RBC shape is that of biconcave elliptocytes. It is speculated that elliptocytes are permanently deformed cells because the weakened horizontal interactions facilitate a shear stress-induced rearrangement of skeletal proteins, precluding recovery of the normal biconcave shape. This hypothesis is not applicable to all forms of elliptocytosis. For example, in SAO, the elliptocytic/ovalocytic cells containing mutant band 3 protein are rigid and “hyperstable” rather than unstable.

Acanthocytosis, Stomatocytosis, and the Bilayer Couple Hypothesis

The mechanism of acanthocytosis and stomatocytosis associated with defects of membrane proteins is much less clear. Most forms of acanthocytosis are associated with either acquired or inherited abnormalities of membrane lipids (e.g., acanthocytosis in end-stage liver disease or abetalipoproteinemia). In rare cases with acanthocytosis, membrane protein abnormalities have been detected, but the associated mechanisms leading to acanthocyte formation are unknown. These abnormalities occur in the McLeod phenotype, the chorea-acanthocytosis syndrome, and other rare disorders. In acanthocytosis erythrocytes, agents that interact with the lipids of the inner lipid bilayer leaflet normalize the shape. These studies suggest that the shape abnormalities reflect an asymmetry in the distribution of membrane lipids between the two halves of the RBC lipid bilayer as predicted by the bilayer couple hypothesis. According to the bilayer hypothesis, the shape of the RBC reflects the ratio of the surface areas of the two hemileaflets of the bilayer. The preferential expansion of the outer leaflet leads to RBC crenation (echinocytosis or acanthocytosis), whereas expansion of the inner lipid bilayer produces a cup shape (stomatocytosis) and surface invaginations.

Hereditary Spherocytosis

Introduction and Epidemiology

The typical features of HS include a dominantly inherited hemolytic anemia of mild to moderate severity, spherocytosis on the peripheral blood film, and a favorable response to splenectomy. The clinical spectrum of HS is variable and includes both mild and asymptomatic forms, as well as severe forms that appear in infancy. The previously reported HS prevalence in Western populations of 1 in 4000 persons is an underestimation, because milder forms of HS might be asymptomatic, suggesting a prevalence of 1 in 2000 individuals. HS has been reported worldwide, particularly in Japanese and African populations, but its prevalence in other ethnic groups is unknown.

Pathobiology

Two major factors are involved in HS pathophysiology: (1) an intrinsic RBC defect and (2) an intact spleen that selectively retains

Fig. 45.1 A SIMPLIFIED CROSS-SECTION OF THE ERYTHROCYTE MEMBRANE. The lipid bilayer forms the equator of the cross-section with its polar heads (*small circles*) turned outward. 4.1R, Protein 4.1R; 4.2, protein 4.2; Rh, Rhesus polypeptide; RhAG, Rh-associated glycoprotein; LW, Landsteiner-Wiener glycoprotein. and damages abnormal HS erythrocytes. An inherited deficiency or dysfunction of proteins of the erythrocyte membrane leads to a multistep process of accelerated HS RBC destruction. Destabilization of the lipid bilayer facilitates a release of lipids from the membrane, leading to surface area deficiency and formation of poorly deformable spherocytes that are selectively retained and damaged in the spleen.

Molecular Pathology

The molecular basis of HS is heterogeneous. Based on densitometric quantitation of membrane proteins separated by polyacrylamide gel electrophoresis, HS can be divided into the following subsets: (1) isolated deficiency of spectrin, (2) combined deficiencies of spectrin and ankyrin, (3) deficiency of band 3 protein, (4) deficiency of protein 4.2, and (5) no abnormality identified.

Isolated Spectrin Deficiency

The reported mutations of isolated spectrin deficiency include defects of both α - and β -spectrin. Mutations of the β -spectrin gene have been identified in a number of patients with dominantly inherited HS associated with spectrin deficiency. A few cases have been associated with de novo β -spectrin gene mutations. With a few exceptions, these mutations are private and may be associated with decreased β -spectrin messenger ribonucleic acid (mRNA) accumulation. Mutations in the highly conserved region of β -spectrin involved in the interaction with protein 4.1R likely lead to dysfunctional binding to protein 4.1R and thereby the linkage of spectrin to actin.

In nondominantly inherited HS associated with isolated spectrin deficiency, the defect involves α -spectrin. In normal erythroid cells, α -spectrin is synthesized in large excess of β -spectrin. Thus patients with one normal and one defective α -spectrin allele are asymptomatic, because α -spectrin production remains in excess of β -spectrin synthesis, allowing normal amounts of spectrin heterodimers to be assembled on the membrane. Patients who are homozygotes or compound heterozygotes for α -spectrin defects suffer from moderate to severe HS.

Combined Deficiency of Spectrin and Ankyrin

The biochemical phenotype of combined spectrin and ankyrin deficiency is the most common abnormality found in the erythrocytes of HS patients. Ankyrin represents the principal binding site for

**TABLE
45.2****Peripheral Blood Film Evaluation in a Patient With Red Cell Membrane Disorder**

Shape	Pathobiology	Diagnosis
Microspherocytes	Loss of membrane lipids leading to a reduction of surface area resulting from deficiencies of spectrin, ankyrin, or band 3 and protein 4.2 Removal of membrane material from antibody-coated red cells by macrophages Removal of membrane-associated Heinz bodies, with the adjacent membrane lipids, by the spleen	HS Immuno-hemolytic anemias Heinz body hemolytic anemias
Elliptocytes	Permanent red cell deformation resulting from a weakening of skeletal protein interactions (such as the spectrin dimer-dimer contact). This facilitates disruption of existing protein contacts during shear stress-induced elliptical deformation. Subsequently, new protein contacts are formed that stabilize elliptical shape Unknown	Mild common HE Iron deficiency, megaloblastic anemias, myelofibrosis, myelophthitic anemias, myelodysplastic syndrome, thalassemias
Poikilocytes/fragments	Weakening of skeletal protein contacts resulting from skeletal protein mutations Unknown	Hemolytic HE/HPP Iron deficiency, megaloblastic anemias, myelofibrosis, myelophthitic anemias, myelodysplastic syndrome, thalassemias
Schistocytes, fragmented red cells	Red cells “torn” by mechanic trauma (fibrin strands, turbulent flow)	“Microangiopathic” hemolytic anemia associated with disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, vasculitis, heart valve prostheses
Acanthocytes	Uptake of cholesterol and its preferential accumulation in the outer leaflet of the lipid bilayer Selective accumulation of sphingomyelin in the outer lipid leaflet Unknown	Spur cell hemolytic anemia in severe liver disease Abetalipoproteinemia Chorea-acanthocytosis syndrome, malnutrition, hypothyroidism, McLeod phenotype
Echinocytes	Expansion of the surface area of the outer hemileaflet of lipid bilayer relative to the inner hemileaflet Unknown	Hemolytic anemia associated with hypomagnesemia and hypophosphatemia in malnourished patients, pyruvate kinase deficiency; in vitro artifact of low blood storage (ATP depletion), contact with glass or elevated pH Hemolysis in long-distance runners, renal failure
Stomatocytes	Expansion of the surface area of the inner hemileaflet of the bilayer relative to the outer leaflet Unknown	Exposure of red cells to cationic anesthetics in vitro; in vivo the drug concentrations may not be sufficient to produce similar effect Alcoholism, inherited disorders of membrane permeability (hereditary stomatocytosis)
Target cells	Absolute excess of membrane lipids (both cholesterol and phospholipids: “symmetric” lipid gain), followed by an increase of cell surface area Relative excess of surface area because of a decrease in cell volume	Obstructive jaundice, liver disease with intrahepatic cholestasis Thalassemias and some hemoglobinopathies (C, D, E)

ATP, Adenosine triphosphate; HE, hereditary elliptocytosis; HPP, hereditary pyropoikilocytosis; HS, hereditary spherocytosis.

spectrin on the membrane; thus it is not surprising that ankyrin deficiency is accompanied by a proportional decrease in spectrin assembly on the membrane despite normal spectrin synthesis. Similar to HS associated with β -spectrin mutations, most ankyrin defects are private point mutations associated with decreased mRNA accumulation. In some cases, mutations of the ankyrin promoter leading to decreased ankyrin expression have been found. Approximately 15% to 20% of ankyrin gene mutations reported are de novo mutations.

A number of patients with atypical HS associated with karyotypic abnormalities involving deletions or translocations of the ankyrin gene locus on chromosome 8p have been described. Ankyrin deletions may be part of a contiguous gene syndrome with manifestations of spherocytosis, mental retardation, typical facies, and hypogonadism.

Deficiency of Band 3 Protein

Deficiency of band 3 protein is found in a subset of HS patients who present with a phenotype of a mild to moderate dominantly inherited HS. Most, if not all, of these patients also have concomitant protein 4.2 deficiency. Numerous band 3 mutations associated with HS have been reported, spread throughout both the cytoplasmic and the membrane-spanning domains.

A number of band 3 mutations clustered in the membrane-spanning domain that replace highly conserved arginines have been described. These arginines, which are all located at the cytoplasmic end of a predicted transmembrane helix, exhibit defective cellular trafficking from the endoplasmic reticulum to the plasma membrane.

Fig. 45.2 PATHOPHYSIOLOGY OF HEREDITARY SPHEROCYTOSIS. The primary defect in hereditary spherocytosis is a deficiency of membrane surface area. Decreased surface area may be produced by two different mechanisms: (1) Defects of spectrin, ankyrin, or protein 4.2 lead to reduced density of the membrane skeleton, destabilizing the overlying lipid bilayer and releasing band 3-containing microvesicles. (2) Defects of band 3 lead to band 3 deficiency and loss of its lipid-stabilizing effect. This results in the loss of band 3-free microvesicles. Both pathways result in membrane loss, decreased surface area, and formation of spherocytes with decreased deformability. These deformed erythrocytes become trapped in the hostile environment of the spleen where splenic conditioning inflicts further membrane damage, amplifying the cycle of red cell membrane injury.

Alleles have been identified that influence band 3 expression and that, when inherited in trans to a band 3 mutation, aggravate band 3 deficiency and worsen the clinical severity of the disease.

Deficiency of Protein 4.2

Recessively inherited HS caused by mutations in protein 4.2 is relatively common in Japan. In these cases, an almost total absence of protein 4.2 from the erythrocyte membranes of homozygous patients is detected. Protein 4.2-deficient erythrocytes can also have a decreased content of ankyrin and band 3. Protein 4.2 deficiency also occurs in association with band 3 mutations, probably as a result of abnormal binding of protein 4.2 to the cytoplasmic domain of band 3.

Detailed listing of HS mutations is available in mutation databases maintained by the National Human Genome Research Institute and Yale University (<http://research.nhgri.nih.gov/RBCmembrane/>) and the Human Gene Mutation Database (HGMD®, <http://www.hgmd.org>).

Molecular Basis of Surface Area Deficiency

Hereditary spherocytes are intrinsically unstable, releasing lipids under a variety of in vitro conditions, including adenosine triphosphate (ATP) depletion or exposure of cells to shear stress. The loss of membrane material occurs through the release of vesicles containing integral proteins devoid of spectrin. During in vitro incubation, the loss of membrane material is sufficient to augment the surface area deficiency, as evidenced by increased osmotic fragility of the cells after incubation. It is assumed but not proved that a similar process takes place in vivo.

The molecular basis of HS is heterogeneous; thus it is likely that surface area deficiency is a consequence of several distinct molecular mechanisms whose common denominator is either a weakening of the vertical connections between the skeleton and the lipid bilayer membrane or a weakening of the stabilizing effect of transmembrane

proteins on adjacent lipid molecules of the plasma membrane. Hypothetic pathways that can lead to surface area deficiency are depicted in Fig. 45.2. In patients with isolated spectrin deficiency or a combined deficiency of spectrin and ankyrin, the loss of RBC surface may be caused by an uncoupling of the lipid bilayer membrane from the underlying skeleton. In normal RBCs, the skeleton forms a nearly monomolecular submembrane layer occupying more than one-half of the inner surface of the membrane. Consequently, spectrin deficiency leads to a decreased density of this network. As a result, areas of the lipid bilayer membrane that are not directly supported by the skeleton are susceptible to release from the cells in the form of microvesicles.

In HS associated with a deficiency of band 3 protein, two hypothetical pathways may lead to a loss of surface area. One mechanism may involve a loss of band 3 protein from the cells. Because band 3 protein spans the lipid bilayer membrane many times, it is likely that a substantial amount of “boundary” lipids are released together with the band 3 protein, thus leading to surface area deficiency. Another possible mechanism may involve a formation of band 3-free domains in the membrane, followed by the formation of membrane blebs, which are subsequently released from the cells as microvesicles. Such a hypothesis is based on the observation that aggregation of intramembrane particles (composed principally of band 3) in ghosts leads to the formation of particle-depleted domains from which membrane lipids bleb off as microvesicles. Additional evidence supporting the latter model comes from the band 3 knock-out mouse model and from human, cow, and zebrafish cases of complete band 3 deficiency. Erythrocytes lacking band 3 spontaneously shed membrane vesicles, leading to spherocytosis and hemolysis.

Alterations in Cation Content and Permeability

HS RBCs, particularly those collected from the spleen, are somewhat dehydrated and abnormally permeable to monovalent cations, presumably as a consequence of the underlying membrane defect. The cellular dehydration may be caused by activation of pathways causing a selective loss of potassium and water or a hyperactive Na^+/K^+ pump.

Entrapment of Nondeformable Spherocytes in the Spleen

The importance of the spleen in the pathophysiology of hemolysis in HS was appreciated in the original description of the disease and has been substantiated by subsequent studies. HS cells are selectively destroyed in the spleen because of their poor deformability and because of the unique anatomy of the splenic vasculature that acts as a microcirculation filter.

The poor RBC deformability is principally a consequence of a decreased cell surface/cell volume ratio resulting from the loss of surface material. Normal discocytes have an excess surface, which allows them to deform and pass through narrow microcirculation openings. In contrast, HS RBCs lack this extra surface, and their poor deformability may be further impaired by cellular dehydration.

The principal sites of RBC entrapment in the spleen are fenestrations in the wall of splenic sinuses, where blood from the splenic cords of the red pulp enters the venous circulation. In rat spleen, the length and width of these fenestrations, 2 to 3 μm and 0.2 to 0.5 μm , respectively, are approximately half the RBC diameter. Electron micrographs show that very few HS RBCs traverse these slits. Consequently, the nondeformable spherocytes accumulate in the red pulp, which becomes grossly engorged.

Splenic Conditioning and Destruction

Once trapped in the spleen, HS erythrocytes undergo additional damage or conditioning with further loss of surface area and an increase in cell density, as is evident in cells removed from the spleen at splenectomy. Some of these conditioned RBCs reenter the systemic circulation, as revealed by the “tail” of the osmotic fragility curve, indicating the presence of a subpopulation of cells with a markedly reduced surface area. After splenectomy, this RBC population disappears.

Contributions to conditioning may include a relatively low pH in the spleen as well as in the sequestered RBCs that may further compromise the poor HS RBC deformability, and contact of RBCs with macrophages that may inflict additional damage on the RBC membrane. The conditioning effect of the spleen appears to represent a cumulative injury. The average residence time of HS RBCs in the splenic cords is between 10 and 100 minutes compared with 30 to 40 seconds for normal RBCs, and only 1% to 10% of blood entering the spleen is temporarily sequestered in the congested cords, whereas the remaining 90% of blood flow is rapidly shunted into the venous circulation.

Inheritance

The HS genes are assigned to several chromosomes, including chromosome 1 (α -spectrin), chromosome 8 (ankyrin), chromosome 14 (β -spectrin), chromosome 15 (protein 4.2), and chromosome 17 (band 3). In approximately two-thirds of HS patients, inheritance is autosomal dominant. In the remaining patients, inheritance is non-dominant. In many of these patients, HS is caused by a de novo mutation, which is inherited in an autosomal recessive fashion in subsequent generations. Recessively inherited HS cases manifesting with severe hemolytic anemia have been reported. The majority of the affected patients were found to be severely deficient in RBC spectrin, associated with α -spectrin defects. The remaining cases characterized by a recessive inheritance pattern are caused by a defect in protein 4.2, a deficiency that is associated with relatively mild hemolysis.

Only a few cases of homozygous HS have been reported. These patients have a severe hemolytic anemia, whereas their mostly consanguineous parents have a mild to moderate form of the disease or are asymptomatic.

Although the clinical severity of HS is highly variable among different kindred, in general it is relatively uniform within a given family, in which HS is typically inherited as an autosomal dominant disorder. However, HS kindred have been described in which there was great variability in the clinical severity of affected family members. Several explanations might account for these observations, including variable penetrance of the genetic defect, a de novo mutation, presence of a mild recessive HS in the kindred, presence of a modifier allele that influences the expression of a membrane protein, or a tissue-specific mosaicism of the defect.

Clinical Manifestations

Typical Forms

The typical HS patient is relatively asymptomatic. As noted in the earliest descriptions of HS, mild jaundice can be the only symptom of the disease. Anemia is usually mild to moderate but may be absent because of compensatory bone marrow hyperplasia manifest by reticulocytosis. Splenomegaly gradually develops in most patients, with the spleen occasionally reaching large dimensions.

Mild Forms and Carrier State

In some families, anemia is absent, the reticulocyte count is normal or only minimally elevated, laboratory evidence of hemolysis is minimal or absent, and the changes in RBC shape can be mild, escaping detection on the peripheral blood film. The presence of HS is detected only by laboratory testing or during evaluation of a relative with a more symptomatic form of the disease. Some patients are first diagnosed during transient viral infections such as infectious mononucleosis or parvovirus infection, during pregnancy, or even in the 7th to 9th decades of life as the bone marrow's ability to compensate for hemolysis wanes.

Severe and Atypical Forms

The relatively uncommon patients with nondominant forms of HS can present with a severe life-threatening hemolysis early in life. Some patients can be transfusion dependent during early infancy and childhood. The underlying molecular defects include severe spectrin or band 3 deficiency.

Hereditary Spherocytosis and Nonerythroid Manifestations

In most HS cases, the clinical manifestations are confined to the erythroid lineage, probably because many of the nonerythroid counterparts of the RBC membrane proteins (e.g., spectrin and ankyrin) are encoded by separate genes or because some proteins (e.g., protein 4.1R, β -spectrin, ankyrin) are subject to tissue-specific alternative splicing. However, several HS kindred have been reported with a cosegregating neurologic or muscular abnormality, such as a degenerative disorder of the spinal cord, cardiomyopathy, or mental retardation. The observation that both erythrocyte ankyrin and β -spectrin are also expressed in muscles and the brain, particularly the cerebellum, and spinal cord raises the possibility that these HS patients may have a defect in one of these proteins. This hypothesis is further supported by studies of *nb/nb* mice, a mouse model of HS caused by an ankyrin mutation. These mice develop a neurologic syndrome with a progression that coincides with the loss of ankyrin from the Purkinje cells of the cerebellum.

Mutations of band 3 without HS have been described in patients with distal renal tubular acidosis. With a few rare exceptions, most patients with heterozygous mutations of band 3 and HS have normal renal acidification.

Laboratory Manifestations

Most HS patients have mild to moderate anemia or no anemia at all, reflecting the fact that the hemolytic rate can be very mild and that the hemolysis is fully compensated for by increased RBC production, as evidenced by reticulocytosis. Some patients, however, particularly those with nondominantly inherited HS, are severely anemic, with hemoglobin concentrations as low as 4 to 6 g/dL.

Despite the increased percentage of reticulocytes with a larger volume than mature RBCs, the mean corpuscular volume (MCV) of HS RBCs is often low normal or even slightly decreased, and the mean corpuscular hemoglobin concentration (MCHC) is usually increased (>35 g/dL), together reflecting mild cellular dehydration.

The finding of an MCHC greater than 35.4 g/dL combined with an RBC distribution width (RDW) $<14\%$ has been found to be an excellent screening test for HS. Another screening method measures MCV by light scattering and provides a histogram of hyperdense erythrocytes (MCHC >40 g/dL) claimed to identify nearly all HS patients. These hyperdense erythrocytes can be detected with newer laser-based blood counters or using aperture impedance analysis available in many clinical laboratories.

Evidence of accelerated RBC destruction, as indicated by increased lactate dehydrogenase and unconjugated bilirubin levels and by decreased haptoglobin, as well as by reticulocytosis, is present in typical HS patients. However, these abnormalities can be absent in individuals with a mild form of the disease.

Blood Film

In a typical case of HS, spherocytes are readily identified by their characteristic shape on the peripheral blood film (Fig. 45.3). They lack central pallor, their mean cell diameter is decreased, and they appear more intensely hemoglobinized, which reflects both altered RBC geometry and increased cell density. In a three-dimensional view, some spherocytes have a spherostomatocytic shape that is occasionally appreciated on the peripheral blood film. In mild forms of the disease, the peripheral blood smear can appear normal because the loss of surface area can be too small to be appreciated by blood

smear evaluation; the cells appear as “fat” disks rather than as true spherocytes.

Additional morphologic features have been described in some HS patients (see Fig. 45.3). A subset of HS patients whose RBCs are deficient in band 3 protein have some pincer-like RBCs on the peripheral blood film, a finding that is both sensitive and specific for this HS subset. These pincer-like cells disappear after splenectomy. Surface spiculations or acanthocytic spherocytes have been described in cases of HS associated with defects in β -spectrin. Frequent sphero-ovalocytes and stomatocytes have been reported in Japanese patients with protein 4.2 deficiency.

Osmotic Fragility and Eosin-5'-Maleimide Binding

Both osmotic fragility (OF) testing and eosin-5'-maleimide (EMA) binding are used in evaluating HS patients.

The osmotic fragility test (Fig. 45.4) measures the *in vitro* lysis of RBCs suspended in solutions of decreasing osmolarity. The normal RBC membrane is unstretchable and is virtually freely permeable to water. Thus the cell behaves as a nearly perfect osmometer in that it increases its volume in hypotonic solutions progressively until a “critical hemolytic volume” is reached. At this point, the RBC membrane ruptures, and hemoglobin escapes into the supernatant solution. As a result of the loss of membrane and the ensuing surface area deficiency, the critical hemolytic volume of spherocytes is considerably lower than that of normal RBCs. Consequently, these cells hemolyze more than normal RBCs when suspended in hypotonic sodium chloride solutions. However, a finding of increased osmotic fragility is not unique to HS and is also present in other conditions associated with spherocytosis on the peripheral blood film, such as autoimmune hemolytic anemia.

The osmotic fragility curve often reveals uniformly increased osmotic fragility. A “tail” of the osmotic fragility curve can be present in nonsplenectomized HS patients, indicating a subpopulation of particularly fragile RBCs conditioned by splenic stasis. This subpopulation of cells disappears after splenectomy. In patients with mild HS, osmotic fragility can be normal and abnormalities can be found only after incubation that further augments the loss of surface area;

Fig. 45.3 BLOOD FILMS FROM PATIENTS WITH HEREDITARY SPHEROCYTOSIS (HS) OF VARYING SEVERITY. (A) Two blood films of typical moderately severe HS with a mild deficiency of RBC spectrin and ankyrin. Although many cells have a spheroidal shape, some retain a central concavity. (B) HS with pincer-like RBCs (arrows), as typically seen in HS associated with band 3 deficiency. Occasional spiculated RBCs are also present. (C) Severe atypical HS caused by a severe combined spectrin and ankyrin deficiency. In addition to spherocytes, many cells have irregular contour. (D) HS with isolated spectrin deficiency caused by a β -spectrin mutation. Some of the spherocytes have prominent surface projections resembling sphero-acanthocytes.

Fig. 45.4 TESTING IN HEREDITARY SPHEROCYTOSIS (HS). (*Top*) Eosin-5-maleimide (EMA) binding. EMA binding, a flow cytometric test that measures the fluorescence intensity of intact RBCs labeled with the dye eosin-5'-maleimide that reacts with membrane band 3 protein, has been shown to be useful as a first-line test for the diagnosis of hereditary spherocytosis. Histogram of fluorescence of EMA-labeled erythrocytes from normal controls (*red*) and a patient with typical hereditary spherocytosis (*blue*). Decreased fluorescence is observed from HS erythrocytes. (*Bottom*) Osmotic fragility curves in hereditary spherocytosis. The shaded region is the normal range. Results representative of both typical and severe spherocytosis are shown. A tail, representing fragile erythrocytes conditioned by the spleen, is common in spherocytosis patients before splenectomy. (Reproduced with permission from Gallagher PG: *Abnormalities of the erythrocyte membrane*. Ped Clin N Am 60:1349, 2013.)

however, the sensitivity of the incubated osmotic fragility test can be outweighed by a loss of its specificity. The relative contributions of cell dehydration and surface area deficiency can be accurately determined by osmotic gradient ektacytometry, available in specialized laboratories.

OF testing is unreliable in patients who have small numbers of spherocytes, including those who have been recently transfused, and it is abnormal in other conditions where spherocytes are present.

The binding of EMA to band 3 and Rh-related proteins with a 1:1 stoichiometry in the erythrocyte membrane is the basis for the EMA binding test. After binding of fluorescently labeled EMA to erythrocyte membranes, the relative amount of fluorescence, reflect-

ing the amount of EMA binding, is analyzed by flow cytometry. The intensity of EMA binding is decreased in HS erythrocytes (Fig. 45.4). Although defects of band 3 protein are only found in ~25% of typical HS patients, decreased EMA fluorescence is also observed in HS erythrocytes with primary defects in ankyrin and spectrin, thought to be caused by transmission of long range effects of varying protein defects across the membrane, influencing EMA binding. EMA binding has high sensitivity and specificity. In laboratories with the ability to perform fluorescence-activated cell sorting-based studies, it is simple and rapidly performed, even on samples after shipment or storage.

Like osmotic fragility, EMA binding struggles in the diagnosis of mild HS where results may be normal or indeterminate. Other erythrocyte abnormalities such as defects of erythrocyte hydration and variants of dyserythropoietic anemia can also yield abnormal results.

Autohemolysis and Other Tests

RBC autohemolysis, the spontaneous hemolysis of RBCs incubated under sterile conditions without glucose, was previously advocated as a sensitive test for the detection of HS. This test is being used less frequently and is probably no more sensitive than the incubated osmotic fragility test. Other tests described in the literature such as the glycerol lysis test, the pink test, hypertonic cryohemolysis, and the skeleton gelation test are infrequently performed in diagnostic laboratories in the United States. The former two tests, which use glycerol to retard the osmotic swelling of RBCs, are preferred by some laboratories because they are easy to perform and can be adapted to microsamples. Cryohemolysis testing in particular remains popular in Europe.

Detection of the Underlying Molecular Defect

Because the most common finding in erythrocytes of patients with HS is a deficiency of one or more of the membrane proteins, molecular studies often include sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) solubilized RBC membrane proteins followed by densitometric quantitation. The results are expressed as ratios of individual red cell membrane proteins to band 3. This technique reveals abnormalities in approximately 70% to 80% of patients, defining the distinct biochemical phenotypes discussed previously. Direct quantitation of membrane proteins by radioimmunoassay is superior to densitometric quantitation and permits accurate measurement of the copy number of the individual proteins per RBC.

Application of molecular genetic analyses including DNA sequencing and other molecular studies complement clinical and laboratory screening and provide definitive diagnosis in most cases. Mutation detection in the major erythrocyte membrane protein genes is now available commercially in the United States. Gene-based studies are of use in diagnosing difficult cases and in cases in which a molecular diagnosis is desired. Molecular analyses have potential pitfalls. In some cases, variants of unknown significance are detected, making genetic diagnosis uncertain. Mutations not detected by study of coding regions and splice junctions may be causative, such as in distant regulatory elements, deep intronic splicing mutations, and intragenic deletions. In these cases, diagnosis is assigned based on clinical, laboratory, and biochemical findings.

Complications

Gallstones

Bilirubin stones are found in approximately 50% of patients with HS, often even in those with a very mild form of the disease. Gallstones have occasionally been detected during infancy, but they are

most likely to occur in older children and young adults. The coinheritance of Gilbert syndrome increases the risk for gallstones in HS patients. Because of the high incidence of gallstones, HS patients should be periodically examined by ultrasonography for the presence of gallstones, beginning in childhood.

Crises

True hemolytic crises are relatively rare and only occasionally reported in association with infections. Aplastic crises during viral infections are largely attributable to infection by parvovirus B19. This infection (erythema infectiosum, fifth disease) manifests with fever, chills, lethargy, malaise, nausea, vomiting, abdominal pain with occasional diarrhea, respiratory symptoms, muscle and joint pains, and a maculopapular rash on the face (slapped cheek appearance), trunk, and extremities. The virus selectively infects erythroid precursors and inhibits their growth. The ensuing anemia, often profound, can be the first manifestation of HS. Multiple family members with undiagnosed HS who are infected with parvovirus have developed aplastic crises at the same time. Infection with parvovirus is a particular danger to susceptible pregnant women because it can infect the fetus, leading to fetal anemia, hydrops fetalis, and fetal demise.

Rarely, at least in developed countries, patients present with megaloblastic crises caused by folate deficiency. This typically occurs in patients with increased folate demands, such as those recovering from an aplastic crisis, pregnant women, and older adults. Megaloblastic crisis in pregnancy has been reported as the first manifestation of HS. Folate supplementation is recommended for patients with moderate to severe HS.

Other Complications

In patients with more severe forms of HS, other complications include gout, leg ulcers, or chronic dermatitis of the legs that heal after splenectomy. Symptoms of expanded erythroid space, including paravertebral or renal pelvic masses of extramedullary hematopoiesis, which can mimic an underlying neoplasm, may occur. Several cases of hemochromatosis in HS patients have been reported. In some, iron overload resulted from repeated transfusions; in others, the patients had two genetic defects, one involving HS and the other involving a hemochromatosis carrier state. Other rare complications include thrombosis, pulmonary hypertension, spinocerebellar degenerative syndromes, movement disorders, myopathy, and hypertrophic cardiomyopathy.

More than a dozen cases of HS and hematologic malignancy, including myeloproliferative disorders, multiple myeloma, and leukemia, have been reported. It is unknown if long-standing hematopoietic stress predisposes to the development of these secondary disorders or if they occurred randomly.

DIFFERENTIAL DIAGNOSIS

Because of the relatively asymptomatic presentation of HS, this diagnosis should be considered during an evaluation for unexplained splenomegaly, unconjugated hyperbilirubinemia of unknown cause, gallstones at a young age, severe anemia during pregnancy, or transient anemia during acute infections. The diagnosis of HS can be missed in mild forms of the disease, because spherocytosis might not be apparent on the peripheral blood film. Autoimmune hemolytic anemia should be ruled out by negative results of a Coombs test.

More typical forms of HS, characterized by relatively uniform spherocytosis with increased MCHC, are usually easily distinguished from other disorders manifesting with spherocytosis, such as immune hemolytic anemias and unstable hemoglobins. In some patients, the spherostomatocytes in the rare Rh-null syndrome and the intermediate syndromes of hereditary stomatocytosis can be confused with HS RBCs.

Spherocytosis is transiently improved, and both the osmotic fragility and hemolysis are normalized in patients with obstructive jaundice. This is because of an expansion of RBC surface area that follows an increased uptake of phospholipids and cholesterol from the abnormal plasma lipoproteins. In normal RBCs, this leads to target cell formation; in HS, spherocytes are transformed to discocytes. Spherocytosis and the increased osmotic fragility of HS red cells are likewise improved by iron deficiency, but the RBC life span remains shortened. In addition, coexistence of β -thalassemia trait and HS partially corrects the HS phenotype.

THERAPY AND PROGNOSIS

Splenectomy

Splenectomy is curative in almost all patients with typical forms of HS, because RBC survival is normalized, and anemia and hyperbilirubinemia are corrected. Spherocytosis and the increase in osmotic fragility persist, but the tail of the osmotic fragility curve, indicating the presence of a subpopulation of cells conditioned by the spleen, disappears. In patients with severe, nondominantly inherited HS, splenectomy produces a dramatic clinical improvement, but hemolysis is only partially corrected.

Several weeks to months before splenectomy, patients should be immunized with polyvalent vaccine against pneumococcus as well as vaccines against *Haemophilus influenzae* type b and meningococcus.

Indications for Splenectomy

Risks and benefits should be considered carefully in HS patients before splenectomy is performed (see box on [Splenectomy for Hereditary Spherocytosis](#)). A multitude of factors influence the decision for splenectomy in HS patients, including the risk for overwhelming postsplenectomy sepsis, the emergence of penicillin-resistant pneumococci, and the potentially increased risk for cardiovascular disease and pulmonary hypertension later in life. Indications for splenectomy include growth retardation, skeletal changes, symptomatic hemolytic disease, anemia-induced compromise of vital organs, the development of leg ulcers, or the appearance of extramedullary hematopoietic tumors. Whether to perform splenectomy in patients with moderate HS without any of these factors remains controversial.

Because of an increased frequency of postsplenectomy infection in young children, most practitioners avoid splenectomy in infancy and early childhood.

Operative Considerations

When splenectomy is warranted, laparoscopic splenectomy has become the procedure of choice in many centers. Laparoscopic splenectomy has been associated with less postoperative discomfort, a quicker return to preoperative diet and activities, a shorter hospitalization time, decreased costs, and smaller scars. Early complications of splenectomy include local infection, bleeding, and pancreatitis. In general, the morbidity rate of splenectomy is lower in patients with HS than with other hematologic diseases. However, the benefits of surgery must be weighed against possible complications, such as postsplenectomy infections. Although these complications are rare and their frequency is likely to diminish further with appropriate vaccinations, the indiscriminate performance of splenectomy in all HS patients with splenomegaly is unwarranted.

Subtotal (Partial) Splenectomy

Partial splenectomy was developed for infants and young children with severe HS, anemia, and poor growth with the goals of palliating anemia and decreasing transfusion requirements while preserving splenic function. More recently, some have advocated expanding the procedure to all patients being splenectomized for HS. The goal of the operation is to decrease hemolysis while maintaining

Splenectomy for Hereditary Spherocytosis

Splenectomy is a permanently curative treatment in most cases of HS. Thus for years, splenectomy was recommended for all HS patients regardless of the severity of anemia, gallbladder disease, or other symptoms. However, increasing concerns regarding overwhelming postsplenectomy infection (OPSI), the emergence of penicillin-resistant pneumococci, and increased risk for cardiovascular diseases have tempered these recommendations. When considering splenectomy, health care providers, the patient, and the patient's family should review and consider the risks and benefits. Individual factors that may pose additional risk, such as distance from medical care in case of febrile illness and residence in or travel to areas where parasitic diseases such as malaria or babesiosis occur, should be considered. Expert opinions vary on indications for splenectomy. There are no studies to guide practice. However, because the risk for OPSI is highest in infancy and childhood, most agree it is best to avoid total splenectomy in early childhood.

Benefits

- Anemia ameliorated
- Risk for hemolysis-associated gallbladder disease eliminated
- Risk for aplastic crisis eliminated

Risks

- OPSI—especially with encapsulated organisms (*Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae*)
- Increased risk for thrombotic complications
- Increased risk for vascular complications (pulmonary hypertension, cardiovascular disease)

Indications for Splenectomy

- Expert opinions vary
- Severe, symptomatic spherocytosis
- Growth failure, skeletal changes, leg ulcers, and extramedullary hematopoietic tumors (signs of severe anemia)
- Older patients with vascular compromise of vital organs
- Moderate HS with compensated, asymptomatic anemia: controversial; decision should be individualized

splenic phagocytic function. In initial cohorts of patients treated with partial splenectomy, stable increases in hemoglobin levels with decreased reticulocyte counts have been observed. The volume of splenic tissue left behind ranges from 10 mL to 30 mL. Although initial data are promising, it is not clear whether the remaining splenic tissue will effectively prevent postsplenectomy sepsis. In addition, regrowth of the splenic remnant has been reported in many patients, which can eventually lead to recurrence of HS and another operative procedure.

There are no specific data to support the use of prophylactic antibiotics postsplenectomy. Some practitioners avoid the prescription of prophylactic antibiotics, others recommend prophylactic antibiotics for at least 5 years postsplenectomy, and others recommend their use for life.

Postsplenectomy Failures

Postsplenectomy failures are caused either by the presence of an accessory spleen missed during surgery (accessory spleens were found in 17% to 39% of all patients) or by the presence of another superimposed RBC disorder such as pyruvate kinase deficiency. The recurrence of hemolytic anemia several years after splenectomy should raise the suspicion of development of splenunculi, resulting from autotransplantation of splenic tissue during surgery. The presence of an accessory spleen or splenunculus is suggested by the absence of both Howell-Jolly bodies and the “pitted” cells with crater-like surface indentations readily seen by interference contrast microscopy. A definitive confirmation of splenosis is made by a radiocolloid liver-spleen scan or by a scan using chromium (Cr)-labeled heated RBCs, which are taken up by the ectopic splenic tissue.

Genetic Counseling

After a patient is diagnosed with HS, family members should be examined for the presence of HS. A history, physical examination for splenomegaly, complete blood count with indices, reticulocyte count, examination of the peripheral blood smear for spherocytes, and biochemical evaluation including bilirubin and haptoglobin levels should be obtained for available close relatives.

Future Directions

Advances in high throughput DNA sequencing methodology have greatly facilitated the precise genetic diagnosis in many cases of suspected inherited membrane-associated disorders. Both targeted gene capture and whole exome sequencing have rapidly developed into effective tools for the identification of disease-causing variants in genetic disease, particularly monogenic disorders. Because they can be applied to disorders with recessive or dominant inheritance or de novo occurrence, like HS, they obviate the need for cumbersome biochemical assays and for linkage analysis in large numbers of individuals. As more patients are studied, it is likely that new HS-associated loci will be discovered. Identification of novel mutations will provide insight into the structure and function of associated membrane protein genes, and our understanding of genotype-phenotype relationships, particularly those with variable influence on disease severity, will be extended.

HEREDITARY ELLIPTOCYTOSIS AND RELATED DISORDERS

Introduction and Epidemiology

Hereditary elliptocytosis designates a group of inherited disorders that have in common the presence of elliptical RBCs on peripheral blood films. Elliptocytosis was first described by Dresbach in 1904, and its heritability was firmly established by Hunter. Subsequent reports have revealed a considerable heterogeneity of clinical expression and have defined several distinct syndromes, including HPP and SAO.

Hereditary elliptocytosis is common in people of African and Mediterranean ancestries. In the U.S. population, the prevalence of HE is approximately 3 to 5 per 10,000. The true incidence of HE is unknown because its clinical severity is heterogeneous and most patients are asymptomatic without anemia. HE is considerably more frequent in areas of endemic malaria. In equatorial Africa, the prevalence of common HE has been estimated at between 0.6% and 1.6%. Worldwide, HE appears to be more common among people of African origin. In Southeast Asian populations, the prevalence of SAO, a variant of HE, is as high as 30%.

The molecular basis of HE remained obscure until a defect of membrane skeletal proteins was suggested. Subsequently defects in the erythrocyte membrane proteins α -spectrin, β -spectrin, protein 4.1R, GPC, and band 3 were described.

On the basis of RBC morphologic characteristics, HE can be divided into three major groups. Common HE, a dominantly inherited condition, is morphologically characterized by biconcave elliptocytes and, in some patients, rod-shaped cells. The clinical severity of common HE is highly variable, ranging from an asymptomatic condition to a severe recessively inherited hemolytic anemia, including hemolytic HE and HPP, in which the blood film reveals numerous RBC fragments, microspherocytes, and poikilocytes. Spherocytic HE, also called hemolytic ovalocytosis, is a much less common condition in which both round “fat” ovalocytes and spherocytes are present on the blood film. SAO, a disorder highly prevalent in the malaria belt of Southeast Asia and the Pacific, is characterized by rigid, spoon-shaped cells that have either a longitudinal slit or a transverse ridge.

Pathobiology of Common Hereditary Elliptocytosis

The possibility that the primary lesion of HE and HPP erythrocytes resides in the proteins of the RBC membrane skeleton was first raised by the findings of thermal instability of HPP spectrin, retention of the elliptical shape in HE membrane skeletons, disintegration of membrane skeletons after exposure to shear stress, defective self-association of spectrin dimers to tetramers, altered susceptibility of spectrin to tryptic digestion, and a deficiency of the membrane skeleton proteins spectrin and protein 4.1R. Gene cloning and determination of the primary structure of these proteins was soon followed by reports of mutations in the genes encoding erythrocyte membrane proteins.

Spectrin Mutations

The most common defects in HE, found in approximately two-thirds to three-quarters of all patients, are mutations of α - or β -spectrin. Both α - and β -spectrin are elongated flexible molecules consisting of triple-helical repeats connected by nonhelical segments. These polypeptides are associated side to side in an antiparallel position, forming a flexible, rod-like $\alpha\beta$ heterodimer in which the NH₂-terminal of α -spectrin and the COOH-terminal of β -spectrin form the head region of the heterodimer. Spectrin heterodimers associate head to head to form spectrin tetramers, the major structural subunits of the membrane skeleton. Spectrin tetramers in turn are interconnected into a highly ordered two-dimensional lattice through binding, at their distal ends, to actin oligomers with the aid of protein 4.1R.

The contact site between the α - and β -spectrin chains of the opposed heterodimers is a combined “atypical” triple-helical repetitive segment in which the first two helices are contributed by the COOH-terminal of β -spectrin, whereas helix 3 is the first helical segment of α -spectrin. Spectrin dimer-tetramer interconversion is governed by a simple thermodynamic equilibrium that under physiologic conditions strongly favors spectrin tetramers. Most α -spectrin defects are at or near the NH₂-terminal of α -spectrin, which is involved in the heterodimer contact (the α I domain defined by limited tryptic peptide mapping; see the discussion under Laboratory Manifestations), and impair the self-association of spectrin into tetramers. Most α -spectrin mutations are point mutations. These mutations create abnormal proteolytic cleavage sites that typically reside in the third helix of a repetitive segment and give rise to abnormal tryptic peptides on two-dimensional tryptic peptide maps of spectrin.

Elliptocytogenic β -spectrin mutations are COOH-terminal point mutations or truncations that disrupt the formation of the combined β triple-helical repetitive segment and consequently the self-association of spectrin heterodimers to tetramers. All of these mutations open a proteolytic cleavage site residing in the third helix of the combined repetitive segment, which gives rise to a 74-kDa α I peptide.

Although most spectrin mutations reside in the vicinity of the $\alpha\beta$ -spectrin self-association site, a few mutations remote from the self-association site have been described. These mutations are asymptomatic in the simple heterozygous state but cause hemolytic anemia, which can be severe, in homozygous patients. Unlike mutations located in the self-association contact site, which are predicted to disrupt the conformation of the local protein structure, mutations outside this region are predicted to perturb long-range protein-protein interactions, disrupting the positively coupled, cooperative interactions of $\alpha\beta$ spectrin self-association, spectrin-ankyrin interactions, and ankyrin-band 3 interactions. One HE-associated mutation in a linker region remote from the self-association contact site disrupted the stability propagated from one spectrin repeat to the next.

Protein 4.1R Mutations

Another group of elliptocytogenic mutations, although much less common than spectrin mutations, are quantitative or qualitative

defects of protein 4.1R. Protein 4.1R is a multifunctional protein that contains several important sites of protein interactions, including the spectrin-binding domain, where 4.1R binds to the distal end of the spectrin $\alpha\beta$ heterodimer, markedly increasing the binding of spectrin to oligomeric actin, and the basic NH₂-terminal domain, where 4.1R interacts with GPC, phosphatidylinositol, and phosphatidylserine, facilitating the attachment of the distal end of spectrin to the membrane.

Studies of 4.1R mRNA from normal RBCs revealed 4.1R isoforms resulting from complex tissue- and developmental stage-specific patterns of alternate mRNA splicing. Alternate translation initiation sites are present in the protein 4.1R mRNA. When an upstream initiator methionine is used, isoforms greater than 80 kDa are synthesized. During erythropoiesis, this upstream initiator methionine is spliced out and a downstream initiator methionine is used, leading to the production of the 80-kDa mature erythroid protein 4.1R isoform. On SDS-PAGE, protein 4.1R is resolved into two bands of different sizes: 4.1a and 4.1b. The larger band, 4.1a, is typically found in normal RBCs, whereas the shorter one, 4.1b, represents the major isoform of reticulocytes. The 4.1b isoform is converted into the 4.1a isoform by deamidation of Asn 502.

A partial deficiency of protein 4.1R is associated with mild, dominantly inherited HE, whereas a complete deficiency (a homozygous state) leads to a severe hemolytic disease. Homozygous protein 4.1R(−) erythrocytes fragment more rapidly than normal at moderate shear stresses, an indication of their intrinsic instability. Membrane mechanic stability can be restored by reconstituting the deficient RBCs with protein 4.1R or the protein 4.1R/spectrin/actin-binding site. Homozygous protein 4.1R(−) erythrocytes also lack p55 and have only 30% of the normal content of GPC. These homozygous protein 4.1R(−) erythrocytes, as well as GPC-deficient Leach erythrocytes, demonstrate decreased invasion and growth of *Plasmodium falciparum* in vitro.

Mutations associated with protein 4.1R deficiency have included deletions that include the exon encoding the erythroid transcription start site and mutations of the transcription initiation codon. Qualitative defects of protein 4.1R protein include deletions and duplications of the exons encoding the spectrin-binding domain, leading either to truncated or elongated forms of protein 4.1R. Electron microscopic studies of homozygous protein 4.1R(−) erythrocyte membranes revealed a markedly disrupted skeletal network with disruption of the intramembrane particles, suggesting that protein 4.1R plays an important role in maintenance not only of the skeletal network but also of the integral proteins of the membrane structure.

Glycophorin C Deficiency

GPC has been found absent because of a variety of molecular defects. In contrast to other forms of HE, which are dominantly inherited, heterozygous carriers are asymptomatic, with normal RBC morphology, and homozygous patients have no anemia and only mild elliptocytosis apparent on the peripheral blood film.

GPC deficiency with elliptocytosis, the so-called Leach phenotype, caused by reduced expression of GPC, should be distinguished from the immunochemically defined phenotypes Gerbich and Yus, in which abnormal glycoproteins are formed that can functionally substitute for normal GPC and preserve the normal RBC shape. The Leach phenotype is usually caused by a large deletion of genomic DNA (~7 kb) that removes exons 3 and 4 from the GPC/glycophorin D locus. In one patient, the Leach phenotype was caused by a frameshift mutation.

GPC-deficient patients are also partially deficient in protein 4.1R and lack p55, presumably because these proteins form a complex and recruit or stabilize each other on the membrane. It has been speculated that the protein 4.1R deficiency in Leach erythrocytes is the cause of the elliptocytic shape. In contrast, patients deficient in glycophorin A, the major transmembrane glycoprotein, are asymptomatic.

Fig. 45.5 SCHEMATIC REPRESENTATION OF THE MOLECULAR ASSEMBLY OF THE MEMBRANE SKELETON AND THE MOLECULAR DEFECTS IN HEREDITARY ELLIPTOCYTOSIS (HE) AND HEREDITARY PYROPOIKILOCYTOSIS (HPP). Spectrin is composed of α - and β -spectrin heterodimers (SpD) that associate in their head regions into tetramers. At their distal ends, SpD bind to the junctional complexes of oligomeric actin (band 5 [5]) and protein 4.1. Additional proteins found in the junctional complex, such as adducin and tropomyosin, are shown in the lower enlarged area. The membrane skeleton is attached to transmembrane proteins by interactions of β -spectrin with ankyrin (protein 2.1; [black arrowhead] designates the ankyrin-binding site in β -spectrin), which in turn binds to the cytoplasmic domain of band 3 (3), and by linkage of protein 4.1 to glycophorin C (GPC). The known protein dysfunctions in HE and HPP include (1) defects of the SpD head region because of a mutation of either α - or β -spectrin, causing impaired assembly of SpD into tetramers, and (2) defects of proteins of the junctional complex such as a qualitative or quantitative defect of protein 4.1R or GPC. *SP*, Spectrin.

Membrane Effects

Most of the elliptocytogenic mutations of spectrin reside within, or in the vicinity of, the spectrin heterodimer self-association site, disrupting this region and consequently disrupting the two-dimensional integrity of the membrane skeleton (Fig. 45.5). These defects are detected by ultrastructural examination of the membrane skeleton, which reveals disruption of a normally uniform hexagonal lattice. Consequently, membrane skeletons are mechanically unstable, as are whole cell membranes and the cells. In patients with severely dysfunctional spectrin mutations or patients homozygous or doubly heterozygous for spectrin mutations, the membrane instability is

sufficient to cause RBC fragmentation with hemolytic anemia under conditions of normal circulatory shear stress.

The pathobiology of the elliptocytic shape is less clear. RBC precursors in common HE are round and the cells become progressively more elliptical as they age in vivo. RBCs subjected to shear stress in vitro, or RBCs flowing through microcirculation in vivo, have an elliptical or parachute-like shape, respectively. It is possible that elliptocytes and poikilocytes are permanently stabilized in their abnormal shape because the weakened spectrin heterodimer contacts facilitate skeletal reorganization, which follows axial deformation of cells resulting from application of a prolonged or excessive shear stress. This reorganization is likely to involve breakage of the unidirectionally stretched protein connections followed by the formation of new protein contacts that preclude the recovery of a normal biconcave shape. This process has been shown to account for permanent deformation of irreversibly sickled cells.

In HPP, the recessively inherited form of HE characterized by severe hemolysis, RBCs have two abnormalities. They contain a mutant spectrin that characteristically disrupts spectrin heterodimer self-association, and they are also partially deficient in spectrin, as evidenced by a decreased spectrin/band 3 ratio. In some HPP cases, this biochemical phenotype is a consequence of a double heterozygous state for an elliptocytogenic α -spectrin mutation and a defect involving reduced α -spectrin synthesis. Such synthetic defect of α -spectrin is fully asymptomatic in the heterozygous carrier, because under normal conditions, the synthesis of α -spectrin is approximately three to four times greater than that of β -spectrin.

When present in conjunction with an elliptocytogenic mutation of α -spectrin, such a synthetic defect augments the expression of the mutant spectrin. Because the elliptocytogenic α -spectrin mutants are often unstable, the combination of the two defects leads to spectrin deficiency in the cells. Other HPP patients are homozygous or doubly heterozygous for one or two elliptocytogenic spectrin mutations, respectively. In such cases, the spectrin deficiency may be a consequence of spectrin instability that reduces the amount of spectrin available for membrane assembly. Furthermore, in RBCs containing a high fraction of unassembled dimeric spectrin, the spectrin deficiency may in part be related to the stoichiometric ratio of one ankyrin copy per one spectrin tetramer (i.e., two spectrin heterodimers). Consequently, only approximately one-half of spectrin heterodimers succeed in attaching to the ankyrin-binding sites. The phenotype of HPP, characterized by the presence of fragments and elliptocytes, together with evidence of RBC surface area deficiency (as reflected by the presence of microspherocytes on the peripheral blood film), suggests that the membrane dysfunction involves both vertical interactions (a consequence of spectrin deficiency) and horizontal interactions involving the elliptocytogenic spectrin mutation.

The RBC lesion in protein 4.1R deficiency shows similarities in regard to cell shape and membrane stability to the elliptocytogenic mutations of spectrin, suggesting that the deficiency principally affects the spectrin-actin contact (see Fig. 45.5) rather than the skeleton attachment to GPC via protein 4.1R (a vertical interaction).

The molecular basis of elliptocytosis and the mechanical instability of GPC-deficient RBCs are not fully understood. However, recent studies suggest that the deficiency of GPC is not directly responsible for the altered mechanical properties. Instead, the mechanical instability appears to be related to a concomitant partial deficiency of protein 4.1R, as evidenced by a full correction of membrane instability by introduction into the cells of protein 4.1R or its spectrin-binding peptide, which facilitates the contact of β -spectrin to actin. The superimposed deficiency of protein 4.1R is likely to be related to the fact that GPC serves as an attachment site for protein 4.1R to the membrane, recruiting protein 4.1R to the RBC membrane. The effects of these defects on the mechanical stability of GPC-deficient cells appear to be relatively minor, because GPC-deficient patients have no detectable hemolytic anemia and the mechanical properties of the RBCs are normal when tested by micropipette aspiration.

Inheritance

In most patients, HE is inherited as an autosomal dominant disorder. The clinical severity is highly variable among different kindred (reflecting heterogeneous molecular lesions) and, to a lesser extent, within a given kindred, presumably because of other genetic or acquired defects that modify disease expression. Occasionally HE is inherited as an autosomal recessive condition from an asymptomatic parent who carries the same molecular defect of spectrin as the HE offspring. In one kindred with a submicroscopic chromosome X deletion, inheritance was X-linked.

The inheritance of the related disorder HPP is autosomal recessive: one of the parents carries the α -spectrin mutation and either is asymptomatic or has mild HE, whereas the other parent is fully asymptomatic and has no abnormalities detectable by current biochemical approaches. However, several HPP patients have recently been studied who were doubly heterozygous for two α -spectrin mutations; in the heterozygous parents, these mutations were either silent or expressed as mild HE.

Clinical Manifestations

In view of the striking molecular heterogeneity of common HE, it is not surprising that the clinical spectrum of this disorder is variable, ranging from an asymptomatic trait without hemolysis to a life-threatening hemolytic anemia.

Mild Hereditary Elliptocytosis and Asymptomatic Carrier State

In most of these patients, HE is found accidentally during evaluation of the peripheral blood film. Although some HE patients have a mild compensated hemolytic anemia, others do not have any evidence of hemolysis, their RBC survival is normal, and the peripheral blood film may reveal only modest ($\geq 15\%$) elliptocytosis. The molecular basis of mild HE is heterogeneous, and the reported molecular defects include both α - and β -spectrin mutations, partial deficiency of the 4.1R protein, and the absence of GPC. Some individuals carrying the spectrin mutation are completely asymptomatic, including normal RBC morphologic features; this is often the case in one of the parents of a patient with HPP.

Hereditary Elliptocytosis With Sporadic Hemolysis

Worsening of hemolysis together with the appearance of poikilocytes on the peripheral blood film has been reported in patients with hypersplenism, infections, or vitamin B₁₂ deficiency, as well as in those with microangiopathic hemolysis such as disseminated intravascular coagulation or thrombotic thrombocytopenic purpura. In the latter two conditions, worsening hemolysis can be caused by microcirculatory damage superimposed on the underlying mechanical instability of the RBCs.

Hereditary Elliptocytosis With Neonatal Poikilocytosis

Neonatal offspring of parents with mild HE present with symptomatic hemolytic anemia and a marked poikilocytosis. During the first year of life, the hemolysis and poikilocytosis abate, and the clinical picture transforms into that of mild HE. Such patients typically carry one mutant α -spectrin allele. The severity of the molecular defect, in terms of the percentage of spectrin dimers and the amount of mutant spectrin in the cells, is the same in the neonatal period as it is later in life. The worsening of hemolysis in the neonatal period has been attributed to the presence of fetal hemoglobin, which binds poorly to 2,3-diphosphoglycerate (2,3-DPG). The ensuing elevation of free

2,3-DPG levels has a marked destabilizing effect on the spectrin–protein 4.1R–actin interaction, thereby further destabilizing the membrane skeleton.

Hereditary Elliptocytosis With Chronic Hemolysis

Patients with HE with chronic hemolysis present with moderate to severe hemolytic anemia with elliptocytes and poikilocytes on peripheral blood film; some require splenectomy. In some of the kindred, the hemolytic HE has been transmitted through several generations. In some kindred, not all of the HE patients have chronic hemolysis; some have a mild hemolysis only, presumably because of another genetic factor modifying the disease expression.

Homozygous and Compound Heterozygous Hereditary Elliptocytosis

Several HE individuals have been described who were apparent homozygotes for the HE gene. These individuals were found to be either homozygotes or compound (double) heterozygotes for one or two α - or β -spectrin mutations. The clinical severity is variable, from a relatively mild hemolytic anemia to a severe, life-threatening disease, depending on the severity of the underlying molecular defect, and in some cases is indistinguishable from HPP.

Hereditary Pyropoikilocytosis

It is now established that HPP represents a subtype of common HE, as evidenced by the coexistence of both HE and HPP in the same family and by the presence of the same molecular defect of spectrin. Unlike HE patients carrying the spectrin mutation, the RBCs of HPP patients are also partially deficient in spectrin. Typically, one parent of the HPP offspring carries an α -spectrin mutation, whereas the other parent is fully asymptomatic and has no detectable biochemical abnormality. In many such patients the asymptomatic parent carries a silent “thalassemia-like” defect of spectrin synthesis, enhancing the relative expression of the spectrin mutant and leading to a superimposed spectrin deficiency in the HPP offspring. Subsequent studies of the original HPP kindred revealed that defective spectrin synthesis from the null allele was caused by a splicing mutation of the α -spectrin gene. Some HPP patients inherited two α -spectrin mutations; either their parents were hematologically normal or one had mild HE. In these HPP patients, spectrin deficiency may be related to instability of the mutant spectrin. The thermal instability of spectrin originally reported as diagnostic of HPP is not unique for this disorder; it is also found in HE patients carrying this α -spectrin mutation, in the homozygous and in the heterozygous states. HPP is seen predominantly in black patients, but it has also been diagnosed in Arabs and whites.

Molecular Determinants of Clinical Severity

The severity of hemolysis in common HE often varies not only among different kindred but within a given family as well. The two principal determinants of severity of hemolysis are the spectrin content of the cells and the percentage of dimeric spectrin in the crude spectrin extract. The fraction of dimeric spectrin in such extracts in turn depends on several factors. The first of them is the degree of dysfunction of the mutant spectrin. Typically, mutations that are either within or near the combined $\alpha\beta$ triple-helical repetitive segment representing the spectrin heterodimer self-association site produce a more severe clinical phenotype and a more severe defect of spectrin function than those seen with point mutations in the more distant triple-helical repeats. Second, the percentage of the dimeric spectrin depends on the fraction of the mutant spectrin in the cells, which in turn is determined by the gene dose (e.g.,

simple heterozygote versus homozygote or double heterozygote) or the presence of other genetic defects such as the presence, in trans, of a defect leading to a reduced α -spectrin synthesis in some patients with HPP.

The low-expression α -spectrin allele α^{LELY} is the best-characterized abnormality affecting spectrin content and clinical severity. Initially a polymorphism of the α V domain, α^{V41} , was identified in HE patients who, when they inherited α^{V41} in trans, had more severe HE than expected. Subsequently an amino acid substitution of exon 46, Leu1857Val, and partial skipping of exon 46, linked to the α^{V41} polymorphism, were identified as the characteristics of the α^{LELY} allele. These abnormalities are located within the site at which spectrin monomers assemble into heterodimers (the spectrin heterodimer nucleation site). In vitro studies suggest that the inability of α -spectrin chains to assemble into the mature membrane skeleton is because of a combination of decreased $\alpha\beta$ dimer-binding affinity and increased proteolytic cleavage of the mutant α -spectrin chains. The presence of α^{LELY} in trans diminishes the propensity of the otherwise normal allele to associate with the corresponding β -chain, favoring the attachment of the elliptocytogenic α -spectrin allele. Conversely, coexistence of the α -spectrin mutation in cis and the mutation involving the α -spectrin nucleation site diminishes the propensity of the mutant allele to be incorporated into the spectrin heterodimer, thereby ameliorating the clinical severity of this mutation. The α^{LELY} allele is clinically silent by itself, even when inherited in the homozygous state, probably because α -spectrin is normally synthesized in threefold to fourfold excess.

Laboratory Manifestations

Blood Film and Laboratory Evidence of Hemolysis

A careful blood smear evaluation is essential for the diagnosis of HE and for the classification of the disorder into the three major subtypes outlined previously. In patients in whom elliptocytosis is the only morphologic abnormality, hemolysis is characteristically minimal or absent, with the exception of spherocytic elliptocytosis, in which the presence of round “fat” ovalocytes is associated with accelerated RBC destruction. In patients with hemolytic forms of common HE, poikilocytosis is characteristically found on the blood film. In severe forms of HE, particularly in homozygous HE, many RBCs circulate as cell fragments, producing a marked decrease in MCV. The finding of RBC fragments together with a striking microspherocytosis and often only occasional elliptocytes is characteristic of HPP (Fig. 45.6).

Osmotic and Thermal Fragility

Osmotic fragility is increased in HPP, in spherocytic elliptocytosis, and in HE patients with poikilocytosis apparent on the peripheral blood film. In patients with a mild common HE without poikilocytosis on the peripheral blood film, osmotic fragility is normal.

Thermal instability of RBCs was originally reported as a characteristic feature of HPP. It reflects thermal instability of the mutant

Fig. 45.6 BLOOD FILMS OF PATIENTS WITH VARIOUS FORMS OF HEREDITARY ELLIPTOCYTOSIS (HE). (A) Simple heterozygote with mild common HE. Note the predominant elliptocytosis with some rod-shaped cells (arrow) and virtual absence of poikilocytes. (B) Simple heterozygote with severe common hemolytic elliptocytosis. Note the numerous small fragments and poikilocytes. (C) “Homozygous” common HE because of doubly heterozygous state for two mutant α -spectrins. Both parents have mild HE. Note the many elliptocytes, spherocytes, as well as numerous fragments and poikilocytes. (D) Hereditary pyropoikilocytosis. The patient is a double heterozygote for a structural α -spectrin mutant and a presumed α -spectrin synthetic defect. Note the prominent microspherocytosis, micropoikilocytosis, and fragmentation. Only few elliptocytes are present. Some poikilocytes are in the process of budding.

spectrin: In normal RBCs, spectrin is denatured and RBCs fragment at 50°C. HPP RBCs fragment and their spectrin denatures at 41°C. However, the diagnostic value of this test is limited, because thermal instability of RBCs is also noted in HE RBCs containing mutant spectrin. In contrast, an occasional patient with otherwise typical HPP may have normal thermal stability of RBCs and spectrin. RBCs in common HE have unstable membranes and membrane skeletons when subjected to shear stress.

Electrophoretic Separation of Solubilized Membrane Proteins

In HE and HPP, SDS-PAGE can reveal proteins of abnormal mobility, the origin of which can be subsequently identified by Western blotting (e.g., truncated α - or β -spectrins in HE and HPP, or elongated or truncated forms of the 4.1R protein, and a partial or, rarely, complete deficiency of the 4.1R protein in HE). In HPP, SDS-PAGE reveals a partial deficiency of spectrin, as indicated by a decreased spectrin/band 3 ratio. Spectrin deficiency, in conjunction with an elliptocytogenic spectrin mutation affecting the spectrin heterodimer contact, is invariably found in cases of HPP.

Nondenaturing Gel Electrophoresis of Low-Ionic-Strength Spectrin Extract

Analysis of the ratio of tetrameric and dimeric spectrin in the low-ionic-strength extracts reveals the most common functional abnormality in HE (i.e., weakened self-association of spectrin heterodimers into tetramers). Because the spectrin dimer-tetramer interconversion has a high activation energy, it is kinetically immobilized at near 0°C. Consequently, the percentage of spectrin dimers and tetramers in the 0°C crude spectrin extract reflects the relative distribution of these species in the RBC membrane *in situ*. Mutations of α - or β -spectrin residing within or near the $\alpha\beta$ -spectrin heterodimer self-association site invariably lead to an increase in the fraction of dimeric spectrin in the crude 0°C spectrin extract.

Tryptic Peptide Mapping of Spectrin and the Detection of the Underlying DNA Defect

Tryptic digestion of spectrin followed by electrophoretic separation gives rise to highly reproducible tryptic peptide patterns. Among these peptides, the 80-kDa α I domain peptide representing the self-association site of the normal α -spectrin is among the most prominent. Nearly all α - or β -spectrin mutations reported are associated with a formation of tryptic peptides of abnormal size and mobility that are generated from the normal 80-kDa α I domain peptide. The cleavage sites of the most common abnormal tryptic peptides are found in the third helix of a given triple-helical repetitive segment. The reported mutations reside in the vicinity of these cleavage sites either in the same helix or, less commonly, in helix 1 or 2 of a given repetitive segment. Consequently, tryptic peptide mapping remains a powerful tool with which to map the site of the underlying spectrin mutation, which can be subsequently defined by polymerase chain reaction amplification and sequencing of the respective region of the genomic DNA or complementary DNA (cDNA).

Differential Diagnosis

Various acquired and inherited conditions can be associated with elliptocytosis and poikilocytosis, including iron deficiency, thalassemias, megaloblastic anemias, myelofibrosis, myelophthisic anemias, myelodysplastic syndromes, and pyruvate kinase deficiency. The percentage of elliptocytes in these conditions is seldom greater than 60%. However, this is not diagnostically useful, because some HE patients can have a relatively low percentage of elliptocytes. In normal

patients the percentage of elliptocytes is not greater than 5%, although in earlier reports it was listed as high as 15%. Previous diagnostic criteria of HE, based on the percentage of elliptocytes, such as 25%, 33%, or 40%, and their axial ratio, do not appear useful. The most reliable differentiation of HE from the other conditions mentioned is based on a positive family history rather than on the percentage of elliptocytes.

Therapy and Prognosis

As in the case of HS, RBCs from patients with more severe forms of HE are retained by the spleen, producing a marked engorgement of splenic pulp. Consequently, patients with symptomatic hemolysis benefit from splenectomy. This procedure is virtually never indicated in heterozygotes with autosomal dominant HE because most do not have clinically significant hemolytic anemia. If hemolysis is still active after splenectomy, folate should be administered daily. Recommendations for antibiotic prophylaxis, immunizations, and monitoring for intercurrent illnesses are similar to those noted earlier for HS patients before and after splenectomy. Serial interval ultrasonographic investigations to detect gallstones should be performed in patients with significant hemolysis.

Spherocytic Elliptocytosis

Spherocytic elliptocytosis, which shares features of HS and HE, has been designated spherocytic HE, HE with spherocytosis, or hereditary hemolytic ovalocytosis. The diagnosis is based on the simultaneous presence of elliptical RBCs and spherocytes or "fat," round sphero-ovalocytes in the peripheral blood film. In contrast to common HE, cells of other shapes, such as rod-shaped cells, poikilocytes, and fragments, are absent. Importantly, hemolysis, despite relatively mild alterations in RBC morphologic features, and increased osmotic fragility are the main diagnostic features distinguishing this disorder from common HE.

The molecular basis of spherocytic HE is unknown. However, patients with mutations, particularly truncations at the C-terminal of β -spectrin, have many of the clinical features of spherocytic HE and probably represent an example of this disorder. Patients who lack GPC have rounded, smooth elliptocytes and could be classified as having a mild, recessively inherited variant of spherocytic HE. Finally, some patients with recessively inherited defects of protein 4.2 can display some features of spherocytic HE, particularly mild ovalostomatocytosis.

Southeast Asian Ovalocytosis

SAO is characterized by the presence of oval RBCs, many containing one or two transverse ridges or a longitudinal slit. The condition is widespread in certain ethnic groups of Malaysia, Papua New Guinea, the Philippines, and Indonesia. Numerous functional abnormalities of ovalocytes have been reported, including increased RBC rigidity, decreased osmotic fragility, increased thermal stability, resistance to shape change by echinocytogenic agents, and a reduced expression of many RBC antigens. A remarkable feature of ovalocytes is their resistance to *in vitro* invasion by several strains of malaria parasites, including *P. falciparum* and *Plasmodium knowlesi*. In areas of endemic malaria, SAO individuals have reduced numbers of intracellular parasites *in vivo*, with decreased prevalence and disease severity of malaria in SAO patients compared with controls.

SAO individuals are heterozygotes for two band 3 gene mutations in cis: the deletion of nine codons encoding amino acids 400 through 408 from the boundary of the cytoplasmic and membrane domains of band 3, and the 56 Lys to Glu substitution. The 56 Lys to Glu substitution represents an asymptomatic polymorphism known as band 3 Memphis. The SAO phenotype is associated with a tighter binding of band 3 to ankyrin, increased tyrosine phosphorylation of

the band 3 protein, inability to transport sulfate anions, and a markedly restricted lateral and rotational mobility of band 3 protein in the membrane.

Laboratory Manifestations

The finding of 30% or greater of oval RBCs on the peripheral blood film, some containing a central slit or a transverse ridge, in the context of a notable absence of clinical and laboratory evidence of hemolysis in a patient from the ethnic groups noted earlier is highly suggestive of the diagnosis. A useful screening test is the demonstration of the resistance of ovalocytes or their ghosts to changes in shape produced by treatments that produce spiculation in normal cells, such as metabolic depletion or exposure of ghosts to salt solutions. In contrast to normal RBCs, which form spicules in response to such stimuli, SAO RBCs or ghosts do not change shape after these treatments. The mechanism of this resistance to changes in shape is not clear, and it may reflect the high rigidity of the RBC membrane.

Because the underlying cause of SAO is the deletion of 27 bases from the band 3 gene, isolation of genomic DNA or reticulocyte cDNA with subsequent amplification of the deletion-containing region appears to be the most specific test for establishing the diagnosis of SAO. A single, severely affected homozygous SAO individual who was transfusion dependent has been described.

Molecular Basis of Southeast Asian Ovalocytosis Membrane Rigidity and Malaria Resistance

The RBCs of SAO are unique among axially deformed cells in that they are rigid and hyperstable rather than unstable. The SAO

mutation is the first example of a defect of an integral membrane protein leading to RBC membrane rigidity, an observation previously attributed to properties of the membrane skeleton. The basis of the increased rigidity is unclear.

The molecular basis of malaria resistance of SAO RBCs is likely related to altered properties of the band 3 protein, which serves as one of the malaria receptors, as evidenced by the inhibition of in vitro invasion by band 3-containing liposomes. In normal RBCs, the invasion process is associated with a marked membrane remodeling that involves redistribution of intramembrane particles that contain band 3 protein. Such particles cluster at the site of parasite invasion, forming a ring around the orifice through which the parasite enters the cell. The invaginated RBC membrane, which surrounds the invading parasite, is free of intramembrane particles. The reduced lateral mobility of band 3 protein in SAO RBCs may preclude band 3 receptor clustering, thereby preventing the attachment of the parasites to the cells. Decreased exchange of anions across the RBC membrane has also been proposed to contribute to the resistance of ovalocytes to malaria invasion. In addition, SAO RBCs consume ATP at a higher rate than normal cells, and the partial depletion of ATP levels in ovalocytes has been suggested to account, at least in part, for the resistance of these cells to malaria invasion in vitro.

Acanthocytosis and Related Disorders

Acanthocytes (from the Greek *acantha*, “thorn”) or spur cells are RBCs with prominent thorn-like surface protrusions that vary in width, length, and surface distribution. Spur cells must be distinguished from echinocytes (Greek *echinos*, “sea urchin”) or burr cells, characterized by multiple small projections that are uniformly distributed throughout the cell surface (Fig. 45.7). Acanthocytes should also

Fig. 45.7 MORPHOLOGIC DIFFERENCES BETWEEN ACANTHOCYTES (A) AND ECHINOCYTES (B) AS DEMONSTRATED BY SCANNING ELECTRON MICROSCOPY. (Modified from Bessis M: Red cell shapes: An illustrated classification and its rationale. In Bessis M, Weed RI, Leblond PF, eds: Red Cell Shape Physiology, Pathology, Ultrastructure, New York, 1973, Springer-Verlag.)

be distinguished from keratocytes (“horn” red cells) that have few massive protuberances.

Acanthocytosis was first described in cases of abetalipoproteinemia and subsequently in severe liver disease, the chorea-acanthocytosis syndrome, the McLeod blood group phenotype, and other conditions. The molecular mechanisms leading to acanthocytosis in abetalipoproteinemia and severe liver disease have been extensively studied and have been attributed to changes in composition of membrane lipids and their altered distribution between the two hemileaflets of the lipid bilayer.

Spur Cell Hemolytic Anemia of Severe Liver Disease

Spur cell hemolytic anemia is an uncommon ominous complication of severe liver disease that is manifested by rapidly progressive hemolytic anemia and acanthocytes on the peripheral blood smear.

Pathobiology

The human RBC membrane contains nearly equal amounts of free (unesterified) cholesterol and phospholipids. The free cholesterol in the plasma readily equilibrates with the RBC membrane cholesterol pool. This is in contrast to esterified cholesterol, which cannot be transferred from plasma into the RBC membrane. The plasma of patients with severe liver disease contains abnormal lipoproteins that have a high free cholesterol/phospholipid ratio. The excess free cholesterol readily partitions into the RBC membrane, leading to a marked increase in free cholesterol in the cells. Consequently, normal cells can develop a spur cell shape after their transfusion into a patient with severe liver disease or after incubation with the liver disease patient's plasma or cholesterol-enriched liposomes.

Spur cell formation involves two steps. The first step is evident in RBCs of splenectomized patients with spur cell hemolytic anemia: RBCs have an expanded surface area with irregular contour and targeting, reflecting accumulation of free cholesterol in the membrane (Fig. 45.8). This extracholesterol accumulates preferentially in the outer bilayer leaflet, as suggested by findings of increased accessibility of cholesterol to cholesterol oxidase and a selective decrease in lipid fluidity of the outer hemileaflet of the lipid bilayer.

The second step in acanthocyte formation involves RBC remodeling by the spleen. As a result, RBCs become spheroidal, and the surface projections are considerably longer and more irregular. The end result of these processes is poorly deformable RBCs with long bizarre projections that are readily trapped in the spleen, which is

often markedly enlarged because of passive congestion as a result of underlying portal hypertension. Cholesterol also alters membrane permeability and interacts with several membrane skeletal proteins, but the role of these changes in spur cell lesions is unclear.

Clinical Manifestations

Most patients with chronic liver disease have a mild to moderate anemia related to gastrointestinal blood loss, iron and folic acid deficiencies, or hemodilution or as a direct effect of alcohol on RBC precursors. Peripheral blood smears from these patients often reveal target cells that are particularly prominent in obstructive jaundice.

In some patients, particularly those with end-stage liver disease, anemia rapidly worsens and spur cells appear in high percentage in the peripheral blood. This is accompanied by worsening jaundice, rapid deterioration of liver function, hepatic encephalopathy, and hemorrhagic diatheses. A similar clinical syndrome has been described in patients with advanced metastatic liver disease, cardiac cirrhosis, Wilson disease, fulminant hepatitis, and infantile cholestatic liver disease. The development of spur cell hemolytic anemia is an ominous sign in most patients, predicting a survival seldom exceeding weeks to months. In theory, splenectomy could provide a marked improvement, because the spleen is the major sequestration site of nondeformable acanthocytes; in reality, splenectomy is seldom considered because of severity of the underlying liver disease.

Abetalipoproteinemia

Bassen and Kornzweig first described an association of acanthocytosis with atypical retinitis pigmentosa, progressive ataxic neurologic disease, and a “celiac disease” later attributed to fat malabsorption. Subsequently several investigators reported a congenital absence of β -lipoprotein, accounting for the diverse manifestations of the disorder.

Pathobiology

Abetalipoproteinemia is an autosomal recessive disorder found in people of diverse ethnic backgrounds. The primary molecular defect involves a congenital absence of β -apolipoprotein in plasma. The B apoproteins (B100 and B48) are generated by alternate transcription of a single gene residing on the short arm of chromosome 2. Their deficiency is secondary to defective cellular secretion of the apoprotein

Fig. 45.8 BLOOD FILM OF A PATIENT WITH LIVER CIRRHOSIS AND SPUR CELL ANEMIA. Erythrocytes have an expanded surface area with irregular contour and targeting, reflecting accumulation of free cholesterol in the membrane, preferentially in the outer bilayer leaflet. Splenic remodeling leads to increasing spheroidicity with longer and more irregular surface projections.

by liver cells, caused either by aberrant posttranslational processing or by defective aposecretion. In some patients this is because of qualitative or quantitative defects in the microsomal triglyceride transfer protein, which catalyzes the transport of triglyceride, cholesterol ester, and phospholipid from phospholipid surfaces. Microsomal triglyceride transfer protein is the only tissue-specific component, other than apolipoprotein B, required for secretion of apolipoprotein B-containing lipoproteins. As a result, apoprotein B is absent in plasma, as are the individual lipoprotein fractions that contain this apoprotein. These lipoprotein fractions include chylomicrons and very-low-density lipoproteins that transport triglycerides, as well as the low-density lipoproteins that are products of very-low-density lipoproteins and transport cholesterol. Consequently, preformed triglycerides are not transported from the intestinal mucosa, and they are nearly absent in the plasma. Plasma cholesterol and phospholipids are markedly reduced, with a relative increase in sphingomyelin at the expense of lecithin.

As is the case in acanthocytosis of liver disease, the acanthocytic lesion is acquired from the plasma. Erythrocyte precursors are of normal shape, and the acanthocytic lesion develops as the cells mature and age in the circulation. Normal cells acquire this shape when transfused into the recipient.

The most striking abnormality of RBC membrane lipids involves a net increase in sphingomyelin. Because plasma lipids readily exchange with the lipids of the RBC membrane, it is likely that this change simply mirrors the alterations in plasma lipid composition. In contrast to RBCs in spur cell anemia of severe liver disease, the content of membrane cholesterol is normal or only slightly increased.

The role of membrane lipids in the acanthocyte shape transformation was first established by findings of restoration of biconcave shape after extraction of lipids from the cell membrane by detergents. The molecular basis of the acanthocytic shape is unknown, but several indirect observations suggest that it is related to an increase of the surface area of the outer hemileaflet of the lipid bilayer relative to the inner leaflet. Several other abnormalities have been noted in abetalipoproteinemia, including a decrease in plasma lecithin cholesterol transferase activity and an increased susceptibility of membrane and plasma lipids to oxidation as a result of malabsorption-induced deficiency of vitamin E. The contributions of these abnormalities to the acanthocyte red cell lesions are unknown.

Clinical Manifestations

This autosomal recessive disease can become evident in the first few months of life, manifested by fat malabsorption with normal absorption of other nutrients. Intestinal biopsy is diagnostic, revealing engorgement of mucosal cells with lipid droplets. Other features include retinitis pigmentosa and a progressive ataxia with intention tremors that usually develops at 5 to 10 years of age, progressing to death in the second or third decade of life. The hematologic manifestations are mild and include mild normocytic anemia with acanthocytosis (50–90%) and normal or slightly elevated reticulocyte counts. Occasional patients can have more severe anemia resulting from the nutritional deficiencies (iron and folate) that accompany fat malabsorption. The treatment includes dietary restriction of triglycerides and supplementation with the lipid-soluble vitamins A, K, D, and E. Vitamin E can stabilize or even improve both the retinal and neuromuscular abnormalities.

Autosomal recessive abetalipoproteinemia should be distinguished from the homozygous form of familial hypobetalipoproteinemia. Although the clinical presentation of both disorders is similar, the latter disorder is milder, and the parents have occasional acanthocytes on the peripheral blood film, and their plasma low-density lipoprotein levels are decreased. The molecular lesions in familial hypobetalipoproteinemia involve a variety of apoprotein B gene mutations, leading to aberrant apoprotein B gene transcription or translation.

Varying degrees of acanthocytosis without anemia have also been described with isolated deficiency of apoprotein B100.

Neuroacanthocytosis Syndromes

The neuroacanthocytosis syndromes are a group of degenerative neurologic disorders with phenotypic and genetic heterogeneity that share the feature of acanthocytes on peripheral blood smear. These disorders include chorea-acanthocytosis, the X-linked McLeod syndrome (see [McLeod Phenotype](#)), and several other neurodegenerative diseases, including Huntington disease-like 2 caused by mutations in junctophilin-3 and pantothenate kinase-associated neurodegeneration (formerly known as Hallervorden-Spatz syndrome and its allelic variant syndrome—hypobetalipoproteinemia, acanthocytosis, retinitis pigmentosa, pallidal degeneration [HARP]) caused by mutations in pantothenate kinase 2.

Chorea-acanthocytosis syndrome is an autosomal recessive syndrome of adult onset that is manifest by multiple neurologic abnormalities, including limb chorea, progressive orofacial dyskinesia with tics, tongue-biting neurogenic muscle hypotonia, and atrophy. The hematologic manifestations are minimal and include a variable percentage of acanthocytes on the peripheral blood film without anemia and normal or only slightly decreased RBC survival. The mechanism of acanthocytosis in this syndrome is unknown. Studies of plasma and RBC membrane lipids have revealed a high content of unsaturated fatty acids, presumably accounting for reduced RBC membrane fluidity. Additional abnormalities of uncertain significance include an uneven distribution of intramembrane particles, impaired phosphorylation of the erythrocyte actin-bundling protein dematin, abnormal accumulation of transglutaminase products, and altered function and structure of band 3.

Mutations have been identified in the chorein gene (also known as *CHAC* or *VPS13A*—vacuolar protein sorting 13 homolog A) in many affected patients. Chorein does not belong to any known human gene family, and computer searches have not identified any known structural motifs or domains. The function of the chorein gene product remains unknown in either erythrocytes or the brain. In yeast, a chorein homologue is involved in protein sorting and transport and in regulation of levels of phosphatidylinositol-4-phosphate in cell membranes.

McLeod Phenotype

The McLeod syndrome is characterized by a mild compensated hemolytic anemia with a variable percentage of acanthocytes on the peripheral blood film and, in some patients, late-onset myopathy or chorea. The McLeod blood group phenotype is an X-linked anomaly of the Kell blood group system in which RBCs, white blood cells, or both react poorly with Kell antisera. The affected cells lack Kx, the product of the *XK* gene, which appears to be a membrane precursor of the Kell antigens. The *XK* gene encodes a novel 444-amino acid integral membrane transporter. In most patients, pathogenic nonsense or deletion mutations leading to absent or shortened XK protein that lacks the Kell protein binding site. Male hemizygotes who lack Kx have variable acanthocytosis (8–85%) and mild, compensated hemolysis. Because of the RBC mosaicism predicted by the Lyon hypothesis of X chromosome inactivation, female heterozygote carriers can have occasional acanthocytes on the peripheral blood film. Lyonized women with more severe symptoms have been described. Diagnosis may be challenging. CK levels are almost always elevated. In affected males, erythrocytes demonstrate absent Kx antigen and reduced Kell antigens. Because of the susceptibility to alloimmunization, it is important to diagnose affected patients because if they are transfused, they can develop antibodies compatible only with McLeod red cells.

The McLeod syndrome has been reported in association with chronic granulomatous disease of childhood, retinitis pigmentosa, and Duchenne muscular dystrophy. This association is caused by the close proximity of the genetic loci for these disorders in the p21 region of the X chromosome (Xp21), suggesting the occurrence of various manifestations because of contiguous gene syndromes. This may explain the occasional findings of either echinocytes or

stomatocytes in Duchenne dystrophy, or a choreiform disorder in some patients with the McLeod phenotype.

The Kell antigen consists of two protein components: a 37-kDa protein that carries the Kx antigen, a precursor molecule necessary for the Kell antigen expression, and a 93-kDa protein that carries the Kell blood group antigen. RBCs with the McLeod phenotype have no detectable Kx antigen, and they have a marked deficiency of the 93-kDa protein that carries the Kell antigen. McLeod RBCs should be distinguished from Kell null (K_0) RBCs, which have a normal shape. In K_0 cells, only the Kell antigen carrying the 93-kDa glycoprotein is absent, whereas these cells have twice the amount of the Kx antigen. As in the other acanthocytic disorders, the surface projections of acanthocytes may be related to asymmetry of the surface area of the two lipid bilayer hemileaflets, as indicated by correction of the acanthocytosis by agents that expand the inner lipid layer, as well as the finding of an increased rate of exchange of phosphatidylcholine (localized preferentially in the outer lipid hemileaflet) with an exogenous source.

Acanthocytosis in Other Conditions

Acanthocytes have also been noted in malnourished patients, including those with anorexia nervosa and cystic fibrosis. In these patients, RBC shape normalizes after restoration of the nutritional status. Likewise, a small number of cells with long spicules resembling acanthocytes are found in patients with hypothyroidism, after splenectomy, and with myelodysplasia.

Differentiation of Acanthocytes From Other Spiculated Red Blood Cells

Echinocytes (Burr Cells)

In contrast to acanthocytes, echinocytes, also called burr cells, have rather uniform surface projections. Although early echinocytic forms have a regularly scalloped cell contour, advanced forms of echinocytes have a spheroidal shape and the surface projections appear as short, narrow spikes (see Fig. 45.8). Although the finding of echinocytes on a peripheral blood film is often an artifact related to blood storage, contact with glass, or an elevated pH, several hemolytic anemias have been reported in association with echinocytosis on peripheral blood films. These conditions include mild hemolytic anemia in long-distance runners and in patients with hypomagnesemia and hypophosphatemia (presumably because of decreased intracellular ATP stores), uremia because of an unknown plasma factor, and pyruvate kinase deficiency.

Inspection of wet blood preparations (but not dried blood films) reveals echinocytosis in most patients with liver disease. In contrast to spur cells in patients with severe liver disease, these echinocytes have a normal cholesterol content, and the molecular abnormality may be related to the binding of abnormal echinocytogenic high-density lipoproteins to the RBC surface.

The mechanisms of echinocytosis in these diverse disorders are likely to be heterogeneous, as suggested by findings that many diverse factors, such as exposure of RBCs to certain drugs, calcium loading, or ATP depletion, can induce the transformation of discocytes to echinocytes *in vitro*. However, *in vitro* studies of the discocyte-echinocyte-stomatocyte equilibrium have suggested a possible common denominator. As discussed earlier, the lipid bilayer of normal RBCs is asymmetric in lipid composition: The outer half of the lipid bilayer is relatively enriched in sphingomyelin and phosphatidylcholine, whereas the inner half is preferentially enriched in the negatively charged phosphatidylserine and phosphatidylethanolamine. Agents that preferentially bind to one or another class of these phospholipids dramatically influence RBC shape. Consequently, agents that preferentially accumulate in the outer half of the RBC lipid bilayer, expanding this lipid bilayer, produce an echinocytic shape, presumably by creating an asymmetry between the two surface

areas of the two halves of the lipid bilayer. Conversely, agents that asymmetrically expand the inner half of the lipid bilayer, such as chlorpromazine, lead to stomatocytic shape transformation. In the case of echinocytes produced by ATP depletion or calcium loading, the altered phospholipid distribution between the two bilayer hemileaflets may be a consequence of calcium-induced phospholipid scrambling or a decrease in the activity of aminophospholipid translocase, an ATP-dependent enzyme that actively translocates aminophospholipids from the outer leaflet to the inner hemileaflet.

Keratocytes, Bizarre Poikilocytes, and Schistocytes

Mechanical trauma of circulating RBCs has occasionally produced bizarre shapes resembling acanthocytes, such as cells with horny projections (keratocytes). Some acanthocyte-like cells are also seen in splenectomized HE and HS patients. Similar shape changes are seen in heated RBCs, in which spectrin has been damaged by thermal denaturation, suggesting that these cells are bizarre poikilocytes rather than true acanthocytes.

RED BLOOD CELL MEMBRANE DISORDERS MANIFESTED BY TARGET CELL FORMATION

The common feature of target cells is an increase in the ratio of the cell surface area to cell volume. In microcytic RBCs of patients with various forms of thalassemia and hemoglobinopathies, the increased surface to volume ratio, and consequently the target cell shape, reflect at least in part the relative abundance of cell surface area. In liver disease and other disorders discussed subsequently, the target cell formation reflects an absolute expansion of the cell surface area because of a net accumulation of membrane phospholipids and cholesterol.

Liver Disease

The presence of target cells in association with either normal or slightly increased cell volume is characteristically found in patients with obstructive jaundice, including various forms of liver disease associated with intrahepatic cholestasis. These target cells have a normal survival in the peripheral circulation and do not typically account for the anemias often encountered in patients with liver disease.

In these patients, target cell formation is a consequence of a net uptake of both free cholesterol and phospholipids into the RBC membrane from the plasma because of abnormalities in the cholesterol/phospholipid/protein ratios of low-density lipoproteins. Target cells have a decreased osmotic fragility, because the excess of membrane surface area leads to an increase in the critical hemolytic volume.

Lecithin-Cholesterol Acyltransferase Deficiency

The lecithin-cholesterol acyltransferase (LCAT) enzyme catalyzes the formation of cholesterol esters in lipoproteins. It circulates in plasma as a complex with components of high-density lipoproteins. LCAT deficiency, caused by mutations in the *LCAT* gene, is a rare autosomal dominant disorder manifested by hyperlipidemia, premature atherosclerosis, corneal opacities, chronic nephritis, proteinuria, mild anemia, and the presence of target cells on the blood film. The anemia is caused by mild hemolysis together with a diminished compensatory erythropoiesis. As in obstructive jaundice, the target cells in LCAT deficiency have a marked increase in both cholesterol and phospholipids. In addition, the membrane phosphatidylcholine is increased at the expense of sphingomyelin and phosphatidylethanolamine. Bone marrow aspiration and biopsy reveal the presence of sea-blue histiocytes. Analysis of plasma lipoproteins reveals multiple abnormalities secondary to the underlying enzyme deficiency. Inherited

LCAT deficiency should be distinguished from an acquired deficiency of this enzyme, which is found in patients with severe liver disease.

Stomatocytosis and Related Disorders

Stomatocytes were first described in a girl with dominantly inherited hemolytic anemia. On blood films, her RBCs contained a wide transverse slit or stoma (Fig. 45.9). In a three-dimensional view, these cells have a shape of a cup or a bowl. The slit-like appearance is an artifact that results from folding of the cells during blood smear preparation.

Stomatocytes are seen in a variety of acquired and inherited disorders. The latter are often associated with abnormalities in RBC cation permeability that lead to changes in RBC volume, which can be either increased (hence the designation hydrocytosis or overhydrated stomatocytosis) or decreased (xerocytosis or desiccacytosis [dessicate]), or in some cases near normal.

There is no unifying theory to explain this morphologic abnormality. In vitro, stomatocytes can be produced by drugs that

preferentially intercalate into the inner half of the asymmetric lipid bilayer, expanding its surface area relative to that of the outer half of the bilayer.

Hereditary Stomatocytosis-Hydrocytosis

Hereditary hydrocytosis designates a heterogeneous group of hereditary hemolytic anemias that are transmitted in an autosomal dominant manner. The disorder is characterized by a moderate to severe hemolytic anemia with 10% to 30% stomatocytes (see Fig. 45.9), an elevated MCV, and a reduced MCHC. Osmotic fragility of RBCs is markedly increased, as some of the swollen RBCs approach their critical hemolytic volume. For unexplained reasons, RBC membrane lipids and consequently membrane surface area are also increased, but this increase in surface area is insufficient to correct the osmotic fragility of the RBCs. RBC deformability is decreased.

The principal cellular lesion involves a marked increase in intracellular sodium and water content with a mild decrease in intracellular potassium as a result of a marked sodium influx into the RBCs. Despite a marked compensatory increase in active transport of sodium (Na) and potassium by the Na^+/K^+ -ATPase (which normally maintains the low sodium and high potassium concentrations in the cells) and an ensuing increase in glycolysis, the pump hyperactivity is unable to compensate for the vastly increased sodium leak. Stomatatin (also known as band 7.2b), an integral membrane protein, is decreased or absent from the erythrocyte membranes of most affected patients. This deficiency appears to be a maturational loss in the bone marrow and in the circulation, perhaps because of a defect in cellular trafficking. Stomatatin gene mutations have not been found in unrelated stomatocytosis patients deficient in this protein.

In some patients with hereditary hydrocytosis, missense mutations in RhAG, I61R, or F65S, have been found. In oocytes these mutations induce a monovalent cation leak, possibly opening the pore of an ammonium transporter. Additional studies suggest that the F65S mutation exhibits a gain-of-function phenotype with increased cation conductance/permeability.

Splenectomy can improve, but not fully correct, the hemolysis. In some patients, splenectomy can be deleterious or even contraindicated (see later), perhaps because of altered endothelial cell adherence and membrane phospholipid asymmetry.

Hereditary Xerocytosis and the Intermediate Syndromes

Hereditary xerocytosis or desiccacytosis describes an autosomal dominant hemolytic anemia characterized by RBC dehydration and decreased osmotic fragility. Affected individuals have characteristically moderate to severe hemolysis with an increased MCHC, reflecting cellular dehydration. Hydrops fetalis with fetal anemia or fetal ascites or the presence of pseudohyperkalemia have been reported in a number of xerocytosis kindred. Frequently the MCV is mildly increased. In Coulter-type electronic counters, the conversion of pulse height (from the resistance of a cell passing through an electric field) to a cellular volume is dependent on cell shape. Xerocytes do not deform to the same degree as normal cells, which causes the MCV to be approximately 10% too high. The peripheral blood film (see Fig. 45.9) does not always reveal stomatocytes (which are more prominent on wet films), but frequently target cells, desiccacytosis (dessicate), and spiculated cells are seen. In some of the cells, hemoglobin is concentrated (“puddled”) in discrete areas on the cell periphery.

The mechanism of cellular dehydration is unclear and complex, involving a net potassium loss from the cells that is not accompanied by a proportional gain of sodium. Consequently, the net intracellular cation content and cell water are decreased. In some reports a decrease in RBC 2,3-DPG has also been noted.

Most HX patients have heterozygous missense mutations in PIEZO1. *In vitro* studies of HX-associated PIEZO1 mutations demonstrate a gain-of-function phenotype, with many mutants

Fig. 45.9 PERIPHERAL BLOOD SMEARS FROM PATIENTS WITH HEREDITARY XEROCYTOSIS (DESICCACYTOSIS) (TOP) AND STOMATOCYTOSIS (HYDROCYTOSIS) (BOTTOM). (Top) A Wright-stained peripheral blood smear from a patient with hereditary xerocytosis caused by a PIEZO1 mutation showing rare stomatocytes, occasional desiccocytes—dense, abnormal erythrocyte forms where hemoglobin appears puddled at the periphery, and rare target cells. (Bottom) A Wright-stained peripheral blood smear from a patient with hereditary hydrocytosis is shown. Numerous stomatocytes, erythrocytes with a central mouth-like “stoma” are seen.

demonstrating delayed channel inactivation, indicating increased cation permeability may lead to dehydration of HX erythrocytes. Piezo proteins are putative ion channels mediating mechanosensory transduction in mammalian cells. Animal models suggest mechanically activated Piezo1 plays a critical role in erythrocyte volume homeostasis. In a small subset of HX patients, defects of the Gardos channel encoded by the *KCNN4* gene have been described.

Some of the reported cases of hereditary stomatocytosis share features of both hereditary stomatocytosis and xerocytosis categorized as “intermediate” syndromes. These patients characteristically have both stomatocytes and some target cells on the peripheral blood smear. Osmotic fragility is either normal or slightly increased. Sodium and potassium permeability is somewhat increased, but the intracellular cation concentration and the RBC volume are either normal or slightly reduced. These cells were reported to have subnormal glutathione content. In some patients, RBCs undergo in vitro hemolysis at 5°C, hence the designation *cryohydrocytosis*. A similar susceptibility to cold-induced cation permeability in which potassium and water loss predominates and xerocytes instead of hydrocytes are present, has also been described.

A study of stomatocytosis, spherocytosis, and spherostomatocytosis patients whose erythrocytes demonstrated significant cation leaks at 0°C and in some cases, band 3–deficient membranes, revealed a series of missense mutations located in an intramembrane domain of band 3. In vitro studies suggest that these mutations convert band 3 from an anion exchanger to a nonselective cation leak channel.

Several investigators have also reported a dominantly inherited hemolytic anemia with stomatocytosis, occasional target cells, spherocytes, and a decreased osmotic fragility in which the main RBC membrane abnormality involved a nearly 50% increase in phosphatidylcholine and a corresponding decrease in phosphatidylethanolamine. Because abnormalities in membrane phospholipid composition have not been systematically investigated, it is uncertain whether the disorder represents a distinct disease entity.

The results of splenectomy in this group of disorders are variable. In some patients, the hemolytic anemia is improved, although often not fully corrected, by splenectomy, whereas in others, the severity of the hemolysis is unchanged. Splenectomy should be carefully considered in patients with hereditary stomatocytosis. Several patients with stomatocytosis (both hydrocytosis and xerocytosis) have developed hypercoagulability after splenectomy, leading to catastrophic thrombotic episodes or chronic pulmonary hypertension. Fortunately, the majority of persons with hereditary stomatocytosis are able to maintain an adequate hemoglobin level, so that splenectomy is not required.

Rh Deficiency Syndrome

Rh deficiency syndrome designates rare individuals who have either absent (Rh_{null}) or markedly reduced (Rh_{mod}) Rh antigen expression, mild to moderate hemolytic anemia associated with the presence of stomatocytes, and occasional spherocytes on the peripheral blood film. Hemolytic anemia is improved by splenectomy.

The Rh antigens are present in ~20,000 to 30,000 copies per cell and reside on minor transmembrane proteins with an electrophoretic mobility of 28 to 33 kDa on SDS-PAGE. The Rh gene locus encodes two closely linked genes, one encoding the D polypeptide and the other encoding the CcEe proteins, the antigenic expression of which is a consequence of alternate splicing of their pre-mRNA.

Rh proteins are part of a multiprotein complex that includes two Rh proteins and two Rh-associated glycoproteins (RhAG). Other proteins that associate with this complex include CD47, LW, glycophorin B, and protein 4.2. The Rh-RhAG complex interacts with ankyrin to link the membrane skeleton to the lipid bilayer. The Rh proteins share sequence homology to the Mep/Amt family of ammonium transporters in lower organisms and may participate in ammonium transport.

Rh_{null} erythrocytes have no Rh antigen and have reduced or absent LW, Fy5, Ss, U, and Duclos antigens. Rh, RhAG, LW, glycophorin

B, CD47, and protein 4.2 are also reduced or absent. Rh_{null} erythrocytes have increased osmotic fragility, reflecting a marked reduction in membrane surface area. These cells are also dehydrated, as indicated by decreased cell cation and water content and increased cell density. The potassium transport and the Na^+/K^+ pump activity are increased, possibly because of reticulocytosis. Phospholipid asymmetry is also altered.

Although the clinical syndromes are the same, the genetic basis of the Rh deficiency syndrome is heterogeneous, and at least two groups have been defined. The amorph type is caused by defects involving the RH30 locus encoding the RhD and RhE polypeptides. The regulatory type of Rh_{null} and Rh_{mod} phenotypes results from suppressor or modifier mutations at the RH50 locus. When one chain of the Rh-RhAG complex is absent, the complex either is not transported to or is assembled at the membrane.

Familial Deficiency of High-Density Lipoproteins

Familial deficiency or absence of high-density lipoproteins (Tangier disease) because of mutations in ABCA1, a protein involved in cellular export of cholesterol, leads to accumulation of cholesterol esters in many tissues. Clinical manifestations include large orange tonsils, hepatosplenomegaly, lymphadenopathy, cloudy corneas, and peripheral neuropathy. Reported hematologic manifestations include a moderately severe hemolytic anemia with stomatocytosis and thrombocytopenia. Erythrocyte membrane lipid analyses reveal a low free cholesterol content, leading to a decreased cholesterol/phospholipid ratio and a relative increase in phosphatidylcholine at the expense of sphingomyelin.

Sitosterolemia

Sitosterolemia or phytosterolemia is a recessive disorder associated with elevated plasma levels of plant sterols. Affected patients exhibit xanthomatosis and early-onset premature cardiovascular disease. Reported hematologic manifestations include hemolytic anemia with stomatocytosis and macrothrombocytopenia. Mutations in the transporters ABCG5 or ABCG8 lead to gastrointestinal hyperabsorption and decreased biliary elimination of plant sterols as well as altered cholesterol metabolism. Plant sterols are not synthesized endogenously in humans but are passively absorbed in the intestine. ABCG5 and ABCG8 actively pump plant sterols out of the intestinal cells back into the intestine and out of liver cells into bile ducts. It has been hypothesized that the stomatocytic phenotype is caused by intercalation of plant sterols into the inner leaflet of the lipid bilayer.

Acquired Stomatocytosis

Stomatocytes have been noted in diverse acquired conditions, including neoplasms, cardiovascular and hepatobiliary disease, alcoholism, and therapy with drugs, some of which are known to be stomatocytogenic in vitro. In some of these conditions, the percentage of stomatocytes on the peripheral blood smear can approach 100%. However, the clinical significance of this observation is unclear because stomatocytes are absent in most patients with the conditions listed. Furthermore, some stomatocytes can be found in normal individuals (3–5%). The most consistent association is that of stomatocytosis and heavy alcohol consumption.

RED CELL MEMBRANE VARIANTS AND INFECTIOUS DISEASE

Viral, bacterial, and parasitic infection can all cause anemia. Multiple mechanisms leading to hemolysis have been described. As mentioned earlier in this chapter, parvovirus B19 selectively infects erythroblasts through interaction with globoside, which encodes the P blood group

antigen and temporarily shuts down erythropoiesis. Although this infection is tolerated well by healthy patients, it can lead to severe, at times life-threatening, aplastic crises in patients with anemias because of premature erythrocyte destruction. As one might predict, parvovirus cannot invade erythroblasts of the rare P-negative individuals.

Most infections cause hemolytic anemias triggered by several distinct, and at times overlapping, mechanisms. *Plasmodium*, *Babesia*, and *Bartonella* species directly attack the membrane and lyse the red cells. Some bacteria, such as *Clostridium perfringens*, elaborate hemolytic toxins or phospholipases that damage the membrane. Other infectious agents trigger occasional production of autoantibodies against red cell membrane components, which in turn leads to autoimmune hemolytic anemia. Finally, many sepsis syndromes are associated with anemia because of disseminated intravascular coagulation.

Malaria and the Erythrocyte Membrane

The red cell membrane defects described earlier in this chapter cause mild to severe hemolytic anemias. At the same time, many red cell membrane alterations have developed as a defense against microorganisms and parasites invading and lysing red cells. This is especially true for malarial parasites. Although four different species of the malaria parasite *Plasmodium*, including *P. falciparum*, *P. ovale*, *P. vivax*, and *P. malariae*, infect humans, almost all of the 1.5 to 2 million annual deaths caused by malaria are attributable to *P. falciparum*.

Because malaria coexisted with humans over the course of human evolution, it comes as no surprise that multiple erythroid genotypes were selected that confer some level of resistance to infection or mitigate disease severity. The ensuing heritable phenotypes include, among others, resistance to red cell adhesion and/or invasion, slower intraerythrocytic growth, decreased or increased adhesion of infected red cells to vascular endothelium, and increased phagocytosis of parasitized red cells.

Malaria and other infections causing hemolytic anemias are described in more detail in [Chapter 158](#), which also discusses hemoglobinopathies and red cell enzyme variants that reduce invasion and/or retard parasite growth. Consequently, we focus here on the heritable erythrocyte membrane alterations that developed as a defense against malaria.

Erythrocyte Preference

Two parasites, *P. vivax* and *P. ovale*, selectively infect reticulocytes, whereas *P. malariae* infects older erythrocytes. In contrast, *P. falciparum* infects red cells of all ages. This fact and the tendency of *P. falciparum*-infected erythrocytes to sequester in circulation explain the markedly higher severity of *P. falciparum* malaria.

Attachment and Invasion

Duffy Antigen

The *P. vivax* merozoite is completely dependent on attachment to the Duffy blood group antigen (also known as the *Duffy antigen receptor for chemokines* [DARC]) for erythrocyte invasion, and consequently it cannot invade Duffy-negative RBCs. It has been hypothesized that this is why the Duffy-negative phenotype is common in large areas of Africa. The Duffy-negative phenotype is caused by mutation in a *GATA1* motif in the Duffy antigen gene promoter, preventing its expression in erythroid cells, leaving its expression in other tissues intact. Elucidation of this mutation explained a long-standing conundrum of transfusion medicine: why individuals with the Duffy-negative phenotype never develop antibodies against the Duffy antigen.

Glycophorins

All major erythrocyte glycophorins, A, B, and C/D, are involved in attachment of *P. falciparum* to the RBC membrane. Consequently,

invasion of *P. falciparum* into red cells from patients lacking glycophorin A (En[a-]), glycophorin B (S-s-U-), or glycophorins C and D (Gerbich negative, Ge-) is diminished. As noted earlier, the Gerbich-negative phenotype is associated with mild, asymptomatic ovalocytosis.

Protein 4.1R and Spectrin

Deficiency of protein 4.1R or self-association defects of spectrin are associated with elliptocytosis of varying severity. Both phenotypes appear to reduce the burden of RBC invasion.

Band 3 and Southeast Asian Ovalocytosis

Conflicting explanations of the basis of the protective phenotype of SAO (described earlier) from malaria have been described. Initial reports suggested that SAO erythrocytes were resistant to malarial invasion. These results were repeatedly questioned until recent studies demonstrated SAO cells to be resistant to invasion by the more virulent *P. falciparum* strains. This may explain the apparent contradiction with the reports of comparable parasitemias in SAO carriers and patients with a normal red cell phenotype from Papua New Guinea.

The protection from cerebral malaria afforded by SAO erythrocytes is likely because of reduced cytoadherence of SAO red cells to the cerebral vasculature. Under conditions of flow, *P. falciparum*-infected ovalocytes adhere more strongly than normal infected red cells to the endothelial receptor CD36. Because this receptor is not expressed in the brain, this raises a possibility that ovalocytosis protects from cerebral malaria by diminishing the number of parasitized red cells available for adhesion to the cerebral vasculature via alternative receptors. Moreover, ovalocytes appeared resistant to invasion by parasite strains that tend to bind to intracellular adhesion molecule I (ICAM1), the likely receptor for cytoadherence in the brain, but the exact mechanism is not yet known.

Knops Blood Group System

Severe malaria, particularly cerebral malaria, has been associated with the formation of rosettes, clumps of cells formed by the adhesion of malaria-infected erythrocytes to complement receptor 1 (CR1) on uninfected erythrocytes. Identification of the Knops blood group antigens on CR1, followed by observations that frequencies of various Knops antigens varied significantly in whites and individuals of African ancestry, led to the hypothesis that some Knops group antigens might be protective from rosetting and severe malaria. Case control studies with genotyping and/or flow cytometry have yielded conflicting results, but several have linked low-expression CR1 alleles with malaria resistance. Further studies have shown that the expression of CR1 and other complement proteins increases with age. Together these data suggest that genetic and age-related differences in complement protein expression contribute to the variability observed in individuals with severe malaria.

Although these erythrocyte membrane polymorphisms offer fascinating insight into natural defenses against one of the most serious diseases affecting humans, the mechanism of resistance to malaria has not been fully elucidated for any of them. Malaria has clearly had a profound impact on the genetic makeup of populations living in endemic areas and provided us with multiple clues about the host-parasite relationship. Better understanding of these natural defenses might eventually be converted into effective therapeutic interventions.

AUTOIMMUNE HEMOLYTIC ANEMIA

Marc Michel and Ulrich Jäger

Autoimmune hemolytic anemia (AIHA) is caused by autoimmune-mediated destruction of red blood cells (RBCs) by autoantibodies with various properties and target specificities. Exact laboratory diagnosis is often difficult; therefore, experienced diagnostic reference centers play an important role. The disease can be primary (idiopathic) or caused by an underlying condition (secondary), including autoimmune diseases, infections, drugs, or neoplasms. The clinical course of the disease as well as treatment decisions are influenced by the type of antibody involved. Success in treatment and the evaluation of therapies have lagged behind the achievements in laboratory diagnosis but will hopefully improve with the introduction of new effective drugs. Currently, almost all treatments in AIHA are based on experience and opinion but not on evidence. There are no established guidelines. Thus, management of the disease requires general hematologic skills and critical evaluation of treatment recommendations.

HISTORY

The history of diagnostic and therapeutic progress in AIHA has been described by Dacie,¹ one of the great pioneers in this field. Milestones were the discovery of the first RBC autoantibody (Donath–Landsteiner antibody) in 1904, the introduction of the Coombs test in 1945, the establishment of splenectomy as effective treatment of AIHA in the 1950s, and the finding that rituximab is an effective treatment in the past decade. The diagnosis and treatment of patients with AIHA were recently reviewed by several authors.^{2–8}

EPIDEMIOLOGY

Because only a low proportion of patients have spontaneous or treatment-induced long-term remissions and the death rate is low, the prevalence of AIHA is relatively high and has been estimated as 17 in 100,000 (in Denmark). The incidence of AIHA in children and teenagers is 0.2–1.0 per million per year.⁹ There is some evidence of a familial clustering of AIHA in children, but no hereditary genetic background has been identified.

Primary AIHA and Evans syndrome are slightly more prevalent in women and in children.¹⁰ In secondary AIHA, the female-to-male ratio is very high in systemic lupus erythematosus (SLE), but low in chronic lymphocytic leukemia (CLL)-associated AIHA. The incidence of chronic cold agglutinin disease (CAD) is estimated to be one per million per year, with a female prevalence. Geographical differences have been suggested, with a higher incidence of CAD in Northern climates.

PATHOBIOLOGY

Hemolysis is initiated when an autoantibody binds to the RBC membranes and recruits complement. Destruction of the RBC can occur directly in the circulation (intravascular hemolysis) or by removal of the cell by macrophages in the spleen, liver, or both (extravascular hemolysis) (Fig. 46.1). Several immunoglobulin (Ig) subclasses can fix complement: IgG, IgA, and IgM. Macrophages recognize opsonized erythrocytes via receptors specific for the Fc fragment of IgG and for C3d. RBCs coated with IgG or complement

alone are destroyed in the spleen and liver, IgG-coated cells in the spleen, and IgM-coated cells in the liver.^{11,12} This has major implications for treatment, particularly for the effect of steroids and splenectomy.

Warm Antibody Hemolytic Anemia

About 70% to 80% of cases of AIHA are caused by WAIHAs. The RBC antibodies in WAIHAs are mostly polyclonal IgG (IgG₁₋₄), which have a low capacity to activate the complement system (Table 46.1). The direct antiglobulin test (DAT) in WAIHAs is positive either with IgG (37%) or IgG + C3d (43%). Rarely, the DAT is only positive with C3d (when the amount of IgG on the RBCs is very small). Patients with IgG antibodies may have also IgA antibodies, but IgA antibodies without IgG antibodies are a very rare cause of WAIHAs. WAIHAs are often directed against Rh antigens but also against other blood group antigens (non-Rh-related autoantibodies) such as band 3 protein or glycophorin A. The antibodies fix complement and bind tightly to the RBCs at 37°C. Therefore, there is only a small amount of antibody detectable in the serum. The antibody-coated RBCs are removed from the circulation by splenic (to a lesser degree also by hepatic) macrophages via Fc_γRIII receptors. IgG₃ and IgG₁ have the highest affinity for the Fc receptors of macrophages. Erythrocytes that are only partially phagocytosed by the macrophages become spherocytes, which are removed in the splenic cords because of their rigid structure. Destruction of RBCs may also be caused by other mechanisms such as antibody-dependent cellular cytotoxicity.¹³

IgM WAIHAs are a very rare cause of AIHA. This type of AIHA can be suspected if RBC autoagglutination occurs at room temperature. The DAT result is positive with C3d alone (65%) or with IgG (24%). Using sensitive methods, IgM on the RBCs can be detected in 71%.¹⁴ Non-Hodgkin lymphoma (NHL) is the underlying disease in some of these cases. This AIHA is severe, often fatal, and refractory to steroids and splenectomy.

Cold Antibody Hemolytic Anemia

CAIHAs in primary or secondary CAIHA are usually monoclonal IgM. The IgM has two binding sites for C1q and fixes complement easily. The targets are polysaccharides (I, I¹, I, or Pr antigens). The “i” antigen is a nonbranched polysaccharide in the cord blood, and the “I” antigen is a similar but branched molecule expressed in the RBCs of adults. The CAIHAs bind to the RBCs at low temperatures and cause their lysis at temperatures above 22°C. The DAT is typically positive with C3d alone. When CAIHAs are present at high titers, they may activate the complement system directly and produce a membrane attack complex and intravascular hemolysis with hemoglobinuria. Usually the complement-coated RBCs are sequestered by liver macrophages.

Paroxysmal cold hemoglobinuria (PCH) is caused by the Donath–Landsteiner (DL) antibody. This is a rare, usually polyclonal IgG cold antibody to P antigen (glycosphingolipid globoside), which binds to the RBCs at 4°C. The cells are lysed at higher temperatures. The DAT is positive with C3d, and the diagnosis is made by the DL test. In this test, normal RBCs and patient and normal serum are

Fig. 46.1 MECHANISM OF EXTRAVASCULAR HEMOLYSIS IN AUTOIMMUNE HEMOLYTIC ANEMIA. (A) Macrophage encounters an IgG-coated erythrocyte and binds to it via its Fc receptors. Thus entrapped, the red blood cell (RBC) loses bits of its membrane as a result of digestion by the macrophage's ectoenzymes. The discoid erythrocyte transforms into a sphere. (B) RBCs lightly coated with IgG (and therefore incapable of activating the complement cascade) are preferentially removed in the sluggish circulation of the spleen. (C) RBCs with a heavy coat of IgG; thus, C3b (black circles) can be removed both by the spleen and the liver. (Courtesy Cunningham MJ, Silberstein LE: *Autoimmune hemolytic anemia*. TABLE 46.1

Properties and Specificities of Red Blood Cell Autoantibodies

	Immunoglobulin (Subclass)	Type of Antibody	Clonality	Specificity	Hemolysis	Site of Removal of Red Blood Cells
WAIHAs	IgG ₍₁₋₄₎ , IgA	Incomplete	Mostly polyclonal	Rh-antigens and non-Rh-antigens	Extravascular	Spleen (liver)
CAIHAs	IgM	Complete	Mostly clonal	Anti-i, -I ^T , -I, -Pr	Intravascular	Liver
Donath–Landsteiner antibody	IgG	—	Polyclonal	P antigen	Intravascular	—

CAIHA, Cold autoimmune hemolytic anemia; Ig, immunoglobulin; WAIHA, warm autoimmune hemolytic anemia.

incubated at 4°C. Agglutination occurs after warming to 37°C. The prominent clinical feature of PCH is a brisk, immediate but sometimes also delayed hemoglobinuria after cold exposure even in patients with low antibody titers. In the past, it has been associated with secondary or tertiary syphilis. Now, two types can be distinguished clinically¹⁵: (1) an acute, severe form (often associated with hemoglobinuria) but self-limiting AIHA after (respiratory) infections in children, and (2) a rare, chronic AIHA in nonsyphilitic persons with various underlying conditions, including NHL. Patients with chronic PCH respond poorly to steroids and splenectomy.

Mixed Warm and Cold AIHA

A small number of patients have a mixed AIHA with a positive DAT for both IgG and C3d indicating coexistence of warm IgG autoantibodies and high-titer cold agglutinins.¹⁶

ETIOLOGY AND PATHOPHYSIOLOGY

Our knowledge about the etiology of AIHA is still limited. Factors that may play a role are antigen mimicry; immune deficiency; and, to a lesser extent, probably genetic factors. AIHA, similar to other autoimmune diseases, is a consequence of the loss of immunologic (self-) tolerance against antigens expressed on the erythrocyte surface.

Production of RBC antibodies is a result of the interaction of T and B cells, as well as regulatory factors (e.g., T regulatory cells, cytokines).¹⁷ Disturbances of the Th1/2 T-cell subset balance as well as the occurrence of clonal regulatory T cells specific for a RBC autoantigen have been described. This may be linked to the fact that AIHA does not only occur in immunocompetent individuals but frequently occurs in patients with acquired T-cell defects such as HIV infection or immunosuppressive therapy, particularly after organ transplantation. Polymorphisms or altered expression of negative regulators of T-cell responses such as cytotoxic T lymphocyte antigen 4 (CTLA4) or interleukin-10 may also play a role. Mouse models (New Zealand black mice) have revealed an association of genetic loci with antierythrocyte antibody production or cold agglutinin escape tolerance after *Mycoplasma* infection.

Various target antigens have been described, with Rhesus polypeptides, glycophorin, and erythrocyte band 3 being the most prominent in WAIHA. Cold reactive antibodies frequently target the I or i blood group-specific antigens. Events linked to the development of secondary AIHA by induction of cross-tolerance (molecular mimicry) are infections (*Mycoplasma pneumoniae* [I antigen target], parvovirus, herpes viruses), neoplastic diseases (paraneoplasia), and drugs by various mechanisms. There are important differences in the pathogenesis of WAIHA and CAIHA. The pathogenesis of primary WAIHA is largely unknown. Secondary WAIHA is a complication of several congenital or acquired immune deficiencies. Both moderate (e.g., in CLL) and severe (HIV, posttransplant, congenital severe

T-cell deficiencies) T-cell and humoral immune deficiency predispose to WAIHA, but no correlation between the type and severity of immune deficiency and the risk of AIHA has been established. One phenomenon that is poorly understood is the lack of a clear relationship between the presence of RBC antibodies and anemia. In many instances, there is no anemia despite a strongly positive DAT or high titers of CAIHAs. There is also only a poor correlation between antibody titers and severity of anemia. Another unexplained finding in secondary AIHA is the occurrence of both WAIHAs and CAIHAs in the same condition; for example, in lymphomas or infections.

Antibodies in primary AIHA are frequently polyreactive and polyclonal (no clonal B cells detected by polymerase chain reaction [PCR]). Antibodies in CAD are mostly produced by PCR-detectable oligoclonal or monoclonal B-cell populations. The nature of these antibodies has been extensively studied in CAD. However, in only a few cases has it been established that the RBC antibody is clonal. In most reports, clonality of RBC antibodies was assumed if the patient had a paraproteinemia.

B-cell neoplasms expressing IgMκ antibodies directed against RBC antigens have few somatic mutations, which seem to be fairly restricted to certain Ig heavy and light chain families (VH4-34, VκIV).¹⁸ Moreover, a VH4-34 CLL confounding subclone was shown to arise from a preexisting CAD-producing B-cell population. The restricted clonality of CAD-producing B cells is further corroborated by the detection of clonal Ig rearrangements and recurrent chromosomal aberrations (trisomy 3).^{19,20} CLL cells may also drive AIHA by presenting the autoantigen (e.g., erythrocyte protein band 3) to T cells.

SYMPTOMS, CLINICAL FINDINGS, AND RISKS

The symptoms of AIHA depend on the type of antibody, the mode of onset, and the severity of anemia. In patients with WAIHA, the onset is mostly gradual or subacute, and the symptoms (i.e., tiredness, reduction of physical activity, and shortness of breath in elderly patients) are attributable only to anemia. However, patients with postinfectious, drug-induced AIHA, or patients with DL or Pr antibodies often present with acute severe symptoms such as malaise, fever, jaundice, abdominal pain, shortness of breath, and hemoglobinuria. The course in such patients may be fulminant and even fatal. Patients with chronic CAIHA (CAD) often have an indolent course. Symptoms suggestive of CAIHA are cold sensitivity, cold-dependent acrocyanosis, acral numbness, and rarely livedo reticularis. Anemia worsens after cold exposure or conditions associated with an acute phase reaction.

During clinical examination, a subicterus may be seen. Lymphadenopathy, palpable splenomegaly, or any organomegaly is rare in patients with primary AIHA. Its presence suggests secondary AIHA.

Patients with WAIHA are at an increased risk of venous thromboembolism, sometimes associated with a lupus anticoagulant (LA).^{21,22} Older patients with AIHA are at an increased risk of cardiovascular complications, which may also be partly caused by the treatment.

LABORATORY DIAGNOSIS OF AUTOIMMUNE HEMOLYTIC ANEMIA

AIHA is essentially a laboratory diagnosis. The diagnostic pathway of AIHA should proceed in a stepwise fashion answering the following questions:

Step 1: Hemolytic Anemia?

The first step is to establish the diagnosis of hemolytic anemia (see box on Four Important Questions for the Diagnosis and Management of Autoimmune Hemolytic Anemia). This diagnosis is established by the presence of the following pentad of findings: normocytic or macrocytic anemia (male hemoglobin (Hb) <13.0–14.0 g/dL;

female <12.0 g/dL), reticulocytosis (corrected reticulocyte count >2% or absolute reticulocyte count >100,000/μL to 120,000/μL), low haptoglobin, elevated lactate dehydrogenase (LDH), and elevated unconjugated (indirect) bilirubin. Haptoglobin is an α₂-globulin that binds Hb. This Hb–haptoglobin complex is degraded in the liver. Hemopexin is another plasma protein with a very high binding affinity to Hb. It scavenges heme released from RBCs and protects the organisms from the adverse effects of circulating Hb. The determination of hemopexin is not essential for the diagnosis of AIHA. Indirect bilirubin is usually not more than 5 mg/dL except in associated liver disease (Epstein-Barr [EBV]-associated AIHA). Additional findings are increased urobilinogen in the urine and spherocytes in the blood smear (Fig. 46.2). Leukoerythroblastosis occurs only in peracute AIHA, but microangiopathic hemolytic anemia should always be suspected in such cases. Bone marrow examination is usually not necessary except in patients in whom secondary AIHA, in particular lymphoma, is suspected. RBC survival is shortened, but its measurement with radioisotopes has no diagnostic value, not even for the prediction of the efficacy of splenectomy.

Four Important Questions for the Diagnosis and Management of Autoimmune Hemolytic Anemia

It is of utmost importance to differentiate between various types of AIHA. A stepwise approach helps in making the right decisions:

Question 1: Hemolytic anemia? The basic features of hemolytic anemia are low haptoglobin levels, elevated indirect bilirubin, and elevated LDH.

Question 2: Autoimmune hemolytic anemia? A DAT is initially performed with a polyspecific antibody to detect IgG or complement C3d bound to RBCs. If the DAT result is positive, the diagnosis of AIHA is established.

Question 3: Warm or Cold Autoimmune Hemolytic Anemia? The DAT is further elaborated with monospecific antibodies to IgG and complement (C3d). If the DAT result is positive with IgG alone or with IgG + C3d, the AIHA is most probably caused by a warm antibody (WAIHA). If the DAT is positive with C3d only, the AIHA is most probably caused by a cold antibody (CAIHA).

Question 4: Primary or secondary AIHA? More than half of AIHAs are secondary to underlying diseases. Secondary AIHA should be suspected in patients with additional findings or who are refractory to initial steroid treatment. In this case, the underlying disease has to be diagnosed (e.g., by serologic tests, computed tomography (CT) scan, or bone marrow biopsy).

Fig. 46.2 BLOOD SMEAR SHOWING NUMEROUS SPHEROCYTES (ARROWS).

Among methodologic diagnostic problems, reticulocyte counting is the biggest, because in many laboratories low-precision microscopic counts are still performed. Automatic flow cytometric methods are more precise, reliable, and convenient. With flow cytometry, the number of highly fluorescent reticulocytes (which are increased in AIHA but are low in hereditary spherocytosis) can also be measured. Falsely very high mean corpuscular volume (MCV) and mean corpuscular Hb concentration occur in some cases of CAIHA because RBC counts are falsely low because of agglutination of RBC at room temperature. If a CAIHA is suspected, blood samples should be sent to the laboratory in warmed containers.

All of the findings of the pentad are not always present. Reticulocytosis is often (in $\approx 25\%$) not present at the onset of AIHA. This is mostly because of a delayed initial bone marrow response of erythropoiesis. After 1 week, most of these patients have reticulocytosis. In other patients (particularly in secondary cases), absence of reticulocytosis may be attributable to impairment of erythropoiesis caused by bone marrow infiltration or blunted erythropoiesis caused by an acute-phase reaction. If the reticulocyte count is very low, pure RBC aplasia (PRCA), either immune mediated or induced by a parvovirus (or HHV6) infection, should be suspected. Haptoglobin may be falsely normal or even increased, particularly in patients with malignant or immune diseases, because haptoglobin is an acute-phase protein. Haptoglobin may be falsely low in patients with a haplotype H_0H_0 and in patients with severe liver disease. Both increased bilirubin and elevated LDH have a limited specificity for AIHA.

Step 2: Autoimmune Hemolytic Anemia?

The next step is to find out whether the hemolytic anemia is an AIHA. This is best done by the DAT (Fig. 46.3). In this test, washed RBCs of the patient (obtained from an ethylenediaminetetraacetic acid [EDTA] blood sample) are incubated in a tube with a polyspecific antibody to IgG and complement (C3d). If the RBCs agglutinate, the test result is positive. In many laboratories, the tube test has been replaced by the tube gel test, which is easier to perform, more

reliable, and probably more sensitive (Fig. 46.4). In the indirect antiglobulin test (IAT), patient plasma or serum is incubated with test RBCs, and (after washing) RBC-bound IgG is detected with the DAT. IAT is usually not required for the diagnosis of AIHA except when a drug-dependent antibody is suspected. For the differentiation of drug-dependent antibodies and autoantibodies, an acid eluate of the patient's RBCs should be made and tested in the IAT. If the IAT result is positive, the patient has autoantibodies. The severity of AIHA does not correlate with the strength of the DAT but rather with the immunoglobulin subclass of the antibody (IgG₁ or IgG₃). The result of the DAT is not a reliable marker of treatment success because patients with a complete hematologic remission may remain DAT positive, and DAT positivity or negativity has only limited value to predict the duration of hematologic remission.

Falsely Negative and Positive Direct Antiglobulin Test Results Without Hemolysis or Anemia

If the conventional DAT test result is negative, hemolytic anemia is defined as DAT negative. However, AIHA cannot be definitely excluded because about 5% (2% to 11%) of AIHA patients are DAT negative. If AIHA is suspected for clinical grounds despite a negative DAT result, more sensitive quantitative tests are required to determine the amount of IgG on the RBCs. The threshold of positivity of the conventional DAT is 100–200 IgG molecules per RBC, but in some AIHA patients, the RBC IgG is less than this amount. In about one-third of DAT-negative cases, one of the more sensitive test results (e.g., immunoradiometric tests) will be positive. However, the relationship between the amount of RBC IgG and hemolysis is not clear cut, and there is no “hemolysis threshold.”²³ The reasons for these discrepancies between the in vitro and in vivo activity of RBC antibodies are largely unknown. Differences in macrophage activity may be one possible explanation. A search for antibodies in the RBC eluate in which antibodies are more concentrated is also useful. IgA antibodies are rare and sometimes not included in the analysis. Finally, there is the possibility of low-affinity antibodies. Such antibodies are washed out when the washes are made with 37°C saline. A high rate of DAT-negative AIHA has been observed in AIHA induced by nucleoside analogues but also in other secondary AIHA.

Fig. 46.4 RESULT OF A DIRECT ANTIGLOBULIN TEST PERFORMED ON GEL COLUMNS, WITH A POSITIVE RESULT SHOWN WITH AN ANTI-IGG AND ANTI-C3D. ctrl, Control; IgA, immunoglobulin A; IgG, immunoglobulin G; IgM, immunoglobulin M.

The DAT result is positive in 1 in 10,000 to 3 in 10,000 normal persons and 10% of hospital patients without anemia or signs of hemolysis.^{23a}

Step 3: Warm or Cold Autoimmune Hemolytic Anemia?

In a further step, the DAT is carried out with monospecific antibodies to IgG and complement (C3d) to find out whether a warm or cold antibody is the cause of hemolysis. If the DAT result is positive with IgG alone or with IgG plus C3d, the AIHA is most probably a WAIHA. If the DAT result is positive with only C3d, the AIHA is most probably a CAIHA. The differentiation between WAIHAs and CAIHAs is extremely important for the choice of treatment.

There are some special diagnostic problems in CAIHAs. If CAIHAs are suspected, it must be taken care that the blood that is sent to the laboratory is kept at 37°C to get reliable results. Patients with only RBC C3d may (rarely) have WAIHAs when the amount of RBC IgG is very small. In patients with C3d positivity, the cold agglutinin titer should be determined. If it is greater than 1:512, the diagnosis of a CAD is established. There is no threshold titer that separates normal from abnormal. If the titer is less than 1:512, the thermal amplitude of the antibody must be determined. If the thermal amplitude is above 22°C, the diagnosis is CAD. Mixed type AIHA is rare. The criteria are a positive IgG DAT result and a positive eluate (WAIHAs) result plus a C3d-positive DAT result and the presence of CAIHAs with a thermal amplitude of greater than 30°C (CAIHAs). Many published cases of mixed type antibodies do not fulfill these criteria.²⁴

Step 4: Primary or Secondary Autoimmune Hemolytic Anemia?

In the last diagnostic step, it must be determined whether the AIHA is primary or a complication of an underlying disease (secondary). The decision regarding which diagnostic procedures should be used for this purpose depends mainly on the type of AIHA (WAIHAs or CAIHAs) and should include history, physical examination, laboratory tests, and imaging procedures if indicated. In children and younger patients with WAIHA, evidence for an infection should be sought. A list of all recent medication should be made. A history of weight loss, fever, or poor general condition and arthritis points to a malignancy or immune disease as the underlying condition. Palpable lymphadenopathy and splenomegaly do not belong to the clinical picture of primary WAIHA. In this case, lymphoma (particularly splenic marginal zone lymphoma [SMZL]) should be suspected. Laboratory tests should include acute-phase proteins, LDH, quantitative determination of immunoglobulins, and other tests guided by the clinical history. A bone marrow examination is not obligatory except when lymphoma is suspected. Abdominal ultrasonography is reasonable in all cases to exclude splenomegaly, the remote (but important) possibility of an ovarian teratoma (in women), lymphadenopathy, or solitary extranodal lymphomas. Some experts recommend CT of the abdomen or thorax in all cases, but there is concern of radiation exposure. An activated partial thromboplastin time with a lupus-sensitive reagent may reveal a LA. Fluorescence-activated cell sorting or PCR for the detection of monoclonal lymphocytes may be done, but the clinical usefulness of such tests to guide treatment decisions is uncertain.

In CAIHA, a history of a febrile illness should prompt a thoracic radiography, and if results are positive, a serologic test for mycoplasma pneumoniae is required. The quantitative determination of serum IgG and a search for a clonal immunoglobulin by immune fixation are important. If immune fixation findings are positive, a search for lymphoma is necessary, which may include bone marrow biopsy even when there is no lymphadenopathy. In addition to classical CAD, cold agglutinins occurring in association with other cancers, aggressive lymphomas, or infection should be termed *cold agglutinin syndrome*.²⁵

Other tests, including blood glucose, HbA_{1c}, renal and hepatic function tests, HIV serology, hepatitis B antigen, and exclusion of latent tuberculosis are necessary to avoid complications of steroids (in WAIHAs) or rituximab (in CAIHAs and WAIHAs).

IMMUNOLOGIC PHENOMENA ASSOCIATED WITH AUTOIMMUNE HEMOLYTIC ANEMIA

Evans syndrome is the combination of WAIHAs with autoimmune thrombocytopenia (ITP), a typical but rare association. Platelet antibodies are usually directed against glycoprotein IIb/IIIa. Neutropenia occurs in 25% of patients. There is no sex predilection; about half of the cases are secondary. Evans syndrome is relatively more common in patients with SLE, antiphospholipid antibodies (APAs), and autoimmune lymphoproliferative syndrome (ALPS).²⁶ A search for an ALPS is mandatory in younger patients with Evans syndrome. In roughly 50% of the cases, AIHA and ITP occur simultaneously; in 25%, the disease starts with ITP; and in 16%, the disease starts with AIHA. There may be an interval of several years between the onset of AIHA and ITP.¹⁰

WAIHA, CAIHA, or a positive DAT result without anemia may be associated with PRCA. PRCA may be either immune mediated such as in T-cell neoplasms (particularly T-cell large granulocytic leukemia) or may be caused by an infection with parvovirus. Patients with parvovirus-associated AIHA often present with PRCA.

AIHA is definitely associated with APAs and LA. In one single-center prospective study, LA was found in 30% predominantly idiopathic AIHA. AIHA (4%) and Evans syndrome (10%) are frequent in patients with APAs. It is well established that patients with AIHA have a significantly (2.8-fold to 3.8-fold) elevated risk of venous thromboembolism.²² It is likely but not proven that patients with AIHA associated with LA are at a higher risk.

In lymphomas, some cases of AIHA are associated with C1-esterase inhibitor deficiency and mixed cryoglobulinemia.

SECONDARY AUTOIMMUNE HEMOLYTIC ANEMIA

About half of cases of AIHA (or probably even more) are secondary. The main causes are immune diseases and malignancies. Other underlying conditions are infections, drugs, transplantation, and congenital defects.

Temporal Relationship of Secondary Autoimmune Hemolytic Anemia to the Underlying Condition

The temporal relationship of AIHA to an underlying condition is complex. AIHA antedates the diagnosis of malignancy in many cases—in NHL, sometimes for years. In population-based studies, clonal B cells have been detected in some patients with seemingly idiopathic AIHA. In most instances, AIHA occurs concurrently with the malignancy. In some other cases, AIHA occurred only at the recurrence and rarely in complete remission (CR) after successful treatment. In CLL, AIHA occurs in a late phase of the disease. The patients have poor prognostic factors and often have been treated with various agents.

In immune diseases, particularly SLE, AIHA is a complication of the early phase of the disease. Infection-related AIHA occurs shortly after the onset of symptoms except in HIV infection, in which AIHA is a complication in the late advanced stage of the disease.

Serologic Type of Autoimmune Hemolytic Anemia in Secondary Autoimmune Hemolytic Anemia

It is an interesting phenomenon that in underlying diseases associated with AIHA, all serologic types of AIHA may occur, but usually one serologic type (WAIHA, CAIHA, or DL antibody) prevails.

The only exception is ovarian teratoma, which is only associated with WAIHA.

Autoimmune Hemolytic Anemia in Immune Diseases

Autoimmune Hemolytic Anemia in Systemic Lupus Erythematosus and Primary Antiphospholipid Syndrome

The prevalence of AIHA in patients with SLE is 7.5% (average of seven studies; range: 5.2% to 12.5%). AIHA may occur at any time during the course of SLE, but two-thirds of cases of AIHA occur at diagnosis or soon thereafter. Almost half of the patients are already taking steroids. Most patients are women and have WAIHA. Evans syndrome is common. Compared with SLE patients without AIHA, those with AIHA are younger; have a higher prevalence of thrombocytopenia, APAs, renal disease, serositis, and central nervous system involvement; and have a higher risk of venous thrombosis.²⁷

The prevalence of AIHA in primary antiphospholipid syndrome (PAPS) is about 10%. AIHA precedes PAPS in 25% of cases, but in others occurred after a median time of 4.4 years after the diagnosis of PAPS. Patients with PAPS and AIHA have an increased risk for the development of SLE.²⁸

Autoimmune Hemolytic Anemia in Inflammatory Bowel Disease

In the only larger study the prevalence of AIHA in ulcerative colitis was 1.7%.^{28a} The mean time from diagnosis of colitis to AIHA was 17 months. Three-quarters of these patients had total colitis. AIHA may also be associated with Crohn disease, but the prevalence is lower than in ulcerative colitis.

Autoimmune Hemolytic Anemia in Other Immune Diseases

A few or single cases of an association of WAIHA with Sjögren syndrome, dermatomyositis, biliary cirrhosis, Graves' disease, Churg-Strauss syndrome, crescentic glomerulonephritis, polymyalgia rheumatica, scleroderma, or autoimmune pancreatitis and of CAIHA with rheumatoid arthritis have been reported. A high prevalence of AIHA was found in small children with giant-cell hepatitis.

Autoimmune Hemolytic Anemia in Transplanted Patients

AIHA is a rare but important and dangerous complication of allogeneic hematopoietic stem cell transplantation (HSCT). Aside from AIHA, causes of hemolytic anemia in transplanted patients may be lymphocyte passenger syndrome and ABO incompatibility. AIHA may be caused by severe immunosuppression by drugs to prevent rejection or graft-versus-host disease (GVHD), viral infections, EBV lymphoproliferative disorder (LPD), or the recurrence of an immune disorder after transplantation (biliary cirrhosis).

The highest rate of AIHA occurred in small children after unrelated cord HSCT for inborn metabolic defects (44%) and in children with severe combined immune deficiency after haploidentical HSCT with T-cell-depleted stem cell grafts.

In adults, the incidence of AIHA ranges from 3.0% to 4.4% after allogeneic HSCT.²⁹ The median time from HSCT to AIHA is 4–10 months. Most patients have WAIHAs. Risk factors for AIHA are unrelated donor, T-cell depletion, and extensive GVHD. In most cases, AIHA occurred in patients in CR of the underlying disease, but in one study AIHA was associated with a relapse of chronic myeloid leukemia in the majority of patients.

After transplantation of solid organs, the highest risk of AIHA was in patients with pancreatic transplantation. A number of patients with AIHA or CAIHA were observed after liver transplantation but only a small number after cardiac, lung, intestinal, and renal transplantation. The most likely cause of AIHA in these patients is severe drug-induced immunosuppression.

TABLE 46.2 Secondary Autoimmune Hemolytic Anemia in Malignancies

Malignancy	Prevalence	WAIHAs	CAIHAs
MGUS	Very low	None	All
All NHL	0.23–2.6%		
CLL	4.3–9%	90%	10%
SMZL	10%	2/3	1/3
LPL	3–5%	None	Most
Angioimmunoblastic T-cell lymphoma	13%	One third	Two thirds
Hodgkin lymphoma	0.19–1.7%	All	None
Ovarian teratoma	Very low	All	None
Solid tumors	Very low	Two thirds	One third

CLL, Chronic lymphocytic leukemia; LPL, lymphoplasmacytic lymphoma; MGUS, monoclonal gammopathy with unknown significance; NHL, non-Hodgkin's lymphoma; SMZL, splenic marginal zone lymphoma.

Autoimmune Hemolytic Anemia in Pregnancy and After Blood Transfusion

Very few cases of AIHA and Evans syndrome occurred during pregnancy, all with WAIHAs. In these patients, there seems to be a higher risk for preeclampsia. AIHA responds well to steroids and resolves in most cases after delivery. In two cases, the newborns had mild hemolysis.

Development of RBC autoantibodies is common in multitransfused patients and is associated with the presence of alloantibodies. However, anemia is rare.

Autoimmune Hemolytic Anemia in Malignancies

Autoimmune Hemolytic Anemia in Lymphoproliferative Disorders

AIHA is a typical, relatively common immune-mediated paraneoplastic syndrome in LPD. It occurs in almost all histologic subtypes of NHL, but there is no correlation between the frequency of lymphoma and the risk of AIHA. AIHA is relatively most common in SMZL and angioimmunoblastic T-cell lymphoma (Table 46.2). In most LPD WAIHAs is predominant. Most WAIHAs, particularly in CLL, seem to be polyclonal. The proportion of patients with WAIHAs is highest in CLL and Hodgkin lymphoma; in other malignancies, the ratio of WAIHAs to CAIHAs is 2:1. In lymphoplasmacytic lymphoma (LPL), almost all antibodies are clonal CAIHAs.

Autoimmune Hemolytic Anemia as a Risk Factor for Lymphoproliferative Disorder

In various population-based studies, AIHA emerged as a risk factor for subsequent development of diffuse large B-cell lymphoma, LPL, CLL, monoclonal gammopathy with unknown significance (MGUS), and multiple myeloma. Data regarding the type of AIHA and a possible influence of treatment were not available in these studies. It is uncertain whether autoimmune disorder per se is the causal factor or whether these patients had a clinically silent clonal disorder at the time of AIHA.

Autoimmune Hemolytic Anemia in Chronic Lymphocytic Leukemia

The prevalence of AIHA is highest in CLL, ranging from 4.3% to 9%. The prevalence is highest in poor-risk patients (Binet stage B or C, increased ZAP70 expression, unmutated IgVH status, and CD38 positivity) and patients who had already been treated. However, AIHA may also occur in very early stages of CLL, including B-cell monoclonal lymphocytosis. In a large group of nontreated CLL patients, the prevalence of positive DAT result (with or without

anemia) was 14%.³⁰ Most CLL patients with AIHA are men. The vast majority of patients have (presumably) polyclonal WAIHAs, but in all studies, there is small number of cases with CAIHA (specificity anti-I), often with IgM paraproteinemia.

Autoimmune Hemolytic Anemia in Monoclonal Gammopathy With Unknown Significance and Lymphoplasmacytic Lymphoma

The clinical picture of primary chronic CAD suggests the presence of an “idiopathic” CAIHAs, but in fact, most of these patients have a clonal disease with either only clonal IgM (IgM-MGUS) or LPL with IgM paraproteinemia and bone marrow infiltration (or Waldenström macroglobulinemia). Traditionally, the latter category would be classified as secondary AIHA. More than 90% of patients with “CAD” have a monoclonal IgMκ; 7% had IgG or IgA monoclonal immune globulin with λ chains. The course of CAD is usually indolent. Fewer than half of patients require transfusions, and the risk for progression to highly malignant lymphomas is small.

Autoimmune Hemolytic Anemia in Other Lymphoproliferative Diseases and Myeloma

The prevalence of AIHA is low in NHL, ranging from 0.23% to 2.6%. AIHA has been described in all histologic subtypes of NHL. Based on the prevalence of NHL, the association with AIHA is highest with SMZL, LPL, angioimmunoblastic T-cell lymphoma, and γ heavy chain disease. The antibody may be either a warm (two-thirds) or a cold (one-third) antibody. In NHL, there seems to be a relatively frequent association of AIHA with LA, C1-esterase deficiency, or essential cryoglobulinemia.

A number of predominantly WAIHAs have been described in IgG and IgA myelomas.

Autoimmune Hemolytic Anemia in Myeloid Disorders

Generally, AIHA is rare in patients with myeloid malignancies. A number of cases have been reported in myelodysplastic syndromes, particularly chronic myelomonocytic leukemia. Very few cases were described in acute myelogenous and lymphoblastic leukemia, myelofibrosis, and polycythemia.

Autoimmune Hemolytic Anemia in Solid Tumors

A special, rare, but highly interesting cause of WAIHA is ovarian dermoid cyst. These patients respond very poorly to drug therapies, but the AIHA resolves completely, and the DAT result becomes negative a few weeks after ovariectomy. The same behavior has been described in microcystic adenoma of the pancreas and dermoid cyst of the mesentery associated with AIHA.

AIHA is rarely but definitely associated with solid tumors. It is a very rare complication of lung, renal cell, and ovarian cancer. In some cases of renal cell cancer, AIHA resolved after curative surgery.

Infection-Related Autoimmune Hemolytic Anemia

In immunocompetent patients, AIHA may occur after viral, bacterial, or parasitic infections (Table 46.3). Virus-associated AIHA occurs mostly in newborns and children; bacterial AIHA occurs more often in adults. The onset of AIHA is often shortly after signs of infection but sometimes after a latency time up to weeks. After some specific infections, patients may develop preferentially a warm or a cold antibody (sometimes with specific targets such as I, i, P, or Pr antigen), but in almost all instances beside the dominant antibody (cold or warm), there are a few cases of another antibody (see Table 46.3). Of particular interest is varicella-zoster virus-associated and rubella-associated CAIHAs, because the cold antibody is mostly directed to the Pr antigen and the AIHA is clinically severe. In *Mycoplasma*-associated AIHA, the antibody target is almost always “P”. After *Mycoplasma* infection, the DAT result is positive in 50% to 60% of cases, but anemia is rare. In some specific infections, the antibody was a DL antibody, but in a large study, most DL antibodies were

found after unspecific respiratory infections.¹³ In many cases, the course of AIHA is short, uncomplicated, and self-limited, but some cases with a severe, even fatal, course, particularly in patients with Pr antibodies and in *Mycoplasma*-associated AIHA, have been reported. In AIHA associated with bacterial infections or in leishmaniasis, treatment of the infection seemed to be beneficial.

AIHA has been described in a few cases of acute hepatitis A, B, C, or E, and in a number of cases of untreated chronic hepatitis C. However, in a large study, an increased prevalence of AIHA has only been found in interferon (IFN)-treated hepatitis C patients.³¹

Anecdotal reports have described patients in whom WAIHAs were associated with measles, *Chlamydia pneumoniae*, or miliary tuberculosis and CAIHAs with adenovirus, measles, leptospiral pneumonia, *Escherichia coli* infection (all anti-I), pneumococcal pneumonia (anti-Pr), *Haemophilus influenzae* (DL), or *Bartonella henselae* (DAT negative).

Some cases of AIHA have been described after vaccination against hepatitis B, influenza (MF59 adjuvanted), diphtheria–tetanus–pertussis, or rubella. Such associations could not be confirmed in systematic studies.

Drug-Induced Autoimmune Hemolytic Anemia

Historically, methyldopa, an antihypertensive drug, was the first known drug to induce AIHA. The prevalence of methyldopa-induced AIHA is 1% with 10% to 20% DAT-positive patients without anemia, indicating that DAT positivity is not always followed by overt disease. Currently, IFN-α and purine nucleoside analogues are the most common causes of drug-induced AIHA (Table 46.4). The diagnosis of drug-induced AIHA in a patient with AIHA after drug exposure can only be made if the *indirect* DAT result is positive and the RBC eluate contains a RBC antibody. Such tests have not been performed in all patients in whom drug-induced AIHA was claimed.

The temporal relationship between drug exposure and AIHA is complex. In some instances, AIHA may occur after long-term exposure to a drug (IFN or targeted antibodies). In AIHA caused by

TABLE 46.4 Drug-Induced Autoimmune Hemolytic Anemia

Drug	Risk Factors	AIHA Onset	Type of AIHA	Response to Treatment	Diseases Treated

purine analogues, AIHA occurs typically after a few cycles of therapy of CLL and is probably dose related (lower incidence and severity at reduced doses of fludarabine). Chlorambucil is said to induce AIHA, particularly after the end of treatment. This has not been found in all studies.

Interferon-induced AIHA has been described in various diseases (particularly hepatitis C and malignant diseases). It is caused by WAIHAs, occurs usually after long exposure to the drug, and disappears spontaneously after cessation of the drug within weeks. AIHA induced by purine analogues (fludarabine, cladribine) occurs mostly during or immediately after the end of drug treatment, but the onset is delayed in some cases. The antibodies are warm or mixed antibodies. This complication occurs predominantly in patients with CLL but seems to be very rare in lymphoma patients treated with these drugs. The incidence of AIHA in patients with CLL after fludarabine or cladribine monotherapy ranges from 2% to 11%. When fludarabine is combined with cyclophosphamide (and rituximab), AIHA is less frequent and probably less severe, but this may be attributable to the lower fludarabine dose in these protocols. Patients with a positive DAT result before treatment have a higher risk of purine analogue-induced AIHA. With steroids alone, about half of the patients achieve a lasting CR. So far no cases of AIHA have been reported after treatment of CLL with bendamustine.

An interesting and as yet unexplained phenomenon is the fact that some patients with CLL-associated AIHA may achieve remissions after fludarabine or cladribine treatment. However, it is general practice to avoid purine analogues in patients with AIHA. Other drugs that have been associated with WAIHAs (in single case reports) were IFN- β , the monoclonal anti-CD11 antibody efalizumab, the recently developed checkpoint inhibitors, namely anti-CTLA4 and anti-PD1/PD-L1 antibodies, and lenalidomide.

A peculiar type of CAIHA has been described in some patients with paroxysmal nocturnal hemoglobinuria who had been treated with the anti-C5 antibody ecuzulimab. These patients had an incomplete response to ecuzulimab. The RBCs of these patients accumulate C3d on their surfaces.

Autoimmune Hemolytic Anemia in Immune Deficiency States

AIHA is one of the classical complications of common variable immune deficiency (CVID). The prevalence of AIHA was 4% to 5.5% in large studies. AIHA preceded the diagnosis of CVID in more than half of the cases (median time from diagnosis of AIHA to CVID: 5.5 years). Evans syndrome is common.

AIHA (often combined with thrombocytopenia) occurs in 23% to 51% of patients with ALPS. The diagnosis of ALPS is made by the demonstration of a high number of circulating TCR $\alpha\beta$ ⁺ double-negative (CD4⁻ CD8⁻) T lymphocytes. The basic defect of ALPS is a disturbance of apoptosis.²⁶

AIHA is also common in deficiency of purine nucleoside phosphorylase (a T-cell deficiency with almost normal B cells). At least 15% of patients with Wiskott-Aldrich syndrome have AIHA. AIHA occurs before the age of 5 years and is associated with high serum IgM levels. These patients are candidates for allogeneic stem cell transplantation.

DIFFERENTIAL DIAGNOSIS

In patients with DAT-positive hemolytic anemia, the distinction from drug-dependent immune hemolytic anemia is important. In recipients of ABO- or D-incompatible allografts, anti-RBC antibodies are probably produced by immunocompetent memory B cells from the donor. This so-called *passenger lymphocyte syndrome* (PLS) is frequent in heart and lung transplantation ($\leq 68\%$). A difficult problem is differential diagnosis of DAT-negative AIHA or Evans syndrome. In younger patients with isolated hemolytic anemia with or without symptoms, hereditary diseases such as hereditary spherocytosis, sickle cell anemia, and thalassemia must be considered. Family history and RBC morphology are most helpful in these cases. In patients with drug-induced hemolytic anemia, nonimmune hemolysis caused by

glucose-6-phosphate-dehydrogenase deficiency should be considered. Babesiosis or other infections may cause nonimmune hemolytic anemia. In severely ill patients with hemolytic anemia and thrombocytopenia, idiopathic or cancer-related thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, or disseminated intravascular coagulation should prompt a search for schistocytes in the blood smear.

Paroxysmal nocturnal hemoglobinuria is diagnosed by a deficiency of glycosylphosphatidylinositol anchor proteins on the cell surface caused by a mutation of the *PIG-A* gene. Type II mixed cryoglobulinemia is a condition caused by a monoclonal IgM autoantibody with anti-IgG activity with rheumatoid factor properties frequently associated with hepatitis C. The clinical picture is characterized by a systemic vasculitis syndrome but not by anemia.

TREATMENT

For many years, drugs and procedures routinely used in the treatment of AIHA were not subjected to studies that today are regarded as the gold standard for approval and recommendation. Only a few randomized studies have been performed, and were usually small, and often with a heterogeneous population of patients with a short observation time. Thus, the treatment recommendation in this chapter should be viewed critically.⁸

Goals of Treatment

As in all diseases, the goal of treatment of AIHA is the achievement of a complete clinical and laboratory sustained remission without any residual signs of the disease. Such results can be obtained not only in primary AIHA but also in a substantial number of secondary cases when the underlying disease disappears spontaneously (infection), when the causative drug is withdrawn, or after (curative) treatment (surgery or chemoimmunotherapy) of an underlying malignancy. In most patients with primary WAIHAs, the expectations for success must be tempered. Therefore, a practical goal is the achievement of a good clinical response with freedom from symptoms in the absence of side effects of treatment. Remission of AIHA after treatment is often defined by laboratory values, but there is no consensus on the definition of CR or partial remission (PR) regarding Hb concentration. Formally, one could define CR as absence of transfusion requirement, a normal Hb value (according to the age and sex of the patient), and absence of signs of hemolysis (normal reticulocyte counts, haptoglobin, and LDH; negative DAT result). Such CR is sometimes seen in secondary AIHA. In primary AIHA, CR is often defined as Hb above 11.0 g/dL without sign of hemolysis, but the DAT result may remain positive. A minimal requirement for PR is the absence of transfusion requirement and a satisfactory clinical condition (usually Hb >9–10 g/dL). Thus, in AIHA, the treatment goals must be defined individually and tailored to the patient's needs.

Blood Transfusions

Blood transfusions may be necessary for emergency treatment of AIHA. The problem is to find well-matched RBC concentrates. In critical cases, transfusions should not be avoided or delayed because of uncertainty in matching (see box on Transfusion Therapy in Selected Patients With Severe Autoimmune Hemolytic Anemia). The decision is made on an individual basis depending on the speed of development and severity of anemia, the type and cause of hemolytic anemia (the highest acute death rates were observed in patients with fludarabine-associated AIHA, IgM WAIHAs, and DL antibodies), and the age and clinical condition of the patient. Because the antibody in WAIHAs is directed against blood group antigens, no truly matched blood transfusions are possible, but RBCs can be safely given if alloantibodies are excluded.³ However, some precautions have to be taken. In patients without a history of previous transfusions or

Transfusion Therapy in Selected Patients With Severe Autoimmune Hemolytic Anemia

Immediate blood transfusion should not be withheld from patients with severe anemia. Small amounts of RBCs may be lifesaving in patients with acute cardiac or cerebral dysfunction caused by anemia. However, precautions have to be taken to avoid transfusion reactions. This requires close cooperation between clinicians and the blood bank. The exclusion of alloantibodies is most important. Patients with a low risk for severe reactions caused by an alloantibody are those without a history of previous transfusions or pregnancy. In high-risk patients, extended RBC phenotyping should be performed for selection of compatible RBC concentrates. In all instances, a biologic in vivo compatibility test has to be performed at the beginning of the transfusion.

pregnancy the risk of alloantibodies is low, allowing for transfusion of only ABO- and RhD-matched RBCs. In all other patients, extended phenotyping with respect to Rh subgroups (C, c, E, e), Kell, Kidd, and S/s using monoclonal IgM antibodies should be performed for selection of compatible RBC concentrates. Warm autoadsorption or allogeneic adsorption procedures for detection of alloantibodies may be used in exceptional cases. In patients with CAIHAs, transfused blood must be prewarmed using commercial warming coils. In all instances, an important precaution is a biologic in vivo compatibility test, which includes rapid infusion of 20 mL of blood; 20 minutes observation; and, if there is no reaction, further transfusion at usual speed.

Treatment of Primary Warm Antibody Hemolytic Anemia

First-Line Treatment With Steroids

Newly diagnosed severe WAIHAs should be treated immediately with glucocorticoids (steroids) (Fig. 46.5 and Table 46.5; see also box on Initial Steroid Therapy). Therapy starts with an initial dose of 1 mg/kg/day of prednisone orally or an equivalent dose of methylprednisone intravenously. It is recommended to continue with this dose until a hematocrit of greater than 30% or a Hb level of greater than 10 g/dL is achieved. CR or PR is obtained in approximately 80% of patients. Failure to achieve this goal after 3 weeks should result in a switch to second-line therapy. In responding patients, prednisone dose is gradually reduced to 20–30 mg/day within a few weeks. Subsequently, the dose is tapered slowly by 2.5 mg to 5 mg/day per month guided by Hb and reticulocyte counts. If the patient is still in remission after 3–4 months at a dose of 5 mg/day, withdrawal of steroids can be attempted. The exact rate of patients remaining in CR after the end of steroid therapy is not known but is estimated to be around 20% to 40%.³² Most responders require maintenance steroids to keep the Hb above 9–10 g/dL. About 40% to 50% of patients need 15 mg/day or less prednisone (regarded as the highest tolerable dose for long-term treatment). However, 15% to 20% need higher maintenance prednisone doses.

For rituximab, two prospective studies have been reported.^{33,34} The first was an open-prospective phase II study testing the efficacy and safety of low-dose rituximab and the second was a randomized phase III open trial that showed the benefit of rituximab in combination with prednisolone over prednisolone alone with an overall response rate (ORR) of 75% at 1 year in the rituximab arm. Combination of rituximab with steroids compared with steroid monotherapy produced an increased response rate (75% vs 36% at 1 year) and a longer relapse-free survival (70% vs 45% at 3 years). Despite these encouraging data, the real value of rituximab in first-line remains to be established.

Therapeutic management of steroid treatment should include blood glucose monitoring, prophylaxis against osteoporosis (commence early), supplementation with folic acid, and heparin treatment in selected cases.

*Dose of prednisone ≥ 10 mg/day to maintain at least a partial response (i.e Hb level > 10 g/dL with at least a 2 g increase from baseline without recent transfusion)

**Complete response = normal hemoglobin level without hemolysis.

***The response to each one of these drugs can take as long as 2 to 3 months. They can be considered before splenectomy in case of contra-indication to splenectomy or patient's refusal.

Fig. 46.5 PROPOSED ALGORITHM FOR THE TREATMENT OF PRIMARY WARM ANTIBODY AUTOIMMUNE HEMOLYTIC ANEMIA IN ADULTS. IV, intravenous; IVIg, intravenous immunoglobulin; PDN, prednisone. (Modified from Lechner K, Jäger U: How I treat autoimmune haemolytic anemias in adults. Blood 116:1831, 2010.)

Great concerns are osteoporosis, osteonecrosis, and bone fracture, particularly of the lumbar spine. About 30% to 50% of patients on long-term steroid treatment experience fractures. The highest loss of bone density occurs early, even at smaller steroid doses, and the risk of fracture increases by 75% during the first months of treatment.

Thus, patients on steroid therapy should receive bisphosphonates, vitamin D, and calcium from the beginning. Folic acid is also recommended. Steroid-induced diabetes is a major risk factor for treatment-related deaths from infections. Although heparin treatment is not recommended for all patients, the possibility of pulmonary embolism must be considered, particularly in patients with AIHA and LA or recurrent AIHA after splenectomy. Previous studies have also found a beneficial effect of standard heparin in AIHA.

Second-Line Treatment

Second-line treatment is considered in patients (1) refractory to initial steroids as defined earlier, (2) in need of a maintenance dose of more than 15 mg/day of prednisone (absolute indications), or (3) who need between 15 mg/day and 0.1 mg/kg/day (relative indication; Fig. 46.6). Patients with prednisone requirement of 0.1 mg/kg/day or less are potential candidates for long-term, low-dose prednisone. Patients' refractory to steroid treatment should be reevaluated for underlying diseases or warm IgM antibodies.

Currently, there are two major second-line options for primary WAIHAs with proven short- (and long-) term efficacy splenectomy (preferentially laparoscopic) and therapy with the monoclonal anti-CD20 antibody rituximab.³⁵ From a scientific point of view on the

TABLE 46.5**Treatment Options for Primary and Secondary Warm Autoimmune Hemolytic Anemia and Cold Autoimmune Hemolytic Anemia**

Disease or Condition	First Line	Second Line	Beyond Second Line	Last Resort
Primary AIHA	Steroids (+ rituximab)	Splenectomy Rituximab	Azathioprine, MMF, cyclosporine, cyclophosphamide	High-dose cyclophosphamide, alemtuzumab
B- and T-cell NHL	Steroids	Chemotherapy +/- rituximab (splenectomy in SMZL)	Other anti-CD20 antibodies, ibrutinib	
Hodgkin lymphoma	Steroids	Chemotherapy		
Solid tumors	Steroids Surgery			
Ovarian dermoid cyst	Ovariectomy			
SLE	Steroids	Azathioprine	MMF	Rituximab Autologous SCT
Ulcerative colitis	Steroids	Azathioprine		Total colectomy
CVID	Steroids + IgG replacement			
ALPD	Steroids	MMF	Sirolimus	
Wiskott-Aldrich syndrome	Steroids	Allogeneic SCT		
Allogeneic SCT	Steroids	Rituximab ^a	Splenectomy T-cell infusion	
Organ transplantation	Reduction of immunosuppression, steroids			
Drug induced	Withdrawal	Steroids		
Primary CAD	Protection from cold exposure	Rituximab Chlorambucil	Fludarabine + rituximab	Ecuzulimab ^b bortezomid ^b
PCH	Supportive treatment (postinfectious)	Rituximab ^a (chronic)		

^aEarly second-line treatment because of known poor response to steroids.^bOff-label use in single cases.

AIHA, Autoimmune hemolytic anemia; ALPD, autoimmune lymphoproliferative disorders; CAD, cold agglutinin disease; CVID, common variable immune deficiency; IgG, immunoglobulin G; MMF, mycophenolate mofetil; NHL, non-Hodgkin's lymphoma; PCH, paroxysmal cold hemoglobinuria; SCT, stem cell transplantation; SLE, systemic lupus erythematosus; SMZL, splenic marginal zone lymphoma.

Fig. 46.6 PERIPHERAL SMEAR IN COLD AGGLUTININ DISEASE. Low-power scan shows uneven distribution of red blood cells (RBCs) (A), which at slightly higher power (B) shows the RBCs to be clumped together or agglutinated. This must be distinguished from rouleaux formation. High-power scan shows nucleated RBCs (C), polychromatophilia, and microspherocytes (D).

TABLE 46.6 Second-Line Treatment Options After Steroids

Treatment	Dosing and Application	Side Effects	Precautions
Splenectomy (acute)	Preferentially laparoscopic	Infections, thrombosis	Postoperative thromboprophylaxis
Splenectomy (long term)	—	Infections Venous thrombosis	Vaccination, patient information
Rituximab	375 mg/m ² on days 1, 8, 15, and 22 IV	Infusional reactions Infections	Premedication with antihistamines (and steroids)
Danazol	200–400/day PO	Hepatotoxicity	None
Cyclophosphamide	PO or IV Dose adjusted to neutrophil count	Neutropenia Mutagenesis	Neutrophil count monitoring, bladder protection after high doses
Azathioprine	2.0–3.0 mg/kg/day PO Dose adjusted to neutrophil count	Neutropenia	Neutrophil count monitoring; avoid interaction with other drugs (e.g., allopurinol)
MFF	1–2 × 1 g/day PO	Gastrointestinal	
Cyclosporine	PO Dose adjusted to blood levels of CyA Target level, 200–400 ng/mL	Nephrotoxicity Gum hyperplasia	Monitoring of CyA levels and creatinine
Alemtuzumab	SC (variable doses)	Neutropenia	Antiinfectious prophylaxis
Complement inhibition with eculizumab, TNT009		Infections	Vaccination

CyA, Cyclosporine A; IV, intravenous; MFF, mycophenolate mofetil; PO, oral; SC, subcutaneous.

basis of published data, no definite preference for one these treatments is possible because of the insufficient quality of data. For both treatments, there have been no randomized studies comparing these two options. The decision for the preferred treatment in a specific patient has therefore to be made on an individual basis based on judgment of the treating physician, the validity of available data on short- and long-term efficacy, the assumed individual risk of adverse events, and the preference of the patient (Table 46.6).

Splenectomy

For splenectomy, there are more, but older data on the short-term efficacy, few data on long-term efficacy, and good recent data on long-term adverse events. CR or PR is achieved in two-thirds of patients (38% to 82%), depending on the percentage of secondary cases. In addition, there is good evidence that a substantial number of patients will remain in remission without the need for medical intervention for years. In the initial series by Chertkow and Dacie,³⁶ only 2 out of 28 patients were in remission for more than 5 years, but 6 patients remained in a stable PR for up to 7 years. In 52 splenectomized patients (percentage of primary AIHA unknown), Coon³⁷ found that 63% had a hematocrit of 30% or greater without steroids after a mean follow-up of 33 months, and 21% had a hematocrit of 30% or greater with a prednisone requirement of 15 mg/day or less after a mean follow-up of 73 months. In a study by Allgood and Chaplin,³⁸ 44% of patients were in CR after more than 1 year after splenectomy.

Splenectomy can safely be performed laparoscopically in almost all patients with primary AIHA with normal-sized spleens. Withdrawal of steroids after splenectomy should be carried out slowly (as described for primary treatment) to prevent hemolytic crises in case of recurrence. The mortality rate of laparoscopic splenectomy was 0.5% in a large national study. The main short-term risks of splenectomy (in general) are infections, pulmonary embolism, and splenic-portal thrombosis (rare in patients with a normal-sized spleen), but these risks have not been studied specifically in primary WAIHAs.

There is a lifelong increased risk of infections and of venous thrombosis and a very small risk of pulmonary hypertension. The

most serious, often fatal, but rare infectious complication is overwhelming pneumococcal septicemia. The risk of infections is highest shortly after splenectomy and decreases after 1 year. In a Scandinavian population-based study, the adjusted relative risk of major infections (requiring hospital contact) in a matched indication comparison 1 year after splenectomy for ITP (with a probably similar risk as AIHA) was 1.4. Although fatal postsplenectomy infections seem to be less common in recent years, it is mandatory to take all measures to reduce this risk. There is good but not definite evidence that preoperative vaccination reduces the risk of severe infections. Vaccination for pneumococci, meningococci, and *Haemophilus influenzae* should be done before splenectomy. Pneumococcal vaccination should be repeated regularly. Long-term antibiotic prophylaxis is probably not required in adults, but patients should be informed about this risk and should take antibiotics immediately in case unexplained fever. Risk in children may be reduced by subtotal splenectomy. The long-term risk of venous thrombosis is moderate. Information for patients about short- and long-term risks is required and may be one of the reasons for the fact that surgical treatment is underused. However, splenectomy is the only therapy so far that may provide freedom from treatment in a substantial number of patients for more than 2 years and possibly cure in about 20%.

Rituximab

Rituximab is currently the best available drug option for second-line treatment. Given at a standard induction dose of 375 mg/m² intravenously on days 1, 8, 15, and 22. In a metaanalysis, the ORR for WAIHAs after rituximab was 70% (67% for primary and 72% for secondary).³⁹ The CR rate was 42% (32% primary and 46% secondary). The CR rate was highest after 2–4 months. The rituximab schedule and dose are empirically derived from lymphoma treatment, and it is not known whether other schedules including maintenance are equal or better.

There are limited data on short-term and almost no data on long-term efficacy and no data on long-term adverse effects. With regard to short-term efficacy, there seems to be not much difference between rituximab and splenectomy. In one study, almost all patients (10 out of 11) had steroid-refractory primary WAIHAs, but four

patients received additional therapies.⁴⁰ Eight patients achieved CR and three PR, but six patients still had moderate signs of hemolysis and therefore did not formally fulfill the criteria for a CR. Thus, the true response rates for steroid-refractory WAIHAs seem to be considerably high, but still not completely clear.³⁹ The efficacy and toxicity of rituximab monotherapy was previously tested in several additional retrospective studies in a mixed population of refractory primary or secondary AIHA. Response usually occurs within 3 weeks. Patients taking steroids before initiation of rituximab should continue on steroids until response to the CD20 antibody. In the D'Arena et al⁴⁰ study, at a mean follow-up of 604 days, all patients were still in CR or PR. The longest remission duration was 2884 days. Because of the small patient number, data on long-term efficacy of rituximab should be regarded with caution. Predictors of long-term response are achievement of a CR, conversion to a negative DAT result, and previous splenectomy. Retreatment with rituximab is feasible and may be necessary after 1–3 years. Rituximab has been given to children without apparent safety problems.

The caveats of rituximab therapy are that the drug is not licensed for the indication and that infectious complications are rare but sometimes life threatening, particularly with repeat or maintenance treatment. There is a small long-term risk of progressive multifocal leukoencephalopathy. Nevertheless, rituximab is the preferred option for patients who are not eligible for splenectomy. If one explains the benefits and risks of the two second-line treatments to a patient, he or she usually favors rituximab because it is a noninvasive outpatient treatment, and splenectomy remains an option in case of failure.

Treatment of Patients With Refractory or Recurrent Disease After Splenectomy or Rituximab

In patients failing splenectomy, an accessory spleen should be excluded. Patients who are refractory to splenectomy or with recurrence after splenectomy can be retreated with steroids, assuming that the disease has become more responsive. This may work well in patients with previous requirement of lower steroid doses (≤ 15 mg/day of prednisone). The other option is to initiate treatment with rituximab immediately.

Patients who are refractory to rituximab should undergo splenectomy, if eligible. There are no data on the influence of initial remission duration on the efficacy of retreatment. In patients relapsing late (>1 year) after rituximab, retreatment with the antibody maybe a good option.

A potentially interesting drug for second-line treatment (which has also been used as first-line treatment along with steroids) is danazol, an attenuated androgen (see Table 46.6).¹⁷ It has established efficacy in C1 esterase deficiency, and efficacy has been claimed in several immune diseases, including WAIHAs. Initial very promising results (ORR: 60% to 70%) in AIHA could not be confirmed in subsequent studies, but it may worthwhile to carry out further studies because the toxicity seems to be relatively low with the exception of a potentially increased risk for hepatocellular carcinoma.

The advantage of high-dose Igs is low toxicity but remission rates are low, and routine use in patients with AIHA is not recommended in a recent guideline.

Treatment Options Beyond Second-Line Therapy in Primary Warm Autoimmune Hemolytic Anemia

Given the nature of the disease, the use of immunosuppressive treatments of all kinds seems logical. Response rates of up to 60% have been reported, but data are frequently based on low patient numbers or anecdotal reports. Cyclophosphamide was very effective in two studies. Other published data of treatment with azathioprine or cyclophosphamide are less favorable, with only about one-third of patients having any response. Evaluation is even more complicated by the fact that patients frequently received concomitant treatment with steroids. Dosing of azathioprine is difficult because of the narrow therapeutic window, hypersensitivity because of genetic defects, and

interaction with other drugs. Cyclophosphamide may have long-term mutagenic effects. Other immunosuppressive drugs such as cyclosporine or mycophenolate mofetil (MMF) have shown high response rates in very small series.

Repeated cycles of high-dose cyclophosphamide (50 mg/kg/day for 4 days) remain an option in selected, highly refractory patients. In a pilot study, six out of nine patients received a CR with a median duration of 15 months or more. Alemtuzumab has also been effective at a dose of 10 mg/day for 10 days. Promising results were recently published for a combination of low-dose rituximab (100 mg on days 1, 8, 15, and 22) with alemtuzumab (10 mg on days 1–3). The results of autologous stem cell transplantation were disappointing, but allogeneic transplantation may be used as a last-resort treatment in patients with Evans syndrome.

In general, second-line treatment should be selected taking into account severity of AIHA, age, comorbidity, and patient preference. Because of the low curative potential of all treatment options, patient safety remains the major concern.

Treatment of Secondary Warm Autoimmune Hemolytic Anemia

In secondary AIHA, the treatment goal depends on the type and severity of the underlying disease. The treatment goal may vary from palliative treatment of AIHA to cure by eradication of the underlying disease. Preferred treatment options are listed in Table 46.6.

Warm Autoimmune Hemolytic Anemia Associated With Systemic Lupus Erythematosus

Steroids used at a similar dosage as in primary WAIHAs induce high response rates. Maintenance treatment with azathioprine, cyclophosphamide, or both may be required. Rituximab is effective against WAIHAs and SLE but may be associated with a higher risk of progressive multifocal leukoencephalopathy in this setting.

Warm Autoimmune Hemolytic Anemia Associated With Chronic Lymphocytic Leukemia

In previously untreated CLL with isolated DAT-positive anemia but no other treatment indication, treatment with prednisone as in primary WAIHAs is the first choice. In case of refractoriness or relapse, rituximab monotherapy is moderately effective but produces response rates of more than 80% in combination with cyclophosphamide and dexamethasone. Cyclosporine also has good activity. In refractory AIHA or in AIHA with advanced or progressive CLL, treatment of the underlying disease with a rituximab-containing regimen according to International Workshop on Chronic Lymphocytic Leukemia guidelines is recommended.⁴¹ In elderly or comorbid patients with active CLL, chlorambucil with prednisone with or without rituximab is a good choice. In general, fludarabine-containing regimens should be used with caution in the presence of a positive DAT result or overt AIHA. In this case, bendamustine with (or without) rituximab is a good alternative. Alemtuzumab has proven activity against CLL and AIHA, and is a good second-line option, particularly in patients with associated PRCA. The tyrosine kinase inhibitor ibrutinib was effective in a patient with WAIHAs and CLL.⁴²

Warm Autoimmune Hemolytic Anemia in Other Non-Hodgkin Lymphomas

AIHA in NHLs does not respond well to steroids in general and splenectomy is only effective in SMZLs. Sustained responses in most other lymphoma subtypes have been obtained with lymphoma-specific treatment with or without rituximab.

Summary and Comment on the Experience on Warm Autoimmune Hemolytic Anemia Antibodies in Adults of a Referral Center; Provided by Professor Marc Michel, Hôpital Henri Mondor, Creteil, France.

Roumier et al recently reported their experience on a series of 60 adult patients diagnosed with WAIHA and seen at their institution over a 10-year period (2001–2011).⁴³ This analysis provides new insights into the management and outcome of WAIHAs in the rituximab era in comparison with data from a previous series of 72 patients from their center seen before the year 2000.

Compared with the previous series, the major findings of this recent study were the following:

- 1) The rate of secondary cases of WAIHAs in adults has increased beyond 50% now that an extensive workup including more systematically lymphocyte immunophenotyping in peripheral blood and a CT-scan of the chest and abdomen is performed in the absence of any obvious underlying disorder.
- 2) B-cell lymphoma represents the first cause of secondary WAIHA, especially in patients aged over 50 years, and in the absence of clonal disease or primary immunodeficiency, 10% of the patients had some features of “unclassified lymphoproliferation” (see Fig. 46.2) that will need to be better characterized in the future
- 3) The overall prognosis and outcome of adult WAIHA has significantly improved over the last decade (mortality rate was 8% in the recent series compared with 18% in the older one) presumably in part thanks to the corticosteroid-sparing effect of rituximab increasingly used as a second- or third-line option.
- 4) The initial response rate to corticosteroids was not significantly different when patients with primary or secondary WAIHAs were compared but corticosteroid dependency was observed in 100% of the patients with an underlying lymphoma versus only 53% among patients without lymphoma ($p = .007$).

Drug-Related Warm Autoimmune Hemolytic Anemia

Cessation of the drug may be effective in many cases, and further use of the drug should be avoided. Fludarabine-induced AIHA may be life threatening but responds to steroid therapy.

Treatment of Warm Autoimmune Hemolytic Anemia in Congenital and Acquired Immune Deficiency States and Special Serologic Types

The treatment of WAIHAs in patients with CVID is very similar to that of those with primary WAHA. Additional regular prophylactic treatment with IgG concentrates reduces the risk of recurrence. Splenectomy is effective, but the risk of serious infections is high.

In ALPS, treatment should be started with steroids and then switched to MMF, but sirolimus has the highest efficacy in improving not only AIHA but also lymphadenopathy. AIHA associated with IgM hypergammaglobulinemia in Wiskott-Aldrich syndrome is an indication for allogeneic stem cell transplantation.

Patients with AIHA after allogeneic stem cell transplantation respond poorly to steroids but often do respond to rituximab. An early switch to rituximab may be reasonable in these patients. AIHA in drug-related severely immunosuppressed patients after transplantation of solid organs responds best to reduction of immune suppression. Patients with IgM WAIHAs respond poorly to steroids. These patients are candidates for early rituximab treatment. The same is true for chronic AIHA caused by DL antibodies.

Treatment of Cold Autoimmune Hemolytic Anemia

Primary Chronic Cold Agglutinin Disease

Primary CAD is defined as a CAIHAs in patients with IgM-MGUS or in lymphoma without overt clinical signs but with bone marrow

Difficult Diagnosis of Secondary Warm Autoimmune Hemolytic Anemia Antibodies

A 43-year-old woman was referred for an acute hemolytic anemia of unknown etiology. She was a heavy smoker with no previous medical history. She started complaining of unusual fatigue and shortness of breath in absence of overt bleeding 2 weeks before being admitted into another hospital. On clinical examination, she was pale with a mild jaundice, her blood pressure and temperature were normal. A mild hepatomegaly with splenomegaly was found with no other abnormalities. Upon admission, her Hb level was 4.2 g/dL with a MCV of 125 fL. The reticulocytes count was $603 \times 109/L$, platelet and leukocytes counts were normal. Numerous spherocytes were found on the blood smear with no other morphological abnormalities (see Fig. 46.2). The LDH level was 2866 U/L (upper limit of the normal value = 250 U/L); total bilirubin was 62 $\mu\text{mol/L}$ (normal $<30 \mu\text{mol/L}$) with otherwise normal liver tests. Haptoglobin level was undetectable. The DAT with an anti-IgG and anti C3d was negative on two separate occasions. Glucose-6-phosphate dehydrogenase and pyruvate kinases blood levels were within the normal range and the search of a paroxysmal nocturnal hemoglobinuria clone was negative. The patient was transfused and then referred to our center.

Upon admission, a new DAT with an anti-IgA immunoglobulin was performed, which was found to be strongly positive. There was no evidence of an underlying lymphoma on the CT scan of chest and abdomen and on the bone marrow biopsy. Hepatitis C serology was found positive as well as the PCR. The final diagnosis was WAIHAs caused by an IgA autoantibody associated with chronic hepatitis C virus (HCV). The patient initially achieved a response to high-dose prednisone but then had a relapse when the dose was tapered to 20 mg/day. She did not respond to rituximab and mycophenolate mofetil but eventually achieved a complete remission after splenectomy 1 year after disease onset. This case illustrates: 1) spherocytes on the blood smear are not specific of hereditary microspherocytosis and can be found in AIHA; 2) before considering alternative diagnosis of hereditary or acquired hemolytic anemia or retaining the diagnosis of DAT-negative AIHA, an extended DAT with the use of anti-IgA antibodies must be performed; and 3) even in the absence of liver abnormalities or past history of hepatitis, testing for the presence of an underlying HCV infection is valuable in the setting of WAIHA.

infiltration. All patients should be advised to avoid cold exposure. Drug treatment is required in only half of the patients. Treatment is initiated in symptomatic patients or when Hb levels drop below 9–10 g/dL. Because IgM-coated RBCs are mainly destroyed in the liver, CAIHA does not respond to splenectomy and poorly to steroids. The most effective and best evaluated treatment is rituximab in a standard lymphoma dose. Two studies have provided similar results. In a prospective phase II study, 20 out of 27 patients responded, but most responses ($n = 19$) were partial. The median response duration was 11 months, but most patients responded to retreatment with rituximab. A combination of rituximab and oral fludarabine induced higher ORRs (76%) with a longer duration (median: 66 months).⁴⁴ In a metaanalysis, the ORR for rituximab in CAD was 57% with a CR rate of 21%.³⁹

Given the role of complement in CAD, it is not surprising that the terminal complement inhibitor eculizumab is effective.^{45,46} Recent results suggest that inhibition of the complement classical pathway at the level of C1s results in remarkable responses and even CRs (TNT009).^{47,48}

Positive results have been obtained with the proteasome inhibitor bortezomib in single rituximab-refractory patients. Preparation of patients with high-titer CAIHAs for surgery by cryofiltration may be required in rare instances.

Secondary Cold Autoimmune Hemolytic Anemia

In CAIHAs associated with lymphomas or solid tumors, treatment of the underlying disease by chemo(immuno)therapy or curative resection results in good responses. Cases of infection-related CAIHAs

usually resolve spontaneously, but antibiotic therapy may accelerate the process.

FUTURE DIRECTIONS

Future research should mainly be directed toward generation of better treatment options. The generation of international guidelines is still hampered by the lack of evidence. Every effort should be made to initiate valid comparisons of major treatment options such as steroids, splenectomy, and rituximab, potentially through registries or randomized trials.

Novel therapeutic options may be provided by next-generation anti-CD20 antibodies or antibodies against other targets such as

complement factors. Insights into the way T cells drive and control the immune reaction could lead to novel immunotherapeutic approaches. Synthetic peptides modulating Th1 responses via regulatory T cells may be developed into therapeutic tools. Another option would be to target structures on macrophages responsible for RBC destruction (e.g., the CD47–SIRP- α interaction). There is hope that novel targeted therapies will replace splenectomy and even steroid treatment of patients with AIHA.

EXTRINSIC NONIMMUNE HEMOLYTIC ANEMIAS

William C. Mentzer and Stanley L. Schrier

By definition, extrinsic causes of hemolysis are abnormalities in the environment in which the red blood cells (RBCs), usually normal themselves, circulate. These abnormalities can be acute or chronic in nature. They can arise from congenital lesions but usually result from acquired lesions. Inherited anomalies of glucose-6-phosphate dehydrogenase (G6PD) deficiency, which reduces the RBCs ability to deal with oxidative insults, can leave RBCs more vulnerable to environmental insults. Determination of hemolysis with various levels of compensation as the cause of an anemia is accomplished using the approaches described in [Chapter 34](#). Signs of extrinsic hemolysis with minimal or no anemia can be valuable clues to diseases of other organ systems. Among the most important forms of extrinsic hemolytic anemia are those caused by immune mechanisms; these are discussed in [Chapter 46](#).

Clinical and morphologic findings suggest the many misfortunes that can befall RBCs in their travels. They can be trapped in an abnormal bone marrow stroma network, sheared by jets in an abnormal heart, cut and fragmented by fibrin strands stretched across damaged areas in the microvasculature, or attacked by parasites. They can undergo stasis and perhaps metabolic depletion in giant hemangiomas or in an enlarged spleen. An abnormally functioning liver or kidney can cause a buildup of substances in plasma that alter RBC shape and metabolism. Drugs can cause oxidation or other metabolic damage. Oxidant injury provokes degradation of hemoglobin with the formation of hemichromes (see [Drug-Induced Oxidative Hemolysis](#) later). Degraded hemoglobin and hemichromes bind avidly to the cytoplasmic tail of the major transmembrane protein band 3 (see [Chapter 45](#)) and cause clustering of band 3 oligomers. Immunoglobulins (Igs) and complement then bind to the external membrane face over clusters of band 3, promoting immune destruction. Other membrane proteins may be subject to oxidative attack. Toxins, venoms, heat, and mechanical trauma can directly destroy the membrane. These agents may cause an alteration in the asymmetry of the phospholipid bilayer, causing phosphatidylserine to move from the inner leaflet of the membrane bilayer to the outer leaflet, where it can be recognized by macrophages.

In general, only the most devastating damage leads to direct intravascular destruction. Usually, the initial insult leads to an eventual change in the external portion of the RBC membrane, which causes macrophages to retard, hold, remove, or otherwise modify RBCs. Infection or inflammation can activate these macrophages. Some RBC changes are accompanied by a decrease in RBC deformability, which retards flow and thereby facilitates the action of macrophages on the affected RBC. All of these changes lead to extravascular hemolysis.

FRAGMENTATION HEMOLYSIS: MICROANGIOPATHY

Clinical Manifestations

Patients present with various degrees of hemolytic anemia and compensation, with evidence of RBC fragmentation on smear ([Fig. 47.1](#); see box on [Differential Diagnosis of Extrinsic Nonimmune Hemolytic Anemias](#)). RBC removal is generally extravascular, with minimal or moderately decreased levels of haptoglobin. If RBC damage is sufficiently severe, signs of intravascular hemolysis may be present. Because of the underlying pathology, some of these syndromes show

evidence of platelet removal, leading to thrombocytopenia. Occasionally, the underlying cause produces activation and depletion of procoagulant factors with consequent activation of the fibrinolytic system, consistent with disseminated intravascular coagulation (DIC; see box on [Causes of Red Blood Cell Fragmentation Hemolysis](#)).

Pathophysiology

Fragmentation hemolysis occurs when mechanical forces disrupt the physical integrity of the RBC membrane. In vitro shear stresses in excess of 3000 dynes/cm² cause RBC fragmentation. In vivo studies in patients with mitral prosthetic regurgitation and hemolysis show high peak shear stresses of 4500 dynes/cm², very rapid acceleration or deceleration, or both.

Research suggests alternative mechanisms of producing microangiopathic hemolysis that involve platelets and small vessel thrombi. The platelet-rich, fibrin-poor microvascular thrombi found in many patients with TTP now are thought to be caused by abnormally decreased ADAMTS-13 activity.^{1,2} This metalloprotease is responsible for converting the highly thrombogenic ultra large multimers of von Willebrand factor made by platelets and endothelial cells into the smaller forms normally found in circulation. Mutations in or antibodies against ADAMTS-13 result in unusually large multimers of von Willebrand factor attached to endothelial cell surfaces, where platelets may excessively aggregate, leading to formation of microvascular thrombi even in the absence of endothelial damage. In the case of disseminated cancer, the cause of microangiopathy may be microvascular tumor emboli.

Whatever the mechanism of mechanical trauma, the RBC membrane is viscoelastic and has self-sealing properties (see [Chapter 45](#)), so that little hemoglobin leaks out as the cell is being cut. However, prolonged distortion of the membrane produces a plastic change; therefore, the smaller RBC fragments usually do not become microspheres or microdisks but continue to display evidence of the shearing event or distortion in the form of typical irregular shapes. These irregular shapes and the rigidity that they reflect subsequently interfere with the ability of RBCs to fold, elongate, and deform sufficiently to pass through 3-μm capillaries and even smaller slits in the walls of the sinusoids of the reticuloendothelial system. This sequence leads to their destruction.

Differential Diagnosis

Generally, the differential diagnosis of fragmentation hemolysis can be deduced from the clinical findings. The presence of a prosthetic heart valve or a regurgitant jet that fragments or accelerates (i.e., Waring blender syndrome) can be readily discerned. The clinical picture of TTP-HUS is generally dramatic and acute (see [Chapter 134](#)). Atrioventricular malformations may be associated with DIC and platelet removal; the diagnosis requires a high index of suspicion and imaging studies. The presence of preeclampsia in a pregnant woman with microangiopathic hemolysis usually is obvious, but HELLP syndrome is a serious complication of pregnancy that can occur without other signs of preeclampsia or hypertension. This syndrome can produce hepatic rupture, visual failure, DIC, seizures, and congestive heart failure, and requires treatment by prompt

Fig. 47.1 PERIPHERAL BLOOD SMEARS FROM EXAMPLES OF EXTRINSIC NONIMMUNE HEMOLYTIC ANEMIA. (A) Microangiopathic hemolytic anemia. Note the schistocytes, fragmented cells, spherocyte, and polychromasia. More examples of damaged red blood cells (RBCs), including classic “helmet cell” (top), are seen to the immediate right insert. (B) Thermal injury from a burn. Thermally damaged RBCs form numerous microspherocytes and tiny RBC fragments. (C) Malaria infestation. RBCs containing *Plasmodium falciparum* malaria. Note the high rate of infestation, the presence of only ringed forms, and the multiply infested RBCs (center).

Differential Diagnosis of Extrinsic Nonimmune Hemolytic Anemias

There is no simple approach to the differential diagnosis of hemolysis caused by extrinsic nonimmune hemolytic anemia. The physician must pay close attention to the clinical finding. Useful clues come from a determination of whether RBC breakdown is predominantly extravascular or intravascular, but most important in the analysis is the observation of RBC morphology, which can focus the differential diagnosis. Unhelpful terms such as *aniso* and *poik* should be discarded. RBCs are spherocytic, stomatocytic, fragmented, echinocytic, acanthocytic, spurred, or bite cells, or can be mixtures of these types.

delivery of the fetus. Cancer can be an underlying cause of microangiopathy. Vessels supplying malignant tumors are thought to be structurally abnormal. They exhibit the same sort of fibrin stranding that produces fragmentation hemolysis in DIC and TTP–HUS.

Continued use of invasive diagnostic and therapeutic procedures with insertion of foreign bodies into the circulation has been complicated by microangiopathic hemolysis. A transjugular intrahepatic portosystemic shunt can cause the syndrome in approximately 10% of patients. The hemolysis usually disappears after 12–15 weeks. Similarly, use of coil embolization to seal off a patent ductus arteriosus may also cause significant hemolytic anemia. Vasculitis has also been implicated as a cause.

Multiple drugs are associated with microangiopathic hemolysis, most commonly quinine.^{3,4} A recent review found that in only 22 of 78 drugs reported to produce drug-induced thrombotic microangiopathy was a definite association found.⁴ Cyclosporine, tacrolimus, and mitomycin C have been implicated as causing a HUS picture that typically develops within weeks to months of exposure. Total body irradiation and bone marrow transplantation also are associated with microangiopathic hemolysis. Both chemotherapeutic agents and targeted cancer agents, including immunotoxins, monoclonal antibodies, and tyrosine kinase inhibitors, are associated with thrombotic microangiopathy.⁵ The thienopyridines ticlopidine and clopidogrel are both capable of producing a significant thrombotic microangiopathy that differs somewhat in presentation. Ticlopidine-associated TTP typically occurs between 2 and 12 weeks after initiation of therapy and presents with severe thrombocytopenia, microangiopathic hemolytic anemia, highly elevated lactate dehydrogenase, and normal renal function, and is associated with severe deficiency of

Causes of Red Blood Cell Fragmentation Hemolysis

- Damaged microvasculature
- Thrombotic thrombocytopenic purpura–hemolytic uremic syndrome (TTP–HUS)
- Associated with pregnancy: preeclampsia or eclampsia; hemolysis plus elevated liver enzymes plus low platelets (HELLP syndrome)
- Associated with malignancy, with or without mitomycin C treatment
- Vasculitis: polyarteritis, Wegener granulomatosis, acute glomerulonephritis, or *Rickettsia*-like infections
- Systemic lupus erythematosus
- Abnormalities of renal vasculature: malignant hypertension, acute glomerulonephritis, scleroderma, or allograft rejection with or without cyclosporine treatment
- Disseminated intravascular coagulation
- Malignant hypertension
- Catastrophic antiphospholipid antibody syndrome
- Atrioventricular malformations
- Kasabach–Merritt syndrome
- Hemangioendotheliomas
- Atrioventricular shunts for congenital and acquired conditions (e.g., stents, coils, transjugular intrahepatic portosystemic shunt, Levine shunts)
- Cardiac abnormalities
 - Replaced valve, prosthesis, graft, or patch
 - Aortic stenosis or regurgitant jets (e.g., in ruptured sinus of Valsalva)
- Drugs: cyclosporine, mitomycin, ticlopidine, clopidogrel, tacrolimus, or cocaine
- Systemic infection: bacterial endocarditis, brucellosis, cytomegalovirus, HIV, ehrlichiosis, Rocky Mountain spotted fever.

plasma ADAMTS13 activity.⁶ In contrast, clopidogrel-associated TTP usually presents within 2 weeks of drug initiation and is associated with mild thrombocytopenia, microangiopathic hemolytic anemia, mildly elevated lactate dehydrogenase levels, marked renal insufficiency, and near-normal levels of ADAMTS13 activity. Other reported exposures associated with microangiopathic hemolytic anemia include the use of cocaine and the herb Echinacea. The mechanisms of drug-induced thrombotic microangiopathy are not well understood but include immune-mediated causes (as in the case of quinine) and direct toxicity to the endothelium.⁴

Fig. 47.2 MORPHOLOGIC CHANGES ARE PRODUCED BY HEATING NORMAL RED BLOOD CELLS AT THE INDICATED TEMPERATURES. Budding begins abruptly at 50°C (122°F) and eventually leads to spherocytosis.

Thrombotic microangiopathic hemolytic anemia can also be the presenting feature of severe, systemic infection, including viral (cytomegalovirus [CMV], HIV), fungal, and bacterial infections.⁷ Whether infection “triggers” the development of TTP or instead the presentation remains debatable.

In one large series, 10 of 351 (2.8%) patients diagnosed with TTP were subsequently diagnosed with disseminated malignancy.⁸ Symptoms suggesting an underlying malignancy include dyspnea, cough, atypical pain, and poor response to plasma exchange. The diagnosis was made by bone marrow biopsy in six of the 10 patients, and all patients died shortly after the diagnosis of malignancy was made.

A current review highlights four hereditary and four acquired disorders that lead to thrombotic microangiopathy.² TTP may be hereditary, due to mutations in ADAMTS13, or acquired, due to autoantibody inhibition of ADAMTS13 activity. In addition, complement mutations causing uncontrolled activation of the alternative pathway, mutations in components of cobalamin metabolism, and mutations in a protein kinase C-associated protein, diacylglycerol kinase, are other hereditary causes of thrombotic microangiopathy. Acquired causes in addition to autoantibodies to ADAMTS13 include shiga toxin (hemolytic uremic syndrome), drug mediated on an immune basis (i.e., quinine), drug mediated on a toxic, dose-related basis (i.e., gemcitabine, cyclosporine), and acquired antibodies to complement factor H.

Therapy

Management is primarily directed toward the underlying disease or event. Compensation of RBC production should be optimized by replacing iron or folic acid if the patient is deficient in these nutrients. Occasionally, removal or repair of a damaged native or prosthetic heart valve is necessary when the hemolysis produces a disabling transfusion requirement. Treatment of TTP with plasma exchange has been found to be superior to plasma infusions, with fresh-frozen plasma and cryo-free plasma appearing to have equal efficacy. Thrombotic microangiopathy associated with cyclosporine is often reversible with cessation of cyclosporine.

OTHER FORMS OF MECHANICAL DAMAGE TO RED BLOOD CELLS

Heat Denaturation

Normal RBCs undergo budding and fragmentation when exposed to a temperature of 49°C (120°F) in vitro (Fig. 47.1B). In some of the hereditary hemolytic anemias, this process occurs at temperatures as low as 46°C (115°F; see Chapter 45). Under some clinical

circumstances, temperatures sufficient to cause heat denaturation of RBCs have been generated. Occasionally, cell warmers used with transfusions in cold agglutinin disease have malfunctioned and cooked the RBCs about to be transfused. In one case, a patient's mother warmed the RBCs with a hot water bottle, reasoning that such cells would cause less vein irritation to her child. Such transfusion was followed by evidence of intravascular and extravascular hemolysis, and the peripheral smear showed RBC budding and fragmentation (Fig. 47.2). Presumably, similar events can lead to hemolysis in patients who have sustained very extensive burns. In patients with heat stroke, the temperature usually is below 42°C (108°F), a temperature at which little RBC denaturation occurs.

Mechanical Trauma

The classic example of RBC damage caused by mechanical trauma is march hemoglobinuria, which occurs in soldiers after a long march, in joggers after running on a hard road, or in karate or conga drumming enthusiasts after practice. Anemia is rare, and reticulocytosis is uncommon. Evidence of typical intravascular RBC destruction is present and is thought to be caused by direct trauma to RBCs in the vessels of the feet or hands. Switching jogging paths or wearing better footwear often relieves the problem. Some cases show evidence of an underlying RBC membrane abnormality. Strenuous exercise may induce oxidant stress, as evidenced by increased levels of malonyldialdehyde, a marker of lipid peroxidation, in marathon runners after a race. Occasionally, malfunction of the cell savers used during abdominal or thoracic surgery mechanically injures RBCs.

Cardiopulmonary Bypass

Postperfusion syndrome occurs in some patients after cardiopulmonary bypass. The syndrome includes acute intravascular hemolysis and leukopenia as part of a febrile, inflammatory clinical picture. Affected patients may develop pulmonary distress and even adult or acute respiratory distress syndrome. Visible hemoglobinemia occurs, with rising plasma hemoglobin levels, and is associated with an increase in lysed RBC ghosts seen in the whole blood and plasma. These ghosts are coated with the complement complex C5bC9 (see Chapter 24). Presumably, the complement pathway is activated as the blood passes through the oxygenator. The reason why complement activation results in lytic attack on RBCs (and granulocytes) is unknown. Free hemoglobin released into the plasma secondary to intravascular hemolysis may contribute to acute kidney injury after cardiopulmonary bypass. Treatment involves knowledge of the process and requisite support until the situation corrects itself.

Osmotic Attack

Abrupt changes in osmolality can cause hemolysis. Freshwater drowning may be associated with so much water in the lungs that the RBCs swell as they undergo an *in vivo* osmotic fragility test in the pulmonary vasculature. Conversely, saltwater drowning can cause profound dehydration of RBCs, producing a situation analogous to xerocytosis (see Chapter 45). Rarely, acute hemolysis occurs from mistaken infusion of or exposure to concentrated hypertonic solutions such as those used in hemodialysis. To manage such an event, the physician must recognize its cause, appreciate the shrunken RBCs on a peripheral smear, and restore isotonicity as quickly as possible. In these cases, use of a hemodialysis device, if available, may be helpful.

Hypersplenism

In all organs of the monocyte–macrophage system (i.e., reticuloendothelial system), blood cells leaving the arterial bed are generally unloaded into channels such that the RBCs must pass through the wall of the sinus to reenter the circulation. The sinusoidal wall has slits 2–3 μm long and usually is endothelialized on one side and has a macrophagic lining on the other side. The normal human adult RBC is a discocyte with a surface area 40% larger than a sphere of that volume (see Chapter 33). This excess surface area allows an RBC with a diameter of approximately 8 μm to twist, elongate, and deform sufficiently to squeeze through these 2–3- μm slits. The excess surface area, occasionally referred to as the *ratio of surface area to volume* (SA:V), is critical and is normally approximately 1.4. Any condition that reduces SA:V reduces the ability of RBCs to traverse these sinusoidal slits because plump spheres cannot deform sufficiently.

Factors that interfere with interaction of the cytosol and the membrane also impair the ability of the RBC to deform. Oxidant attack may produce Heinz bodies that come to lie adjacent to the membrane. They interfere with the smooth movement of the membrane over the cytosol, a process called *tank treading*. Such cells are selectively blocked from leaving the splenic cords and entering the sinuses. Inflammation or infection may enhance the ability of splenic macrophages to attack and ingest RBCs. Although not strictly a mechanism of hypersplenism, Kupffer cell erythrophagocytosis is a prominent finding in patients undergoing graft-versus-host hemolysis seen after liver transplantation.

The spleen is more complicated than other reticuloendothelial organs in that the afferent arterioles pass through lymphoid nodules (i.e., white pulp) and then terminate in the cords of Billroth (i.e., red pulp), into which blood cells are discharged. In the slow flow of the cords of Billroth, blood cells are selectively attacked by macrophages and are in direct contact with several classes of lymphocytes. The blood cells must then pass through the cordal walls before they can approach the sinus wall, which they must pass through to reenter the circulation. The spleen provides a double filter, and the blood cells must be remarkably deformable to pass through it. This slow passage permits highly selective action by macrophages, which have receptors that can detect several sorts of alterations in these blood cells. These receptors include the Fc receptor for the appropriate portion of the Ig molecule, receptors for complement components such as C3b, and perhaps receptors that detect alterations in the outer portion of the phospholipid bilayer or in the externally oriented glycopeptides. The macrophage then holds, retards, modifies (i.e., pitting function), or removes (i.e., culling function) the blood cells identified. Normally, the pitting function of the spleen allows it to remove Howell–Jolly bodies and normally occurring endocytic vacuoles (called *pocks* because of their appearance on phase interference or Nomarski microscopy). The normal culling function of the spleen is exemplified by its removal of senescent RBCs.

All the activities of the spleen presumably are markedly accentuated in a large spleen, and if the increased activity is sufficiently extensive, hypersplenism ensues. The size of the spleen, not the portal pressure, is important in determining the degree of RBC sequestration. Other factors that may play a role are the state of activation of

TABLE 47.1 Causes of Splenomegaly

Cause	Example
Neoplasia	Lymphoma, hairy cell leukemia
Infection	Bacterial endocarditis, malaria, schistosomiasis, tuberculosis
Portal bed obstruction	Alcoholic cirrhosis, splenic vein thrombosis
Collagen vascular disease	Systemic lupus erythematosus, malignant phase of rheumatoid arthritis
Chronic inflammatory disease	Rheumatoid arthritis
Chronic hereditary or acquired hemolytic anemia	Severe β -thalassemia, autoimmune hemolytic anemia
Lipoidosis	Gaucher disease
Amyloidosis	AL and AA types
Tropical splenomegaly syndrome	Hyperreactive malarial splenomegaly syndrome

the splenic macrophages and the size of the small slits between the splenic cords and sinuses. The macrophages and slits seem to be under a degree of control, as evidenced by variations in splenic removal of RBCs in patients with malaria.

The clinical picture of hypersplenic hemolysis is dominated by the specific cause of the splenomegaly. Although the causes of splenomegaly are legion, there are several general mechanisms (Table 47.1). Usually some degree of anemia is seen, with evidence of a compensatory increase in RBC production. Because stasis and trapping in the spleen are associated with macrophagic attack and remodeling of the RBC surface, the reduction in SA:V leads to spherocytosis. If the RBCs undergo a prolonged period of distortion when traversing the cordal–sinus barrier, tailed RBCs will be present as the RBC membranes undergo a plastic change (see Chapter 45). Because the enlarged spleen can trap and remove platelets and white blood cells, variable thrombocytopenia and leukopenia may occur. The bone marrow may show normal to increased cellularity with erythroid hyperplasia.

Management depends on the cause of splenic enlargement. The anemia or pancytopenia usually is not profound; however, splenectomy may be contemplated if the anemia is severe. Alternatives to splenectomy include splenic embolization and high-intensity focused ultrasound ablation. In most situations, recognition of the possibility of hypersplenism is most important in guiding the approach to diagnosis of an unexplained anemia. Massive splenomegaly is frequently associated with expansion of the plasma compartment, and measurement of hemoglobin, hematocrit, or RBC levels may give a falsely low value of the RBC mass present. In that circumstance, the true RBC mass can be determined by ^{51}Cr assay.

A good example of massive splenomegaly causing plasma volume expansion is tropical splenomegaly syndrome, also known as *hyperreactive malarial splenomegaly syndrome*. Diagnostic criteria include massive splenomegaly more than 10 cm below the costal margin with no other cause identified; immunity to malaria; elevated serum IgM levels; and clinical response to treatment with antimalarial drugs such as chloroquine, proguanil, or pyrimethamine and folic acid. The pathophysiology of the splenomegaly seems to be poorly controlled B-lymphocytic production of antibodies, and IgM stimulation may be a response to malarial antigens or an unidentified mitogen. Malarial parasites are almost never found. The apparent anemia is in large part caused by plasma volume expansion, although RBC survival is reported to be slightly attenuated. Antimalarial therapy for several months reduces spleen size, so splenectomy is unnecessary.

TABLE 47.2 Mechanisms by Which Infection Can Cause Hemolysis

Mechanism	Example
Direct parasitization of red cells	Malaria, babesiosis
Immune mechanisms	Cold agglutinin hemolysis after infectious mononucleosis or mycoplasmal pneumonia (see Chapter 46)
Induction of hypersplenism	Malaria, schistosomiasis
Altered red cell surface topology	<i>Haemophilus influenzae</i> infection
Release of toxins and enzymes	Clostridial infection causing thrombotic thrombocytopenic purpura–hemolytic uremic syndrome, <i>Escherichia coli</i> O197, HIV infection

Infection

Infection can cause hemolytic anemia via several pathophysiologic mechanisms (Table 47.2).

Parasite Infections

The classic example of direct parasitization is infection by *Plasmodium falciparum* (Fig. 47.1C), *Plasmodium vivax*, or *Plasmodium malariae*. Infection with malaria, primarily *P. falciparum*, is a major health problem in the developing world, causing an estimated 300–500 million infections and 1–3 million deaths annually.⁹ The burden of disease rests most heavily on young children and pregnant women. *Falciparum* malaria can cause a life-threatening anemia, with severe anemia defined as hemoglobin less than 5 g/dL associated with parasitemia and a normocytic blood film.⁹ Malaria is primarily a disease of the tropical developing world but is still seen in the United States and its territories, primarily as an import from outside the United States. Of the 1298 cases reported in the United States in 2008, 117 (9%) were classified as severe, two of which were fatal. In each of the malaras, sporozoites injected by the mosquito in its saliva make their way to liver cells. After 1–2 weeks, they become merozoites, which burst out of the liver cells and into the bloodstream. Then, in a remarkable process, the parasite, by means of its apical end and related organelles called *rhoptries*, attaches to a specific receptor on the RBC surface. For *P. vivax*, the Duffy blood group antigen appears to be involved.

P. falciparum binds to sialic acid residues on the RBC surface that are on glycophorin A. After specific attachment, a convulsive movement occurs during which the RBC engulfs the parasite by a process resembling receptor-mediated endocytosis. Upon invasion of the RBC, the malarial parasite starts digesting the hemoglobin, depositing the undigested heme in the form of hemozoin. Knobs appear on the RBC surface, and the RBC becomes a sphere. Many proteins of parasitic origin are inserted into the RBC membrane, and some appear to cluster underneath these knobs. A parasite protein called *mature parasite-infected erythrocyte surface antigen* binds to membrane protein 4.1, and another parasite protein called *ring-infected erythrocyte surface antigen* binds to β spectrin. Both spectrin and protein 4.1 are integral components of the membrane skeleton, and the consequence of the binding of malarial proteins is RBC membrane stabilization. Thus stabilized, the parasitized RBC can continue to survive while the parasite continues to digest its contents.¹⁰

The parasite recruits the RBC's metabolic machinery, degrades and ingests hemoglobin, and grows, eventually bursting out of the RBC, and the cycle begins again. The RBCs are lysed intravascularly

as a consequence of direct parasitic destruction, extravascularly as a consequence of changes in the splenic microvasculature and in the activation state of the monocyte–macrophage system. Treatment consists of the use of appropriate antimalarials and the support of erythropoiesis, including the use of RBC transfusion or exchange (or both) when indicated.

The anemia of malarial infections also involves mechanisms distinct from lysis of parasitized RBCs. Erythropoiesis is suppressed, leading to suppression of erythroid precursors and inadequate reticulocytosis during acute infection.¹¹ This inadequate hematopoietic response may be exacerbated by underlying iron deficiency, hemoglobinopathies, or concomitant infection (e.g., HIV), all potential contributors to the severity of anemia. In addition, loss of uninfected erythrocytes plays a major role in the development of anemia, with an 8- to 10-fold greater loss of unparasitized RBCs compared with parasitized cells. Uninfected RBCs have reduced deformability, and the degree of reduced deformability correlates with the severity of infection. Poorly deformable RBCs likely are cleared by the spleen. A recent study in rats indicates that CD8 T-cell–dependent parasite clearance in the spleen is involved in the damage of uninfected RBCs and their subsequent destruction.¹² Evidence of in vivo removal of immature malarial forms prompts the question of whether “uninfected” cells that are lost represent previously infected cells that nevertheless remain abnormal. Insertion of a merozoite *rhoptry* protein, ring surface protein 2, on RBCs in which infection was aborted has been implicated in the clearance of unparasitized erythrocytes and erythroid progenitors. In addition, uninfected RBCs demonstrate increased binding of Igs that are probably nonspecific immune complexes. Acute malarial infection, particularly with *P. falciparum*, also leads to alteration in splenic function that incites premature destruction of uninfected RBCs.¹³

The lifespan of transfused RBCs is likewise decreased.⁵¹Cr-labeled normal RBCs infused into patients infected with malaria demonstrate a shorter lifespan than in normal control participants; this effect may persist after clearance of the parasitemia. Alternatively, parasites can be removed from RBCs along with the RBC membrane by the process of pitting, producing parasite-free spherocytes. This mechanism potentially explains the observed disparity between anemia and parasitemia.

Other infections that have somewhat similar pathophysiologies include Carrión disease (i.e., bartonellosis), in which a bite from the sandfly injects *Bartonella bacilliformis*, which attaches to the RBC surface of up to 80% of erythrocytes and causes lysis, leading to the massive hemolysis that characterizes acute infection. It appears that invasion of RBCs partly depends on the flagella of *Bartonella* spp. Incubation with anti-flagellin antiserum reduces invasion of RBCs. The bacteria also secrete deformin, a factor that leads to deep pitting on the surface of RBCs, presumably providing a portal of entry into the erythrocyte. There also may be a role for splenic clearance of infected cells, and prior splenectomy appeared to protect a patient from hemolysis during acute infection.

Babesia organisms also directly invade RBCs by mechanisms somewhat resembling those seen in malaria,¹⁴ producing fever and hemolytic anemia. The parasite is transmitted by ticks and transfusions of infected blood products,¹⁵ and can be transmitted vertically. Most tick-borne cases occur on the West Coast, particularly in Washington and California, and in the northern portion of the Midwest; cases occurring on the East Coast are concentrated in Massachusetts and Nantucket Island. However, transfusion-associated cases have been reported throughout the United States.¹⁵ In one report of transfusion-associated babesiosis, the median interval from transfusion to onset of clinical manifestations was 37 days. The organisms can be seen invading RBCs on smear examination, somewhat like *P. falciparum* malaria, but these organisms produce no pigment. The highest risk of death from babesiosis occurs in individuals who are older than 50 years or are immunocompromised because of acquired immunodeficiency syndrome (AIDS), drugs, transplantation, or asplenia. Sporadic reports indicate that acquired chronic toxoplasmosis is occasionally associated with hemolytic anemia.

Alteration of the Red Blood Cell Surface by Bacterial Products

Infection can produce hemolysis by altering the RBC surface. An example is the hemolysis caused by *Haemophilus influenzae* type b. Severely affected patients, particularly those with meningitis, have developed hemolytic anemias requiring RBC transfusions. The capsular polysaccharide of the bacterium, composed of polyribosyl ribitol phosphate (PRP), is released during infection and binds to the RBC surface. Infected patients develop antibodies to PRP. When the balance between PRP-coated RBCs and anti-PRP antibodies is correct, an immune-type hemolysis occurs and requires complement. RBC destruction is thought to be both intravascular and extravascular.

Bacterial Products Causing Hemolysis by Direct Damage to Red Blood Cells

The most dramatic example of hemolysis caused by bacterial action is clostridial infection, during which the organism releases enzymes that acutely degrade the phospholipids of the membrane bilayer and the structural membrane proteins. The resulting spherocytes are extremely sensitive to osmotic lysis. The setting can be any infection, but our experience is limited to acute cholecystitis, surgery of the biliary tree, and infections surrounding an obstetric event, including criminal or self-induced abortion, or other infection of the gravid uterus. Patients may also have an underlying gastrointestinal, genitourinary, neuroendocrine, or hematologic malignancy.¹⁶ The signs of infections may be obvious, but fever may be unimpressive. Signs of collapse appear acutely, and the clue is profound intravascular hemolysis, with a spherocytic anemia developing with shocking suddenness. The blood smear characteristically has numerous spherocytes with little evidence of microangiopathy, may be tinged red because of marked hemoglobinemia, and may have ghost cells. A clue to the severity of the process may be the inability of the laboratory to perform chemical determinations or to type and cross-match the blood because the sample is hemolyzed. With even the slightest suspicion of hemolysis caused by bacterial action, the physician immediately starts full doses of penicillin and clindamycin; evaluates the patient for DIC (see [Chapter 139](#)); and prepares to support the patient for shock, DIC, acute renal failure, and hemolytic anemia. Whether hysterectomy is lifesaving in the case of septic abortion is unclear.

Hemolysis Caused by Less Well Understood Infections

HIV infection can cause Coombs-positive autoimmune hemolytic anemia, a TTP-like syndrome, and microangiopathic hemolysis. CMV infection has been reported to cause severe Coombs-negative hemolytic anemia in immunocompetent adults.¹⁷ Case reports of autoimmune hemolytic anemia and HUS associated with CMV infection have emerged. The hemolytic anemia in visceral leishmaniasis may be caused in part by generation of oxidative metabolic products. Severe microangiopathic hemolytic anemia has been described in cases of cutaneous anthrax.

Hemolysis Associated With Liver Disease

Hemolysis in liver disease by itself usually is not of overwhelming clinical importance, but it may contribute to the severity of anemia when coupled with defects in RBC production and the type of gastrointestinal blood loss that occurs in several forms of liver disease. Hemolysis in patients with liver disease has several causes. The spleen may be enlarged as a consequence of portal hypertension and produce a hypersplenic picture, a phenomenon seen commonly in hepatic cirrhosis.

Reduction of Dangerous Methemoglobin Levels

Levels of methemoglobin in excess of 20% to 30% can be dangerous, but they can be easily treated with methylene blue (1–2 mg/kg) infused intravenously over 5 minutes as 0.1–0.2 mL/kg of a 1% solution. In the presence of a functioning, intact reduced form of nicotinamide adenine dinucleotide phosphate (NADPH)–methemoglobin reductase system, methylene blue is reduced to leukomethylene blue, which reduces methemoglobin to hemoglobin.

The literature on RBC shape change in liver disease is considerable. The target cell in cirrhosis has an increased SA:V that appears to be a consequence of increased cholesterol and phospholipid content of the membrane bilayer. The cholesterol increase is usually proportionately greater, resulting in an increased cholesterol-to-phospholipid ratio. This increase in lipid probably accounts for the increased RBC surface area, such that more membrane than usual is present in relation to cellular contents. These RBCs probably circulate as bell-shaped RBCs called *codocytes*. However, on dried blood films, they assume the appearance of target cells. Target cells do not have a shortened survival. The RBCs of patients with liver disease frequently are echinocytes when wet preparations are examined, but these echinocytes are not easily apparent on dried blood smears. The echinocytes seem to be produced by a material in the patient's plasma that causes normal RBCs to become echinocytic; this material is an abnormal echinocytogenic high-density lipoprotein. Echinocytes do not necessarily have a shortened survival. Some forms of echinocytic RBCs are normally deformable when studied in the ektacytometer or rheoscope.

A brisk, clinically important hemolysis can occur in some patients with severe liver disease. The peripheral smear in these individuals usually shows acanthocytes (i.e., distorted RBCs). Extreme forms are called *spur cells*, which are probably acanthocytes additionally remodeled by an enlarged spleen (see box on [Reduction of Dangerous Methemoglobin Levels](#)) and are considerably enriched in cholesterol. They are rapidly removed in the spleen, which is usually enlarged.

Increased RBC membrane proteolytic activity may be a partial explanation for the differences between acanthocytosis and spur cells, and additional pathophysiologic mechanisms may be involved. Although the adult RBC cannot synthesize phospholipids de novo, it can identify and remove peroxidized fatty acid chains that interfere with normal membrane lipid fluidity. When the fatty acid is removed, a lytic lysoderivative remains; therefore, the missing fatty acid chain must be replaced. A store of acyl groups in the form of acylcarnitine exists in RBC membranes. When needed, the fatty acid (i.e., acyl group) is transferred to acyl-coenzyme A and then inserted into the potentially lytic lysophospholipid by the enzyme lysophosphocholine acyltransferase. Lysophosphocholine acyltransferase is inhibited in spur RBCs, and the same inhibition can be produced by heavily loading RBCs with cholesterol in vitro.

In a case of almost fatal oxidative hemolysis, hydrogen peroxide was injected directly into the Hickman catheter of a patient with AIDS because some persons infected with HIV had circulated a pamphlet suggesting that hydrogen peroxide could be used therapeutically to control HIV infection. We now are seeing AIDS patients with dapsone-induced methemoglobinemia and hemolytic anemia (see [Chapter 42](#)). Methemoglobinemia, if severe, is treated as described in the preceding paragraph and in [Chapter 24](#).

In spur cell anemia, the RBCs have an abnormal membrane SA:V ratio, their membrane fluidity is impaired, and they are unable to remove and repair peroxidatively damaged fatty acids. Occasionally, spur cell hemolytic anemia is severe enough to necessitate consideration of splenectomy. Operative morbidity in such cases is considerable because the underlying liver disease usually produces problems with thrombocytopenia and leukopenia, as well as with procoagulants and intolerance to anesthesia. Spur cell anemia is typically associated with alcoholic cirrhosis, but can also be seen in patients with nonalcoholic cirrhosis. The anemia tends to be severe and portends a poor

prognosis. Transfusions are of limited efficacy because the membrane abnormalities are acquired by transfused RBCs.¹⁸ In one case, spur cell anemia occurred in a pediatric patient after orthotopic liver transplantation and resolved after retransplantation.¹⁹

Acute alcoholism can be associated with hypophosphatemia, defined as levels less than 0.2 mg/dL. Such hypophosphatemia presumably interferes with RBC intermediary metabolism (see [Chapters 33 and 44](#)), and RBC adenosine triphosphate (ATP) levels fall. Very low ATP levels are associated with RBC rigidity, which leads to fragmentation, loss of surface area, and spheroidicity. The RBCs then are further trapped in the spleen. This hypophosphatemia syndrome can also cause neuromuscular disorders, including weakness, paresthesias, tremors, and seizures. It should be treated aggressively with orally and intravenously administered phosphate supplements. Hypophosphatemia also occurs in patients with cirrhosis, patients receiving total parenteral nutrition whose phosphate intake is not carefully monitored, and patients taking large amounts of phosphate-binding antacids.

Stomatocytosis can occur in severe liver disease and is thought to be a sign of acute alcoholic intoxication. The change in RBC shape can also be seen in acute pancreatitis. The stomatocyte is a cell well on its way to becoming a spherocyte. The reduction in SA:V leads to trapping in the microvasculature of the spleen and other organs of the monocyte–macrophage system, producing various degrees of hemolysis.

Renal Disease

The anemia in renal disease is multifactorial. A major component is impaired RBC production, which can be well controlled with erythropoietin. Renal disease also impairs platelet function, which may lead to occult blood loss. However, hemolysis also can occur and is multifactorial. Disease of the small renal arterioles can produce fragmentation hemolysis of the sort seen in TTP–HUS, preeclampsia, and malignant hypertension (see the box on [Causes of Red Blood Cell Fragmentation Hemolysis](#)). Otherwise, whether uremia produces significant shortening of RBC survival is not clear. Patients with chronic renal failure who are undergoing hemodialysis may be particularly susceptible to oxidative damage to their RBCs. RBC glutathione is reduced in some patients, and the activity of the enzymes G6PD and glutathione peroxidase is relatively low. The ability of these RBCs to deal with generation of peroxides probably is impaired.

Venoms, Bites, Stings, and Toxins

The best-known example of toxin-caused hemolysis is discussed in the earlier section, Bacterial Products Causing Hemolysis by Direct Damage to Red Blood Cells.

Insect, Spider, and Snake Bites

Hemolysis occurs after bee and wasp stings, snake bites, and spider bites. Isolated cases of acute intravascular hemolysis after bee and wasp stings have been reported. Two kinds of dangerous spiders live in the United States: the southern black widow and the brown recluse spider. Both sexes of the black widow produce the venom, but only the female has fangs capable of penetrating human skin. Black widow spider bites produce generalized muscle pain and muscular rigidity. Hemolysis is not common. Brown recluse spider bites cause a considerable local reaction, called the *volcano lesion*. DIC and hemolysis may occur after a lag of 24–48 hours. Envenomation results in cleavage of RBC glycoporphins, presumably making the RBCs more susceptible.²⁰ Corticosteroids may be beneficial. The hemolysis appears to be self-limiting, but RBC transfusion support may be needed.

In some parts of the world, cobra bites can cause intravascular hemolysis because the venom contains phospholipases. In the United

States, the two classes of venomous snakes are pit vipers (e.g., rattlesnakes, cottonmouths, moccasins, and copperheads) and coral snakes. Pit viper venom affects hemostasis and may produce DIC with bleeding but rarely hemolysis. Coral snake venom produces severe neurologic impairment. Therapy consists of support and use of the appropriate antivenin and prophylactic antimicrobials, and tetanus injections.

Drugs and Chemicals Exclusive of Those Producing Oxidative Hemolysis

Potassium Chlorate

Potassium chlorate ingestion is listed as a cause of hemolysis, but this compound is no longer available in hospital pharmacies and has no currently recognized medical use. Arsine gas is generated in industrial plants that engage in lead plating, galvanizing, etching, and soldering. Inhalation of a toxic amount produces a severe intravascular hemolysis of unknown pathogenesis and may require urgent RBC and plasma exchange.

Copper

The idea that copper can produce human hemolytic disease is best supported by observations of episodes of severe hemolysis and acute liver failure in patients with Wilson disease. The patient usually is a child, adolescent, or young adult for whom the diagnosis of Wilson disease has not yet been made. The initial clinical presentation is usually dominated by Coombs-negative hemolytic anemia accompanied by weakness and dark urine. Associated findings include coagulopathy, a rapid progression to renal failure, relatively modest rises in serum aminotransferases, and a low alkaline phosphatase level. In addition to the presence of a brisk reticulocytosis, the typical findings of intravascular hemolysis may be present, including elevated lactate dehydrogenase, low haptoglobin, and markedly elevated bilirubin levels. Review of the peripheral smear may not reveal any specific morphologic findings, although both stomatocytosis and blister cells consistent with oxidant injury have been described. In one reported patient with concomitant transfusion-dependent hemoglobin E/ β thalassemia, the acute hemolysis led to a severe unexpected drop in the posttransfusion hemoglobin level. Because of the hereditary deficiency in the copper-binding protein ceruloplasmin, urine and serum nonceruloplasmin-bound copper levels in patients with hemolysis are very high.

Free copper can interfere with glucose metabolism by hexokinase inhibition and alternatively can generate oxidative hemolysis, perhaps by acting as a Fenton reagent. It is important to establish the diagnosis promptly. When this condition is suspected, the practitioner should look for Kayser–Fleischer rings on physical examination, and measure serum and urine copper and ceruloplasmin levels. Treatment with penicillamine or trientine plus zinc reduces the serum copper level and stops the hemolysis.²¹ In the case of acute liver failure, the treatment is urgent liver transplantation. Plasmapheresis and hemofiltration may be beneficial in reducing the copper level and can serve as a bridge to transplant. In some cases, plasmapheresis in combination with chelation therapy or the use of a fractionated plasma separation and adsorption dialysis system may avert the need for transplant in impending acute liver failure. Other forms of copper poisoning may cause hemolysis in patients who do not have underlying Wilson disease. The amount of copper ingested would have to exceed the copper-binding capacity of normal ceruloplasmin levels.

Lead

There are at least two general forms of lead intoxication. One type is chronic, slow cumulative poisoning (i.e., saturnism). An example

is occupational exposure. Symptoms are predominantly neurologic and nephrologic, with variable degrees of anemia, which may be caused by a production defect combined with hemolysis. Relatively acute poisoning occurs when lead inadvertently finds its way into a food source or is consumed as part of an exotic medication. Subacute lead poisoning leads to central nervous system symptoms, hepatitis, nephrotoxicity, hypertension, and abdominal colic along with seizures and severe hemolytic anemia. Physical examination may reveal a lead line on the gums. Peripheral smear shows extensive coarse basophilic stippling and reticulocytosis; however, RBC morphology is not otherwise characteristic. Some researchers state that intravascular destruction occurs, but no proof has been provided. Bilirubin levels are not significantly elevated.

The diagnosis of lead-related hemolysis can be made from the history and findings on physical examination, which include a lead line on the gingiva and coarse basophilic stippling on RBCs, which reflects the pathologic aggregation of ribosomes. The diagnosis is confirmed by measuring blood and urine lead levels. The level of acuity determines the therapy.

The cause of the anemia is complex. Lead interferes with several steps in heme synthesis, particularly those involving heme synthetase and δ -aminolevulinic acid dehydratase (see Chapter 38). The inhibition of heme synthetase probably accounts for the elevation in free erythrocyte protoporphyrin, which provides a useful corroborative diagnostic test for lead toxicity. Inhibition of heme synthesis also probably accounts for the elevated urinary levels of δ -aminolevulinic acid and coproporphyrin. Lead poisoning mimics the basophilic stippling and accumulation of pyrimidines seen in hereditary deficiency of the enzyme pyrimidine 5'-nucleotidase, probably because lead attacks the enzyme (see Chapter 44).

Ribavirin

Current treatment of chronic hepatitis C virus (HCV) infection may consist of combination therapy with pegylated interferon (IFN) and ribavirin, a nucleoside analogue. Ribavirin's activity against HCV includes inhibition of inosine monophosphate dehydrogenase, a key step in de novo guanine synthesis. Treatment with ribavirin may produce dose-dependent hemolytic anemia, which is typically reversible 1–2 months after discontinuing treatment.²² The hemoglobin drops by an average of 2–3 g/dL and may fall below 11 g/dL in one third or more of patients. The anemia may necessitate a dose reduction of ribavirin or may be treated with recombinant erythropoietin at 40,000 units weekly. A decrease in the total cumulative dose of ribavirin may be associated with decreased sustained virologic response, which would suggest that dose reduction secondary to anemia would have an adverse impact on treatment efficacy. However, in one retrospective study, a drop in hemoglobin of greater than 3 g/dL was instead associated with improved sustained virologic response rate compared with those with a drop in hemoglobin 3 g/dL or less,²³ suggesting conversely that the degree of hemolytic anemia may serve as a biomarker of efficacy. Ribavirin is transported into the erythrocytes and accumulates as ribavirin monophosphates, diphosphates, and triphosphates.²² The steady-state concentration of ribavirin in erythrocytes is approximately 100-fold higher than that of plasma, and higher erythrocyte ribavirin levels correlate with worsened anemia during therapy. Accumulation of phosphates leads to a decrease in ATP levels compared with control erythrocytes. Because ATP is required to generate the glucose-6-phosphate needed for glycolysis and the hexose monophosphate shunt, reduced levels of ATP may lead to oxidative damage, as evidenced by increased aggregates of band 3, which bind anti-band 3 IgG and complement. The ribavirin prodrug viramidine induces less anemia than ribavirin, although efficacy was decreased when used at fixed doses compared with a ribavirin-containing regimen. Fellay et al²⁴ have detected two polymorphisms in the inosine triphosphatase (*ITPA*) gene, which encodes a protein that hydrolyzes inosine triphosphate, and were protective against severe anemia in patients treated with HCV. These two polymorphisms were associated with reduced

ITPA activity and accumulation of inosine triphosphate in red blood cells. The mechanism of this protective effect is not yet fully understood. The anemia in patients treated with ribavirin may be exacerbated by concomitant treatment with pegylated IFN, which suppresses hematopoiesis, and may also be associated with autoimmune hemolytic anemia. Anemia may also be exacerbated when ribavirin and IFN are used in combination with the protease inhibitor,²⁵ a regimen that is efficacious in the treatment of genotype 1 disease.

DRUG-INDUCED OXIDATIVE HEMOLYSIS

General Concepts

The potential for normal RBCs to undergo auto-oxidative destruction is great because the cell is loaded with 20-mM hemoglobin, most of which is bonded to oxygen at the iron(II) atom in heme. The bond that allows the reversible association and dissociation of oxygen from the heme moiety of hemoglobin involves partial transfer of an electron from iron(II) to oxygen. That oxygen then has an extra electron, which makes it a superoxide radical. Ordinarily, when oxygen leaves hemoglobin, it returns the electron. If it does not, a highly reactive superoxide ion is released, leaving behind it an iron(III) moiety called *methemoglobin*.

Methemoglobin cannot reversibly bind oxygen. Methemoglobin in itself is not harmful to RBCs, but if the oxidative assault persists, methemoglobin is converted to hemichromes, which are variably denatured hemoglobin intermediates in which the distal histidine unit binds to the oxidized heme. This step is associated with conversion from a high to a low spin state, as measured by electron spin resonance. Continued oxidation leads to irreversibility of hemichrome oxidation, precipitation, and eventually formation of Heinz bodies. Hemichromes and Heinz bodies can destroy membrane function directly or by causing oxidation of membrane proteins and lipids.²⁶ Approximately 3% of hemoglobin is converted to methemoglobin each day, but the finding that only 1% of hemoglobin normally is in the form of methemoglobin indicates that a mechanism preventing oxidation in RBCs is in effect. These mechanisms are limited because RBCs lack the ability to either efficiently generate ATP or synthesize enzymes. The primary means for preventing or addressing oxidant injury are the generation of the reduced form of nicotinamide adenine dinucleotide (NADH) via the Embden–Meyerhof glycolytic pathway and the generation of NADPH via the hexose monophosphate shunt. NADH is used to reduce methemoglobin by cytochrome b5 reductase, and NADPH is used to reduce glutathione and for catalase activity. Defects in this defense system against oxidation lead to an enhanced tendency to oxidative hemolysis. Examples are G6PD deficiency states.²⁷ G6PD catalyzes the initial rate-limiting step in the hexose monophosphate shunt. Deficiencies lead to a reduced ability to generate NADPH in response to oxidant stress. Any agent or event that interferes with the smooth offloading of oxygen enhances the generation of O_2^{-1} and methemoglobin, as indicated in the equation. If the reducing power of the RBC is inadequate, hemichromes and Heinz bodies are generated. Many agents appear to cause oxidative hemolysis by interfering with the smooth functioning of the heme cleft.

Pathophysiology

After the oxidative attack has been initiated, the sequence proceeds along a recognizable track. The oxidative attack is directed at hemoglobin and the RBC membrane. However, these structures are not clearly separable because the precipitated hemichrome and Heinz bodies come to lie against the cytosolic face of the membrane. Methemoglobin may be detectably elevated, with levels as

Agents That Cause Oxidative Hemolysis

- Therapeutic agents
 - Nitrofurantoin (Furadantin)
 - Sulfasalazine (Azulfidine)
 - *p*-Aminosalicylic acid
 - Phenazopyridine (Pyridium)
 - Clotrimoxazole
 - Quinolones
 - Phenacetin
 - Rasburicase
 - Dapsone and other sulfones
 - Primaquine
- Recreational drugs
 - Isobutyl nitrate
 - Amyl nitrite
- Miscellaneous agents
 - Naphthalene mothballs
 - Methylene Blue
 - Paraquat
 - Hydrogen peroxide

high as 50% to 60% of total hemoglobin. The hemichromes, by themselves or with their iron portions acting as a Fenton reagent, mediate the generation of hydroxyl free radicals, which add their effect to that of superoxide and hydrogen peroxide. Lipid peroxidation may take place, leading to membrane blebbing and cell lysis, as well as loss of asymmetry of the phospholipid membrane bilayer. Movement of phosphatidylserine and phosphatidylethanolamine to the outer bilayer of the membrane results in increased recognition by macrophages in the reticuloendothelial system. Membrane proteins may be crosslinked, with binding of denatured, oxidized hemoglobin to the membrane cytoskeleton, which may increase splenic macrophage recognition. In addition, the RBCs are rigid and susceptible to trapping in sinusoidal structures, whether or not they have Heinz bodies lying against the membrane. In vitro evidence suggests that oxidized RBCs are increasingly susceptible to phagocytosis by macrophages. These features may account for extravascular destruction. The oxidative lesions can be severe enough to cause intravascular destruction as well, producing hemoglobinemia and hemoglobinuria.

The smear may show bite cells, which look as if a macrophage had taken a bite, removing a Heinz body-containing segment of membrane. RBC rigidity may result in irregularly shaped cells because these undeformable cells are unable to undergo elastic recoil after fighting their way through the sinus wall. Recurrent loss of membrane material may produce spherocytes. Severe hemolysis may produce the kind of circulating ghost or hemighost called a *blister cell* or *bite cell*. These RBCs have an empty veil of membrane on one side and puddled hemoglobin on the other. A Heinz body preparation may be positive. However, the absence of bite cells does not rule out the diagnosis.

The clinical picture is determined by the specific agent used. Screening for G6PD deficiency or a related disorder using an enzyme assay or the ascorbate cyanide test may be useful. Although any defect in the antioxidant defense mechanisms, such as G6PD deficiency, considerably increases the susceptibility to hemolysis, many agents can produce oxidant hemolysis even in persons with normal defense mechanisms (see box on [Agents That Cause Oxidative Hemolysis](#)). Paraquat ingestion has occurred inadvertently and in suicide attempts. Profound cyanosis with methemoglobinemia can occur within hours, with levels of 120% or higher. The condition may be succeeded by hemolysis, with Heinz bodies seen in appropriate preparations of RBCs.

Toxic ingestion or inhalation of nitrites may occur in suicide attempts from industrial exposures; via diets high in pickled or smoked foods; through intentional recreational use; or in infants from formulas prepared using well water high in nitrates, which are

reduced to nitrites in the infant gut.²⁸ Nitrites bind to hemoglobin, producing methemoglobinemia, which may be so profound as to produce coma. If methylene blue infusion does not quickly turn the chocolate color of blood back to normal, the physician must consider the possibility that the patient is G6PD deficient and therefore unable to generate adequate amounts of NADPH (discussed earlier in the section [Drug-Induced Oxidative Hemolysis: General Concepts](#)). In that case, exchange transfusion may be lifesaving. Benzocaine topical anesthesia in the form of a spray or cream can cause severe methemoglobinemia, with cyanosis and dyspnea requiring methylene blue treatment.

Pyridium (phenazopyridine) can cause oxidative hemolysis even in the absence of renal disease. This agent is commonly used for treatment of bladder irritation. The *Physician's Desk Reference* recommends maximum therapy of 2 days. However, patients not uncommonly are given a prescription for 1–4 weeks of therapy.

It has been recognized for more than 130 years that therapy with dapsone causes oxidative hemolysis. In the past, dapsone was used primarily to treat leprosy and dermatitis herpetiformis, and was not often encountered as a cause of oxidative hemolysis. Dapsone has come into more widespread use in some communities as a very effective prophylactic agent against *Pneumocystis carinii* pneumonia in patients with AIDS. The reduced levels of glutathione reported in patients with AIDS may enhance dapsone toxicity. Dapsone is also used in the treatment of malaria where it regularly causes hemolytic anemia in G6PD-deficient patients.²⁹ Some clinics screen potential recipients for G6PD deficiency (see [Chapter 44](#)) and, if results are negative, proceed with dapsone therapy. However, dapsone can cause oxidative attack on normal RBCs, leading sequentially to methemoglobinemia, Heinz bodies, and hemolysis, all occurring at generally accepted standard doses. Dapsone is metabolized to a hydroxylamine derivative that is directly toxic to RBCs.

MISCELLANEOUS, POORLY CHARACTERIZED CAUSES OF EXTRINSIC HEMOLYTIC ANEMIAS

Interferon- α as a Cause of Hemolytic Anemia

Both microangiopathic and autoimmune hemolysis have been reported with IFN- α use. Zuber et al³⁰ reported eight patients with chronic myeloid leukemia who developed thrombotic microangiopathy confirmed by renal biopsy. Seven of these patients had identifiable hemolysis, and three had thrombocytopenia. They also reviewed 13 other cases of microangiopathy associated with IFN- α reported in the literature and observed that most cases occurred in the setting of prolonged therapy in chronic myeloid leukemia. Two cases of chronic hepatitis with microangiopathy were notable for having received unusually high doses of IFN for this indication. Cases of autoimmune hemolysis have been reported with IFN- α therapy in the setting of chronic myeloid leukemia or chronic hepatitis C.

Hemolysis With Intravenous Immunoglobulin G

Strictly speaking, hemolysis with intravenous IgG is a form of immune hemolysis. However, preparations of IgG contain anti-A and anti-B antibodies, and rarely cause an alloimmune hemolytic anemia, as described in two young women undergoing treatment for idiopathic thrombocytopenic purpura. If this situation occurs and more intravenous IgG is needed, performing a minor cross-match and choosing a preparation of intravenous IgG that gives no reaction is recommended. In addition to isoantibody production, anemia has been reported with intravenous IgG because of immune complex-mediated complement activation.

For hemolytic anemia with large granular lymphocyte leukemia, see box on [Hemolytic Anemia in Chronic Large Granular Lymphocytic Leukemia](#).

Hemolytic Anemia in Chronic Large Granular Lymphocytic Leukemia

Although large granular lymphocytic leukemia usually manifests as neutropenia and a rheumatoid-like picture, several patients with a severe Coombs-negative hemolytic anemia in the absence of splenomegaly have been described. Large granular lymphocytic leukemia has occurred in a splenectomized patient. The mechanism is unknown, but one report identified direct cytotoxicity against RBCs by the large granular lymphocytic cell lines.

There have been no formal studies on therapy for large granular lymphocytic leukemia-related hemolysis, although immunosuppressive therapy with prednisone or methotrexate has been reported as being partially or wholly successful.

NON-MALIGNANT LEUKOCYTES

This page intentionally left blank

NEUTROPHILIC LEUKOCYTOSIS, NEUTROPENIA, MONOCYTOSIS, AND MONOCYTOPENIA

Lawrence Rice and Moonjung Jung

Abnormalities of leukocyte number are commonly encountered in medical practice. The clinical significance of leukocytosis or leukopenia varies from none at all to being an early clue to a life-threatening process, whether a primary hematologic or secondary reactive process. Potential causes of leukocytosis or leukopenia are myriad. This chapter considers disorders faced by adult practitioners in hospital and outpatient clinics where the predominant hematologic abnormality is neutrophilic leukocytosis, neutropenia, monocytosis, or monocytopenia; other chapters consider lymphocytosis, lymphopenia, eosinophilia, pancytopenia, and hematologic neoplasms.

The normal range for leukocyte count in most laboratories is from about 4500/mm³ to 11,000/mm³. Neutrophils (and band forms) comprise the majority of circulating leukocytes (1800/mm³ to 7700/mm³); monocytes are about 4% of cells (mean absolute count: 300/mm³). The physician must always think in terms of absolute counts of leukocyte subpopulations (total leukocyte count multiplied by the differential percentage). Thus, in a patient presenting with a normal white blood cell (WBC) count of 5000/mm³ and an elevated lymphocyte percentage of 65%, the differential diagnosis to be considered is that of neutropenia, not lymphocytosis, because the absolute neutrophil count (ANC) is decreased but absolute lymphocytes are normal (only relatively increased).

When approaching a patient with abnormal leukocyte number, several factors impact heavily on the differential diagnosis and the vigor with which diagnosis and therapy should be pursued. Diagnostic considerations are vastly different when the abnormality first manifests **in the hospital versus in the outpatient clinic**. Also crucial is the **degree of the abnormality**, providing guidance to its likely cause and consequence. For example, agranulocytosis is a life-threatening disorder in which neutrophils are at or near zero, has a limited spectrum of underlying causes (drug reactions being paramount), and demands immediate interventions. **Duration** has major implications; determining the onset of changes and whether they are stable or progressive informs as to etiology and significance. Whether the abnormality is **symptomatic**—for example, whether a neutropenic or monocytopenic patient has or has had infectious complications—bears on likely etiologies and need for therapy. If there are known or suspected **comorbid conditions**, such as autoimmune or inflammatory disorders, this can crystallize the approach; occasionally, the leukocyte abnormality may be the first sign of a previously unrecognized disorder or may provide important confirmation (e.g., neutropenia in a patient with systemic lupus erythematosus [SLE]). If the leukocyte abnormality is accompanied by **additional hematologic abnormalities** (unexplained abnormalities of red blood cells [RBCs], platelets, or cell morphology), this would point away from disorders considered in this chapter and often toward a primary hematologic disease. Beyond history and physical examination, the peripheral blood smear is key to establish the direction of further evaluation.

NEUTROPHILIC LEUKOCYTOSIS (NEUTROPHILIA)

A high WBC count, particularly a high neutrophil count, is common with any infectious or inflammatory disorder. In the emergency department, leukocytosis is often equated with significant bacterial

infection or is at least a sign of illness severe enough to warrant hospital admission rather than outpatient management. Leukocytosis can also be a prominent presenting feature of leukemias and myeloproliferative neoplasms (MPNs). The presence of increased neutrophils assures that acute leukemia is not present. When leukocytosis is extreme, it indicates chronic myeloid leukemia (CML), other MPNs, or a leukemoid reaction.

Leukemoid reaction has been defined as a reactive (nonclonal) neutrophilic leukocytosis with WBC count above 50,000/mm³. This must be differentiated from a neoplastic proliferation.

Leukoerythroblastosis refers to the presence in the peripheral blood of immature myeloid cells (generally myelocytes) and nucleated RBCs, often with giant platelets as well. This is always abnormal. Patients with leukoerythroblastosis do not necessarily have leukocytosis, but they usually do. Most patients (two-thirds) with leukoerythroblastosis have an underlying myelophthisic process, such as primary or secondary myelofibrosis, metastatic tumor, necrosis, or granulomas in the bone marrow (BM). Therefore, BM examination is indicated when leukoerythroblastosis is unexplained. Teardrop poikilocytes and elliptocytes on blood smear would strengthen concerns for myelophthisis. In 20% of patients with leukoerythroblastosis, the cause is hemolytic anemia, and miscellaneous other causes consist mainly of those with shock (septic, hemorrhagic, cardiogenic, anaphylactic) when hypoperfusion of areas of BM disrupt the microenvironment and permit disorderly egress of precursor cells.

Left-shifted neutrophils refer to relative immaturity of circulating cells, often manifest as an increased percentage of band neutrophils. Marked left-shift includes less mature precursor forms, myelocytes and metamyelocytes. Left-shift is nonspecific and may occur with infection or any cause of marked neutrophilia.

Detailed directed history and physical examination are indispensable to the evaluation of neutrophilia (Table 48.1). Fever and chills suggest infection (or inflammation), mandating a search for more specific symptoms that could pinpoint the focus. Examples include a sore throat, pharyngeal erythema, and exudate in pharyngitis; productive cough and abnormal lung auscultation in pneumonia; and dysuria and flank tenderness in urinary tract infection. Medication history mainly explores glucocorticoid use. With mild chronic neutrophilia, smoking habits and obesity become considerations. Recent vigorous exercise, emotional stress, burns, shock, or trauma can increase circulating neutrophils because of catecholamine-induced demargination. A positive family history may suggest hereditary neutrophilia. Often neglected are attempts to delineate the time course of the leukocyte abnormality by seeking prior medical contacts and blood count results at the time. On the physical examination, care should be directed to lymph node palpation because this can be an important clue for infection or malignancy. Palpable splenomegaly may not only direct the evaluation toward hematologic disorders but can be a cardinal sign of a variety of infectious and inflammatory disorders.

Blood smear should always be a part of initial evaluation when there are abnormalities of blood counts. BM aspirate or biopsy morphology may be helpful when pathophysiology and diagnosis are unclear. When appropriate, essential information can be gained by sending BM for microbiologic cultures, cytogenetic or molecular, or other ancillary studies.

TABLE 48.1 Causes of Neutrophilia

- 1. Hematologic malignancy (CML, CNL, CMML)
- 2. Infection
- 3. Inflammation, physiologic stress, hemorrhage, hemolysis
- 4. Hereditary or congenital neutrophilias
- 5. Smoking
- 6. Drugs: colony-stimulating factors, glucocorticoids, epinephrine, lithium
- 7. Nonhematologic malignancy
- 8. Asplenia
- 9. Obesity
- 10. Recovery from neutropenia

CML, Chronic myeloid leukemia; CMML, chronic myelomonocytic leukemia; CNL, Chronic neutrophilic leukemia.

Leukemoid Reaction Versus Chronic Leukemia

A relatively common reason for hematologic consultation is for very high WBC count. CML is reviewed elsewhere in this text, as are chronic myelomonocytic leukemia (CMML) and the very rare chronic neutrophilic leukemia. Marked neutrophilic leukocytosis or overt leukemoid reaction (WBC count >50,000/mm³) can represent an overly exuberant reaction to any stimulus associated with neutrophilia. In patients with leukemoid reaction, a disproportionate number have infection with *Clostridium difficile*, an organism that elicits a vigorous neutrophil response. Leukemoid reactions may be associated with solid tumors, sometimes due to paraneoplastic production of colony-stimulating factor (e.g., granulocyte colony-stimulating factor [G-CSF] or granulocyte-macrophage colony-stimulating factor [GM-CSF]) or other cytokines (e.g., interleukin [IL]-6 or IL-17), or to particularly aggressive tumors with necrotic areas. The course of neutrophilia usually correlates with the course of solid cancer. It is important to quickly differentiate a reactive neutrophilic leukocytosis from a clonal leukemic proliferation.

The history and clinical context are usually quite different between leukemoid reaction and CML. Most patients with leukemoid reaction are encountered very ill in the hospital with obvious underlying illnesses (e.g., sepsis, organ rejection). Prior WBC counts, which are often available, demonstrate normal WBC counts until the recent onset of acute illness. This contrasts with CML, typically presenting in outpatients with hypermetabolism (weight loss, sweats, low-grade fever), symptoms referable to splenomegaly, or frequently asymptomatic. On physical examination, the spleen is palpable (occasionally massive) in the great majority of patients with CML but splenomegaly is unusual with leukemoid reaction (in the absence of comorbidities such as liver disease).

Laboratory findings reliably differentiate CML from leukemoid reaction. The total leukocyte count is commonly extremely high with CML (median 100,000/mm³ in some series), but counts above 100,000/mm³ are rare and above 150,000/mm³ virtually unheard of with leukemoid reaction. Circulating myelocytes and even a few blasts are more typical of CML, but may be seen in both disorders. Similarly, changes in platelet number and morphology can be seen with both but are more characteristic of CML (especially when changes are extreme). RBC changes do not reliably separate the disorders except in a few cases with prominent teardrops, which point toward MPN. More helpful is the leukocyte differential: patients with CML almost always have some degree of absolute basophilia and eosinophilia, but infection and glucocorticoid excess induce eosinopenia. (When the leukocyte count is 100,000/mm³, realize that 2% to 3% basophils is a substantial absolute increase.)

The leukocyte alkaline phosphatase (LAP) score, high with leukemoid reaction and classically low with CML, has limited utility now that more sensitive and specific tests for CML have emerged. When CML is reasonably considered, testing should be done for the Philadelphia chromosome, t(9;22)(q34;q11.2) by chromosome G-banding,

or *BCR-ABL1* fusion product by fluorescence in situ hybridization or reverse-transcriptase polymerase chain reaction. When other MPNs are judged reasonably possible, *JAK2* V617F mutational status may be informative. In cases with very high suspicion for MPNs but negative *JAK2* V617F mutation, *JAK2* exon 12, *MPL*, and *CALR* mutations can be assessed in a serial manner.

Infection

To protect against the ever-present threats to health and longevity, evolution has armed us with reactant cytokine cascades designed to increase the number of phagocytes and dispatch them to threatened locales. Neutrophilia is classically seen as a response to bacterial infection, responding to such cytokines as IL-6, tumor necrosis factor (TNF), and G-CSF. Neutrophilia is also a frequent response to other types of infections, such as fungal, parasitic, mycobacterial, and sometimes viral.

Changes in neutrophil morphology may be useful in predicting whether bacterial or other infection underlie a neutrophilic response. The authors have confirmed some published reports that prominent neutrophil vacuolization is highly specific and moderately sensitive for serious bacterial infection, as are prominent Dohle bodies (in the absence of a primary hematologic disorder). The authors blindly scored blood smears from 50 patients with serious bacterial infection (half bacteremic), 25 with influenza, 25 with noninfectious fever, and 25 control smears. Toxic granulation of neutrophils, touted as a sign of bacterial infection, was found useless in distinguishing infections from other febrile illnesses.

Inflammation and Stress

Acute or chronic inflammation can cause neutrophilia by mechanisms similar to infection, mediated by the proinflammatory cytokines G-CSF, GM-CSF, TNF, IL-1, IL-6, IL-8, and others. Diseases such as rheumatoid arthritis (RA), vasculitis, inflammatory bowel disease, thyrotoxicosis, eclampsia, and many others are commonly accompanied by neutrophilia. Another rare but notable example is familial Mediterranean fever, in which an inherited *MEFV* mutation leads to dysfunctional pyrin downregulation of neutrophil activation, leading to chronic inflammatory serositis and secondary AA amyloidosis.

Physiologic stresses, including exercise and emotional stress, lead to endogenous catecholamine and glucocorticoid release in addition to inflammatory cytokines. This causes a rapid doubling of circulating neutrophils caused by demargination and by more rapid BM egress of maturing neutrophils. Paulsen found early peaks in M-CSF, growth hormone, and cortisol after exercise followed by increases in G-CSF, IL-6, and monocyte chemoattractant protein 1. Acute hemorrhage and hemolytic anemia are other physiologic stresses. This contributes to increased steady-state neutrophil counts recorded in patients with sickle cell anemia, and the degree of elevation correlates with pain crisis frequency, other complications, and mortality; leukocyte reduction has been postulated to be one mechanism of hydroxyurea's beneficial actions. The stress of acute myocardial infarction is commonly accompanied by mild neutrophilia, and the early magnitude of rise has correlated with poor outcomes.

Hereditary and Congenital Neutrophilias

In newborns, neutrophilia and leukoerythroblastosis are among the hematologic abnormalities associated with trisomy 13, trisomy 18, and trisomy 21 (Down syndrome). A transient clonal MPN can be seen in children with Down syndrome and is usually self-limited, but it does put patients at increased risk for later acute megakaryoblastic leukemia.

Very rare hereditary neutrophilias are sometimes first appreciated in adults. In 1971, Herring reported a mother and three of her four children with lifelong neutrophilia (WBC: 14,000/mm³ to 164,000/

mm^3 ; granulocytes: $9000/\text{mm}^3$ to $62,000/\text{mm}^3$), unusual bleeding, thickened calvariae, and hepatosplenomegaly. They had no increase in infections. The LAP score was high, BM revealed few Gaucher-like histiocytes, karyotype was normal by routine G-banding, but chromatid breaks and gaps were increased. In 2009, French investigators identified a mutation in the *CSF3R* gene in a kindred with hereditary chronic neutrophilia. The point mutation led to constitutive activation of the G-CSF receptor, driving neutrophil proliferation and differentiation. One of 12 affected individuals in this kindred developed overt myelodysplastic syndrome (MDS). The frequency of this and other mutations are unknown with hereditary neutrophilias.

Smoking

Smoking has been well associated with mild neutrophilia in epidemiologic and animal studies. Perry et al found a 27% higher WBC count in smokers. Sunyer et al correlated the degree of leukocytosis and percentage of neutrophils with the number of cigarettes smoked. The effect can persist up to 5 years in those who stop smoking. A suggested mechanism is chronic inflammation because inflammatory markers, including C-reactive protein (CRP) and fibrinogen, are elevated. In a rodent model, cigarette smoke caused overexpression of hematopoietic growth factor genes IL-6, G-CSF, and GM-CSF. Thus, mild neutrophilia without other symptoms in a smoker could be attributed to this practice without further evaluation.

Drugs

Systemic glucocorticoids cause neutrophilia mainly by interfering with neutrophil adhesion to the capillary wall and decreasing neutrophil turnover rate. Maximal neutrophil counts occur 4–6 hours after dexamethasone use in normal volunteers. G-CSF increases circulating neutrophils by increasing BM production and mobilization. Epinephrine increases proinflammatory cytokines and demargination. Suggested mechanisms for lithium-induced neutrophilia are induction of G-CSF and downregulation of CXCR4-chemokine receptor 4, thus facilitating egress from the BM.

Malignancy

Leukocytosis is frequently associated with solid tumors without direct BM involvement. Some malignant tumors have been reported to produce G-CSF or GM-CSF, occasionally producing leukocytosis in the range of a leukemoid reaction.

Asplenia

Whereas neutrophilia is classically observed early after splenectomy, lymphocytosis predominates in the long run. Nevertheless, chronic mild neutrophilia can also be seen in functionally asplenic individuals. Furthermore, there may be an exaggerated neutrophil response to infections or other stresses. On the blood smear, Howell–Jolly bodies are a very sensitive and specific (when numerous) sign of functional asplenia.

Obesity

Chronic mild neutrophilia has been observed with obesity. Fat tissue can release inflammatory cytokines, creating a state of low-grade inflammation manifest by elevated CRP. Leptin, a hormone released by adipocytes, may act on CD34⁺ cells to promote neutrophil differentiation. More recently, chronically inflamed visceral adipose tissue in obesity was found to simulate BM hematopoietic progenitor cells to proliferate and expand, causing both neutrophilia and monocytosis via IL-1 β . In an obese patient with chronic mild neutrophilia

and no obvious other underlying disorder, this can be assumed to be the cause.

NEUTROPENIA (AND AGRANULOCYTOSIS)

The risk of neutropenia-related infection begins to rise at an ANC near $1000/\text{mm}^3$, rising dramatically below $500/\text{mm}^3$ and more so below $100/\text{mm}^3$; thus, an ANC of $500/\text{mm}^3$ to $1000/\text{mm}^3$ is considered moderate neutropenia, and below $500/\text{mm}^3$ is considered severe. This corresponds to National Cancer Institute criteria for medication adverse hematologic event reporting: grade 1 toxicity is $1500/\text{mm}^3$ to lower limit of normal, grade 2 is $1000/\text{mm}^3$ – $1500/\text{mm}^3$, grade 3 is $500/\text{mm}^3$ to $1000/\text{mm}^3$, and grade 4 is less than $500/\text{mm}^3$. Beyond the ANC, the risk for infection is greatly influenced by the nature of the underlying problem, the BM myeloid reserve, and whether other risk factors for infection are present (e.g., immunoglobulin deficiency or breaks in mucosal barriers). The course with mild and moderate neutropenia is often benign.

The history focuses on the severity and duration of neutropenia, whether infectious complications have occurred (including severe stomatitis or gingivitis), and whether prior blood counts can be obtained. A history of drug exposures and their timing is especially relevant, not only for prescribed medications but also for over-the-counter, herbal, and illicit drugs. Symptoms of systemic inflammatory illness, such as arthritis, skin rash, and photosensitivity, can bear on the etiology and significance of the low WBC count. Fevers, weight loss, and sweats could be clues to many disorders, including malignancy. Liver disorders commonly present with cytopenias, so a history of hepatitis, jaundice, and HIV risk factors should be specifically sought. Symptoms of anemia or bleeding could be clues to more general hematologic disorders. As with most hematologic problems, physical examination should devote extra attention to lymph node areas and the spleen. Oropharynx and skin examination also take on added importance.

Peripheral blood smear review is irreplaceable to direct the workup. MDS does not characteristically present with isolated neutropenia, but this occasionally is the predominant presenting feature in this relatively common syndrome affecting older patients. Specific blood smear findings which could suggest MDS include pseudo-Pelger–Huet neutrophils, hypogranularity, Dohle bodies, and macrocytic and/or dimorphic RBCs with a hypochromic population. Megaloblastic processes, such as vitamin B₁₂ and folic acid deficiency, similarly do not characteristically present with isolated neutropenia, but this occasionally predominates (especially in the presence of acute infection). Hypersegmentation of neutrophils is always present with megaloblastic processes, including those that are drug-induced (e.g., methotrexate, hydroxyurea). Hypersegmented neutrophils are also seen with uremia, as an autosomal dominant benign polymorphism, and in MDS and MPN. In a neutropenic patient, one should always specifically look for large granular lymphocytes (LGLs). A modest increase could indicate a reactive T-cell natural killer (NK) cell process, and a more dramatic increase could alert to clonal T-NK or NK cell proliferations (LGL leukemia). Hairy cells, other morphologic types of circulating lymphoma cells, and blasts are obvious indicators of hematologic malignancy. Morphologic suspicions for such processes could be confirmed by flow cytometry. Reactive lymphocytes may suggest viral infection but also occur with drug reactions and other processes.

Further laboratory testing in patients with neutropenia may often be unnecessary. Especially in mild or moderate cases, the lack of specific diagnostic tests has created some overlap and confusion among what have been called *chronic idiopathic neutropenia*, *chronic benign neutropenia*, *ethnic neutropenia*, and *autoimmune neutropenia*. Autoimmune neutropenia is a relatively common cause of both mild and more severe neutropenia, but tests for antineutrophil antibodies are not clinically validated (see later). Serologic tests for antinuclear antibodies and rheumatoid factor can be helpful when autoimmune neutropenia is considered, as positive results may raise suspicion for an undiagnosed collagen vascular disorder or may just support a less

specific autoimmune problem. Direct antiglobulin test and antiphospholipid antibodies can also be supportive when there is suspicion for an autoimmune process. Quantitative immunoglobulin levels may reveal an underlying immunodeficiency when there is evidence of autoimmunity or when infectious complications are disproportionate. Serologic tests for some viral infections (HIV, hepatitis, Epstein-Barr virus [EBV]) may sometimes be appropriate. The main utility of flow cytometry occurs when peripheral blood smear suggests an abnormal lymphocyte population (e.g., LGLs or hairy cells). Because LGL leukemia is a relatively common cause of significant neutropenia and because this is a diagnosis frequently initially missed, one should have a low trigger to obtain flow cytometry, assuring that proper markers are analyzed (see later). BM examination may not be helpful or warranted with mild or even moderate isolated neutropenia or in straightforward cases of severe neutropenia (e.g., after drug exposure), but can be essential when the diagnosis is in doubt and especially if other cell lines are compromised.

Severe Congenital Neutropenias

It is beyond the scope of this chapter to review in detail the heterogeneous genetic disorders that manifest in early childhood as severe congenital neutropenia (SCN); nevertheless, consultant hematologists should have some familiarity with this problem both because modern therapy has extended survival for many into adulthood, and because milder forms of these disorders may go undiagnosed until young adulthood. More severe forms of SCN present in infancy with severe stomatitis and recurrent bacterial infections. The molecular bases have been greatly elucidated in recent years, among them being: (1) an autosomal dominant mutation of the neutrophil elastase gene *ELANE* in 50% to 60% of patients, (2) an autosomal recessive mutation of *HAX1*, which is associated with mental retardation and other congenital defects found in Kostmann syndrome, and (3) an autosomal recessive mutation of *SBD5* in Schwachman-Bodian-Diamond syndrome, which presents with variable degree of neutropenia, BM failure, and exocrine pancreatic insufficiency. In young children, the differential diagnosis of SCN includes transient postinfectious neutropenia, alloimmune neutropenia, or hematologic malignancy. BM examination often shows a pattern of maturation arrest. The majority of affected patients are responsive to G-CSF, which has favorably impacted infectious morbidity and mortality. Allogeneic stem cell transplant is another therapeutic option. An intrinsic risk of acute myeloid leukemic transformation, 15% at 20 years, accompanies these disorders, with higher risk in those requiring higher doses and/or responding poorly to G-CSF.

Cyclic neutropenia is a rare autosomal dominant disorder with variable expression, also caused by autosomal dominant mutations of *ELANE* or rarely its transcription regulator. Neutrophil counts vary from mildly to severely low with predictable periodicity, usually about 21 days. The great majority of cases are responsive to G-CSF at low dosage.

Benign Ethnic Neutropenia

Americans of African descent may have chronic mild neutropenia not associated with infectious complications. The 1999–2004 National Health and Nutrition Survey found that black individuals had mean leukocyte counts $900/\text{mm}^3$ lower than white individuals, with ANC below $1500/\text{mm}^3$ in 4.5% (compared with 0.8% of white individuals). The neutropenia correlates in some individuals with a polymorphism in the Duffy antigen receptor chemokine, a cytokine receptor also responsible for a Duffy-negative RBC phenotype. Some reports find this neutropenia more common in males, but other reports find autosomal dominant inheritance. Marrow granulocyte reserve or release (or both) may be compromised. Benign neutropenia has also been seen in other ethnic populations, including those of Middle Eastern or Japanese descent. Thus, an asymptomatic mildly neutropenic person of appropriate ethnicity without abnormalities on blood

smear may require no further diagnostic workup. It may be reassuring to the patient (and the doctor) if prior blood counts can be retrieved to document the chronic, nonprogressive and complication-free course of the neutropenia.

Autoimmune Neutropenia (Primary and Secondary)

Autoimmune neutropenia can be primary or secondary to an autoimmune disorder such as SLE or RA. Neutropenia can be mild or severe. Classically, it is caused by antineutrophil autoantibodies, although autoreactive cytotoxic lymphocytes may also cause this problem. When performed, BM examination often is normocellular or hypercellular, with a late “maturation arrest” picture. Severe cases can display pure WBC aplasia (similar to drug-induced agranulocytosis, which may sometimes also be antibody-mediated). There are several challenges to making the diagnosis. One is that the maturation arrest BM picture is highly nonspecific with regard to mechanism: it could indicate a true stem cell differentiation defect, or the early release of later precursors (as with sepsis or splenic sequestration), or an immune attack aimed at antigens on later myeloid precursors or early recovery from a toxic insult. Another problem is the lack of validated, clinically reliable neutrophil antibody tests. Experimentally, several methods have been used, generally suffering from high false-negative and false-positives rates in detecting antibodies against neutrophil antigens or immune complexes that bind to neutrophil Fc receptors. With no definitive test, diagnosing autoimmune neutropenia rests largely on clinical context and judgment.

Neutropenia caused by antineutrophil antibodies has been seen in infants about 1 year old, usually running a benign clinical course with spontaneous remission in 95% within 2 years. Newborns are at risk of alloimmune neutropenia in the first months of life, but this is not generally accompanied by infectious complications. Secondary autoimmune neutropenias are most common in adults, related to disorders such as SLE, RA, Sjögren syndrome, thymoma, and common variable immunodeficiency. In SLE, neutrophil counts correlate with disease activity and have been related to the induction of TNF-related apoptosis-inducing ligand (TRAIL), a ligand that increases myeloid apoptosis and killing by autologous T cells. Immunosuppressive therapy of the SLE or the use of G-CSF can improve the WBC count.

Felty syndrome was classically described as severe neutropenia and splenomegaly complicating RA, and has been attributed to antineutrophil antibodies, but the distinction between this syndrome and other causes of neutropenia with RA have become blurred. In particular, classic Felty syndrome and LGL syndrome appear to represent points on a disease continuum. About 1% of patients with RA develop Felty syndrome, and it predisposes many to serious infections. Effective therapies have often included methotrexate, gold salts, and rituximab. Because of some risk of exacerbating underlying inflammatory problems, G-CSF should be used with caution.

Large Granular Lymphocyte Syndrome and Natural Killer Cell Proliferations

Proliferations of LGLs (T-NK cells and NK cells) are covered elsewhere, but mention is required here because these are common considerations in adults with neutropenia. These represent heterogeneous disorders, varying from nonclonal reactive processes to indolent clonal proliferations to highly aggressive neoplasms. Both reactive and clonal increases in T-NK cells can be seen with RA, representing a form of Felty syndrome. Reactive LGLs can be seen with other autoimmune disorders, after organ transplantation, with tyrosine kinase inhibitor therapy, or they may be idiopathic. These proliferations are associated with variable degrees of neutropenia, commonly splenomegaly, and increased infectious risks. The diagnosis is suggested on blood smear by large lymphocytes with mature chromatin, excessive cytoplasm, with or sometimes without prominent cytoplasmic granules. Flow cytometry demonstrates increased $\text{CD3}^+\text{CD57}^+$

lymphocytes with the more common T-NK proliferations or may show CD3⁺ CD56⁺ clones with “pure” NK cell proliferation. Somatic activating mutations in the signal transducer and activator of transcription 3 gene (STAT3) were found in 40 % of patients with LGL leukemia, suggesting aberrant STAT3 signaling pathway is an underlying mechanism of this disease. Somatic activating STAT5b mutations were also found in minority of patients. Variably effective treatments for indolent proliferations are corticosteroids, methotrexate, cyclosporine, cyclophosphamide, and purine nucleoside analogs.

Neutropenia With Infectious Diseases

Leukocytosis is the expected response to most bacterial infections, but leukopenia also occurs and is characteristic of infection by certain organisms. Viral infections often cause transient mild leukopenia, so restraint is wise in the diagnostic approach to a newly recognized moderate leukopenia in a febrile, modestly ill patient. Nonbacterial infections in which neutropenia is frequent or even characteristic include HIV, EBV, cytomegalovirus (CMV), hepatitis A and B, measles, rubella, varicella, rickettsia, and anaplasmosis (ehrlichiosis). Bacterial infections with characteristic leukopenia include typhoid fever and brucellosis, and granulomatous infections (tuberculosis, histoplasmosis) also commonly cause neutropenia, especially when the BM is directly involved. In patients with poor BM reserve (e.g., prior chemotherapy, malnutrition, myelodysplasia) an acute infection very often lowers, rather than raises, the neutrophil count. Profound neutropenia is a known consequence of overwhelming sepsis and has been associated with poor outcomes.

Hypersplenism

Hematologists are frequently consulted for cytopenias, only to find an unappreciated large spleen as the etiology (this most commonly due to liver disease with portal hypertension). Splenic enlargement can lead to sequestration and reduction of circulating WBCs, RBCs, platelets, or any combination of these. The degree of cytopenia is somewhat proportional to the degree of splenic enlargement. Substantial neutropenia out of proportion to the depletion of other cell lines and to the degree of splenomegaly suggests an autoimmune component (which can be seen with hepatitis C or autoimmune hepatitis) or medication effect (e.g., interferon).

Chemotherapy-Induced Neutropenia

The major dose-limiting toxicity of most cancer chemotherapy regimens continues to be neutropenia. This results in hospitalizations, antibiotic costs, reduced quality of life, infectious morbidity, dose reductions and treatment delays that compromise efficacy and outcomes, and result in some deaths: 75% of chemotherapy-related mortality. Febrile neutropenia is defined as an ANC less than 500/mm³ (or expected to decrease to <500/mm³ over the next 48 hours) with fever (>38.3°C or sustained >38°C).

Principles of empiric antibiotic coverage for acute febrile episodes in severely neutropenic patients are covered in detail elsewhere. Basically, there is a high risk of sepsis (even when the source is occult), and a favorable outcome depends on prompt effective antimicrobial coverage, so empiric administration of broad-spectrum antibacterial agents is considered medically emergent. There must be coverage of the traditional aerobic gram-negative rod culprits (particularly *Pseudomonas*), yet vigilance must be maintained for the gram-positive organisms that have emerged as major pathogens. With prolonged or repeated episodes of neutropenia, invasive fungi become common threats to survival, particularly *Aspergillus*, *Candida*, *Mucor*, and *Fusarium* spp. Published guidelines can aid the choice of empiric antimicrobials. Because of difficulty demonstrating favorable impact, enthusiasm for granulocyte transfusions has waned in the past 30 years; clinical studies are readdressing this in the modern era.

TABLE 48.2

Drugs Commonly Associated With Neutropenia

1. Antibiotics: vancomycin, semisynthetic penicillins, chloramphenicol, sulfa, linezolid
2. Antithyroid drugs: methimazole, propylthiouracil
3. Cardiovascular: ticlopidine, procainamide
4. Antipsychotics: clozapine, olanzapine, chlorpromazine
5. Anticonvulsants: phenytoin, carbamazepine, valproic acid
6. Antiinflammatory agents: indomethacin, sulfasalazine, phenylbutazone
7. H₂ blockers: cimetidine, ranitidine
8. Analgesics: dipyrrone
9. Antineoplastic: rituximab
10. Anthelmintic: levamisole

The utility of prophylactic antibiotics is problematic because of the wide array of potential pathogens and because of concerns of inducing antibiotic resistance. Prophylactic quinolones have had some favorable impact in very high-risk patients after consolidation therapy for acute leukemia or stem cell transplant.

G-CSF is widely used for primary or secondary prevention of neutropenia to decrease morbidity and mortality of febrile neutropenia. Primary prophylaxis is recommended by various guidelines if the risk of developing febrile neutropenia is greater than 20%. This risk is calculated from age, extent of primary cancer, comorbidities, and the known myelotoxicity of the chemotherapy regimen. G-CSF is begun 24–72 hours after the completion of myelotoxic chemotherapy. Pegfilgrastim allows prophylaxis to be given more conveniently (once per cycle).

Drug-Induced Neutropenia

Drug reactions account for a high percentage of acquired neutropenias, both mild but moreover severe cases (agranulocytosis; Table 48.2). Neutropenia often develops abruptly, within 4 weeks of initiation of a causative agent. Pathophysiology may involve immune mechanisms or more direct toxicity such as enhancement of reactive oxygen species made by nicotinamide adenine dinucleotide phosphate oxidase or myeloperoxidase on neutrophil precursors. The diagnosis is generally strongly suspected from an accurate history that plots leukocyte numbers against the time course of drug exposure; confirmation is leukocyte recovery after drug withdrawal. More specific confirmatory testing, such as for drug-dependent antibodies, is mainly an area of research laboratory investigation. BM examination is not usually required but may be helpful when pathophysiology and diagnosis are in doubt, when the course is atypical, and to provide prognostic information (earlier recovery may be anticipated with a picture of “maturation arrest” than one of myeloid aplasia). Treatment demands discontinuation of suspected offending drugs. Although the efficacy of myeloid growth factors (G-CSF) has been questioned, most recommend this therapy because even a modest shortening of severe neutropenia can occasionally be lifesaving. Mortality of drug-induced agranulocytosis is generally reported to be 10%.

The most commonly implicated drugs are listed in Table 48.2. Some merit additional comment. Some drugs have a direct myelotoxic effect rather than induce an idiosyncratic immune-based reaction. Neutropenia will have more gradual onset related to dose and duration, and may be accompanied by suppression of other hematologic cell lines. Linezolid and most instances of chloramphenicol myelosuppression are examples.

Beginning 2007, an epidemic of agranulocytosis was found among intravenous cocaine users. The adulterant levamisole was found in 71% of confiscated cocaine by the Drug Enforcement Agency, with the incidence of agranulocytosis 2.5% to 13% in those exposed. Nadir BM showed severe myeloid hypoplasia. Levamisole had long been linked to agranulocytosis, having been used as an anthelmintic

and as an immune adjuvant in patients with autoimmune disorders and colorectal cancer.

Severe neutropenia is increasingly recognized in patients treated with rituximab. This neutropenia is unusual for its late onset, generally about 3 months after the last rituximab dose. It occurs with underlying autoimmune disorders, B-cell malignancies, and stem cell transplants—basically in all situations in which rituximab is used—often occurring while the underlying illness is in complete remission. Severe neutropenia has been reported in about 5% of rituximab-treated patients, much higher in some series. Most patients recover quickly, usually after G-CSF therapy, but there have been protracted cases. The authors and others have reported a high risk of relapse (100% in our series) if rituximab is reinitiated. The mechanism is not definitively established, but an intriguing report implicates imbalanced recovery of B-cell clones with a deficiency of stromal-derived factor 1.

MONOCYTOSIS

Monocytosis is extremely nonspecific, usually not requiring investigation per se. Monocytosis has been defined as a sustained absolute increase in monocyte count greater than 800/mm³ to 1000/mm³ (Table 48.3). Transient monocytosis, relative or absolute, is common with recovery from myelosuppression, such as after chemotherapy. Relative or absolute monocytosis may occur in other myelosuppressed states, such as aplastic anemia. This is a favorable factor associated with a lower risk of neutropenic infection, perhaps because some phagocytic capacity is maintained. On the other hand, monocytosis is also very common with hematologic malignancies. In a patient with unexplained cytopenia, monocytosis can be an important clue to an underlying MDS.

Infectious Diseases

Mycobacterial infection is a common cause of monocytosis worldwide, related to its propensity for intracellular infection and tissue granuloma formation. Brucellosis and subacute bacterial endocarditis have also been associated with monocytosis. Certain viral infections, including influenza, varicella-zoster, CMV, and dengue, have been reported to cause monocytosis.

TABLE 48.3 Changes in Monocyte Number

Monocytosis
Infections: tuberculosis, granulomatous infection, brucellosis, subacute bacterial endocarditis
Connective tissue disorder
Recovery from myelosuppression
Hematologic malignancies:
1. MDS, MPD, MDS-MPD overlap, CMML
2. Acute and chronic monocytic leukemia, myelomonocytic leukemia
3. Hodgkin and non-Hodgkin lymphomas
Obesity
Monocytopenia
Hairy cell leukemia
GATA2 deficiency (also known as MonoMAC syndrome, DCML, Emberger syndrome, familial MDS/AML)
Aplastic anemia
Drugs: chemotherapy, IFN-α, glucocorticoids (transient)
Radiation therapy
AML, Acute myeloid leukemia; CMML, chronic myelomonocytic leukemia; DCML, dendritic cell, monocyte and lymphoid deficiency; IFN, interferon; MDS, myelodysplastic syndrome; monoMAC, monocytopenia and mycobacterium avium complex syndrome; MPD, myeloproliferative disorder.

Connective Tissue Disorder

Connective tissue disorders, such as SLE and RA, have been associated with monocytosis in the context of chronic inflammation.

Hematopoietic Malignancies

Monocytosis is common with MDS. CMML is defined as persistent peripheral blood monocytosis greater than 1000/mm³, absent Philadelphia chromosome, and evidence of dysplasia in one or more hematopoietic cell lineages. Juvenile myelomonocytic leukemia, a disease of children that shares pathologic features with CMML, results from defective RAS signaling. Acute myeloid leukemias (AMLs) involving the monocyte line (acute myelomonocytic and acute monoblastic leukemias) may release substantial amounts of lysozyme (muramidase), which is toxic to renal tubules. Serum lysozyme was used to aid in the diagnosis of these leukemias. Monocytosis can result from other myeloid leukemias, MPNs, and lymphomas, particularly Hodgkin disease.

MONOCYTOPENIA

Monocytopenia frequently accompanies granulocytopenia with chemotherapy, aplastic anemia, or other BM-suppressive insults. Isolated or disproportionate monocytopenia is rarely recognized, but observations suggest that this can have serious clinical sequelae when it occurs. In hairy cell leukemia and monoMAC syndrome (GATA2 deficiency), there is a clear association with severe opportunistic infections, particularly those normally engendering a granulomatous response.

Hairy Cell Leukemia

This disorder, considered in detail elsewhere, classically presents with pancytopenia and splenomegaly, often in middle-aged men. The WBC count is sometimes high because of hairy cell proliferation, but monocytes are invariably severely depressed. (Monocytopenia is not seen with “variant hairy cell leukemia.”) Neutropenia only partly explains the very high infectious morbidity and mortality. An extraordinary incidence of opportunistic granulomatous infections used to be encountered, including atypical mycobacteria, tuberculosis, histoplasmosis, and other fungi. These are linked to monocytopenia, with impaired granuloma formation. With remission induced by modern therapies (e.g., 2-chloro-deoxyadenosine), monocytopenia and infectious risks have been mitigated.

GATA2 Deficiency

In 2010, investigators at the National Institutes of Health and in the UK simultaneously described an immunodeficiency syndrome characterized by decreased or absent monocytes, NK cells, B cells, and dendritic cells; this clinical syndrome was named *MonoMAC* or *dendritic cell, monocyte and lymphoid deficiency*. This was largely diagnosed in young adults (median age: 33 years). All patients have opportunistic infections, particularly *Mycobacterium avium* complex and other mycobacteria, opportunistic fungi, and viruses, particularly human papillomavirus. Both autosomal dominant and sporadic cases are described, all linked to mutations in the hematopoietic stem cell regulator *GATA2*. Heterozygous haploinsufficiency mutations in *GATA2* are also responsible for Emberger syndrome (primary lymphedema and a predisposition to AML) and familial MDS/AML. BM examination findings are almost always abnormal, usually hypocellular, with increased reticulin fibrosis, multilineage dysplasia with characteristic separated nuclei in megakaryocytes, and absent B and NK precursors. Clonal cytogenetic abnormalities are seen in most patients, particularly monosomy 7 in 16% and trisomy 8 in 24%.

Because leukemic progression with or without death from infection is high, stem cell transplantation is recommended when feasible. When a family member is used as a BM donor, *GATA2* sequencing must be performed to rule out asymptomatic carrier status before donating. When monocytopenia out of proportion to neutropenia is detected in a patient with or without human papillomavirus-associated warts or MAC infection, examination of B- and NK-cell count by flow cytometry will be informative. Detailed family history may reveal additional patients with infectious complications or MDS/AML.

Chronic Mild Neutrophilic Leukocytosis

A 46-year-old man was referred to the hematology clinic for evaluation of neutrophilia that was noted by his primary care physician on a routine blood test. He reported no fevers, chills, or night sweats. He had good energy and was working full time as a lawyer. He denies fatigue, weight loss, or rashes. His past medical history included hypertension and obesity, but was otherwise healthy. He has been an active smoker for 10 years. Family history was negative for blood diseases. Vital signs were normal. Body mass index was 40.5 kg/m². Physical examination revealed only an obese abdomen. Laboratory values showed WBC 12,500/mm³, ANC 8500/mm³, Hb 14 g/dL, hematocrit (Hct) 42%, platelets 400 K/mm³. Chemistries were unremarkable. Peripheral blood smear showed only increased neutrophils, with unremarkable RBCs and platelets. A complete blood cell count 2 years ago showed WBC 11,800/mm³, ANC 8100/mm³, Hb 14.2 g/dL, platelets 385 K/mm³. What is the next step in evaluation?

This patient has mild neutrophilia of at least 2 years of duration. Obesity and smoking are common causes of neutrophilia. There is no evidence of chronic infection, inflammation or hematologic malignancy. No further work up is warranted, only follow-up, at the present time.

Acute Severe Neutrophilic Leukocytosis

A 78-year-old woman nursing home resident presented to the emergency department with altered mental status, diarrhea, and abdominal pain. She was recently treated with ciprofloxacin for urinary tract infection. On physical examination, she is difficult to arouse. Vital signs show blood pressure 105/66 mmHg, heart rate 98/min, respiratory rate 18/min, temperature of 100.4°F. Abdominal examination reveals distention, active bowel sounds, no organomegaly. Laboratory findings show WBC 88,000/mm³, Hb 10.5g/dL, platelets 200/mm³, neutrophils 65%, lymphocytes 5%, monocytes 4%, eosinophils <1%, basophils <1%, bands 25%. Hematology is consulted for the high WBC. Peripheral blood smear shows increased neutrophils, metamyelocytes, and myelocytes. RBCs are normocytic and normochromic. Platelets are unremarkable. Nursing home records show normal blood counts except mild anemia with a Hb of 10.9 g/dL a month ago.

The almost certain cause of the extreme leukocytosis in this patient is leukemoid reaction, perhaps due to urosepsis. *Clostridium difficile* infection is classically associated with severe neutrophilia and the recent antibiotic use with diarrhea and abdominal distention suggests this as another possibility. The absence of splenomegaly, eosinophilia, and basophilia, and near normal blood counts a month ago makes CML or other MPN very unlikely. We would recommend appropriate antibiotics, clinical follow-up, but no molecular testing at this time.

LYMPHOCYTOSIS, LYMPHOCYTOPENIA, HYPERGAMMAGLOBULINEMIA, AND HYPOGAMMAGLOBULINEMIA

Martha P. Mims

Any discussion of quantitative abnormalities of lymphocytes and immunoglobulins is necessarily linked because the B-cell compartment is responsible for immunoglobulin production, and the T-cell compartment helps provide the stimulus. Nevertheless, clinicians are often consulted when a quantitative disorder of one or the other is recognized. Thus, although overlapping, the defects are presented separately.

QUANTITATIVE DISORDERS OF LYMPHOCYTES

The normal number and distribution of lymphocyte subtypes in the peripheral blood varies with age, but no careful study has demonstrated gender or ethnic differences in lymphocyte count. In general, circulating T cells exceed B cells by a ratio of approximately four to one, with that ratio increasing slightly with age (Table 49.1). Natural killer (NK) cells are grouped with lymphocytes but comprise only about 10% of the lymphocyte population. Infants have total lymphocyte counts between 5500/ μ L and 7000/ μ L, but this number declines beginning at about 1 year of age to reach 2000/ μ L to 2400/ μ L in adults. At birth, the total number of circulating B cells is approximately 1000/ μ L but decreases over the first 10 years of life to approximately 200/ μ L to 300/ μ L by the age of 18 years. A slow decline in circulating B cells continues throughout adulthood and is primarily accounted for by a decline in transitional and naive B cells with a stable or mild increase in circulating memory B-cell numbers with age. Circulating naive B cells represent about two-thirds of the entire naive B-cell pool, and circulating memory B cells represent only about one third of the entire memory B-cell pool.¹

T cells dominate the circulating lymphocyte population with approximately 3500/ μ L in infancy, declining to 1500/ μ L on average in young adults, with even lower numbers (approximately 1200/ μ L) in elderly adults. In both children and adults, CD4 cells outnumber CD8 cells. Naive CD4 and CD8 T cells decline with age by twofold to fourfold. In one large study, CD4 memory T cells significantly increased with age, but no such trend was seen for CD8 memory T cells.²

Against this background, *lymphocytosis* is defined as a lymphocyte count greater than 8000/ μ L in young children and greater than 4000/ μ L in teenagers and adults. Lymphocytopenia has been defined as a total lymphocyte count of less than 1000/ μ L. Given the composition of the circulating lymphocyte pool, it is critically important to define which lymphocyte subsets are over- or underrepresented when there is a quantitative disorder.²

Lymphocytosis

As in any clinical disorder, a careful history is critical to defining the origin of lymphocytosis. Inherited causes of lymphocytosis are rare. One recently identified inherited lymphocytosis is BENTA disease (B-cell expansion with nuclear factor kappa-B [NF κ B] and T-cell anergy). Germline gain of function mutations in caspase-activating recruitment domain 11 (*CARD11*) drive this disorder, which is characterized by polyclonal lymphocytosis and splenomegaly

beginning in infancy. In most cases of lymphocytosis, however, the issue is to determine whether a lymphocyte disorder is clonal/malignant or benign and related to infection, drugs, or physiologic stress. Rarely, neither a malignancy nor an underlying condition can be identified, in which case the lymphocytosis is termed *persistent polyclonal B-cell lymphocytosis*. When an excess of B cells exists, clonality can usually be defined by examining cell surface expression of κ - and λ -light chains using antibody techniques; with T-cell proliferation, it may be important to define clonality by examining T-cell receptor gene rearrangement using molecular procedures. In the case of NK cell disorders, clonality can be quite difficult to determine.

Clonal Disorders

Malignant causes of peripheral blood lymphocytosis are covered in Chapters 76–80, 84, and 86 and include chronic lymphocytic leukemia (CLL), hairy cell leukemia, splenic marginal zone lymphoma, lymphoplasmacytic lymphoma, follicular lymphoma, mantle cell lymphoma, adult T-cell leukemia or lymphoma, and Sézary syndrome. Occasionally, precursor T-cell or precursor B-cell leukemia presents with circulating small cells, which morphologically appear more similar to mature lymphocytes than blasts.

A recently identified clonal disorder causing lymphocytosis is monoclonal B-cell lymphocytosis (MBL), an accumulation of clonal B lymphocytes that does not meet the criteria for CLL (greater than 5000 clonal B cells/ μ L), but is nevertheless defined by the presence of a clonal population of B cells. Data demonstrate that up to 10% to 15% of patients with lymphocytosis have MBL. Three major subtypes of MBL exist: the CLL immunophenotype (CD5⁺, CD23⁺), which is by far the most common; the atypical CLL type (CD5⁺, CD23⁻); and non-CLL lymphoproliferative disorder (CD5⁻). In a systematic study of blood donors more than 45 years of age, 7.1% had detectable MBL. Of these, the majority had the CLL immunophenotype and more than 93% were low-count MBL (B-cell clonal count less than 500 cells/ μ L). Similar to the relationship between monoclonal gammopathy of uncertain significance and multiple myeloma, only a small proportion of patients with CLL-type MBL (1% to 4% per year) go on to develop progressive disease requiring treatment. Epidemiologic studies of MBL patients have demonstrated strong familial risk for CLL, and the first reports of MBL came from studies of “unaffected” CLL family members. Studies of CLL families suggest that there is an inherited abnormality that increases the risk of developing CLL, and some families exhibit anticipation, with the disease occurring earlier in successive generations. The supposition that MBL is a progenitor lesion for CLL is strengthened by the observation that both low-count and high-count MBL carry the same cytogenetic aberrations observed in good-prognosis CLL. MBL has been identified in up to 30% of individuals infected with hepatitis C virus (HCV), and up to 50% of the HCV-associated cases demonstrate the atypical CLL immunophenotype. The presence of MBL correlates with more advanced liver disease, suggesting that the persistence of viral infection is crucial to development of the B-cell clone. Follow-up for MBL patients is not clearly defined, although it is probably reasonable to evaluate lymphocyte counts with complete blood counts and follow the clone with flow cytometry at periodic

TABLE
49.1**Normal Lymphocyte Subsets With Age^a**

	Cord Blood	2 Days–11 Months	1–6 Years	7–17 Years	18–70 Years
Total lymphocyte count ($\times 10^3$ cells/mL)	5.4 (4.2–6)	4.1 (2.7–5.4)	3.6 (2.9–5.1)	2.4 (2.0–2.7)	2.1 (1.6–2.4)
CD4 ⁺ T cells (%)	35 (28–42)	41 (38–50)	37 (30–40)	37 (33–41)	42 (38–46)
CD45Ra ⁺ in CD4 ⁺ (naive T cells) ^b	91 (82–97)	81 (66–88)	71 (66–77)	61 (55–67)	40 (32–49)
CD8 ⁺ T cells (%)	29 (26–33)	21 (18–25)	29 (25–32)	30 (27–35)	35 (31–40)
B cells (%)	20 (14–23)	23 (19–31)	24 (21–28)	16 (12–22)	13 (11–16)
NK cells (%)	20 (14–30)	11 (8–17)	11 (8–15)	12 (9–16)	14 (10–19)

^aValues are median, with ranges from the 25th to 75th percentiles.^bNaive T cells expressed as a percentage of CD4⁺ T cells.

NK, Natural killer.

intervals depending on the pace of the lymphocyte rise, the clinical scenario, the family history, and the age of the patient.³

Infectious Causes

The most common infections causing lymphocytosis are Epstein-Barr virus (EBV) and cytomegalovirus (CMV). In young children, EBV infection frequently presents as an upper respiratory infection, but in adolescents and young adults, it can result in acute glandular fever with pharyngitis, splenomegaly, lymphadenitis, and profound reactive lymphocytosis. Lymphocytosis is less prominent in older adults. Although the B cells are targeted by EBV, the lymphocytosis consists of CD8⁺ lymphocytes reacting to neoantigens expressed on the surface of infected B cells. The massive T-cell response usually clears the infection in a matter of days to 1 week, and the lymphocytosis resolves. CMV infection can produce a similar lymphocytosis. In the case of CMV, however, the macrophages are the target of infection, and the T-cell lymphocytosis results from a response to the macrophage neoantigen. CMV infection and lymphocytosis are more common in older adults. In both viral infections, lymphocytosis can be profound, with 50% or more of the circulating white blood cells (WBCs) identified as lymphocytes. Examination of the peripheral smear reveals that up to 10% of the circulating lymphocytes are atypical and larger than normal lymphocytes with open chromatin and increased cytoplasm. It is particularly important to recognize lymphocytosis caused by these two viruses in pregnant women because congenital infection can cause fetal death and birth defects. In addition to EBV and CMV, primary infection with human immunodeficiency virus (HIV) can cause lymphocytosis and should be suspected in the presence of a viral syndrome in the appropriate clinical circumstance. In children, infection with Coxsackie A and B6 viruses, echovirus, and adenovirus can cause a brief but profound lymphocytosis. Infections with other viruses, including human herpesvirus 6 (HHV-6) and human herpesvirus 8 (HHV-8) as well as rubella virus, varicella, human T-lymphotropic virus type 1 (HTLV-1), and hepatitis viruses, can cause a lymphocytosis, although much less frequently than CMV and EBV.

Important nonviral infections causing lymphocytosis include *Toxoplasma gondii* and *Bordetella pertussis*. In an immune-competent host, *Toxoplasma* infection is often asymptomatic, but patients can have fever, chills, and lymphadenopathy. Mild lymphocytosis with atypical lymphocytes can be observed. As in the case of EBV and CMV, infections during pregnancy can lead to adverse effects on the fetus. In children and adults, infection with *B. pertussis* can lead to lymphocytosis, with the absolute lymphocyte count frequently greater than 10,000/ μ L. In more severe cases, lymphocytosis is more pronounced.⁴ Unlike viral infections and *Toxoplasma* infection, the lymphocytosis observed in *B. pertussis* infection is caused by increases in all lymphocyte subsets, and it appears that the pertussis toxin blocks migration of the lymphocytes from the bloodstream into lymph nodes.⁴ Tuberculosis, rickettsial infection, brucellosis, and shigellosis may also cause lymphocytosis.

Physiologic Stress

Lymphocytosis related to physiologic stress is a poorly studied phenomenon. After strenuous physical exercise, subjects develop lymphocytosis, which returns to preexercise levels within 15 minutes to 1 hour of ceasing the activity. The exercise-induced rise is thought to be attributable to catecholamine and steroid hormones, and their effect on expression of cell adhesion molecules and on cardiac output and shear stress.⁵ Exposure to catecholamines increases the expression of β_2 -adrenergic receptors on lymphocytes influencing cell trafficking. Reports suggest that a number of other physiologic stresses increase lymphocyte counts, including surgery, trauma, cardiac conditions, sickle cell crises, abdominal pain, and obstetric emergencies. In these cases, all lymphocyte subsets appear to increase, but the increase is most profound for CD4 and CD8 memory T cells. Neutrophil counts also rise in these patients, but in most cases, the lymphocytosis resolves before the peak of the neutrophil count.⁶

Drug Reactions

Drug-induced lymphocytosis can occur as part of a hypersensitivity syndrome. In these cases, the lymphocytosis is usually part of a systemic condition that includes a fever, rash, and lymphadenopathy. Elevation in other WBC counts, including eosinophils and monocytes, is common, and atypical lymphocytes are seen. The time period between drug introduction and the syndrome is usually about 3 weeks with the most common implicated drugs being aromatic anticonvulsants and sulfonamides.⁷ Some studies differentiate this syndrome from drug-induced cutaneous pseudolymphomas in which collections of nonclonal lymphocytes appear in the skin after longer periods of drug exposure, but there is no peripheral lymphocytosis.

Polyclonal B-Cell Lymphocytosis

A final entity causing lymphocytosis is persistent polyclonal B-cell lymphocytosis (PPBL). This rare disorder is seen primarily in young to middle-aged women who smoke and results in mild polyclonal lymphocytosis. The lymphocytes are medium sized with abundant cytoplasm and a variable proportion is binucleate. A polyclonal increase in serum immunoglobulin M (IgM) is also observed, and there is an association with the human leukocyte antigen (HLA) antigen D-related 7 (DR7) phenotype. Examination of the B cells reveals that most are CD19⁺, CD5⁺, and CD23⁺, with a normal kappa-to-lambda ratio and a variety of heavy chain rearrangements. Adenopathy, hepatomegaly, or splenomegaly has been observed in some, but not all, patients. Genetic analysis has demonstrated the presence of isochromosome 3q in a proportion of B cells, as well as the presence of multiple B-cell lymphoma immunoglobulin (*BCL2-Ig*) gene rearrangements. Similar gene rearrangements have been identified in family members of PPBL patients along with increases in serum IgM, suggesting that there may be an underlying genetic

defect. In vitro studies have shown that PPBL cells proliferate in a CD40-CD154 culture system and secrete both IgM and IgG (isotype switching). This suggests that PPBL may arise from deregulation of the microenvironment or from a defect in a different B-cell activation pathway resulting in extensive proliferation. Overall, the clinical course of this disorder is benign, and the lymphocytosis is not usually progressive; however, clonal B-cell disorders have been seen in a few patients with the disorder, suggesting that it may represent a preneoplastic state.⁸

Lymphocytopenia

Inherited Disorders

Although there are few inherited causes of lymphocytosis, such is not the case for lymphocytopenia, in which the genetic bases of a number of inherited immunodeficiency disorders have been identified. Chief among these disorders is severe combined immunodeficiency (SCID), which is characterized by the absence of functional T lymphocytes. T lymphocytes, B lymphocytes, and NK cells share progenitors, signaling pathways in development and function, and metabolic pathways; thus B lymphocytes, NK cells, or both are often severely affected in SCID. Moreover, in the absence of functional CD4⁺ T-helper lymphocytes, B lymphocytes cannot function properly, and hypo- or agammaglobulinemia is observed. In most cases of SCID, the absence of T lymphocytes leads to an extremely low absolute lymphocyte count. As detailed in Chapter 49, SCID can be grouped based on the cellular pathway that is affected. In general, whereas SCID is characterized by complete loss of function of the affected gene, hypomorphic mutations of the same genes lead to quite different phenotypes (Omenn syndrome and atypical SCID). Defects in more than 30 genes are known to lead to SCID. Inheritance is primarily X-linked or autosomal recessive, but in a few cases, such as the DiGeorge anomaly and some cases of Hoyerdal-Hreidarsson syndrome (defects in telomerase), inheritance is autosomal dominant. Until the genetic diagnosis is known, it is useful to characterize SCID syndromes as T⁺B⁺NK⁺, T⁺B⁺NK⁻, T⁺B⁻NK⁺ or T⁺B⁻NK⁻ based on the presence or absence of defects affecting B and/or NK cells. SCID can be classified based on the cellular function which is lacking, including deficiency in cytokine-mediated signaling, defects in V(D)J recombination, absent signaling through the T-cell receptor, defects in antigen presentation, and defects in basic cellular processes. Defects in the interleukin-7 receptor alpha chain (*IL7RA*), actin-regulating protein coronin 1A (*CORO1A*), CD3 chain components (*CD3D*, *CD3E*, *CD3Z*), and CD45 (*PTPRC*) lead to T⁺B⁺NK⁺ SCID. T⁺B⁺NK⁻ SCID defects include deficiencies in cytokine-mediated signaling (*IL2RG*, *JAK3*). Defects in V(D)J recombination (*RAG1*, *RAG2*) or in nonhomologous end joining for repair of double-strand DNA breaks (*DCLRE1C*, *PRKDC*, *LIG4*, and *NHEJ1* mutations) lead to T⁺B⁻NK⁺ SCID. Defects that lead to increased lymphocyte apoptosis (*AK2*, *ADA* gene mutations) lead to T⁺B⁻NK⁻ SCID and are often associated with anomalies outside of the immune system. Defects in thymic embryogenesis and calcium flux, as well as a collection of other abnormalities, including defects in telomerase activity, can also lead to SCID and are usually associated with abnormalities of other organ systems.⁹

In addition to SCID, other inherited disorders can also perturb T- and B-cell numbers. Patients with Wiskott-Aldrich syndrome, caused by mutations in *WASP* (which encodes a cytoplasmic protein responsible for transducing cell surface signals to the actin cytoskeleton), can present with low T-cell counts early in life and become profoundly lymphopenic over time. Abnormalities in immunoglobulins are also noted in this syndrome, with low levels of IgM and high levels of IgA and IgE.¹⁰ Immunodeficiency affects more than half of all patients with ataxia telangiectasia. Patients with ataxia telangiectasia have homozygous or compound heterozygous mutations in the ataxia-telangiectasia-mutated (*ATM*) gene, which encodes a protein kinase with functions in the cellular response to DNA damage. Lymphopenia, especially of naive CD4 cells, is observed in about half

of patients with ataxia telangiectasia, with mutations leading to absent expression of ATM kinase activity.¹¹ Heterozygous germline mutations in *GATA2* lead to a spectrum of clinical syndromes characterized by dendritic cell, monocyte, B cell, and NK lymphoid deficiency (DCML deficiency) with elevated 3 ligand (Flt3L). Mononuclear cytopenia appears to evolve in diverse clinical groups of *GATA2* mutation including monoMAC syndrome (monocytopenia, B-cell and NK-cell lymphopenia, mycobacterial, fungal, and viral infections and alveolar proteinosis), Emberger syndrome (lymphedema, deafness, and myelodysplastic syndrome [MDS]) and familial (MDS)/acute myeloid leukemia (AML).¹² *GATA2* mutation appears to cause loss of progenitor cells, clonal hematopoiesis and elevation of Flt3L, but the molecular mechanisms of marrow failure and transformation to MDS or AML are as yet unclear.

Infections

A variety of viral and nonviral infections can lead to lymphopenia. HIV is the most common virus associated with lymphopenia. The target of HIV is the CD4 receptor, and the virus selectively targets and infects activated expanding CD4 T cells. Large studies in HIV-infected patients have shown that peripheral blood CD4 T-cell counts fall most rapidly in the year after seroconversion (from approximately 1000/μL before seroconversion to 670/μL at 1 year after infection) and then decline more slowly by about 50/μL per year.¹³ In a subset of untreated patients, viremia is absent or well controlled, and lymphocytopenia develops very slowly if at all; particular HLA class I alleles are overrepresented in this group. Lymphopenia is an early and reliable laboratory observation in adult influenza infection and is also detected in infections caused by swine influenza (H1N1) and the highly pathogenic avian influenza (H5N1).¹⁴ Lymphopenia has been reported in patients with severe acute respiratory syndrome (SARS) caused by the SARS-coronavirus. In children, respiratory syncytial virus (RSV) infection is associated with a reduction in lymphocyte count, which is most extreme in the sickest patients; similar effects on lymphocyte counts are seen in measles infections (also a paramyxovirus). In West Nile virus encephalitis, lymphopenia is profound and prolonged, and the initial degree of lymphopenia is predictive of outcome. A variety of other viruses can also cause lymphopenia, including herpes viruses (herpes simplex, HHV-6, HHV-8), parvovirus B19, and Dengue virus. In many viral infections, the degree of lymphopenia is correlated with the severity of the disease.¹⁴

A variety of nonviral infections cause lymphopenia. Infections with *Ehrlichia* (a tick-borne obligate intracellular gram-negative bacteria), *Salmonella typhi*, and *Leptospira* have all been reported to cause lymphocytopenia during the acute illness. CD4⁺ T-cell depletion has been described in a subset of HIV-negative patients with tuberculosis and low albumin levels, low body weight, and more extensive disease. Recovery of CD4 count after treatment of tuberculosis suggests that the lymphopenia is caused by the tuberculosis infection.¹⁵ Lymphocytopenia is often observed in sepsis and is thought to occur as a result of cytokine-mediated apoptosis of B cells, CD4 and CD8 T cells, and follicular dendritic cells. In autopsy series, most deaths from sepsis occur during the prolonged hypoinnate state, and the more prolonged the sepsis, the more profound the loss of splenic lymphocytes. In one large retrospective study, severe persistent lymphopenia (defined as an absolute lymphocyte count of less than 600 cells/μL) on the fourth day following a diagnosis of sepsis was predictive of development of secondary infections, as well as short- and long-term survival.¹⁶

Collagen Vascular Disorders

Autoimmune diseases frequently exhibit decreases in circulating lymphocytes. In systemic lupus erythematosus (SLE), lymphopenia (usually decreases in T cells but occasionally in B cells as well) is not only one of the diagnostic criteria but also a parameter used to assess disease activity. Lymphopenia was observed in more than 60% of

patients at diagnosis, with the cumulative incidence over the course of the disease reaching over 90%. Lymphopenia in SLE seems to be more frequent in patients of African descent, and in one study more than half of patients with lymphopenia demonstrated antilymphocyte antibodies. Antigalectin 8 antibodies have been described in patients with SLE, rheumatoid arthritis, and sepsis. In SLE, these autoantibodies are associated with lymphopenia. Apoptosis may also play a role in lymphopenia in SLE, possibly by upregulation of fas antigen on naive peripheral T cells.¹⁷ CD4 T cells may also be decreased in rheumatoid arthritis, and increasing evidence suggests that deficiencies in DNA repair enzymes such as ATM render rheumatoid arthritis T cells sensitive to apoptosis.¹⁸ Apoptotic loss of naive T cells results in lymphopenia-induced proliferation to preserve T-cell homeostasis; this proliferation is now thought to lead to both premature immune aging and an autoimmune-biased T-cell repertoire. In Sjögren syndrome, a minority of patients has been noted to have deficient CD4 counts, and this has been correlated with the presence of anti-CD4 antibodies. Similarly, low lymphocyte counts have been observed in patients with primary vasculitides, type 1 diabetes, and Crohn disease.¹⁷

Malignancies

Lymphopenia is found in a variety of systemic illnesses; chief among them are cancers. In hematologic malignancies, including Hodgkin lymphoma, diffuse large B-cell lymphoma, and peripheral T-cell lymphoma, patients with lymphopenia have a worse prognosis. Lymphopenia has also been observed in solid tumors, including breast and colon cancer, and soft tissue sarcomas, in which its presence before treatment predicts decreased overall survival. Which specific lymphocyte subsets are involved and the cause(s) of lymphopenia in these tumor types has not been described.

Systemic Disorders

End-stage renal disease (ESRD) has also been associated with lymphopenia, an observation not thought to be exclusively attributable to an effect of dialysis alone. Naive and central memory CD4 and CD8 T cells are significantly reduced in the blood of ESRD patients, apparently because of increased susceptibility of these cells to apoptosis. Lymphopenia occurs in more than 50% of sarcoidosis patients and is associated with chronic disease. Sarcoidosis patients with severe organ system involvement, including neurologic, cardiac, ocular, and advanced pulmonary disease, have lower lymphocyte counts than patients with less severe manifestations (see E-Slide VM03953). Older studies suggest that burn victims have profound decreases in T-cell counts, which may contribute to the infection risk in these patients. Interestingly, lymphopenia is a characteristic of both protein-energy malnutrition and zinc deficiency. Both of these deficiencies perturb the hypothalamic–pituitary–adrenocorticoid axis and increase glucocorticoid levels, which results in increased apoptosis of B and T cells.¹⁹ Intestinal lymphangiectasia, which may be either congenital or secondary to processes that obstruct lymphatic drainage of the gastrointestinal tract, can cause lymphopenia as a result of loss of lymph fluid into the gut along with lymphocytes.

A rare cause of lymphopenia is idiopathic CD4⁺ lymphocytopenia (ICL), which is defined as a CD4 count less than 300/μL or less than 20% of the T-cell count on two occasions that is not caused by HIV or HTLV infection, drug therapy, or a known immunodeficiency. Patients usually come to clinical notice when they present with opportunistic infections. CD4 T-cell counts typically remain low, but counts do not continue to drop or do not fall rapidly after diagnosis. In one large series, only about 20% of patients recovered from lymphopenia within 3 years of diagnosis. Opportunistic infections plague these patients, and autoimmune diseases occur both before and after the diagnosis of ICL. In ICL, unlike HIV infection, increased activation and turnover are observed in CD4 but not CD8 T lymphocytes.²⁰

Drug Effects

A number of drugs are known to cause lymphopenia. Glucocorticoids inhibit production of a number of cytokines and rapidly deplete circulating T cells by enhancing emigration from the circulation, inducing apoptosis, interfering with growth signaling, and inhibiting release from lymphoid tissues. B cells are less affected acutely by glucocorticoid administration, but prolonged administration may result in decreased IgG levels. In clinical trials for multiple sclerosis, delayed release dimethyl fumarate resulted in a decrease in mean lymphocyte count of about 30% in the first year, but about 2% of patients had lymphocyte counts less than 500 cells/μL which persisted for 6 months or longer. Antimetabolite chemotherapeutic agents such as methotrexate, azathioprine, and 6-mercaptopurine lower lymphocyte as well as neutrophil counts, and alkylating agents such as cyclophosphamide have more profound effects on lymphocytes. Purine nucleoside analogs, including cladribine, fludarabine, pentostatin, nelarabine, clofarabine, and others, inhibit DNA synthesis and repair, and cause accumulation of DNA strand breaks. All of these agents are associated with profound lymphopenia, which may persist for several years after completion of treatment. In general, T cells are more affected than B cells. Nelarabine in particular is a prodrug of ara-G and is converted to ara-GTP, which accumulates at higher levels in T cells.²¹

Monoclonal and polyclonal antibodies directed against lymphocytes are useful in clinical practice and can induce profound and long-lasting lymphopenia. Whereas antithymocyte globulin and alemtuzumab produce depletion of both T and B cells, the monoclonal antibodies OKT3, daclizumab, and basiliximab produce a more pronounced decrease in T cells. The drugs rituximab and ofatumumab are monoclonal antibodies directed against distinct epitopes on B cells. These drugs deplete peripheral B cells but do not routinely produce lymphopenia.

Finally, radiation exposure commonly results in lymphopenia, which occurs before depression of other cell counts. In fact, lymphopenia can develop within the first 24 hours of exposure if the dose of radiation is great enough, and a drop of 50% or more predicts an increased risk of death. B cells are more sensitive to radiation than T cells and recover more slowly than T-cell numbers.²²

QUANTITATIVE DISORDERS OF IMMUNOGLOBULINS

In practice, as there are several methods for determining serum immunoglobulin levels it is critical that age-adjusted normal reference ranges are provided by the laboratory when evaluating immunoglobulin level results. Children first achieve adult levels of IgM around 2 years of age, IgG by 6 years of age, and IgA during puberty. Hypogammaglobulinemia is defined as an IgG less than 2 standard deviations from normal, and agammaglobulinemia is usually defined as an IgG level less than 100 mg/dL. Low levels of IgA, IgG, and IgM are characteristic of most forms of SCID.

Hypogammaglobulinemia

Causes of hypogammaglobulinemia can be divided into primary causes related to genetic deficiencies and secondary causes related to malignancies or their treatment, infections, medications, and protein-losing states that deplete antibody.

Secondary Causes

Before embarking on a search for a primary disorder causing hypogammaglobulinemia, it is important to rule out secondary causes. Malnutrition, malabsorption, and any disease state in which large amounts of protein are lost, such as nephrotic range proteinuria, severe burns, lymphangiectasia, or protein-losing enteropathy, can overwhelm the capacity of the B cells to provide adequate immunoglobulin to

maintain normal serum levels. Aside from chemotherapeutic agents, a number of medications can produce hypogammaglobulinemia; these include captopril, antiseizure medications (carbamazepine, phenytoin), gold salts, antimalarials, fenoclofenac, penicillamine, and sulfasalazine, as well as glucocorticoids. Infection with HIV and EBV, and congenital infection with rubella, CMV, and *T. gondii* can produce very low immunoglobulin levels and should be ruled out as appropriate. A host of lymphoid malignancies produce hypogammaglobulinemia, but the defect is most profound in CLL, in which up to 85% of patients are said to possess hypogammaglobulinemia even in the absence of treatment.²³

Primary Immunodeficiencies

The International Union of Immunological Societies has classified the primary immunodeficiency diseases into nine groups, including one class called *predominantly antibody deficiencies*.⁹ These disorders present in both adults and children, although some are very rare. Table 49.2 provides a simple grouping of these antibody disorders, some of which are discussed in greater detail in Chapter 49.

The first group is characterized by a severe reduction in all serum immunoglobulin isotypes, with absence or profound reduction in B cells. Patients with these disorders, particularly those with a

well-defined genetic basis, present with severe bacterial infections, most commonly in the respiratory tract (pneumonia, sinusitis, and otitis media), as well as diarrhea caused by bacteria, parasites, and viruses. The prototypic member of this group is X-linked agammaglobulinemia (XLA) caused by a mutation in the Bruton tyrosine kinase (*Btk*) gene, which produces a block in B-cell maturation. Female carriers of a *Btk* mutation are generally asymptomatic, but most boys with XLA come to clinical attention by the age of 1 year. In addition to low-serum immunoglobulins, a clue to the diagnosis is the absence of lymphoid tissue, including tonsils. Autosomal recessive mutations in the μ heavy chain as well as defects in $\lambda 5$, *Ig α* , *Ig β* , and *BLNK* produce a similar phenotype. Phosphatidylinositol 3-kinase deficiency (*PIK3R1*) and heterozygous mutation of the E47 transcription factor deficiency (*TCF3*) can cause severe reduction in all serum immunoglobulin isotypes. In a small percentage of patients, no clear molecular defect can be identified. Also included in this group are thymoma with immunodeficiency (Good syndrome) and myelodysplasia. Good syndrome is a poorly understood disorder that presents primarily in middle-aged adults. Immunodeficiency can precede or follow the diagnosis of thymoma and does not resolve with thymectomy. In addition to infections, patients experience autoimmune phenomena, including myasthenia gravis, immune thrombocytopenia purpura, pure red blood cell aplasia, and pernicious anemia. Myelodysplastic syndromes can also mimic XLA and

TABLE 49.2 Predominant Antibody Deficiencies

	Disease	Mode of Inheritance/Genetic Locus	Clinical Features
Severe reduction in all serum immunoglobulin isotypes with absent B cells	Bruton tyrosine kinase deficiency	XL/Xq21.3–22	Severe bacterial infections (especially of the respiratory tract), absent lymphoid tissue
	μ heavy chain deficiency	AR/14q32.3	Severe bacterial infections
	$\lambda 5$ deficiency	AR/22q11.21	Severe bacterial infections
	Ig α deficiency	AR/19q13.2	Severe bacterial infections
	Ig β deficiency	AR/17q23	Severe bacterial infections
	BLNK deficiency	AR/10q23.2	Severe bacterial infections
	SP110 deficiency	AR/2q37.1	Hepatic veno-occlusive disease, some with frequent infection
	LRRC8A deficiency	AD/9q34.11	Facial anomalies
	PIK3R1	AR/5q13.1	Recurrent bacterial infection
	Thymoma with immunodeficiency (Good syndrome)	None	Recurrent infection with encapsulated bacteria and diarrhea, autoimmune phenomena
	Myelodysplasia	Variable/monosomy 7, trisomy 8, dyskeratosis congenita	Recurrent infections and pancytopenia
Severe reduction in at least two serum immunoglobulin isotypes with low or normal B-cell numbers	Common variable immunodeficiency syndromes	$\approx 10\%$ with family history AR or AD	Recurrent respiratory tract infections leading to chronic sinusitis, hearing loss, bronchiectasis, autoimmune disease, lymphoproliferation, malignancy (especially non-Hodgkin lymphoma and gastric carcinoma)
	TACI alterations	AD and AR/17p11.2	
	BAFFR alterations	AR/22q13	
	MSH5 alterations	Unk/6p22.1-p21.3	
	ICOS deficiency	AR/2q33	Recurrent infections
	CD19 deficiency	AR/16p11.2	Recurrent infections
	X-linked lymphoproliferative disease (mutation in SH2 domain protein 1A)	XL/Xq25–q26	Fulminant infection with EBV, lymphoma, dysgammaglobulinemia
	CD81 deficiency	AR/11p15.5	Recurrent infections
	CD20 deficiency	AR/11q12.2	Recurrent infections
	CD21 deficiency	AR/1q32.2	Recurrent infections
	LRBA deficiency	AR/4q31.3	Recurrent infections, inflammatory bowel disease, EBV infection
	TNSF12 deficiency	AD/17p13.1	Recurrent bacterial infections, thrombocytopenia, neutropenia
	NFKB2 deficiency	AD/10q24.32	Recurrent infections
	CXCR4 activation	AD gain of function/2q22.1	WHIM syndrome

TABLE
49.2

Predominant Antibody Deficiencies—cont'd

	Disease	Mode of Inheritance/Genetic Locus	Clinical Features
Severe reduction in serum IgG and IgA with increased IgM and normal B-cell numbers (disorders of immunoglobulin class switching)	CD40 ligand deficiency	XL/Xq26.3-Xq27.1	Recurrent infections with bacteria and opportunistic pathogens, neutropenia, autoimmune disease
	CD40 deficiency	AR/20q11-20q13.2	Recurrent infections with bacteria and opportunistic pathogens, neutropenia, autoimmune disease
	<i>NEMO</i> hypomorphic mutations	XL/Xq28	Recurrent infections with bacteria and opportunistic pathogens, neutropenia, autoimmune disease
	AID deficiency	AR/12p13	Recurrent bacterial infections and diarrhea, marked enlargement of lymphoid organs
	UNG deficiency	AR/12q23-q24.1	Recurrent bacterial infections and diarrhea, marked enlargement of lymphoid organs
Isotype or light-chain deficiencies with normal B-cell numbers	Ig heavy-chain deficiency	AR/14q32	Most patients are healthy
	κ-chain deficiency	AR/2p11.2	Most patients are healthy
	Isolated IgG subclass deficiency	Variable/unknown	Most patients are healthy
	IgA deficiency associated with IgG subclass deficiency	Variable/unknown	Most patients are healthy
	Selective IgA deficiency	Variable/unknown	Most patients asymptomatic, but increased prevalence of infections, autoimmune disease, atopy, and celiac disease
	PRKCδ deficiency	AR/3p21.1	Recurrent infection, autoimmunity, and chronic EBV infection
	Activated PI3K-γ	AD gain of function/1p36.22	Recurrent infection, autoimmunity, chronic EBV, and CMV infection
Specific antibody deficiency with normal immunoglobulin level and B-cell number	Inability to make antibodies to specific antigens	Variable/unknown	Recurrent sinopulmonary infection, bronchiectasis, diarrhea, autoimmune disease
Transient hypogammaglobulinemia of infancy	IgG and IgA deficiency	Variable/unknown	More likely to be male (60%–80%), mild infections and diarrhea, atopy

λ5, Immunoglobulin lambda-like polypeptide (a surrogate light chain subunit that is part of the pre-B-cell receptor); AID, activation-induced cytidine deaminase (thought to be essential for initiation of the DNA cleavage required for class-switch recombination and somatic hypermutation); BAFF-R, B-cell-activating factor receptor; BLNK, B linker (a cytoplasmic linker or adaptor protein that plays a critical role in B-cell development); CMV, cytomegalovirus; CXCR4, CXC-chemokine receptor 4 (mediates migration of resting leukocytes and hematopoietic progenitors in response to its ligand, stromal cell-derived factor 1 [SDF1]); EBV, Epstein-Barr virus; ICOS, inducible T-cell costimulator (belongs to CD28 family of costimulatory surface molecules); Ig, immunoglobulin; Igα, immunoglobulin-associated α (necessary for expression and function of the B-cell antigen receptor); Igβ, immunoglobulin-associated β (necessary for expression and function of the B-cell antigen receptor); LRBA, lipopolysaccharide-responsive, beige-like anchor protein (implicated in regulating endosomal trafficking, particularly endocytosis of ligand-activated receptors); MSH5, *mutS* homolog 5 (a protein involved with DNA mismatch repair and meiotic recombination); NEMO, NFκB essential modulator; NFκB, nuclear factor kappa-B; PRKCD, member of the protein kinase c family (involved in B-cell receptor-mediated signaling); PI3K-γ, protein kinase C family member (critical for regulation of cell survival, proliferation, and apoptosis); TACI, transmembrane activator and CAML-interactor; TNFSF12, tumor necrosis factor ligand superfamily, member 12 (weak inducer of apoptosis); UNG, uracil DNA glycosylase (allows creation of single-stranded breaks essential to class switch recombination and somatic hypermutation); WHIM syndrome, warts, hypogammaglobulinemia, infections, and myelokathexis.

generally present with low B cells and pancytopenia with monosomy 7, trisomy 8, or dyskeratosis congenita.²⁴

A second group is characterized by severe reduction of at least two serum immunoglobulin isotypes with normal or low numbers of B cells. Most patients in this group can be categorized as having common variable immune deficiency (CVID), a heterogeneous disorder characterized by recurrent infection and failure to make antibody to vaccine antigens. Both males and females are affected, and patients can have autoimmune and gastrointestinal disease as well as lymphoproliferative disorders. Autoimmune disease can precede the hypogammaglobulinemia. About 10% of patients with a CVID phenotype have a family history of immunodeficiency and can be shown to have mutations in one of five genes expressed in both T and B cells. Homozygous or compound heterozygous mutations in *ICOS* (inducible costimulator), which is expressed on activated T cells and plays a role in activating T-helper cells and providing B-cell help, and *CD19*, a B-cell surface molecule that participates in signaling after antigen binding to the B-cell receptor, have been shown to result in recurrent infections in childhood and hypogammaglobulinemia. Mutations in *TACI* (transmembrane activator and CAML-interactor) and *BAFF-R* (B-cell-activating factor receptor) members of the

tumor necrosis factor (TNF) receptor superfamily, which play roles in B-cell survival and antibody production, and *MSH5*, a mismatch repair gene, are thought to predispose to CVID and IgA deficiency but are not sufficient to independently cause their onset. X-linked lymphoproliferative syndrome caused by mutation in the signaling lymphocyte activation molecular-associated protein SAP (gene, *SH2D1A*) can present atypically or later in life with a CVID phenotype.²⁵ Single-gene mutations of *TNFSF12* (*TWEAK*), *NFKB2*, and *CXCR4* have also been demonstrated to cause low levels of immunoglobulins.

Class-switch recombination defects encompass a third group of antibody deficiencies and result in hyper-IgM syndrome characterized by reductions in serum IgG and IgA with normal or elevated IgM. Mutations in the gene for CD40 ligand make up about 30% of these syndromes. CD40L on the surface of T cells interacts with CD40 on B cells, which is required for immunoglobulin class switching, and CD40 on monocytes, which is required for T-cell response. Patients with *CD40L* mutations and rarer mutations in *CD40* itself and in nuclear factor kappa-B (NFκB) and essential modulator (*NEMO*), required for CD40-induced signaling, have combined antibody and cellular immune deficits, resulting in hypogammaglobulinemia and

recurrent bacterial infection, as well as opportunistic infections with organisms similar to those observed in acquired immune deficiency syndrome (AIDS). Defects in the activation-induced cytidine deaminase gene (*AID*) produce hypogammaglobulinemia with recurrent bacterial infections and diarrhea, as well as enlarged lymphoid organs filled with proliferating B cells. A similar clinical picture is produced by homozygous defects in uracil-DNA glycosylase (*UNG*). *AID* is thought to deaminate cytosine to uracil, and *UNG* subsequently deglycosylates and removes the uracil residue, creating an abasic site, which allows for creation of single-stranded DNA breaks. Deficiencies in these enzymes result in defective class switching and somatic hypermutation. Patients with similar phenotypes but without defects in *AID* or *UNG* have been described and probably have mutations in other essential genes involved in class switching.²⁶

Additional groups of antibody deficiencies exist in which overall antibody levels are normal, but there are defects in specific isotypes, light chains, or specific antibodies with normal numbers of B cells; the majority of patients with these deficiencies are healthy. The most common member of these groups is selective IgA deficiency, which occurs in about 1 in 500 white individuals. The molecular mechanisms underlying this deficiency are unknown, but there is an association with CVID. Finally, an entity termed *transient hypogammaglobulinemia of infancy* has been described in which the normal decline in immunoglobulins after maternal transfer is prolonged. This entity is poorly understood and usually affects boys, who have mild infections and diarrhea. Recovery usually, but not always, occurs by 3 years of age.²⁷

Hypergammaglobulinemia

Hypergammaglobulinemia results from an overproduction of immunoglobulins by plasma cells, either monoclonal and reflective of a plasma cell or lymphoproliferative disorder, or polyclonal and accompanying other disease states. The distinction between polyclonal and monoclonal disorders is made by inspection of the serum protein electrophoretic pattern. Detection of one or several monoclonal bands within a polyclonal background is not unusual, and the literature suggests that small bands frequently disappear and do not become clinically relevant. No data are available to suggest that polyclonal gammopathy drives development of monoclonal gammopathy; however, if a clonal plasmaproliferative disorder is suspected, immunofixation or immunoelectrophoresis should be performed.

Disorders Producing Polyclonal Gammopathy

Polyclonal gammopathy usually reflects one of five major disorders, including liver disease, connective tissue disorders, infections, hematologic disorders, and solid tumors.²⁸ Interleukin-6 (IL-6) and IL-10 have been implicated in polyclonal gammopathy, as have defects in T cells and chronic antigenic stimulation, but the exact sequence of events leading to polyclonal B-cell activation is not known. In general, treatment is directed at the underlying disease, but there are reports of polyclonal gammopathy leading to symptomatic hyperviscosity. In these cases, plasmapheresis and/or corticosteroids seem to be effective. It should also be noted that polyclonal elevations in serum immunoglobulins can sometimes interfere with the direct Coombs test, possibly via nonspecific antibody binding to red blood cells. The degree of gamma globulin elevation does not seem to be helpful in defining the underlying disease state.

In the largest recent review of polyclonal gammopathy, the majority of patients had liver disease, which covered the spectrum from autoimmune disorders (autoimmune hepatitis, primary biliary cirrhosis, and primary sclerosing cholangitis) to viral hepatitis, and alcoholic liver disease. In fact, elevation of serum gamma globulins is a distinguishing characteristic of autoimmune hepatitis, and the levels usually correlate with activity of disease. The most common etiology for polyclonal gammopathy related to liver disease in the United States is likely infection with HCV, but in any particular

clinical setting, the exact distribution likely depends on the population demographic. Other diseases affecting the liver, such as α -1 antitrypsin deficiency and hemochromatosis, are also accompanied by increases in serum immunoglobulins.

Connective tissue diseases, including Sjögren syndrome, SLE, ankylosing spondylitis, and rheumatoid arthritis, are also accompanied by polyclonal gammopathy. In many of these diseases, the degree of gamma globulin elevation may reflect disease activity, although a causative link between the autoimmune phenomena and immunoglobulin levels has not been determined. Several of the periodic fever syndromes, which are sometimes classified with the connective tissue disorders, have elevated immunoglobulin levels as a part of their manifestations. Hyperimmunoglobulinemia D is one such syndrome and is linked to mutations in the mevalonate kinase gene. Patients with this disorder present in the first year of life with febrile attacks, lymphadenopathy, abdominal symptoms, arthritis, and oral and genital ulcers. Most, but not all, patients have elevated levels of polyclonal IgD during and between episodes often accompanied by elevated IgA levels. TNF receptor 1-associated periodic syndrome (TRAPS) results from mutation in the gene (*TNFRSF1A*) for the TNF receptor 1 and can cause prolonged febrile attacks with abdominal pain, arthralgias, and myalgias. During attacks, polyclonal elevation of immunoglobulins (primarily IgA) is observed.²⁹

Infections, usually chronic in nature, are frequently accompanied by polyclonal gammopathy. HIV infection is a common cause, and immunoglobulin levels tend to increase slowly until the diagnosis of AIDS and then decline over the ensuing 6 to 18 months. Polyclonal gammopathy can be a clue to occult infections such as subacute bacterial endocarditis, tuberculosis, perinephric abscess, Lyme disease, and a variety of parasitic infections.

Malignant B- and T-cell disorders can cause polyclonal hypergammaglobulinemia. These diseases include CLL; large granular lymphocytic leukemia; hairy cell leukemia; and angioimmunoblastic T-cell lymphoma (AITL), a rare disease characterized by rash, widespread lymphadenopathy and extranodal involvement, autoimmune phenomena, and polyclonal gammopathy. Interestingly, despite the elevated levels of immunoglobulins observed in AITL, patients exhibit immunodeficiency and a propensity to develop opportunistic infections. Patients with myeloid disorders can also have polyclonal gammopathies; in one large series, nearly 40% of patients with myelodysplastic syndrome had hypergammaglobulinemia, and patients with immunologic abnormalities had inferior survival.³⁰ The incidence of hypergammaglobulinemia is reported to approach 50% in chronic myelomonocytic leukemia (CMML). Hypergammaglobulinemia has been reported in AML both in adults and children, but it appears to be a rare phenomenon. Among solid tumors, ovarian and hepatocellular cancers are most commonly associated with polyclonal gammopathy. There are case reports of cancers, particularly lung and breast tumors, producing and releasing the secretory component of IgA into the bloodstream with the binding of SC to polyclonal IgA, producing hypergammaglobulinemia of serum sIgA.

A variety of other diseases, including asbestos exposure and several subtypes of hypersensitivity pneumonitis and idiopathic interstitial pneumonia, are associated with polyclonal gammopathy. In general, these disorders represent diffuse activation of B cells.

Disorders Producing Monoclonal Gammopathy

The differential diagnosis of monoclonal gammopathy includes monoclonal gammopathy of undetermined significance (MGUS), multiple myeloma, solitary plasmacytoma of bone or extramedullary plasmacytoma, Waldenström macroglobulinemia, lymphoma, CLL, and primary systemic amyloidosis. These individual disorders are described elsewhere in this text; however, there are a few points to be made about the M protein itself and MGUS. These disorders can produce intact immunoglobulins (IgG, IgM, IgD, or IgE), κ -, or λ -light chains alone or in combination with intact immunoglobulins and rarely heavy chains only. The monoclonal protein is usually detected as a discrete band in the γ or β region in serum or urine

**TABLE
49.3****Diseases Associated With Monoclonal Gammopathy**

Plasma cell and related disorders	MGUS Solitary plasmacytoma: Bone Soft tissue Multiple myeloma Waldenström macroglobulinemia Primary amyloidosis	See Chapters 85–87
Lymphoid disorders	Non-Hodgkin lymphoma Hodgkin lymphoma Castleman disease	Monoclonal protein observed in CLL (>20% of cases with IgM, ≈50% with IgG, light chains also observed), extranodal marginal zone lymphomas (>30% of cases and correlated with BM involvement), follicular, mantle cell, and diffuse large B-cell lymphomas also reported with serum M proteins as has AITL Rare but reported <2% with monoclonal gammopathy
Other hematologic disorders	Acquired von Willebrand disease Gaucher disease Pernicious anemia, pure RBC aplasia, hereditary spherocytosis, MPD, MDS	IVIG more effective than factor concentrate in increasing factor VIII coagulant and VWF levels Observed in 25% in one study; M protein declined after splenectomy
Connective tissue disorders	SLE Inclusion body myositis Polymyositis, RA, scleroderma	IgG, IgM, and IgA have been observed, no difference in disease activity or outcome 80% with IgG M protein
Neurologic disorders	POEMS syndrome Peripheral neuropathy Myasthenia gravis, ALS, Alzheimer disease	Most have M-protein of λ light chain Most common is IgM followed by IgG and IgA In half, IgM protein binds to myelin-associated glycoprotein Size of M protein not correlated with severity of neuropathy Some benefit from plasma exchange for those with IgG and IgA Fludarabine and rituximab with some benefit for IgM
Dermatologic disorders	Schnitzler syndrome Scleredema Pyoderma gangrenosum	Neutrophilic urticarial dermatitis, monoclonal IgM protein, and two of: lymphadenopathy, fever, hepatosplenomegaly, joint pain, increased ESR, increased neutrophils, or abnormal bone imaging Frequently an IgA protein
Infections	HIV HCV	Both IgG and IgM M proteins observed M protein present in up to 10% of patients
Immunosuppression	Renal transplant Liver and heart transplant BM transplant	In children CMV infection associated with M protein Most patients with posttransplant lymphoproliferative disorders have M proteins Observed in both autologous and allogeneic transplants Appearance of M protein correlated with GVHD

AITL, Angioimmunoblastic T-cell lymphoma; ALS, amyotrophic lateral sclerosis; BM, bone marrow; CLL, chronic lymphocytic leukemia; CMV, cytomegalovirus; ESR, erythrocyte sedimentation rate; GVHD, graft-versus-host disease; HCV, hepatitis C virus; HIV, human immunodeficiency virus; Ig, immunoglobulin; IVIG, intravenous immunoglobulin; MGUS, monoclonal gammopathy of uncertain significance; MDS, myelodysplastic syndrome; MPD, myeloproliferative disorder; POEMS, polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes; RA, rheumatoid arthritis; RBC, red blood cell; SLE, systemic lupus erythematosus; VWF, von Willebrand factor.

protein electrophoresis (M spike), and then characterized and confirmed by immunofixation electrophoresis (IFE). Monoclonal antibodies have been associated with a wide variety of bacterial antigens as well as various other antigens, including thyroglobulin, von Willebrand factor, and lactate dehydrogenase; however, for most M proteins, the antigen is not recognized. A variety of other disorders are also associated with an M protein ([Table 49.3](#)), including connective tissue disorders, neurologic disorders (including POEMS [polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes] syndrome), renal disorders, and some infections such as HCV and HIV. Patients undergoing bone marrow and solid-organ transplants in which there is immune suppression are also occasionally observed to have M proteins, but these are usually transient and disappear with recovery of the immune system. Acquired

immune disorders such as acquired C1 inhibitor deficiency, type 2 acquired angioedema, and acquired von Willebrand syndrome have also been associated with M proteins.

DISORDERS OF PHAGOCYTE FUNCTION

Mary C. Dinauer and Thomas D. Coates

Phagocytic leukocytes are an essential component of the innate immune system that has evolved to rapidly respond to the presence of invading bacteria, fungi, and parasites. This first line of host defense also includes natural killer (NK) lymphocytes, complement, and other plasma proteins. As reviewed in [Chapters 27 and 48](#), phagocytes are responsible for ingesting, killing, and digesting pathogens. Granulocytic phagocytes (neutrophils and eosinophils) circulate in the bloodstream until they sense chemotactic signals from infected tissues, resulting in adhesion to the vascular endothelium and subsequent migration into the site of infection.¹ Mononuclear phagocytes (macrophages and their circulating precursor, the monocyte), on the other hand, function primarily as resident cells in a variety of tissues such as the lungs, liver, peritoneal cavity, and spleen, where they perform a surveillance role and also interact closely with lymphocytes to promote specific immune responses. Microbial killing is accomplished by two types of mechanisms: (1) *de novo* synthesis of highly toxic and often unstable derivatives of molecular oxygen by an enzyme known as *respiratory burst oxidase* and (2) preformed polypeptide “antibiotics” and proteases stored within several types of lysosomal granules that are delivered into phagocytic vacuoles containing the ingested microbes.

This chapter reviews the major congenital and acquired disorders of phagocyte function, which from the clinical standpoint largely involve neutrophils. As would be predicted, these disorders manifest clinically by recurrent bacterial and fungal infections, often with atypical pathogens or unusual presentations. Interestingly, the converse of this is only rarely observed. Most patients with recurrent infections do not have any identifiable abnormality in their phagocytes. There are at least two explanations for the clinical rarity of phagocyte disorders. First, given their critical role in host defense, nature may be quite intolerant of major abnormalities in phagocytes. Before the modern antibiotic era, patients with severe disorders probably did not survive into their childbearing years. Second, there is a remarkable redundancy in the antimicrobial machinery of the phagocytes that permits one system to compensate for a defect in another. For example, the host does not rely on a single chemotactic signal or neutrophil membrane receptor to ensure that phagocytes accumulate at sites of infection. Instead, multiple chemotactic signals and receptors are used. A similar phenomenon is seen in the reactions that kill microbes, as both oxidative and nonoxidative systems are used.

This chapter is organized according to the cellular functions outlined above: disorders of the respiratory burst microbicidal pathway, abnormalities of phagocyte adhesion and chemotaxis, and defects in the structure and function of lysosomal granules. This chapter is not meant to be an encyclopedic review of the numerous papers published on phagocyte abnormalities. It is important to note that many of these reports describe marginal *in vitro* defects, with little evidence that they are responsible for a clinical problem. Comprehensive reviews offering additional information on phagocyte disorders are available.^{2,3}

APPROACH TO DIAGNOSIS OF PHAGOCYTE FUNCTION DISORDERS

Inherited and acquired clinical disorders of phagocyte function result from defects in one or more of the major steps leading to

microbial killing—adhesion, chemotaxis, ingestion, degranulation, and production of microbicidal oxidants ([Fig. 50.1](#)). Patients with inherited disorders typically present in infancy or childhood with recurrent, unusual, or recalcitrant bacterial and fungal infections, and it is usually not difficult to determine that these are outside the range of normal. The presentation of these different inherited disorders can overlap, so that a specific diagnosis cannot be made on clinical grounds alone. Infections commonly seen include those of skin or mucosa, lung, lymph node, deep tissue abscesses, or childhood periodontitis. These can often have an indolent presentation with only low-grade fevers. Bacterial sepsis is an unusual initial symptom and usually reflects dissemination from an infected site. Inherited defects in phagocyte function are rare and represent only about 20% of the primary immunodeficiencies.² Thus, children with suspected disorders of host defense should also be screened for defects in humoral, cellular, and complement-mediated immunity. An approach to evaluating the patient with significant recurrent infections is shown in [Fig. 50.2](#). Patients in whom a defect is identified should be referred to a center specialized in care of such patients.

In clinical practice, although nearly all patients with well-characterized phagocyte abnormalities have recurrent or unusual infections, the majority of individuals with histories of persistent or recurrent infections do not have identifiable phagocyte disorders or other immune defects. In some cases, these reflect another underlying medical condition or nonimmunologic problem related to an anatomic or obstructive defect. This chapter focuses largely on disorders in which a good correlation exists between the clinical condition and an identifiable defect in phagocyte function.

DISORDERS OF THE RESPIRATORY BURST PATHWAY

Reactive oxygen species generated by the phagocyte respiratory burst are critical for microbial killing. The enzyme responsible for the initial reaction in this pathway is nicotinamide adenine dinucleotide phosphate (NADPH) oxidase found in plasma and phagolysosomal membranes. Upon activation by inflammatory stimuli, NADPH oxidase catalyzes the transfer of an electron from NADPH to molecular oxygen, thereby forming superoxide (as the O_2^- ion; [Fig. 50.3](#), reaction 1).³⁻⁵ This NADPH oxidase, along with enzymes and reactions that are directly involved in the production or metabolism of O_2^- , constitutes the respiratory burst pathway as depicted in [Fig. 50.3](#). Superoxide is the precursor to numerous microbicidal oxidants, including hydrogen peroxide and hypochlorous acid. Five clinically significant defects have been identified in the respiratory burst, involving the following enzymes: NADPH oxidase (reaction 1), leukocyte glucose-6-phosphate dehydrogenase (G6PD; reaction 8), myeloperoxidase (MPO; reaction 4), glutathione reductase, and glutathione synthetase (reaction 9). These reactions are involved in the production of O_2^- (reactions 8 and 1) in the conversion of O_2^- and hydrogen peroxide to other toxic derivatives (reaction 4) or in the detoxification of excess hydrogen peroxide needed to protect the phagocyte during the respiratory burst (reactions 7 and 9). Of note, NOX homologues to the leukocyte NADPH oxidase are present in the gut, vascular cells, and other tissues, which may generate oxidants for local host defense or for regulation of other cellular functions.⁶

Fig. 50.1 STEPS IN THE RESPONSE OF CIRCULATION NEUTROPHILS TO INFECTION. The adhesion molecule E-selectin is upregulated on endothelial cells in response to inflammatory mediators (interleukin-1 [IL-1], endotoxin, tumor necrosis factor- α), resulting in rolling attachment and margination through interaction with sialyl Lewis carbohydrates on its surface. Chemoattractants such as IL-8 cause upregulation of neutrophil $\beta 2$ integrins that, in turn, mediate tight adhesion to ICAM-1 and PECAM-1 on endothelial cells. Activated neutrophils can detect as little as a 2% change in the chemoattractant gradient and move to the site of infection. Neutrophils phagocytose bacteria opsonized by antibody and complement. Both oxidative and nonoxidative antimicrobial mechanisms are then used to kill bacteria. Disorders of phagocyte function associated with each of these steps are noted. *G6PD*, Glucose-6-phosphate dehydrogenase; *ICAM-1*, intercellular adhesion molecule 1; *NADPH*, nicotinamide adenine dinucleotide phosphate; *PECAM-1*, platelet endothelial cell adhesion molecule 1. (Courtesy Kyoto W, Coates TD: *A practical approach to neutrophil disorders*. *Pediatr Clin North Am* 49:929, 2002, with permission.)

Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) is a genetically heterogeneous group of defects that share in common the failure of neutrophils, monocytes, macrophages, and eosinophils to undergo a respiratory burst and generate O_2^- .^{3,7} CGD is relatively rare, having an estimated incidence of between 1 in 200,000 and 1 in 250,000 live births based on data from the United States CGD Registry,⁷ although it is still the most common inherited phagocyte disorder of clinical significance (MPO deficiency is more common, but affected patients are rarely symptomatic). The absence of respiratory burst-derived oxidants results in recurrent, often life-threatening bacterial and fungal infections, and is also associated with formation of inflammatory granulomas.^{3,7-9} The disease was first described in 1957 as a syndrome characterized by severe recurrent infections in boys who also had visceral granulomas

containing pigmented histiocytes. The disease was termed *fatal granulomatous disease* owing to this distinguishing histologic feature and the grim clinical course in most patients. It was not until the late 1960s and early 1970s that the defect in oxygen consumption and O_2^- production was identified and a convenient diagnostic assay, the nitroblue tetrazolium (NBT) test, was developed. In the 1980s a combination of biochemical and molecular genetic approaches led to the identification of four critical subunits of NADPH oxidase and the recognition that mutations in the corresponding genes are responsible for four different genetic subgroups of CGD (Fig. 50.4). Recently, a fifth genetic subgroup was identified in a single patient.¹⁰ Databases for the main four genetic subgroups of CGD have been developed that are accessible through the websites <http://structure.bmc.lu.se/idbase/> and <http://www.hgmd.cf.ac.uk/ac/index.php>. Recent publications on disease manifestations and genotypes in large patient registries are also available and support earlier reports.^{7,9,11,12}

Fig. 50.2 EVALUATION OF PATIENTS WITH RECURRENT BACTERIAL OR FUNGAL INFECTIONS. The history, physical examination, and infections episodes in patients with a possible primary neutrophil dysfunction syndrome are noted. The initial evaluation can be done in most clinical laboratories. A qualified reference laboratory with special expertise in this area should carry out the neutrophil evaluations. Chemotaxis is very difficult to evaluate clinically and should only be attempted in a qualified research laboratory with extensive experience. *CBC*, Complete blood count; *CRP*, C-reactive protein; *DHR*, dihydrorhodamine; *ESR*, erythrocyte sedimentation rate; *FACS*, fluorescence-activated cell sorting; *HIV*, human immunodeficiency virus; *IgE*, immunoglobulin E; *NBT*, nitroblue tetrazolium; *PHA*, phytohemagglutinin; *r/o*, rule out; *SED*, sedimentation.

Fig. 50.3 REACTIONS OF RESPIRATORY BURST PATHWAY. *GSH*, Glutathione; *GSSG*, oxidized glutathione; *HOCl*, hypochlorous acid; *NADPH*, nicotinamide adenine dinucleotide phosphate.

Molecular Genetics of Chronic Granulomatous Disease

CGD results from mutations in any of the five genes encoding essential subunits of the NADPH oxidase (Table 50.1).^{11,12} In turn, the biochemical and genetic analysis of CGD has been instrumental in characterizing this complex enzyme. The oxidase subunits are referred to by their apparent molecular mass (kDa) and have been given the designation *phox*, for *phagocyte oxidase*. A b-type cytochrome known as flavocytochrome *b₅₅₈*, a membrane-bound heterodimer composed of gp91^{phox} and p22^{phox}, is the redox center of the oxidase. Approximately two-thirds of CGD cases result from defects in the X-linked gene encoding the gp91^{phox} subunit of flavocytochrome *b₅₅₈*, which contains both the flavoprotein and heme-binding domains responsible for electron transport. A rare autosomal recessive (AR) form of CGD is caused by mutations in the gene encoding p22^{phox}, the smaller subunit of flavocytochrome *b₅₅₈*, which provides a critical docking site for p47^{phox}, a regulatory subunit. The remaining

cases of AR CGD involve genetic defects in p47^{phox}, p67^{phox}, or p40^{phox}, three regulatory proteins associated with each other in the cytosol of unstimulated cells but which rapidly move to the membrane to activate flavocytochrome *b₅₅₈* and superoxide formation when neutrophils are exposed to inflammatory or phagocytic stimuli. The p40^{phox} subunit appears to play a selective role in stimulating high-level superoxide production within phagosomes via membrane-bound phosphatidylinositol-3-phosphate.¹⁰ Formation of the active NADPH oxidase complex also involves the activation of the small guanine triphosphate (GTP)-binding protein Rac, which then binds to the plasma membrane and p67^{phox}.³ No cases of CGD have been identified resulting from genetic defects in Rac, although a mutation in the blood cell-specific Rac2 isoform was found in an infant with recurrent infections and abnormal neutrophil adhesion, motility, and partial NADPH oxidase defects.³

The gene for gp91^{phox}, termed *CYBB*, spans approximately 30 kb in the Xp21.1 region of the X chromosome. More than 600 distinct mutations have been identified in the gp91^{phox} gene in X-linked CGD (MIM306400), which include deletions, frameshifts, splice site, nonsense, and missense mutations that are distributed throughout the gene (Table 50.2).¹¹ Approximately 10% to 15% of X-linked CGD is caused by new germline mutations. In most X-linked CGD, gp91^{phox} is completely absent, and there is no measurable flavocytochrome *b* or superoxide production (the X91° subtype). In about 5% of X-linked cases, gp91^{phox} can be present in normal levels but be nonfunctional (X91⁺), mutated in such a way that gp91^{phox} is poorly functional (X91⁻), or expressed in only a small fraction of phagocytes (X91⁺). The first two “variant” forms of X-linked CGD result from coding sequence mutations, and the latter are caused by mutations in the regulatory portion of the gp91^{phox} gene. Some X-linked CGD patients have large deletions that affect not only the gene encoding gp91^{phox} but also portions of or all the flanking gene loci for McLeod hemolytic anemia syndrome (absence of the Kell erythrocyte antigen, Kx), Duchenne muscular dystrophy, and X-linked retinitis pigmentosa. Rare point mutations in *CYBB* lead to markedly impaired flavocytochrome *b* expression and activity in macrophages, with much less effect in neutrophils.¹³ Affected patients were susceptible to mycobacterial infections but did not have other bacterial and fungal infections characteristic of CGD, highlighting the importance of macrophages for controlling mycobacteria.

Fig. 50.4 NICOTINAMIDE ADENINE DINUCLEOTIDE PHOSPHATE OXIDASE AND MOLECULAR GENETICS OF CHRONIC GRANULOMATOUS DISEASE. Shown are the membrane and soluble subunits of NADPH oxidase, indicating how these correspond to the five different genetic subgroups of chronic granulomatous disease (CGD) and their approximate incidence. Flavocytochrome b_{558} is the redox center of the enzyme and is located in plasma, specific granule, and phagolysosomal membranes. This heterodimer is composed of the gp91^{phox} and p22^{phox} subunits of the NADPH oxidase, which are affected in X-linked and an autosomal recessive (AR) form of CGD, respectively. The soluble regulatory proteins p47^{phox}, p67^{phox}, and p40^{phox} are found in the cytosol until phagocyte activation by soluble or particulate inflammatory stimuli, after which they move to the membrane where p47^{phox} and p67^{phox} bind flavocytochrome b_{558} , binds Rac, and p40^{phox} binds phosphatidylinositol 3-phosphate, a phosphoinositide present on phagosomal membranes. Mutations in the genes encoding p47^{phox}, p67^{phox} and p40^{phox} account for other AR forms of CGD. Another essential regulatory component of the NADPH oxidase is the small GTPase, Rac, which in its active guanosine triphosphate-bound state, becomes membrane bound, and associates with the oxidase. By a mechanism that is not fully understood, binding of these multiple regulatory subunits activates the flavocytochrome to catalyze the transfer of electrons from cytosolic NADPH across the membrane via the FAD and heme redox centers to molecular oxygen, thereby forming superoxide in the extracellular or intraphagosomal compartment. No cases of CGD have been described owing to mutations in Rac. *FAD*, Flavin adenine dinucleotide; *NADPH*, nicotinamide adenine dinucleotide phosphate

AR CGD involving p22^{phox} (MIM 233690) occurs in approximately 5% of CGD patients and usually involves the complete absence of cytochrome b (A22°), encoded by *CYBA*. Mutations in A22 CGD are heterogeneous and range from large interstitial gene deletions to point mutations associated with missense, frameshift, or RNA splicing defects.¹² Because the full expression of flavocytochrome b in the membrane requires the production of both subunits, a primary deficiency of either component leads to a secondary loss of the other. Thus, neither subunit can be detected on immunoblot analysis in either X91° or A22° CGD. A single patient with A22° CGD has been described with a missense mutation disrupting the binding site for p47^{phox}.

AR patients with p47^{phox}-deficient CGD (MIM 233700) account for approximately one-fourth of cases in the United States and Europe, but only about 7% of cases in Japan. The p47^{phox} subunit is encoded by the *NCF1* gene. A limited number of mutations have been identified in *NCF1*.¹² Virtually all patients are either homozygotes or compound heterozygotes for a mutant allele with a GT deletion at the beginning of exon 2 that predicts a premature stop codon following the amino acid residue and results in absence of the p47^{phox} protein. The high frequency of the p47^{phox} GT deletion mutation appears to reflect the existence of at least one closely linked highly conserved p47^{phox} pseudogene(s) that contains this GT

Clinical Approach to Patients With Disorders of Phagocyte Function

Index of Suspicion

Patients with disorders of phagocyte function usually present at a young age with recurrent, deep-seated bacterial and fungal infections. Unlike patients with severe neutropenia caused by bone marrow (BM) failure, these patients usually do not have sepsis. Blood cultures are often negative. The major diagnostic problem faced by the clinician is to determine if the history of infection is unusual enough to warrant consideration of an underlying neutrophil dysfunction defect. The first point to remember is that primary immunodeficiency disorders are rare and primary neutrophil dysfunction syndromes form only a small percentage of all primary immunodeficiency syndromes. The patient is more likely to have recurrent community-acquired *Staphylococcus* infection than CGD.

Specific features that may suggest a phagocytic defect are shown in Fig. 50.2. Excellent discussions of this problem have been published (see Kyono and Coates², and Dinanur, Newburger and Borregaard³). Four aspects of each patient's infection history should be considered: frequency, severity, location, and responsible pathogen. Patients with unusual features in at least one of these aspects should alert the clinician to a possible underlying phagocyte disorder. When considering frequency, the patient's age and associated medical conditions must be taken into account. For example, recurrent otitis media in a 2-year-old patient is far less worrisome than a similar history in a 40-year-old patient. The more unusual or severe the infections, the less frequently these have to occur before a phagocyte evaluation is indicated. Infections in unexpected anatomic locations, such as hepatic, pulmonary, and rectal abscesses, may indicate an underlying phagocyte defect. Childhood periodontal disease or gingivitis is distinctly uncommon, and in the absence of neutropenic conditions, strongly suggests underlying neutrophil dysfunction. The identification of certain pathogens (e.g., *Serratia marcescens*, *Klebsiella* spp., *Aspergillus* spp., *Nocardia* spp., *Burkholderia cepacia*, invasive candidiasis) in children and young adults can provide the strongest indications for pursuing further studies. A history of delayed separation of the umbilical cord is often mentioned as a sign of phagocytic defect. This is fairly common as an isolated finding and is usually of no significance. However, this in conjunction with omphalitis or other pyogenic infections raises the possibility of leukocyte adhesion deficiency (LAD) or chemotactic defects. A child with nystagmus, fair skin, and recurrent staphylococcal infections should be evaluated for Chediak-Higashi syndrome (CHS).

Evaluation

Performing a good history and physical examination to eliminate common causes of recurrent infection is important before looking for rare syndromes. For example, is the recurrent pneumonia caused by an aspirated foreign body in the bronchus? In general, patients should first be evaluated for lymphocyte or complement defects. A useful algorithm is presented in Fig. 50.2. Note that testing described in this algorithm is not exhaustive, and patients with truly striking histories of unusual kinds of infections should be referred for further evaluation by specialized research laboratories.

deletion. This close physical proximity leads to recombination events between the wild-type gene and pseudogene(s).

A heterogeneous group of mutations in the p67^{phox} gene, *NCF2*, are responsible for A67 CGD, a rare AR form of CGD (MIM233710) accounting for about 5% of cases overall.¹² Almost all mutations identified to date in A67 CGD lead to absent expression of the p67^{phox} protein. However, one A67⁺ patient has been reported in which a nonfunctional form of p67^{phox} with an amino acid deletion is expressed but is unable to translocate to the membrane or bind to Rac.

Finally, a boy with AR p40^{phox} defects (MIM613960) was recently reported.¹⁰ This patient was a compound heterozygote for two null alleles in *NCF4*. Although NADPH oxidase activity on the plasma membrane was normal, phagosome oxidant production was markedly impaired. The main clinical manifestation in this patient was chronic granulomatous inflammation of the intestinal tract rather than opportunistic infections characteristic of CGD, perhaps related to the more selective role of p40^{phox} in regulating NADPH oxidase activity.

TABLE 50.1**Classification of Chronic Granulomatous Disease**

Component Affected	Gene Symbol	Gene Locus	Inheritance	Subtype ^a	NBT Score (% Positive)	O ₂ ⁻ Production (% Normal)	Flavocytochrome <i>b</i> Spectrum (% Normal)	Defect in Cell-Free NADPH Oxidase Assay	Frequency (% of Cases) ^b
Gp91 ^{phox}	CYBB	Xp21.1	X	X91°	0	0	0	Membrane	68
				X91 ⁻	80–100 (weak)	3–30	Low	Membrane	5
				X91 ⁻	5–10	5–10	Low	Membrane	<1
				X91 ⁺	0	0	N	Membrane	1
P22 ^{phox}	CYBA	16p24.3	AR	A22°	0	0	0	Membrane	4
				A22 ⁺	0	0	N	Membrane	<1
P47 ^{phox}	NCF1	7q11.23	AR	A47°	0	0–1	N	Cytosol	17
P67 ^{phox}	NCF2	1q25.3	AR	A67°	0	0	N	Cytosol	5
p40 ^{phox}	NCF4	22q13.1	AR	A40 ⁺	100	<10 (intracellular)	N	n/a	1

^aIn this nomenclature, the first letter represents the mode of inheritance (X-linked [X] or autosomal recessive [A]), and the number indicates the *phox* component that is genetically affected. The superscript symbols indicate whether the level of protein of the affected component is undetectable (°), diminished (–), or normal (+) as measured by immunoblot analysis.

^bCombined data from 209 kindreds evaluated at the Scripps Research Institute/Stanford University CGD Clinic and a cooperative European study representing 57 kindreds and 63 patients. (Courtesy Casimir C, Chetty M, Bohler MC, et al: Identification of the defective NADPH-oxidase component in chronic granulomatous disease: A study of 57 European families. *Eur J Clin Invest* 22:403, 1992; and Curnutte JT: Chronic granulomatous disease: The solving of a clinical riddle at the molecular level. *Clin Immunol Immunopathol* 67:S2, 1993.) These frequencies remain similar to those in more recent reports from Europe and the United States.

^cA single patient reported to date who was a compound heterozygote for a frameshift mutation and a nonfunctional form of p40^{phox} caused by a point mutation. (Matute JD, Arias AA, Wright NA et al: A new genetic subgroup of chronic granulomatous disease with autosomal recessive mutations in p40 *phox* and selective defects in neutrophil NADPH oxidase activity. *Blood* 114:3309, 2009.)

AR, Autosomal recessive inheritance; N, normal; NADPH, nicotinamide adenine dinucleotide phosphate; n/a, not applicable; NBT, nitroblue tetrazolium; X, X-linked inheritance.

TABLE 50.2**Summary of Mutations in the *CYBB* Gene Encoding gp91^{phox} in 261 Kindreds With X-linked Chronic Granulomatous Disease**

Type of Mutation	Number of Kindreds	Frequency (%)	Phenotype
Deletions	63	24.2	X91°
Insertions	27	10.3	X91°
Splice-site mutations	42	16.1	X91°
Missense mutations	59	22.6	X91°, X91 ⁻ , X91 ⁺
Nonsense mutations	70	26.8	X91°

Data from Roos D, Curnutte J, Hossle JP, et al: X-CGDbase: A database of X-CGD-causing mutations. *Immunol Today* 17:517, 1996.

Even though more than 90% of patients with CGD have respiratory burst defects that result in undetectable levels of O₂⁻ production, there is a surprising heterogeneity in the clinical manifestations of the disease.⁷ At one end of the spectrum are patients who begin to have severe bacterial and fungal infections during infancy and who rarely have more than 4 to 12 months between such serious infections. At the other end of the spectrum are patients who are well for many years and then unexpectedly develop a serious infection typical of CGD, such as a staphylococcal hepatic abscess or *Aspergillus* pneumonia. After their first major infection, some of these patients may be relatively healthy again for another 3 to 10 years before the next severe infection occurs. As a group, patients with X-CGD, A22 CGD, and A67 CGD seem to have a more severe clinical course compared with patients with A47 CGD,^{7,9} who have a small amount of detectable oxidant production even in the complete absence of this subunit (Fig. 50.5G). Individuals with partial respiratory burst activity but less than 10% of normal (most X91⁻ patients; see Table 50.1) also tend to have disease of intermediate severity. Polymorphisms in oxygen-independent antimicrobial systems or other components regulating the innate immune response are also likely to play an important role in modifying disease severity.⁹ Specific polymorphisms in the MPO, mannose binding lectin, and FcγRIIa genes are associated with a higher risk for granulomatous or autoimmune or

rheumatologic complications.^{3,8} Because of this heterogeneity, the diagnosis of CGD should be entertained, not only in young children with recurrent severe infections, but also in adolescents and young adults who experience exceptionally severe or unusual infections.

Clinical Manifestations

In approximately two-thirds of patients, the first symptoms of CGD appear during the first year of life with the onset of recurrent, purulent bacterial, and fungal infections.⁷ Table 50.3 summarizes the types of infections and infecting organisms most frequently encountered in CGD. The most common types of infections are those that involve sites in contact with the outside world, which is consistent with the role of neutrophils as a first line of defense against infection. *Staphylococcus aureus*, enteric gram negatives, *Serratia marcescens*, *B. cepacia*, *Nocardia* spp., and *Aspergillus* spp. represent the most frequently encountered pathogens in North American patients, but *Burkholderia* and *Nocardia* spp. are less frequently seen in Europe.⁸ *S. aureus* is the most frequently isolated organism overall. The most common causes of death have been pneumonia or sepsis caused by *B. cepacia* and *Aspergillus* spp., although use of newer azole antifungals has markedly improved the outcome of the latter in recent years.^{7,8}

Most CGD pathogens share the property of being catalase negative, and as such inadvertently “lend” H₂O₂ secreted from the pathogen to the peroxide-starved CGD phagocyte, which in turn uses it (after being converted to hypochlorous acid [HOCl] by MPO; see Fig. 50.3) to kill the microbe. It also appears that at least some of the CGD pathogens are resistant to the nonoxidative killing mechanisms of the phagocyte. It is somewhat surprising how often one fails to identify the infecting organism in CGD—perhaps greater than half the time despite aggressive culturing. In this situation, one treats empirically with the antibiotic that should work and if it fails, one then aggressively pursues more invasive diagnostic procedures looking for one (or more) of the less commonly seen microbes such as *Nocardia* spp., *Candida* spp., mycobacteria, and a host of other bacteria and fungi (see Table 50.3). Other unusual organisms that cause infection in CGD include other members of the *Burkholderia* family, including *Burkholderia cenocepacia*, *Burkholderia gladioli*, and *Burkholderia mallei* (the causative agent in melioidosis, a septic illness common in East Asia), and *Chromobacterium violaceum*, found in

Fig. 50.5 ANALYSIS OF NEUTROPHIL NICOTINAMIDE ADENINE DINUCLEOTIDE PHOSPHATE OXIDASE ACTIVITY FOR THE DIAGNOSIS OF CHRONIC GRANULOMATOUS DISEASE. (A–C) Nitroblue tetrazolium (NBT) slide test. Peripheral blood neutrophils and monocytes from a drop of fresh whole blood were made adherent to glass slides and stimulated with phorbol myristate acetate. (A) Normal neutrophils and monocytes, all of which are NBT positive. (B) Neutrophils and monocytes from an X-linked chronic granulomatous disease (CGD) patient, which are all NBT negative. (C) A mixture of NBT-positive and NBT-negative neutrophils from the X-linked carrier mother of the patient in (B). (D–G) DHR 123 flow cytometry test. Nonfluorescent DHR 123 is taken up by neutrophils, which become fluorescent after reaction with reactive oxygen species produced in the respiratory burst. (D) Normal neutrophils. (E) Neutrophils from an X-linked CGD patient, which do not fluoresce after stimulation. (F) A mixture of nonfluorescent and fluorescent neutrophils from an X-linked CGD carrier. (G) Neutrophils from a p47^{phox}-deficient patient, which show weak fluorescence after stimulation. DHR, Dihydrorhodamine; PMA, phorbol myristate acetate.

TABLE
50.3

Infections in Chronic Granulomatous Disease

Infections	Infections (%)	Infecting Organisms
Pneumonia	70–80	<i>Aspergillus</i> , <i>Staphylococcus</i> , <i>Burkholderia cepacia</i> , <i>Pseudomonas</i> , <i>Nocardia</i> , <i>Mycobacterium</i> (including atypical), <i>Serratia</i> , <i>Candida</i> , <i>Klebsiella</i> , <i>Paecilomyces</i>
Lymphadenitis	50–60	<i>Staphylococcus</i> , <i>Serratia</i> , <i>Candida</i> , <i>Klebsiella</i> , <i>Nocardia</i>
Cutaneous infections/impetigo	50–60	
Hepatic or perihepatic abscesses	20–30	<i>Staphylococcus</i> , <i>Serratia</i> , <i>Streptococcus viridans</i> , <i>Nocardia</i> , <i>Aspergillus</i>
Osteomyelitis	20–30	<i>Serratia</i> , <i>Aspergillus</i> , <i>Paecilomyces</i> , <i>Staphylococcus</i> , <i>B. cepacia</i> , <i>Pseudomonas</i> , <i>Nocardia</i>
Perirectal abscesses or fistulae	15–30	Enteric gram-negative organisms, <i>Staphylococcus</i>
Septicemia	10–20	<i>B. cepacia</i> , <i>Pseudomonas</i> , <i>Salmonella</i> , <i>Staphylococcus</i> , <i>Serratia</i> , <i>Klebsiella</i>
Urinary tract infections or pyelonephritis	5–15	Enteric gram-negative organisms
Brain abscesses	<5	<i>Aspergillus</i> , <i>Staphylococcus</i>
Meningitis	<5	<i>Candida lusitanae</i> , <i>Haemophilus influenzae</i> , <i>B. cepacia</i>

The relative frequencies of different types of infections in chronic granulomatous disease are estimated from data pooled from several large series of patients in the United States, Europe, and Japan: (1) Mouy R, Fischer A, Vilmer E, et al: Incidence, severity, and prevention of infections in chronic granulomatous disease. *J Pediatr* 114:555, 1989; (2) Bemiller LS, Roberts DH, Starko KM, et al: Safety and effectiveness of long-term interferon gamma therapy in patients with chronic granulomatous disease. *Blood Cells Mol Dis* 21:239, 1995; (3) Forrest CB, Forehand JR, Axtell RA, et al: Clinical features and current management of chronic granulomatous disease. *Hematol Oncol Clin North Am* 2:253, 1988; (4) Hitzig WH, Seger RA: Chronic granulomatous disease, a heterogeneous syndrome. *Hum Genet* 64:207, 1983; (5) Tauber AI, Borregaard N, Simons E, et al: Chronic granulomatous disease: A syndrome of phagocyte oxidase deficiencies. *Medicine (Baltimore)* 62:286, 1983; (6) Cohen MS, Isturiz RE, Malech HL, et al: Fungal infection in chronic granulomatous disease. The importance of the phagocyte in defense against fungi. *Am J Med* 71:59, 1981; (7) Hayakawa H, Kobayashi N, Yata J: Chronic granulomatous disease in Japan: A summary of the clinical features of 84 registered patients. *Acta Paediatr Jpn* 27:501, 1985; and (8) Johnston RB, Newman SL: Chronic granulomatous disease. *Pediatr Clin North Am* 24:365, 1977. These series encompass approximately 550 patients with CGD after accounting for overlap between reports. Unpublished data from the United States CGD Registry encompassing 368 patients was also used to estimate the relative frequencies of infections and the responsible organisms. The infecting organisms are arranged in approximate order of frequency for each type of infection. Note: *B. cepacia* was previously classified as *Pseudomonas cepacia*.

brackish fresh water and which can cause a febrile illness with bacteremia in CGD. A previously unknown gram-negative bacteria, *Granulobacter bethesdensis*, was recently identified in a CGD patient with recurrent fevers associated with chronic necrotizing deep lymphatic infection. This organism is a member of the *Acetobacteraceae* family, which has previously not been linked to invasive human disease.

Pneumonia is the most common type of infection seen in CGD with *S. aureus*, *Aspergillus* spp., *B. cepacia*, and enteric gram-negative organisms as the major pathogens. It is noteworthy that *B. cepacia* has emerged as a particularly lethal organism in CGD. This organism often is not covered with the first line of antibiotics used for *S. aureus* and most gram-negative organisms and can quietly proliferate (with persistent fevers) to the point of quick, explosive collapse caused by endotoxic shock. Intravenous trimethoprim-sulfamethoxazole (TMP-SMX) has been most effective in treating patients if given before widespread dissemination of the infection. Proven or suspected *Aspergillus* infections were treated with amphotericin B therapy, but new azole antifungal agents are now typically used.

Lymphadenitis is the second most common infection and is usually caused by gram-negative organisms, *S. aureus*, or *Serratia marcescens*. Incision and drainage should not be delayed if the lesion fails to respond to parenteral antibiotics. Cutaneous abscesses should be similarly managed. Recurrent perinatal impetigo is almost a signature infection in CGD and often requires months of therapy (mostly oral antibiotics) to clear. Hepatic (and perihepatic) abscesses are also common in CGD and are usually, but not always, caused by *S. aureus*. Most lesions require drainage (needle or surgical) to permit efficient healing to occur. Bone infections, most commonly caused by *Serratia* spp. or *Aspergillus* spp., are particularly problematic in CGD and arise from either hematogenous or contiguous spread (as often is the case with *Aspergillus* infections in the lung invading the ribs, vertebral bodies, or the diaphragm). Perirectal abscesses are difficult to treat, even with months of therapy, and can lead to fistula formations.

Chronic inflammation with granuloma formation is a distinctive hallmark of CGD and contributes to some of its more problematic complications.^{8,14} In some cases, this results from imperfectly controlled infections in which stalemates develop between the pathogen

and the patient's leukocytes. These lesions become granulomas as the host uses lymphocytes and activated macrophages to assist in containing the pathogens. However, this complication is not always clearly linked to persistent infection and in these cases, is speculated to involve a dysregulated inflammatory response, inefficient degradation of debris, or both. In the absence of oxidant production, excessive production of cytokines and delayed neutrophil apoptosis at inflammatory sites appear to contribute as underlying mechanisms.

As a result of persistent inflammatory stimulation, CGD patients can have a variety of more chronic complications (Table 50.4). Lymphadenopathy, hepatosplenomegaly, eczematoid dermatitis, and anemia of chronic disease (hemoglobin levels usually 8–10 g/dL) are common manifestations of this process and are most prominent in the first 5 to 10 years of life in those with CGD. Throughout the body, granuloma formation can lead to dysfunction and obstruction in the esophagus, urinary bladder, and kidneys. In the stomach, the gastric antral narrowing can be severe enough in infants and children to resemble pyloric stenosis. Inflammatory involvement of the gastrointestinal tract can be seen in up to one-third of CGD patients, typically in association with the X-linked form. A chronic ileocolitis resembling Crohn disease occurs in about 10% of patients and can range from mild diarrhea to a debilitating syndrome of bloody diarrhea and malabsorption that can necessitate a colectomy. Interestingly, anti-gliadin antibodies suggesting Crohn disease are positive in more than 50% of CGD patients. Other types of chronic inflammation include gingivitis, chorioretinitis, destructive white matter lesions in the brain, and glomerulonephritis. Discoid lupus has been reported in 10% to 20% of patients, and occasional patients may develop systemic lupus erythematosus, sarcoidosis, or rheumatoid arthritis. The underlying mechanisms are poorly defined, although recent studies suggest that these manifestations may be partly related to subtle defects in the absence of NADPH oxidase in memory B or T cells.

Carriers of CGD, whether the X-linked form or any one of the AR forms, are usually asymptomatic with two important exceptions. First, about one-fourth of X-linked carriers are at risk of developing mild to moderately severe discoid lupus erythematosus characterized by discoid skin lesions and photosensitivity.^{3,14} The onset is usually in the second decade of life. The disease does not progress to systemic

TABLE 50.4 Chronic Conditions Associated With Chronic Granulomatous Disease^a

Condition	Relative Frequency (%)
Lymphadenopathy	98
Hypergammaglobulinemia	60–90
Hepatomegaly	50–90
Splenomegaly	60–80
Anemia of chronic disease	Common [†]
Underweight	70
Chronic diarrhea	20–60
Short stature	50
Gingivitis	50
Dermatitis	35
Hydronephrosis	10–25
Granulomatous ileocolitis	10–15
Gastric antral narrowing	10–15
Ulcerative stomatitis	5–15
Granulomatous cystitis	5–10 ^b
Pulmonary fibrosis	<10 ^b
Esophagitis	<10 ^b
Granulomatous cystitis	<10
Chorioretinitis	<10
Glomerulonephritis	<10
Discoid lupus erythematosus	<10

^aThe relative frequencies of chronic conditions associated with chronic granulomatous disease (CGD) were estimated from the series of reports listed in Table 50.3.

^bThe incidence is estimated from the 50 cases of CGD followed at Scripps Research Institute and Stanford University (unpublished data).

lupus nor does one find serologic evidence of even subclinical disease. Those with severe discoid lupus can be treated with Plaquenil. Recurrent stomatitis, significant gingivitis, or both have also been noted in as many as half of X-CGD carriers. A few also have arthralgias, polyarthritis, and Raynaud phenomenon. The second important complication of the X-linked CGD carrier state is serious infection in women who have an unusually high degree of inactivation of the normal X chromosome in their myeloid cells. If the circulating neutrophil population is skewed to the point that fewer than 10% to 15% of the cells function, then the carrier has an increased risk of bacterial infections that in some cases have been severe.³

Diagnosis

The diagnosis of CGD is usually suggested by the unusual clinical histories outlined earlier or by a family history of CGD. The NBT slide test on fresh blood is the classic diagnostic test. A typical result is shown in Fig. 50.5. Fig. 50.5A shows the normal positive staining of a group of seven neutrophils and one monocyte. Fig. 50.5B shows the complete absence of NBT staining in a patient with X91⁺ CGD, the classic X-linked form of the disease. Fig. 50.5C shows the mixed population of NBT-positive and NBT-negative cells observed in that patient's mother, reflecting random X chromosome inactivation. Because nearly 100% of the normal cells in this test are positive, the carrier state in X-linked CGD can be detected when as few as 5% of the cells are NBT negative. This test also permits detection of diffuse populations of weakly positive cells such as those seen in X91⁻ CGD, which are characterized by a partial deficiency of flavocytochrome *b*. Because X-linked CGD can arise by new mutations in the maternal germ line, one does not always see NBT-negative cells in the mother. Flow cytometric assays of oxidase activity, such as those based on the

Diagnosis of Chronic Granulomatous Disease

The diagnosis of CGD is easily established by doing an NBT slide test or flow cytometry of dihydroxyrhodamine (DHR) 123 fluorescence to detect neutrophil NADPH oxidase activity. The NBT slide test is very easy to set up, as is DHR flow cytometry. However, because the probability of getting an abnormal result is very low, there may be confusion in interpretation because of a lack of experience. In the authors' experience, incorrect positive and negative results have been reported for both assays. Thus, if the index of suspicion is high, consultation should be obtained from a center with extensive experience with the test and with the disorder.

Neutrophil respiratory burst activity is preserved in anticoagulated blood maintained at room temperature for several days; thus, DHR testing can be done 1 to 2 days later after shipping to a commercial laboratory. A normal blood sample should always be shipped with the patient specimen as a control for problems in specimen handling during transport.

NBT Slide Test

- No NBT reduction (absence of cells with dark blue formazan deposits) in both X-linked and AR forms of CGD (see Fig. 50.5B).
- Usually no reduction in 50% of cells and normal in 50% for X-linked carrier. The percent positive cells can vary if there is unequal X inactivation and may appear normal or like CGD with extreme lyonization (see Fig. 50.5C).
- False-positive results can occur (i.e., apparent failure to reduce NBT supporting the diagnosis of CGD) if the neutrophils do not adhere to the slide. This happens with greasy slides or with some cases of LAD. Using phorbol myristate acetate to stimulate the cells will avoid this.

DHR Flow Cytometry

- This approach has replaced the NBT slide test in many laboratories. It has the advantage of assessing large numbers of cells and can give quantitation of the amount of oxidant production.
- The change in fluorescence channel number with stimulation is the critical number and not the percent positive cells.
- X-linked CGD patients will not respond at all and show no increase in fluorescence with stimulation (see Fig. 50.5F).
- X-linked carriers will show about 50% of the cells that respond with a normal increase in fluorescence, and the other half will have no response. Degrees of unequal X inactivation are much more accurately quantified by this assay (see Fig. 50.5G).
- AR patients, particularly those with absent p47^{phox}, have some response to stimulation and show a small increase in fluorescence (see Fig. 50.5H). This level of oxidant production is usually not visible on the NBT test.
- AR carriers have a good response, but the histogram may be broader than normal and may even appear bimodal with a weakly fluorescent peak and a strongly fluorescent peak. This is not distinguishable on the NBT slide test.
- Falsely negative results not supporting the diagnosis of CGD have been reported in specimens that have been run a few days after phlebotomy.
- Falsely abnormal results suggesting CGD can be seen in patients with MPO deficiency because MPO is required to generate strong DHR fluorescence.

Genetic Analysis

- Genetic analysis for X-linked and AR CGD is clinically available and should be performed on at least the proband in each kindred.
- Those with fewer than 5% oxidase-positive cells have full-blown CGD.

conversion of dihydroxyrhodamine (DHR) 123 to rhodamine 123, can also provide both quantitative measurements of oxidant generation and the cell-by-cell distribution of activity (see Fig. 50.5D–G). The DHR 123 assay for oxidase activity is now available in many referral centers and through reference laboratories. In addition to X91⁻ CGD neutrophils, weak staining in the NBT test or a small but measurable level of DHR fluorescence can be seen in A47⁺ cells (see Fig. 50.5H) because of a small amount of residual oxidant production. Regardless of diagnostic assay used, is important to have

these tests performed on appropriately handled blood samples and by experienced laboratories to avoid inconclusive or false-normal results.

Genetic classification is useful primarily for purposes of genetic counseling and prenatal diagnosis. With the exception of classic X-linked disease in a male whose mother is a carrier, determining the specific oxidase gene affected in a given CGD patient (see Table 50.1) requires additional laboratory studies. Genetic testing for the four most common genetic subgroups is commercially available. Laboratories specializing in neutrophil biochemistry can also perform immunoblot analysis of neutrophil extracts, flavocytochrome *b* spectroscopy, or functional analysis of membrane and cytosol fractions in the cell-free oxidase assay. In a male with absent flavocytochrome *b* without clear evidence for a maternal carrier, it is necessary to search for the mutation in both the *gp91^{phox}* and *p22^{phox}* genes by DNA sequencing or another method of analysis.

Testing for the McLeod red cell phenotype should be done in all patients diagnosed with X-linked CGD. This causes a mild hemolytic anemia. More importantly, there can be serious problems with development of hemolytic antibodies if these patients are transfused.

Prognosis and Treatment

The cornerstones of therapy in CGD are currently (1) prevention and early treatment of infections, (2) aggressive use of parenteral antibiotics for most infections, (3) use of prophylactic TMP-SMX (5 mg/kg/day of trimethoprim) or dicloxacillin (25–50 mg/kg/day) for sulfa-allergic patients, (4) prophylactic itraconazole (200 mg/day if 13 years of age or older or if weighing at least 50 kg, or 100 mg daily if younger than 13 years of age or weighing less than 50 kg), and (5) use of prophylactic recombinant human interferon- γ (rIFN- γ ; 0.05 mg/m² or 0.0015 mg/kg if less than 0.5 m² three times per week).^{3,8} Using these guidelines, the prognosis for patients with CGD has improved dramatically since the disorder was first described in the 1950s, when almost all patients died in childhood. In a large study based on data collected by a CGD registry in the United States in the 1990s, the overall mortality rate was estimated to be 5% per year for X-CGD and 2% per year for AR CGD,⁷ and a more recent single-institution study on 76 patients reported an overall mortality rate of 1.5% per year.⁸ There is a general consensus that a large majority of newly diagnosed children should survive well into their adult years with aggressive and careful management. As already noted, patients with deficiency of *p47^{phox}* have a tendency for milder disease compared with those with flavocytochrome-negative CGD. On the other hand, some patients (usually X-linked) prove to have more frequent serious infections or inflammatory complications (or both),

likely because of the effects of modifier genes; these patients may warrant more aggressive treatment such as bone marrow transplantation (BMT; see later).

Several approaches can be used to prevent infections. Patients with CGD should receive all their routine immunizations on schedule (including live virus vaccines), with influenza vaccine administered each year as well. Cuts and skin abrasions should be cleansed promptly with soap and water and a topical antiseptic applied (2% hydrogen peroxide, Betadine ointment, or both). Frequent brushing, flossing, use of antibacterial mouthwash, and professional cleaning of teeth can help prevent gingivitis. Constipation should be avoided because it can lead to rectal or anal fissures and abscesses. Early anal infections can be treated with soaking in soapy water (with or without Betadine). The frequency of pulmonary infections can be reduced by not using commercially available bedside humidifiers; avoiding smoking (cigarettes and marijuana); and refraining from handling decaying plant materials (e.g., hay, mulch, rotting sawdust), which often contain numerous *Aspergillus* spp. Avoidance of construction sites, especially demolition of old buildings that may harbor fungi, is recommended. There have been clear outbreaks of *Aspergillus* pneumonias in immunosuppressed children visiting hospitals undergoing renovation.

There is clear evidence that chronic prophylactic TMP-SMX can decrease the number of bacterial infections in CGD patients by more than half without a concomitant increased risk of fungal infection. In addition, itraconazole is an effective agent for prophylaxis for fungal infections in CGD. Liver function tests should be monitored in patients receiving itraconazole.

Prophylactic rIFN- γ has been another mainstay of current management of CGD.^{3,8} The clinical benefit of rIFN- γ is probably related to generally enhanced phagocyte function and killing by nonoxidative mechanisms because its use is not accompanied by any measurable improvement in NADPH oxidase activity in the vast majority of CGD patients. In the original multicenter trial, patients were randomized in a double-blind fashion to receive either placebo or rIFN- γ (0.05 mg/m² three times per week). As summarized in Table 50.5, there was a substantial decrease in the number of serious infections in the rIFN- γ arm. Side effects were observed in some of the patients but typically were restricted to mild fever and flu-like symptoms. No additional adverse reactions, including any increased incidence of chronic inflammatory complications, have been noted with more prolonged courses of prophylactic rIFN- γ (more than 10 years), and the patients continued to have a substantial benefit, with fivefold fewer serious infections compared with the placebo group in the phase III study in Table 50.5. On average, this group of patients averaged one serious infection per patient every 4 to 5 years. However, rIFN- γ is used less frequently in Europe as nonrandomized data did not suggest much benefit, and the usage in a cohort followed at the

IFN, Interferon.

National Institutes of Health was recently reported to be only 36% because of either lack of access or because of side effects (fever, myalgia); the availability of more potent antifungals and oral antibiotics may be a mitigating factor for reducing serious infectious complications in the absence of prophylactic rIFN- γ .

One of the most frequent errors in the management of CGD patients is the failure to treat potentially serious infections promptly and aggressively with appropriate parenteral antibiotics. Even the best antibiotics can be rendered ineffective if given too late in the course of an infection in CGD. Therefore, early intervention is advisable. Although many of the minor infections and low-grade fevers in CGD patients can be managed on an outpatient basis, episodes of consistently high fever over a 24-hour period or clearly established infections (e.g., pneumonia or lymphadenitis) should be treated with parenteral antibiotics that cover, at least initially, *S. aureus* and enteric gram-negative organisms. Reasonable attempts to define the source of the infection and the responsible microbe should also begin promptly. Monitoring markers of inflammation such as the erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) can be very useful, both as a clue to the presence of a significant infection as well as following the patient's response to therapy. If the patient fails to respond, then more aggressive diagnostic procedures should be instituted (computed tomography, bone, and gallium scans; open biopsies if indicated) and empirical changes in the antibiotics used to broaden coverage to *Pseudomonas cepacia*. If fungus is identified or strongly suspected, amphotericin B has been the drug of choice in the past, but newer azole antifungal agents such as voriconazole are supplanting its use. Even with appropriate antibiotics, certain types of infections respond slowly and may require many months of therapy. Surgical drainage or resection can sometimes play a key role in accelerating healing of certain types of infection such as lymphadenitis, osteomyelitis, and abscesses of visceral organs such as the liver or lung. Finally, granulocyte transfusions may be of benefit in the treatment of stubborn or life-threatening infections.^{3,7,8}

Recurrent fever in CGD always raises the possibility of infection in these patients; however, the macrophage activation syndrome (MAS)–hemophagocytic lymphohistiocytosis (HLH) spectrum of disorders should be considered, especially if the patient has splenomegaly, leukopenia, or thrombocytopenia. As in inflammatory disorders such as rheumatoid arthritis, secondary MAS-HLH has been reported in CGD and is probably often overlooked. Specific treatment may be indicated, especially if the patient has significant cytopenias or evidence of hepatic dysfunction.

Use of corticosteroids should generally be avoided, including extensive topical use, except in cases of severe asthma, esophageal strictures, gastric antral narrowing, granulomatous cystitis, inflammatory bowel disease, or certain cases of pneumonia. Clear evidence shows that corticosteroids are beneficial in these clinical settings because the steroids induce rapid regression of obstructive symptoms at low oral doses (e.g., 1 mg/kg/day of prednisone). Steroids can be lifesaving in young children with airway obstruction because of inflammation. Because of the exaggerated inflammatory reaction seen in CGD, there can be significant swelling in the airway and compression by pulmonary nodes that can block air movement and impede drainage. In these cases, the physician and patient should be aware of the risks of the additional immunosuppression caused by the corticosteroids.

Rare patients with X91° CGD have genomic deletions that span the gp91^{phox} gene and the Xk gene, which encodes a membrane protein necessary for expression of the Kell genes.³ Absence of the Xk gene product results in the McLeod syndrome, in which red blood cells have weak Kell antigens and variable acanthocytosis along with nerve and muscle disorders related to its expression in nonerythroid tissues. Transfusion of patients with McLeod syndrome poses a serious problem because they can develop alloantibodies of wide specificity that can preclude any further transfusions except with Kell-negative blood products. McLeod-matched blood is extremely rare, and patients with this syndrome should have their own blood frozen in case it is needed. Note that use of maternal blood does

not solve the problem because only 50% of the mother's blood will match. Because of the difficulty in finding blood, transfusion with non-McLeod blood is likely to occur. Although management is difficult and use of steroids is necessary, the hemolytic anemia can be managed successfully.

Allogeneic BMT can be used to treat CGD, including using matched unrelated donors.^{8,15} Because of the risks associated with this procedure, BMT is generally considered only for patients who have a fully human leukocyte antigen-matched sibling and frequent and severe infections despite aggressive medical management. However, reduced-intensity conditioning regimens for allogeneic transplantations have now been successfully used for BMT in CGD, including several cases with ongoing fungal infections.^{8,15} Despite improved success rates and decreased complications, which patients with CGD should undergo transplantation remains an individualized decision, particularly for those with residual NADPH oxidase activity and little or no history of serious infection or other complications.⁸ Finally, genetic therapies aimed at correcting the defective gene in BM stem cells hold promise for the future if obstacles can be solved to achieve effective and safe gene delivery and their transplantation.⁸ Observations on female carriers of X-linked CGD with skewed X-inactivation and preclinical studies in murine CGD models suggest that complete correction of NADPH oxidase activity in 10% of circulating neutrophils will lead to clinically relevant improvements in host defense.

Neutrophil Glucose-6-Phosphate Dehydrogenase Deficiency

NADPH, the primary substrate for the respiratory burst oxidase, is generated by the first two reactions of the hexose monophosphate shunt pathway, which are catalyzed by G6PD (see Fig. 50.3, reaction 8) and 6-phosphogluconate dehydrogenase (6PGD).¹⁶ The leukocyte and erythrocyte G6PD are encoded by the same gene. Thus, a severe deficiency of G6PD in neutrophils can result in a greatly attenuated respiratory burst because of low levels of NADPH. However, the vast majority of individuals with inherited G6PD deficiency do not have problems with a decreased respiratory burst or recurrent infections. A CGD-like syndrome has very rarely been observed in G6PD-deficient patients who have congenital nonspherocytic hemolytic anemia (CNSHA), in whom hemolysis occurs in the absence of redox stress.^{3,16} Even in CNSHA, most G6PD mutations cause the enzyme to decay over a period of days and weeks, so that levels in the short-lived neutrophil usually do not become critically low even in some of the most unstable G6PD variants. A few rare and poorly understood G6PD mutations that cause CNSHA are associated with extremely low (<5% of normal) levels of G6PD in the neutrophil, resulting in a deficient respiratory burst and CGD-like symptoms. The combination of chronic, severe hemolytic anemia, recurrent infections, and the laboratory demonstration of extremely low G6PD levels in neutrophils and erythrocytes serves to distinguish this disease from CGD. The treatment for neutrophil G6PD deficiency is the same as for CGD, except that the efficacy of rIFN- γ has not been demonstrated in the former. The chronic hemolytic anemia is treated by supportive means, including transfusions.

Disorders of Glutathione Metabolism

As depicted in Fig. 50.3 (reaction 6), the reduced form of glutathione (GSH) serves to protect the neutrophil from the harmful effects of hydrogen peroxide on NADPH oxidase and other neutrophil proteins. Adequate intracellular levels of GSH are maintained by recycling oxidized glutathione (GSSG) to GSH by glutathione reductase (see Fig. 50.3, reaction 7), as well as by de novo synthesis of glutathione by glutathione synthetase (see Fig. 50.3, reaction 9). Severe deficiencies in either of these enzymes are extremely rare and are apparently inherited in an AR manner.³ In the case of glutathione reductase deficiency, the respiratory burst terminates prematurely, presumably

owing to the toxic effects of accumulating hydrogen peroxide on NADPH oxidase. This brief burst of O_2^- , however, appears to be sufficient for adequate microbial killing because the few patients reported have not had problems with recurrent infections. However, they do have congenital hemolytic anemia during periods of oxidant stress caused by diminished levels of glutathione reductase in erythrocytes. In glutathione synthetase deficiency, the respiratory burst proceeds normally. Patients have severe metabolic acidosis caused by elevated levels of 5-oxoproline, which is the product of the first step in glutathione synthesis and is present in increased levels because of a lack of feedback of GSH on the synthetic pathway. Patients with glutathione synthetase deficiency also have intermittent neutropenia (perhaps caused by the acidosis), as well as oxidant-induced hemolysis. There are mild problems with recurrent infections. Therapy with vitamin E (400 IU/day) has been found to be beneficial in patients with severe glutathione synthetase deficiency with hemolysis and infections.

Myeloperoxidase Deficiency

MPO deficiency is the most common inherited disorder of phagocytes but is almost always asymptomatic.¹⁷ MPO is present in azurophilic granules of neutrophils and monocytes, and catalyzes the production of a potent antimicrobial agent, HOCl from chloride and hydrogen peroxide (see Fig. 50.3, reaction 4).^{4,5} HOCl in turn reacts with a variety of primary and secondary amines to form chloramines, some of which can be toxic. Moreover, HOCl is capable of activating latent metalloproteinases (e.g., collagenase) and inactivating antiproteases.

Complete MPO deficiency is seen in approximately 1 in 4000 individuals, and partial deficiency is even more common (1 in 2000 persons). The key features of MPO deficiency are summarized in Table 50.6. The disorder is inherited in an AR manner. In the few cases reported, several different mutations have been identified, which generally appear to affect the posttranslational processing of a precursor polypeptide for MPO. Acquired forms of MPO deficiency are also seen. The gene that encodes for MPO is located on chromosome 17 at q22–q23 near the breakpoint for the 15-to-17 translocation of promyelocytic leukemia. Subpopulations of MPO-deficient cells can be seen not only in the M3 (promyelocytic) form of acute myeloid leukemia but also in the M2 and M4 forms. MPO-deficient cells are also seen in approximately 25% of patients with chronic myeloid leukemia and myelodysplastic syndromes.

One of the most curious features of MPO deficiency is the remarkable lack of clinical symptoms in affected persons, given the prediction that severe MPO deficiency would cripple important antimicrobial reactions catalyzed by HOCl. In vitro, an impressive defect in killing *Candida albicans* and hyphal forms of *Aspergillus fumigatus* is observed.¹⁷ Bacterial killing in vitro is also abnormal in being somewhat slower than normal, but eventually it is complete. MPO-deficient mice also exhibit abnormalities in host defense against *Candida* and *Klebsiella* spp. Excessive or unusual infections in MPO-deficient patients, however, are uncommon, except for rare individuals who also have diabetes mellitus.¹⁷ In these individuals, disseminated fungal infections (usually candidiasis) are seen.

The discrepancy between the in vitro and in vivo manifestations of MPO deficiency in most patients can be explained in several ways. First, the respiratory burst in MPO-deficient neutrophils is substantially augmented, presumably from the absence of HOCl-mediated toxic effects on the NADPH oxidase. Second, other products of the respiratory burst, together with the oxygen-independent antibacterial proteins, appear to have sufficient potency to compensate for the loss of MPO-dependent reactions. Finally, residual amounts of MPO coupled with the normal levels of eosinophil peroxidase may provide at least some degree of peroxidative activity at the sites of infection.

Treatment is usually not required for MPO deficiency except in those individuals with fungal infections. In these patients, aggressive use of antifungal antibiotics is indicated. The prognosis is excellent in the majority of patients with MPO deficiency.

TABLE 50.6

Summary of Myeloperoxidase Deficiency

Incidence	1 in 2000 (partial deficiency) 1 in 4000 (total deficiency)
Inheritance	Autosomal recessive with variable expression; MPO gene on chromosome 17 at q22–q23
Molecular defect	Defective posttranslational processing of an abnormal MPO precursor polypeptide; eosinophil peroxidase encoded by different gene and levels normal
Pathogenesis	Partial or complete MPO deficiency leads to diminished production of HOCl and HOCl-derived chloramines; MPO products are necessary for rapid killing of microbes (especially <i>Candida</i> spp.) but not absolutely required
Clinical manifestations	Usually clinically silent Disseminated candidiasis or fungal disease (rare; usually in conjunction with diabetes mellitus) Acquired deficiency in M2, M3, and M4 AMLs and myelodysplasia
Laboratory evaluation	Deficiency of neutrophil and monocyte peroxidase by histochemical analysis (eosinophil peroxidase normal) Delayed, but eventually normal, killing of bacteria in vitro Failure to kill <i>Candida albicans</i> and hyphal forms of <i>Aspergillus fumigatus</i> in vitro
Differential diagnosis	Acquired partial MPO deficiency seen in M2, M3, and M4 AML; MDS; and Batten disease
Therapy	None in asymptomatic patients Aggressive treatment of fungal infections when they occur Control of blood glucose levels in diabetics
Prognosis	Usually excellent

AML, Acute myeloid leukemia; HOCl, hypochlorous acid; MDS, myelodysplastic syndromes; MPO, myeloperoxidase.

DISORDERS OF PHAGOCYTE ADHESION AND CHEMOTAXIS

Since 1970, numerous investigators have found in vitro chemotactic abnormalities in neutrophils from patients with a wide variety of clinical disorders associated with increased susceptibility to bacterial and fungal infections.³ In most circumstances, the chemotactic abnormality identified was only marginal and not always clearly related to the clinical status of the patient. In other instances, clear and major defects were identified in vitro that correlated with the in vivo propensity for infection. Extensive classification systems have been devised to categorize the numerous acquired defects in chemotaxis. The problem in many of these reports is that it is unclear whether the infections were caused by the in vitro chemotactic abnormality or by the medical complications of the underlying disorder (e.g., acidosis, malnutrition, or exposure to nosocomial infections). A further complicating factor is that there are inherent limitations in the in vitro chemotaxis assay, which is subject to laboratory artifacts both as a result of neutrophil purification procedures as well as the assay itself. Furthermore, the extent to which these in vitro

chemotactic assay systems faithfully reflect prevailing in vivo conditions is not known. Our understanding of chemotactic disorders has been hampered by the limitations of these assays, just as the elucidation of respiratory burst defects was obscured when the major available assay was in vitro bacterial killing. In this section, the most important and best characterized of the chemotactic disorders, LAD, is discussed in detail. A brief discussion of several other clinically significant chemotactic disorders is also provided.

Leukocyte Adhesion Deficiency Type I

LAD type I (LAD I) is a rare AR disorder of leukocyte adhesion, chemotaxis, and ingestion of C3bi-opsonized microbes as a result of decreased or absent expression of the leukocyte β_2 integrins (Table 50.7).^{18,19} The hallmark of LAD I is the occurrence of repeated, often severe bacterial and fungal infections without the accumulation of pus despite persistent granulocytosis (see Table 50.7). The molecular basis for LAD was first suggested by Crowley and colleagues, who found that neutrophils from a patient with this clinical syndrome lacked a high-molecular-weight membrane glycoprotein (see Dinauer,

Newburger, and Borregaard³). The patient's neutrophils could not be made to adhere to plastic surfaces or to respond to serum-opsonized particles in terms of ingestion and respiratory burst activity.

The molecular basis of LAD I is now known to result from mutations in the gene for the common CD18 β_2 subunit for these three leukocyte glycoproteins, now termed β_2 integrins, that belong to the integrin superfamily of adhesion molecules. Integrins are noncovalently linked heterodimeric glycoproteins consisting of an α and a β subunit. Within each of the eight known integrin subfamilies the β subunit is identical (and defines the subfamily), but the α subunit varies and confers the functional specificity on the integrin. The molecular defect in LAD involves all members of the β_2 integrin subfamily: α L β 2 (CD11a/CD18), α m β 2 (CD11b/CD18), and α x β 2 (CD11c/CD18). CD11a/CD18 is often referred to as *LFA-1* while CD11b/CD18 is also called *Mac-1*, *Mo1*, or *CR3*. LAD I patients have an absent, diminished, or structurally abnormal β 2 subunit (CD18; see later), and as a result, the three types of α chains in the β 2 integrin subfamily cannot assemble into normal α - β heterodimers. Thus, all three β 2 integrins are moderately to severely deficient on all leukocytes in LAD.

The β_2 integrins serve as receptors for the opsonic complement fragment C3bi, the intercellular adhesion molecules 1 and 2 (ICAM-1 and ICAM-2) that are expressed on endothelial cells and leukocytes, and fibrinogen. The diminished or absent expression of β_2 integrins in LAD I leukocytes results in the failure of phagocytes to emigrate from the bloodstream to sites of infection. The early interactions with the endothelium, termed *rolling*, are normal in LAD I because these are mediated by a different family of adhesion molecules known as *selectins*. However, β_2 integrins are responsible for the subsequent tight binding of neutrophils and monocytes to ICAMs on cytokine-activated endothelium, and this step is therefore severely defective in LAD I. Transendothelial migration is also impaired. A second major functional defect in LAD is the failure of phagocytes to bind C3bi-opsonized microbes. Because CD11b/CD18 is the predominant phagocyte receptor for this complement fragment, C3bi-mediated ingestion, degranulation, and respiratory burst activity are severely affected in LAD. Finally, β_2 integrin-dependent signals play a key role in activating neutrophils for enhanced migration, phagocytosis of antibody-opsonized microbes, and degranulation.

Despite in vitro defects in lymphocyte responses dependent on LFA-1 (CD11a/CD18), patients with LAD I rarely have clinical manifestations related to impaired lymphocyte function. It is believed that the role CD11a/CD18 plays in lymphoid cell function can be compensated by other adhesion proteins (CD2, CD4, CD8, and so on).

Molecular Genetics of Leukocyte Adhesion Deficiency Type I

The fact that LAD I involves a deficiency of all leukocyte β_2 integrins focused attention on the common β_2 chain (CD18), and mutations in the corresponding gene, *ITGB2*, have been identified in all LAD I patients who have been analyzed at the molecular level to date.^{18,19} Although expression of the leukocyte integrin α subunits is normal in LAD I, these are not transported to the cell surface because the β_2 chain is absent or contains mutations that disrupt its structure or its interaction with the α subunit. Mutations in the α subunits have not been found thus far in patients with LAD I. The CD18 glycoprotein has a large extracellular domain at the N terminus, a single transmembrane domain, and a 46-residue cytoplasmic tail. As with X-linked CGD, CD18 mutations in LAD I are heterogeneous in nature and family specific, and can lead to either undetectable or low (9–20% of normal) levels of α - β dimer expression that correlates with the clinical severity of the disease. More than 50 different mutations have now been characterized in more than 100 families.¹⁸ These include missense mutations, mRNA splicing defects, small deletions, and a premature termination signal. Many patients are compound heterozygotes and have two different mutant alleles for CD18. About half of patients with LAD I in whom the genetic defect

TABLE 50.7 Summary of Leukocyte Adhesion Deficiency Type 1

Incidence	More than 60 patients described in literature
Inheritance	AR
Molecular defect	An absent, diminished, or structurally abnormal β subunit (CD18) caused by one of several types of mutations in the β gene; in the absence of a normal β subunit, the three types of α chains in the β_2 integrin subfamily (CD11a, b, c) cannot assemble into normal α - β heterodimers
Pathogenesis	All three β_2 integrins (CD11a/CD18, CD11b/CD18, and CD11c/CD18) are deficient on all leukocytes, causing multiple abnormalities in cell function: adherence; chemotaxis; and C3bi-mediated ingestion, degranulation, and respiratory burst
Clinical manifestation	Persistent granulocytosis (neutrophil count: 12,000–100,000/mm ³) Severe or moderate phenotypes depending on severity of deficiency Recurrent pyogenic infections with absent neutrophil infiltration Delayed umbilical cord separation Severe gingivitis or periodontitis
Laboratory evaluation	Flow cytometric measurement of surface CD11b in stimulated neutrophils with monoclonal anti-CD11b
Differential diagnosis	CGD May be associated with severe neutrophil actin dysfunction
Therapy	Hematopoietic stem cell transplant in clinically severe patients (CD11b <0.3% of normal) Aggressive use of parenteral antibiotics Possible benefit of prophylactic TMP-SMX
Prognosis	Severe: high incidence of death before 2 years of age unless transplantation is performed Moderate: can survive into 20s and 30s but with recurrent infections

AR, Autosomal recessive; CGD, chronic granulomatous disease; TMP-SMX, trimethoprim–sulfamethoxazole.

has been identified have point mutations in a stretch of 250 amino acids in the extracellular domain of CD18. This region is highly conserved among all β subunits and appears to be important for interaction with the α subunit.

Clinical Features

The key features of LAD I are summarized in Table 50.7. The clinical presentation of LAD is heterogeneous and is related to the severity of the deficiency of the $\beta 2$ integrins. The severe clinical phenotype is associated with less than 0.3% of the normal amount of these glycoproteins on the leukocyte surface; the moderate phenotype has 2.5–6% of normal levels. In both the severe and moderate forms of the disease, persistent granulocytosis (neutrophil count of 12,000–100,000/mm³) is a constant finding, as are recurrent cutaneous abscesses and aggressive periodontitis and gingivitis. Additional clinical features seen more often in the severe clinical phenotype include delayed umbilical cord separation, omphalitis, perirectal cellulitis, severe ulcerative stomatitis, and bacterial sepsis. A striking finding in LAD I is that abscesses and other sites of infections are devoid of pus despite the marked neutrophilia because neutrophils are unable to emigrate to tissues. *S. aureus* and gram-negative enteric bacteria cause the majority of infections in LAD I. Fungal infections can also occur, particularly from *C. albicans* and *Aspergillus* spp.

Note that infants with delayed separation of the umbilical cord who are healthy and have normal blood counts are very unlikely to have LAD I. Although the mean age of cord separation ranges from 7 to 15 days, 10% of healthy infants can have cord separation at 3 weeks of age or later.

Diagnosis

The diagnosis of LAD I is made by flow cytometric measurement of surface CD11b (Mac1; or the shared CD18 subunit) in unstimulated and stimulated neutrophils using commercially available monoclonal antibodies directed against CD11b or CD18 (see Fig. 50.6). Neutrophils contain an intracellular pool of CD11b/CD18 in their secondary (specific) and tertiary granules, which can be mobilized to the cell surface during stimulation. Therefore, the deficiency of CD11b can be more dramatically demonstrated by using stimulated neutrophils. Carriers of LAD I can be identified by this method because they have been found to express approximately 50% of normal levels of CD11b on the surface of their stimulated neutrophils (see Fig. 50.6).

Prognosis and Treatment

Treatment of LAD I depends on the clinical severity of the disorder. In patients with the moderate clinical phenotype, cutaneous and oral infections can be managed as they occur. The use of prophylactic antibiotics such as TMP-SMX appears to be beneficial, as does aggressive prophylactic treatment of periodontal disease. It is important to note that even patients with the moderate phenotype can die of overwhelming infection. In patients with severe LAD I, aggressive management is indicated because of the high incidence of death before the age of 2 years, and hematopoietic stem cell transplantation is recommended. LAD I should also be amenable to gene-replacement therapy in the future.

Leukocyte Adhesion Deficiency Types II and III

LAD type II is a very rare clinical syndrome closely related to LAD I but caused by a defect in selectin-mediated adhesion events from a deficiency in leukocyte Sialyl–Lewis X ligands.^{18,19} It was first reported by Etzioni et al in two unrelated boys of Muslim Arab origin and has since described in a total of five individuals (four Arab and one Turkish). The disease is inherited in an AR manner. Patients presented

Fig. 50.6 EVALUATION OF ADHESION MOLECULE EXPRESSION FOR DIAGNOSIS OF LEUKOCYTE ADHESION DEFICIENCY. Fluorescence of C3b specific antibody labeled neutrophils (solid line) increases compared with a nonspecific control (dashed line) after 30-minute exposure to 10-nM fMLP in healthy donors, patients with severe and moderate forms of leukocyte adhesion deficiency (LAD) I, and a heterozygous LAD I carrier. However, the increase in CD11b fluorescence (solid line) is markedly diminished in LAD I patients. The respective percent of normal stimulated mean channel number is shown in the right column. Note that these results are expressed as percent of normal fluorescence intensity, not as percent of positive cells, as is the case in most flow cytometry assays.

with neutrophilia, recurrent bacterial infections, and periodontitis, similar to LAD I, although these symptoms were generally not as severe. In addition, LAD II is associated with dysmorphic features and psychomotor retardation. LAD II neutrophils express normal levels of CD18. A clue as to the molecular cause of LAD II came from the observation that LAD II red cells were Lewis antigen negative and also had the rare Bombay (hh) erythrocyte phenotype, in which red blood cells express a nonfucosylated variant of the H antigen. These antigenic defects share in common the failure to form certain fucose carbohydrate linkage. The defect in fucose metabolism in LAD II has now been shown to result from mutations in the Golgi guanosine diphosphate–fucose membrane transporter. This leads to a generalized loss of expression of fucosylated glycans on the surface of cells, particularly the sialylated and fucosylated tetrasaccharide, SLeX (CD15a), on the neutrophil surface. As a result, LAD II neutrophils are unable to bind to E- and P-selectin receptors on endothelium and therefore have an impairment in the early steps of rolling and loose binding to blood vessel walls before tight adhesion and emigration into infected tissues. Fucose supplementation has been partially successful in increasing expression of SLeX and decreasing clinical problems.

LAD type III has recently been described in a handful of patients with severe, recurrent infections similar to LAD I, as well as a bleeding tendency similar to Glanzmann thrombasthenia (a $\beta 3$ integrin-related disorder).^{18,19} This disorder results from AR defects in KINDLIN-3, a regulatory protein required for “inside-out” activation of multiple classes of integrins in blood cells. Because the clinical manifestations are typically severe, early BMT may be indicated for patients with LAD III. (see Etzioni¹⁹).

Hyperimmunoglobulin E Syndrome

Hyperimmunoglobulin E syndrome (HIES) is a complex disorder characterized by markedly elevated serum IgE levels, serious recurrent staphylococcal infections, mucocutaneous candidiasis, chronic dermatitis, and skeletal and dental abnormalities.^{20,21} Although not a primary phagocyte defect, neutrophils from patients with this syndrome exhibit a variable and at times profound chemotactic defect. HIES was first described in 1966 and was called *Job syndrome*, in reference to the biblical description of Job as being affected by “sore boils from the soles of his feet unto his crown.” The skin abscesses in patients with HIES lack the erythema that is typical of such lesions and are referred to as *cold abscesses*. The key features of HIES are described in Table 50.8.

TABLE 50.8 Summary of Hyperimmunoglobulin E Syndrome

Incidence	More than 200 patients reviewed in the literature
Inheritance	AD with incomplete penetrance; sporadic forms, AR (rare)
Molecular defect	Dominant-negative mutations in STAT3 (AD inheritance; sporadic), Dock8, or Tyk2 kinase (AR)
Clinical manifestations	Staphylococcal pneumonia Pneumatoceles Fungal superinfection of lung cysts “Cold” cutaneous skin abscesses and furuncles Chronic eczematoid dermatitis Mucocutaneous candidiasis Chronic cutaneous viral infections (AR) Severe allergies (AR) Coarse facies, growth retardation (AD) Osteopenia, recurrent fractures (AD) Sinusitis, keratoconjunctivitis Scoliosis (AD) Hyperextensible joints (AD) Delayed shedding of primary teeth (AD) Vascular disease (AD) Malignancy (AR) Stroke/CNS vasculitis (AR)
Laboratory evaluation	Serum IgE >2500 IU/mL Peripheral blood eosinophilia
Differential diagnosis	Atopic dermatitis Wiskott-Aldrich syndrome, DiGeorge syndrome Hypergammaglobulinemia Chronic granulomatous disease
Therapy	Prophylactic anti- <i>Staphylococcus aureus</i> antibiotics Aggressive treatment of acute infections with parenteral antibiotics Surgical drainage of deep infections and resection of lung cysts Monitor for scoliosis, fractures, vascular disease
Prognosis	Generally good if managed aggressively Some patients develop lymphoid malignancies; patients with AR HIES have an increased risk and broader spectrum of cancer susceptibility 30% survival by 30 years of age without bone marrow transplant (AR)

AD, Autosomal dominant; AR, autosomal recessive; HIES, hyperimmunoglobulin E syndrome; IgE, immunoglobulin E; STAT3, signal transducer and activator of transcription 3.

Most cases of HIES result from inherited or sporadic autosomal dominant (AD) mutations in signal transducer and activator of transcription 3 (STAT3), a Janus kinase (JAK)-activated transcription factor activated in response to many cytokines and growth factors. These mutations, which are located primarily in regions of the protein that interact with other proteins or with DNA, inhibit the activity of the wild-type STAT3 allele and result in a complex pattern of altered cytokine signaling and impaired T helper type 17 (Th17) cell differentiation. Mutations in *DOCK8*, a guanine nucleotide exchange factor, or *TYK2*, a JAK family member, result in the more rare AR forms of HIES that have more profound impairments in lymphocyte function, leading to a broader risk of infection and other immune dysregulation. Approximately 96% of *DOCK8*-deficient patients suffered life-threatening infection (58%), malignancy (17% by median age of 12 years) or noninfectious cerebral events (10%) by age 30 years. Only 33% of these patients who were not transplanted survived to 30 years of age.²⁰

Insights into how STAT3 signaling defects lead to the clinical syndrome characteristic of AD HIES are now emerging. Defective responses to IL-6 may account for the minimal inflammatory responses characteristic of HIES, and the enhanced IgE production may reflect dysregulated immune responses secondary to impaired signaling by IL-10, a negative regulator. Th17 cells are important for control of mucocutaneous *Candida* infection, which is problematic in many patients. In addition, keratinocytes and bronchial epithelial cells are particularly dependent on Th17 cytokines to produce chemokines and antimicrobial peptides, which may explain the predilection for skin and lung infections. The dental and skeletal abnormalities may be related to defective STAT3 signaling in osteoblasts and osteoclasts.

Diagnosis of Chemotactic Disorders

The direct measurement of neutrophil chemotaxis in a clinical setting is very difficult and requires a specialized research laboratory. Because the assays are biologic assays, the laboratory must run the tests at least monthly to maintain competence and have acceptable normal ranges. Neutrophil chemotaxis is significantly affected by inflammation, complement activation, and medications, making it very difficult, especially in a patient with infection, to determine if the infection is attributable to a chemotactic defect or if the defect is attributable to the infection. This is further complicated by the fact that inflammation activates the neutrophils and affects which populations actually come off of the density gradients required to separate the cells for assay. Unlike the respiratory burst, chemotaxis must be done on fresh cells, so samples cannot be reliably shipped.

The neutrophils from patients with primary chemotactic defects have almost no motility in standard biologic assay systems. Some chemotactic disorders can be diagnosed by assays of other characteristic features.

LAD I

- LAD I has a significant chemotactic defect as well as phagocytic defect, and is characterized by leukocytosis. The diagnosis can be made by flow cytometry of the CD11b complex on the surface.
- Fig. 50.6 indicates surface expression of C3b and CD11b on neutrophils. C3b is used as a positive control and is normal in LAD1. With stimulation, CD11b increases (*top panel*).
- The results in this assay are expressed as percent of normal stimulated control mean channel number. It is important to note that this is not the percent positive cell, as is the case for most flow cytometry assays.
- Severe LAD1 has no increase with stimulation.
- Moderate LAD1 shows some shift of fluorescence with stimulation.
- Genetic analysis for this disorder is clinically available.

Other chemotactic disorders: Genetic analysis is available for several primary neutrophil defects, and this approach should be pursued before attempting assay of chemotaxis in a clinical setting.

No other primary chemotactic defects are readily diagnosed by a routine clinical laboratory. Measurement of neutrophil chemotaxis itself to look for secondary defects for any kind of clinical decision making is difficult if not impossible to interpret.

Clinical Manifestations

The clinical manifestations of HIES are at times dramatic. Onset is generally in the first 2 months of life and is manifested by chronic dermatitis. By 5 years of age, patients have a history of recurrent skin abscesses, pneumonias, chronic otitis media, and sinusitis. As patients grow older, recurrent staphylococcal pneumonia is a common problem and can be complicated by the formation of pneumatoceles. Septic arthritis, cellulitis, and osteomyelitis are also observed and are usually caused by *S. aureus*, although other bacterial pathogens have also been found. Patients can have chronic mucocutaneous candidiasis and occasionally exhibit keratoconjunctivitis, sometimes complicated by corneal scarring. One feature noted in the majority of patients by the time they reach the teenage years is the presence of coarse facial features (broad nasal bridge, prominent nose). Dental and bone abnormalities are also common features of HIES. Delayed or failure to shed primary teeth occur in the majority. Hyperextensible joints and scoliosis are frequent. Osteopenia of unknown etiology is observed in most patients, and there is an increased risk of fractures to the long bones and vertebral bodies even in the absence of osteopenia. Vascular disease, including aneurysms, tortuosity of middle-sized arteries, and hypertension is also frequently seen.

Patients with the AR form of HIES, the majority of whom have defects of *DOCK8*, which is also referred to as *DOCK8 immunodeficiency syndrome*, also have recurrent sinopulmonary infections, skin abscesses, and dermatitis, with the latter often the first symptom and developing in infancy. Unlike AD HIES, patients with *DOCK8* defects can develop asthma; severe allergies, including to foods, and chronic cutaneous viral infections with human papillomavirus, molluscum contagiosum virus, and herpes family viruses is a distinctive feature seen in approximately 90% of patients. These patients are also at high risk for a variety of malignancies in late childhood to early adulthood, believed to be caused by loss of immune surveillance for tumors.²⁰ AR HIES patients do not have the nonimmunologic skeletal and dental abnormalities characteristic of AD HIES.

Diagnosis

The diagnosis of HIES should be entertained in any child or young adult who has the above-described clinical picture or simply a history of recurrent infections. The hallmark laboratory finding is a marked elevation of serum immunoglobulin E (IgE), almost always greater than 2500 IU/mL. Levels can be as high as 150,000 IU/mL. Most patients also have peripheral eosinophilia. However, there is no correlation of clinical disease activity with the level of either IgE or peripheral eosinophilia. Atopic dermatitis is the major differential diagnosis because comparably high serum levels of IgE can be seen in patients in this disorder, as well as superficial skin infections. The severe and recurrent nature of the staphylococcal furuncles and pneumonias usually seen in HIES can help distinguish these patients from those with atopic dermatitis. Patients with other primary immunodeficiency syndromes may also manifest elevated IgE levels. Scoring criteria predictive of STAT3 mutations, including recurrent pneumonia, pathologic bone fractures, and lack of Th17 cells, are helpful.²¹ DNA testing should be used to make a definitive diagnosis.

Therapy

The therapy for AD HIES is largely supportive.²¹ Prophylactic antibiotics (e.g., dicloxacillin or TMP-SMX) can be effective in preventing *S. aureus* infections. Dermatitis can be treated with topical steroids. Bathing in diluted bleach can diminish colonization by *S. aureus*. Prophylactic antifungals can be helpful in patients with chronic mucocutaneous candidiasis. Intravenous antibiotics are used for deep-seated infections or for resistant cutaneous infections. Surgical resection of persistent pneumatoceles is sometimes indicated to

prevent superinfection by fungal and gram-negative organisms. Intravenous Ig infusions have shown some success in the management of HIES. Attention should also be paid to blood pressure and other vascular complications. Although a role for hematopoietic stem cell transplantation in AD HIES is unclear, two children with STAT3 mutations who underwent transplantation for non-Hodgkin lymphoma are alive 10 and 14 years later with resolution of all immunologic and nonimmunologic features of HIES.²¹ Patients with AR HIES may need prophylaxis for viral infections, and hematopoietic stem cell transplant probably should be considered.²⁰

Miscellaneous Chemotactic Disorders

It is extremely rare to have primary defects in neutrophil actin polymerization as a cause of abnormal chemotaxis and recurrent infections.^{2,3} In one case, neutrophils had diminished actin polymerization, chemotaxis, and phagocytosis of serum-opsonized particles. Family members had decreased CD11b/CD18 expression and a partial decrease in actin polymerization, which suggested that this disorder might be a variant of LAD I; however, no similar cases have otherwise been described. An apparent AR disorder of actin polymerization has been described in a male infant of Tongan descent who presented with severe skin infections, recurrent pulmonary infiltrates, thrombocytopenia, and invasive *Candida tropicalis* infection. Neutrophil actin polymerization was markedly abnormal and associated with increased expression of an actin-binding protein. Finally, a heterozygous point mutation in β -actin affecting binding to actin-regulatory proteins was discovered in a female patient with recurrent infections, photosensitivity, and mental retardation. Neutrophils had a marked impairment in chemotaxis and in the formyl peptide-induced respiratory burst.

A new syndrome of severe neutrophil dysfunction caused by a dominant-negative mutation in Rac2, a small GTPase expressed in blood cells that acts in many signal transduction pathways, was recently described in an infant boy born to unrelated parents. (see Dinanuer and Newburger³). This baby presented with rapidly progressive and deep-seated soft tissue infections, along with neutrophilia and poor formation of pus but normal expression of β 2 integrins and fucosylated proteins. Neutrophils had marked defects in actin polymerization, chemotaxis, degranulation, and the respiratory burst in response to chemoattractants. Neutrophil responses to other agonists were normal, suggesting that the dominant negative Rac2 mutation produces a selective intracellular signaling defect.

Localized juvenile periodontitis (LJP) is a heterogeneous disorder of unknown etiology characterized by chronic and recurrent periodontal infections and severe alveolar bone loss with onset at the time of puberty.²² Many patients with LJP have been reported to have defective neutrophil chemotaxis in vitro. At present, it appears that LJP is an acquired disorder in some patients and a genetic disorder in others. It may also be a combination of both in certain patients because they may inherit an unusual sensitivity to the chemotactic inhibitors released by certain periodontal microorganisms. The diagnosis of the disorder is made on the basis of severe periodontal disease and destructive alveolar bone loss involving the first molars and incisors developing during adolescence. It is important to note that many qualitative and quantitative neutrophil disorders are also associated with severe periodontal disease. Therefore, the differential diagnosis should include neutropenia (both chronic and cyclic), LAD, CGD, and Chediak-Higashi syndrome (CHS).

One of the most consistently observed chemotactic abnormalities is seen in neonatal neutrophils.²³ These cells exhibit impaired chemotaxis in vitro in response to a wide variety of chemotactic factors. It appears as though this abnormality is caused, at least in part, by defects in cellular adhesion as a result of diminished mobilization of intracellular adhesion-promoting molecules to the cell surface. Defective neutrophil chemotaxis can be seen in normal neonates between birth and 5 days of age. In severely ill infants, the defect may persist for a longer time.

DEFECTS IN THE STRUCTURE AND FUNCTION OF LYSOSOMAL GRANULES

Two major disorders of neutrophil granules have been described, CHS and specific granule deficiency (SGD). A great deal has been learned about the structural and functional abnormalities of neutrophils from patients with these conditions. Although rare, these disorders are also obligatory components in the differential diagnosis for any patient with recurrent bacterial and fungal infections.

Chediak-Higashi Syndrome

CHS is a rare AR, multisystem disease resulting from widespread defects in granule morphogenesis, with giant lysosomes in leukocytes and other cells throughout the body.^{24–26} The disorder is characterized by partial oculocutaneous albinism, frequent (and sometimes fatal) bacterial infections, a mild bleeding diathesis, and peripheral as well as cranial neuropathies associated with defects at the optic chiasm. Those who survive the recurrent infections develop an “accelerated phase” of the disease; one of the hereditary forms of HLH, which, if untreated, is eventually fatal because of a profound pancytopenia that develops.

The most dramatic granule defects are manifested in the various blood cells. Neutrophils contain a highly inhomogeneous population of huge granules derived from coalescence of azurophilic (primary) granules. The giant granules are often more prominent in the BM than in the peripheral blood because many of the abnormal myeloid precursors are apparently destroyed before they leave the BM, resulting in moderate neutropenia with absolute neutrophil counts ranging from 500 to 2000 cells/mm³. Granules are also markedly deficient in antimicrobial granule enzymes such as cathepsin G and elastase, consistent with a defect in granule morphogenesis. Degranulation is delayed and incomplete in Chediak-Higashi neutrophils, resulting in impaired bacterial killing. Chemotaxis is also defective, perhaps related to poor deformability because of the presence of the large granules. Monocytes and macrophages exhibit similar giant cytoplasmic granules, with resultant abnormalities in their phagocytic functions. Giant granules are also seen in lymphocytes and are associated with defects in cytotoxic T-lymphocyte and NK cell function. Eosinophils contain large granules, the functional significance of which is not known. Platelets in this disorder have a storage pool deficiency of adenosine diphosphate and serotonin, presumably caused by the abnormal granule morphogenesis in megakaryocytes, leading to a defect in platelet aggregation.

Abnormal giant granules are also present in other cell types. These include melanocytes, which contain abnormal melanosomes that cannot transfer their contents to adjacent keratinocytes; Schwann cells; astrocytes; and certain cells in the liver, spleen, pancreas, gastric mucosa, kidney, adrenal gland, and pituitary gland.

Molecular Genetics

A gene termed *CHS1* or *LYST* (for its presumed function as a lysosomal trafficking regulatory protein) is affected in the majority of CHS cases and is on the long arm of chromosome 1.^{24,25} The encoded protein is very large (3801 amino acids); its specific function is unknown, but recent studies suggest that it may inhibit lysosome fusion with other intracellular membrane vesicles. A variety of frameshift and nonsense mutations that predict synthesis of truncated forms of the protein have been identified in most, but not all, CHS patients studied to date. There is no correlation between the length of the truncated *CHS1* protein and the severity of the disease. Disorders similar to human CHS have also been described in many mammalian species, including Aleutian mink, *beige* mice, blue foxes, cats, killer whales, and Hereford cattle. Identification of the human *CHS1* gene was aided by positional cloning of the mouse *lyst* homolog affected in *beige* mice.

TABLE 50.9 Summary of Chediak-Higashi Syndrome

Incidence	More than 200 cases described
Inheritance	AR
Molecular defect	A defect in granule morphogenesis in multiple tissues resulting from mutations in the <i>CHS1</i> (<i>LYST</i>) gene encoding a lysosomal trafficking regulator protein
Pathogenesis	Giant coalesced azurophil granules in neutrophils, resulting in ineffective granulopoiesis and neutropenia, delayed and incomplete degranulation, and defective chemotaxis; abnormal granules in other cells (NK cells, cytotoxic T cells, platelets, melanocytes, neurons)
Clinical manifestations	Partial oculocutaneous albinism Recurrent severe bacterial infections (usually <i>Staphylococcus aureus</i>) Cranial and peripheral neuropathies (muscle weakness, ataxia, sensory loss) HLH (accelerated phase)
Laboratory evaluation	Giant granules in peripheral blood granulocytes and in BM myeloid progenitor cells Widespread lymphohistiocytic infiltrates in accelerated phase
Differential diagnosis	Other genetic forms of partial albinism Giant granules can be seen in acute and CMLs
Therapy	Prophylactic TMP-SMX Parenteral antibiotics for acute infections Ascorbic acid (200 mg/day for infants; 6 g/day for adults) HSCT before or at beginning of HLH
Prognosis	Most patients die from infection or complications of HLH during the first or second decade of life unless transplantation is performed

AR, Autosomal recessive; BM, bone marrow; CML, chronic myeloid leukemia; HLH, hemophagocytic lymphohistiocytosis; HSCT, hematopoietic stem cell transplant; NK, natural killer; TMP-SMX, trimethoprim-sulfamethoxazole.

Clinical Manifestations

The key features of CHS are summarized in Table 50.9. The disease usually presents in infancy or early childhood, with infections involving the lungs, skin, and mucous membranes being most commonly encountered. Dental caries and periodontal disease are also common. The most frequent offending organism is *S. aureus*. Gram-negative bacteria, *Aspergillus* spp., and *Candida* spp. also are responsible for many infections. Platelet granule defects result in easy bruising and epistaxis. There is partial oculocutaneous albinism and photosensitivity. Patients may have a white forelock, or an ashen or grayish silver sheen to the hair, which can vary from blond to dark brown. In younger patients, there may be a cartwheel distribution of pigment in the iris and an abnormal red reflex. Neurologic manifestations include peripheral or cranial neuropathies, gait abnormalities, muscle weakness, sensory loss, seizures, or spinocerebellar degeneration. Neurologic symptoms worsen with age.

Approximately 85% of children surviving into the second decade of life develop an accelerated phase of the disease, with fever,

lymphadenopathy, and progressive pancytopenia, that is now recognized to be a genetic form of HLH caused by impaired lymphocyte and NK cell function.²⁶ The development of HLH can sometimes be precipitated by Epstein-Barr virus infection. A reactive-appearing lymphohistiocytic proliferation occurs in the liver, spleen, lymph nodes, and BM, and the prognosis is uniformly fatal unless patients undergo BMT.

Diagnosis

The diagnosis of CHS is made on the basis of the giant peroxidase-positive lysosomal granules in the peripheral blood granulocytes or in BM myeloid cells. Identification of large, acid phosphatase-positive lysosomes in amniocytes and chorionic villus cells has been used to diagnose CHS prenatally. Other clinical features characteristic of CHS can support the diagnosis, including mild oculocutaneous albinism; silvery hair, in which microscopic examination reveals giant melanin granules; and a bleeding diathesis. The development of HLH is characterized by diffuse infiltrates of lymphohistiocytic cells seen on biopsy and by pancytopenia. Occasionally, giant granules that resemble those of CHS can be seen in both acute and chronic myelogenous leukemias.

Therapy

The treatment for the stable phase of CHS is similar to that for other neutrophil disorders. Prophylactic antibiotics such as TMP-SMX appear to be beneficial. Parenteral antibiotics are indicated for acute infections, and responses are often slow. Treatment with high-dose ascorbic acid (200 mg/day for infants; 6 g/day for adults) has been found to improve the clinical status of some patients. Although there is some controversy regarding the efficacy of ascorbic acid, given the safety of this medication, it seems prudent to administer it to all patients. The treatment of HLH (accelerated phase) includes combinations of drugs that suppress the function of activated macrophages and T cells followed by allogeneic hematopoietic stem cell transplantation.²⁶ Indeed, transplantation is ideally performed before or at the beginning of the accelerated phase. Note that transplantation does not prevent the progressive neuropathy of CHS.

Specific Granule Deficiency

Neutrophil SGD is an extremely rare congenital disorder characterized by recurrent bacterial and fungal infections, primarily involving the skin, ears, and lungs.^{3,27} Infections are often indolent and smoldering, and *S. aureus*, *P. aeruginosa*, enteric gram-negative bacteria, and *C. albicans* are the major pathogens. Family studies suggest that it is inherited in an AR manner. Neutrophils from patients with SGD have atypical bilobed nuclei, absent specific granules, and multiple deficiencies of secondary and tertiary granule mRNAs and proteins, including lactoferrin, vitamin B₁₂-binding protein and gelatinase B; although azurophilic granules in this disorder are present and contain MPO and lysozyme, they are markedly deficient in defensins. Monocytes display cell surface and functional defects, eosinophils lack eosinophil-specific granule proteins such as eosinophil cationic protein, and platelets have abnormal α granules, suggesting that the underlying defect may be related to regulation of the synthesis of certain granule and membrane proteins. This defect in synthesis is confined to BM-derived cells because lactoferrin secretion is normal in the glandular epithelia of SGD patients despite the severe deficiency in the neutrophils.

The recurrent skin and pulmonary infections characteristic of SGD appear to be caused by two fundamental defects in the neutrophils. One defect is the marked deficiency of at least two important microbicidal granule proteins, lactoferrin and defensins. The other defect is a relatively severe chemotactic abnormality presumably caused by the absence of the intracellular pool of leukocyte adhesion

molecules that normally reside in the specific granules. As discussed earlier, these $\beta 2$ integrins play a key role in phagocyte chemotaxis.

The molecular defect responsible for most cases of SGD has recently been shown to involve a myeloid transcription factor known as C/EBP ϵ , which regulates expression of certain genes activated during granulocyte differentiation.^{3,27} This came about serendipitously when it was recognized that mice with a targeted deletion in the C/EBP ϵ gene displayed characteristics similar to those of SGD patients, including neutrophils with bilobed nuclei, absent secondary granules, and impaired chemotaxis along with increased susceptibility to bacterial infections. To date, mutations in the C/EBP ϵ gene have been identified in two SGD patients that encode truncated, nonfunctional proteins. However, DNA sequencing of the C/EBP ϵ gene of several other SGD patients has not revealed abnormalities, suggesting that SGD is a genetically heterogeneous disorder.

The diagnosis of SGD can be readily made by microscopic examination. Wright-stained neutrophils are devoid of specific granules but contain normal numbers of azurophilic granules. Electron microscopy reveals small peroxidase-negative vesicles, which presumably represent empty specific granules. The diagnosis of SGD can also be established by demonstrating a severe deficiency in either lactoferrin or vitamin B₁₂-binding protein. An acquired form of SGD can be seen in burn patients or in individuals with various myeloproliferative disorders. The treatment for SGD is similar to that for other neutrophil disorders. If medical management is aggressive, the prognosis appears quite good, with patients surviving into their adult years.

MISCELLANEOUS INHERITED AND ACQUIRED DISORDERS OF PHAGOCYTE FUNCTION

Rare inherited defects in phagocyte production or response to inflammatory cytokines are manifested as recurrent infections.^{28,29} HIES also falls into this category (see earlier discussion). A distinctive group of disorders referred to as *Mendelian susceptibility to mycobacterial diseases* (MSMD) involve inherited defects in macrophage IL-12/23-dependent IFN- γ -mediated immunity. Macrophage production of IL-12 and IL-23 after ingestion of mycobacteria triggers IFN- γ production by T and NK lymphocytes, which in turn activates crucial genes in macrophages. MSMD (MIM 20990) can be caused by inherited AR, AD, or X-linked defects leading to impaired T-cell production of IFN- γ , expression of the IFN- γ receptor, or downstream signaling, which results in a spectrum of recurrent and severe atypical mycobacterial infections, as well as susceptibility to *Salmonella* and, in some subgroups, viral infections.^{28,29} As mentioned earlier, recessive point mutations in X-linked *CYBB* that selectively impair expression of the NADPH oxidase subunit gp91^{phox} in macrophages but not neutrophils are also considered a subgroup of MSMD.¹³ A variety of genetic defects in a scaffolding protein known as *IKK- γ* or *NEMO* that is important for activation of the nuclear factor kappa-B (NF κ B) signaling pathway have been reported in patients with anhydrotic ectodermal dysplasia and immunodeficiency; affected children have recurrent pyogenic infections with a minimal systemic inflammatory response and can also develop opportunistic infections with atypical mycobacteria or *Pneumocystis carinii*.²⁹ Several other kindred have been described with genetic deficiency of another protein, IRAK-4, important for NF κ B activation by pyogenic bacteria via the Toll-like receptor/IL-1 receptor superfamily. Affected children also had recurrent infections with *S. pneumoniae* and *S. aureus*, and a poor inflammatory response but no dysmorphic features or opportunistic infections. Finally, with the increasing use of low-cost gene sequencing, it is likely that new inherited disorders of phagocyte function will be identified in the coming years.

Patients with glycogen storage disease type Ib (GSD-Ib), which results from absence of a glucose-6-phosphate transporter, have impaired neutrophil functions and neutropenia.³⁰ Neutrophil defects include depressed chemotaxis, phagocytosis, and NADPH oxidase activity. Although neutropenia appears to result from increased neutrophil apoptosis, how impaired glucose homeostasis leads to

Management of Infections

The management of infections in patients with primary neutrophil dysfunction syndromes is quite different than in the normal population, and for the most part different from patients with neutropenias.

- Patients tend to present with relatively low fevers and chronic inflammatory processes associated with marked elevation of ESR and CRP. Unless they have untreated abscesses or inflammatory masses, they tend not to present with frank sepsis and positive blood cultures.
- The frequency of infections decreases somewhat with age in children as their normal T-cell and B-cell-mediated immunity develops.
- Although one should always attempt to obtain culture proof of an infection, more often than not, it is not possible to identify an organism, and it is necessary to treat empirically.
- Because these patients tend to develop deep-seated tissue infections, the ESR can be of great value even though it is quite nonspecific. Elevation in the ESR suggests deep tissue inflammation; CRP is more acute and suggests monocyte activation. Persistent significant elevation of the ESR (>15–20 mm/hour) even in the absence of fever or other symptoms may warrant radiologic search for deep-seated infection.
- The authors advocate an “antibiotic sensitivity by ESR response” approach to empiric therapy in stable patients. One can start at parenteral anti-*Staphylococcus* and gram-negative therapy, and monitor the ESR daily. A monotonic decrease in the ESR within several days that is clear-cut suggests the process is sensitive to the antibiotic selected. Although complete resolution

of inflammatory response may take many weeks, usually there is some clear change in the ESR within 1 week. If there is worsening or no clear response, then an antifungal can be added and the ESR monitored in the same fashion. Return of an elevated ESR can be a sign of development of organism resistance.

- If a patient with CGD is particularly ill appearing or febrile, it is important to make sure that *B. cepacia* complex bacteria are covered.
- There is no fixed duration of therapy for any infections in these patients. If the infections are not completely extinguished, they will return and will contribute to development of chronic pulmonary and hepatic fibrosis. Parenteral antibiotics or antibiotics that can deliver very high tissue levels should be continued significantly past normalization of the ESR and disappearance of any radiographic evidence of deep tissue infection. This can take many months for some pneumonias and liver abscesses.
- Short pulses of steroids (4–6 days) can be lifesaving, particularly for pulmonary infections in young children with CGD. They reduce airway inflammation and promote drainage.
- Young children are susceptible to infections with routine childhood viruses and infections, and tend to do well with standard therapeutic approaches and courses of treatment that are two- to three-times longer than the usual recommended course. Again, monitoring with the ESR can be a guide.

All standard childhood immunizations and influenza vaccinations are strongly recommended. Prophylactic antibiotics may be appropriate (see text).

abnormal neutrophil function is uncertain. Interestingly, the BM in the face of neutropenia shows marked hypercellularity with increased mature neutrophils in some patients. The neutrophil count increases within hours of granulocyte colony-stimulating factor (G-CSF) administration, suggesting it is acting in part by releasing neutrophils from the BM. GSD-1b patients can have infections as well as inflammatory bowel disease. Therefore, in addition to management of the metabolic disruption, these patients are also often treated with G-CSF to improve neutropenia.

There are a variety of noncongenital defects in phagocyte function that can be associated with an increased risk of bacterial or fungal infection.^{2,3} Several have already been mentioned, including neonatal neutrophil dysfunction manifested as poor adhesion and chemotaxis. Patients with myelodysplastic syndromes and acute nonlymphoblastic lymphoma can have subpopulations of neutrophils variably defective in adhesion, migration, and production of reactive oxidants, and microbicidal activity that has correlated with an increased risk of infection. Similar defects have been described in diabetes mellitus, Gaucher disease, and renal failure. Severe bacterial infections, surgical trauma, and severe burns can also result in transient depression of a variety of neutrophil functions. The underlying mechanism(s) are incompletely defined and may be related to effects of high levels of inflammatory mediators produced in response to infection or trauma or to products released by bacteria.

CONGENITAL DISORDERS OF LYMPHOCYTE FUNCTION

Sung-Yun Pai and Luigi D. Notarangelo

Over 200 molecular defects that result in primary immune deficiency are known to date. Many of these gene defects have been identified in recent years with the advent of whole-exome and whole-genome sequencing. The study of patients with primary immune deficiencies has unraveled fundamental mechanisms that govern lymphocyte development and function. Importantly, characterization of the molecular basis of these diseases has revealed unanticipated heterogeneity of the clinical and immunological phenotype. This chapter reviews disorders of thymus organogenesis, severe combined immune deficiency (SCID), other combined immunodeficiencies, disorders with immune dysregulation, and defects of humoral immunity.

DEFECTS OF THYMUS ORGANOGENESIS

The thymus is the primary organ where T lymphocytes are generated and educated. Endoderm-derived thymic stem cells derived from the third pharyngeal pouch differentiate into cortical and medullary epithelial cells, which in turn induce the differentiation of hematopoietic precursors into T cells. Thus, defects of thymus organogenesis have important consequences on immune function.

DiGeorge Syndrome

DiGeorge syndrome (DGS) is caused by developmental anomalies of the third and fourth pharyngeal pouches, and is characterized by thymic hypoplasia, hypoparathyroidism, conotruncal heart malformation (especially interrupted aortic arch type B or truncus *arteriosus*), and facial dysmorphisms (micrognathia, hypertelorism, antimongoloid slant of the eyes, cleft palate, and ear malformations). Hypocalcemic seizures are common. Feeding problems, microcephaly, speech delay, neurobehavioral problems (including bipolar disorders, autistic spectrum disorders, and schizophrenia later in life), and scoliosis are frequently observed.

Between 50% and 90% of patients with DGS carry a hemizygous deletion of chromosome 22q11, which occurs in ~1:3000 newborns, most arising *de novo*. Fluorescent in situ hybridization readily identifies the 22q11del in most cases. More rarely, DGS is associated with CHARGE syndrome, chromosome 10p deletion, or with mutations of the *TBX1* gene, contained within the 22q11 interval.

Most patients have “partial DGS”, manifested by mild T-cell lymphopenia and immunodeficiency. Such patients may be asymptomatic, may have oral thrush and recurrent infections, or may develop autoimmune disease such as juvenile idiopathic arthritis, immune thrombocytopenic purpura, and Raynaud phenomenon. Approximately 1% of DGS patients have “complete DGS”, with absence of circulating T cells. Some DGS patients may develop low numbers of oligoclonal T lymphocytes that undergo activation *in vivo* and infiltrate target tissues, causing skin rash, liver dysfunction, and lymphadenopathy. This condition is known as complete atypical DGS.

Treatment of DGS includes correction of severe heart defects, and supplementation with calcium and vitamin D for hypocalcemia. If a significant immune defect is present, prophylaxis of *Pneumocystis jiroveci* pneumonia with trimethoprim-sulfamethoxazole (TMP-SMZ) is indicated. Live-attenuated vaccines can be safely administered to

patients with partial DGS who have good cellular immunity (with CD8⁺ count >300 cells/μL); however, these vaccines are contraindicated in patients with complete DGS. Use of immunosuppressive drugs is indicated in patients with complete atypical form of the disease.

Ultimately, survival in patients with complete DGS requires immune reconstitution. Bone marrow transplantation from human leukocyte antigen (HLA)-identical donors may allow engraftment of mature T cells contained in the graft. However, because of the absence of thymic tissue, no newly developed T cells are generated, and the patient may remain susceptible to pathogens that are not recognized by donor-derived T cells contained in the graft.

By contrast, thymic transplantation represents the treatment of choice for patients with complete DGS, including the atypical variant. The thymus obtained as discarded tissue from unrelated infants undergoing heart surgery is sliced and cultured *in vitro*, then implanted in the quadriceps muscles of the infant. Using this approach, 36 out of 50 infants with complete DGS treated by Dr. Markert at Duke University were reported to survive. In most cases, naive T cells appear at around 4–7 months of age; these cells are tolerant to donor thymic cells, display a polyclonal repertoire, and have normal proliferative capacity. Although the number of CD3⁺ T cells in transplanted patients often remains lower than normal, their diversity and function is sufficient to prevent life-threatening infections.

FOXN1 Deficiency

The transcription factor FOXN1 (whose gene is mutated in the *nude* mouse) plays a critical role in thymus and eccrine glands development. *FOXN1* mutations in humans cause athymia, profound T-cell lymphopenia, alopecia totalis, and nail dystrophy. Similar to DGS, reconstitution of T-cell immunity can be achieved with thymic transplantation.

CHARGE Syndrome

This syndrome is characterized by the association of coloboma, heart anomalies, choanal atresia, mental retardation, genital and ear anomalies, and immunodeficiency. Most cases are sporadic, and represent *de novo* mutations of the *CHD7* or of the *SEMA3E* genes; less frequently, the disease is inherited as an autosomal dominant trait. The immunodeficiency is secondary to defects of thymic development. There is a variable degree of T-cell lymphopenia, which in some cases is very severe, resembling SCID.

SEVERE COMBINED IMMUNE DEFICIENCY DUE TO EARLY DEFECTS IN T LYMPHOCYTE DEVELOPMENT

SCID, the most severe form of congenital immunodeficiency, is caused by defects that completely abrogate the development of T lymphocytes, and in some cases also that of B and/or natural killer (NK) lymphocytes. Advances in the genes responsible, newborn screening, and gene therapy have had a strong impact on diagnosis and therapy of SCID.

Fig. 51.1 GENETIC DEFECTS ASSOCIATED WITH SEVERE COMBINED IMMUNE DEFICIENCY. Schematic representation of blocks (arrows) in lymphoid development associated with genetic defects responsible for SCID. Dashed line indicates that the generation of NK lymphocytes is compromised in γ_c and JAK3 deficiency, but not in IL7R deficiency. ADA, Adenosine deaminase; AK2, adenylate kinase 2; B, B-cell; Bp, B-cell progenitor; CLP, common lymphoid progenitor; DN, double-negative thymocyte; DNA-PKcs, DNA protein kinase catalytic subunit; DP, double-positive thymocyte; γ_c , common gamma chain; HSC, hematopoietic stem cell; IL7R, interleukin-7 receptor; JAK3, Janus-associated kinase 3; LIG4, DNA ligase IV; NK, natural killer cell; NKp, natural killer cell progenitor cell; PNP, purine nucleoside phosphorylase; RAG, recombinaase activating gene; T/NKp, common progenitor of T and natural killer lymphocytes; TRAC, T-cell receptor alpha constant chain.

Pathobiology and Genetics

Genetic defects that cause SCID affect various stages in T-cell development (Fig. 51.1), and can be grouped into three major categories: (1) defects in cytokine receptor signaling; (2) defects in lymphocyte survival; and (3) defects of expression and function of the pre-T-cell receptor

causes cell death and results in extreme lymphopenia, with virtual absence of T, B, and NK lymphocytes. Reticular dysgenesis (RD) is a form of SCID characterized by the association of severe lymphopenia, agranulocytosis, and sensorineural deafness. RD is caused by defects in adenylate kinase 2 (AK2), resulting in increased sensitivity to reactive oxygen species and increased apoptosis.

Cytokine Receptor Signaling Defects

The most common form of SCID in humans is the X-linked form due to mutations of the *IL2RG* gene, which encodes for the common gamma chain (γ_c). This protein is shared by receptors for interleukin (IL)-2, IL-4, IL-7, IL-9, IL-15, and IL-21, and signals through the intracellular kinase Janus-activated kinase (JAK)3. Patients with mutations in *IL2RG* or *JAK3* lack both T and NK cells, because development of these subsets depends on IL-7- and IL-15-mediated signaling, respectively. B lymphocytes are present but antibody production is impaired because of the lack of T cells and of defective signaling through IL-21R.

Defects in Lymphocyte Survival

Proliferation and survival of lymphoid progenitor cells are essential to permit generation of a normal number of mature lymphocytes. Some forms of SCID are associated with increased apoptosis. Adenosine deaminase (ADA) converts adenosine to inosine (and deoxyadenosine to deoxyinosine). In patients with ADA deficiency, accumulation of toxic phosphorylated derivatives of deoxyadenosine

Defects of Expression and Signaling Through the Pre-T-Cell Receptor and the TCR

Rearrangement of the T-cell receptor (TCR) genes by means of VDJ recombination allows expression of the pre-TCR (composed of the pre-T α and the TCR- β chain), and of mature TCR (either as TCR- $\alpha\beta$ or TCR- $\gamma\delta$).

The lymphoid-specific recombinase-activating genes (RAG) 1 and RAG2 proteins initiate VDJ recombination by recognizing recombination-specific sequences that flank the variable (V), diversity (D), and joining (J) elements of the TCR and of immunoglobulin genes, introducing DNA double-strand breaks. These are then repaired through the ubiquitously expressed nonhomologous end-joining (NHEJ) pathway. Mutations of the *RAG1* and *RAG2* genes, and of genes that encode for Artemis, DNA ligase IV, and DNA-protein kinase Cs (PKCs; all components of the NHEJ pathway), result in SCID with a lack of T and B lymphocytes (see Figs. 51.1 and 51.2), but normal numbers of NK lymphocytes. Mutations of Cernunnos/XLF, another component of the NHEJ pathway, severely impair, but do not completely abrogate, T- and B-cell development. Because NHEJ is involved in general mechanisms of DNA repair also in nonlymphoid cells, patients with defects of this pathway also show

Fig. 51.2 GENETIC DEFECTS ASSOCIATED WITH HYPOGAMMAGLOBULINEMIA. Schematic of B-cell development in bone marrow and secondary lymphoid organs, including migration of B cells into the follicular zone where they undergo activation, class-switch recombination (CSR), and somatic hypermutation (SHM). “X” denotes maturation steps at which the genes indicated are required, resulting in a block in differentiation at that stage when the gene is deficient. *ActB*, Activated B cell; *AID*, activation-induced cytidine deaminase; *BTK*, Bruton’s tyrosine kinase; *HSC*, hematopoietic stem cell; *IGLL*, immunoglobulin light-like chain; *IL-21*, interleukin-21; *immB*, immature B cell (also termed *transitional B cell*); *memB*, memory B cell; *MZ-B*, marginal zone B cell; *PC*, plasma cell; *Pre-B*, precursor B cell; *Pre-BCR*, pre-B-cell receptor; *Pro-B*, progenitor B cell; *RAG1*, recombination activating gene 1; *RAG2*, recombination-activating gene 2; *sIgA*, surface IgA; *sIgD*, surface IgD; *sIgG*, surface IgG; *sIgM*, surface immunoglobulin M; *UNG*, uracil-DNA glycosylase.

increased cellular radiation sensitivity, are at higher risk of tumors, and may present with neurologic problems.

Signaling through the pre-TCR is essential to promote progression from $CD4^+CD8^-$ double-negative (DN) thymocytes to $CD4^+CD8^+$ double-positive (DP) cells, and is mediated by the CD3 complex. Mutations of the $CD3\delta$ (*CD3D*), $CD3\epsilon$ (*CD3E*), and $CD3\zeta$ (*CD3Z*) chains interfere with this process and result in SCID. In contrast, mutations of $CD3\gamma$ (*CD3G*) are more often associated with a milder phenotype that includes autoimmunity. Finally, mutations of the CD45 phosphatase, also involved in cell signaling, cause $T^- B^+$ SCID.

Clinical and Laboratory Manifestations

Typical clinical features of SCID include early-onset severe infections caused by bacteria, viruses, fungi, and opportunistic pathogens (including *P. jiroveci* pneumonia), protracted diarrhea, candidiasis, and failure to thrive. Engraftment of maternally derived T lymphocytes is common in SCID, occurring in 40% to 56% of infants with the disease. It may be asymptomatic or may manifest similarly to graft-versus-host disease (GVHD): skin rash, elevation of liver enzymes, diarrhea, and cytopenias. Hypomorphic mutations in SCID-causing genes may lead to residual development of T cells that undergo peripheral expansion and infiltrate target organs, causing various symptoms (erythroderma, diarrhea, hepatosplenomegaly, lymphadenopathy, diarrhea). This clinical phenotype is also known as *Omenn syndrome*.

Some forms of SCID may present with additional clinical features (see earlier section on Defects in Thymic Development). In patients with ADA deficiency, accumulation of toxic metabolites may cause

cupping and flaring of the ribs, liver dysfunction, sensorineural deafness and neurobehavioral problems. Microcephaly is typically seen in forms of SCID associated with cellular radiosensitivity and impairment of DNA double-strand break repair. Sensorineural deafness is observed in RD.

Family history (including consanguinity, deaths in infancy, and gender of other affected family members) may be suggestive of X-linked versus autosomal recessive inheritance. Measurement of absolute lymphocyte count (ALC) and the absolute number of $CD3^+$ T lymphocytes, $CD4^+$ and $CD8^+$ T-cell subsets, $CD19^+$ B lymphocytes, and NK ($CD16^+/CD56^+$ NK lymphocytes) confirms the diagnosis and may direct the work-up towards specific gene defects. The presence of $CD3^+$ cells in a child with clear clinical manifestations of SCID may indicate maternal T-cell engraftment or with hypomorphic mutations that allow residual T-cell development. In both of these situations, the T cells have an activated/memory ($CD45RO^+$), whereas T cells in normal infants are predominantly naive ($CD45RA^+$). In vitro proliferative response to mitogens is drastically reduced in patients with SCID, but may be partially preserved in infants with Omenn syndrome. Other diagnostic tests that may support the diagnosis of SCID include lack of a thymic shadow at chest x-ray, and low or undetectable serum IgA and IgM. IgG serum levels may be normal early in life, reflecting the transplacental passage of maternally derived antibodies.

Diagnosis by Universal Newborn Screening

SCID can be diagnosed at birth by measuring levels of TCR excision circles (TRECs). TRECs are a byproduct of V(D)J recombination and are present as circularized DNA fragments in newly generated,

Diagnostic Approach to Severe Combined Immune Deficiency

- SCID presents early in life with severe infections of bacterial, viral, or fungal origin.
- Opportunistic infections are common in infants with SCID.
- Respiratory infections, protracted diarrhea, and failure to thrive are typical signs at presentation.
- Lymphopenia is present in 50% to 70% of infants with SCID. Age-specific norms must be used in evaluating the ALC as infants and children have much higher ALCs than adults (3500–13,000 in very young infants versus 1000–2800 in adults).
- T-cell lymphopenia is the hallmark of the disease; abnormalities of the absolute count of B and NK lymphocytes are observed in some forms of SCID. However, T lymphocytes may be present in SCID infants with maternal T-cell engraftment or with hypomorphic mutations in SCID-associated genes that allow residual T-cell development. Thus, a normal ALC does not rule out SCID.
- Maternally engrafted T cells proliferate in the infant with SCID in vivo, but the vast majority do not proliferate in vitro when stimulated with traditionally used mitogens such as concanavalin A and phytohemagglutinin, as measured by thymidine incorporation. Thus, if SCID is suspected, but T cells are detectable, maternal engraftment studies and proliferation to mitogens must be sent.
- Universal newborn screening has now been implemented in the majority of states in the United States. The analyte is detection of TRECs by quantitative PCR. TRECs are high in newly generated T cells and low when T cells are absent or when maternally engrafted T cells are present.
- SCID is genetically heterogeneous. The most common form in Western countries is inherited as an X-linked trait and is T-B⁺NK⁻.
- The lack of all lymphocytes (T-B⁻NK⁻ SCID) is highly suspicious for the ADA form of SCID, in which toxic metabolites result in death of all lymphocytes. Testing for ADA enzyme level is critical, because if confirmed to be absent, treatment with PEG-ADA can often result in sufficient reconstitution of T-cell immunity to protect the baby from infection.

naive T lymphocytes that express the $\alpha\beta$ form of the TCR. Levels of TRECs in circulating lymphocytes are particularly high in newborns and infants, and can be detected by PCR amplification of DNA extracted from the Guthrie card. Newborn screening was recommended for addition to the standard panel in the United States in 2010, and in 2015 >70% of births were screened for SCID. Based on screening of ~3,000,000 infants in the United States, the incidence of SCID is now estimated to be 1 in 58,000 births, higher than with clinical screening alone.

Prognosis, Therapy and Future Directions

Supportive Management

Management of SCID includes observance of strict hygiene measures, prevention of *P. jirovecii* pneumonia with TMP-SMZ, prompt investigation and aggressive treatment of infections, immunoglobulin replacement, and adequate support with enteral or parenteral nutrition. Infections caused by cytomegalovirus (CMV; causing interstitial pneumonia, hepatitis and/or gastroenteritis) and Epstein-Barr virus (EBV; causing lymphoproliferative disease) require active surveillance and preemptive therapy. To prevent transmission of viral infection, blood products from CMV-seronegative donors or leukofiltered products should be used, and must be irradiated to prevent transfusion-associated GVHD. Immunosuppression with steroids and cyclosporine A may be needed to treat GVHD-like manifestations associated with Omenn syndrome or maternal T-cell engraftment. Administration of live vaccines must be avoided in infants with SCID. In spite of these measures, SCID is inevitably fatal within the first few years of life, unless immune reconstitution is achieved with treatment.

Ultimately, infants with SCID should be evaluated for specific gene defects. However, definitive treatment of SCID (typically by hematopoietic cell transplantation; HCT) should not await demonstration of a specific gene defect, as this may take some time. An exception to this general principle is ADA deficiency that can be easily diagnosed by measuring enzyme activity in red blood cells, allowing prompt initiation of enzyme-replacement therapy (ERT), which improves lymphocyte counts. Weekly intramuscular injection of pegylated bovine ADA acts extracellularly to transform adenosine and deoxyadenosine into inosine and deoxyinosine, respectively, thus preventing accumulation of toxic phosphorylated derivatives. Disadvantages of ERT include expense, as it must be continued indefinitely, waning of therapeutic effect over time, and the development in some patients of neutralizing antibodies to PEG-ADA.

General Principles of Hematopoietic Cell Transplantation for SCID

HCT is the standard treatment that promotes long-term immune reconstitution in infants with SCID. HCT for other conditions is generally performed with chemotherapy or radiation conditioning, to prevent graft rejection and eliminate or reduce host hematopoietic stem cells (HSCs), favoring donor hematopoiesis. Because of the lack of T lymphocytes, infants with SCID (especially the NK⁻ forms) are generally considered to have an inherent inability to reject the graft, and may therefore receive HCT from an HLA-identical related donor (sibling) without conditioning. T-cell reconstitution in this case is generally prompt, with initial reconstitution in the first 1–3 months mediated by expansion of mature T cells present in the donor bone marrow, and later reconstitution derived from newly generated T cells that mature in the thymus from donor HSC and progenitors. GVHD prophylaxis is not needed. Unconditioned HCT may also be performed from mismatched related donors (parent), with T-cell depletion of the graft to avoid fatal GVHD. Here the reconstitution is slower, since the generation of T cells is entirely dependent on thymic ontogeny and can take 4–6 months. Engraftment of T cells may not always occur in this setting and up to 25% of patients may require repeat transplantation. GVHD prophylaxis is not needed if the T-cell depletion is sufficiently rigorous. These approaches to HCT without conditioning can lead to sustained T-cell immune reconstitution because of the selective advantage for donor cells differentiating into the T lineage. However, this approach rarely results in significant donor HSC engraftment, which is generally <1%, and thus may fail to correct impairment of humoral immunity.

HCT from matched unrelated adult or cord blood donors has been generally performed with myeloablative conditioning, similar to that used for other nonmalignant disorders. As in the case of sibling donor HCT, memory T cells present in the graft after unrelated adult donor HCT may provide some initial protection against infection (according to their antigen specificity). In contrast, the naive T lymphocytes contained within cord blood provide little antigen-specific immunity early after HCT. Conditioning prior to unrelated donor HCT, or prior to mismatched related HCT, improves the rate of HSC engraftment, but results in short-term and long-term toxicity and increased risk of GVHD. Reduced-intensity conditioning regimens have been proposed with the aim to facilitate stem cell engraftment while reducing the risk of treatment-related toxicity; however, there is no clear evidence that such regimens are associated with better outcome in patients with SCID treated by HCT.

Survival and Long-Term Outcomes After HCT for SCID

While survival after HCT for SCID has improved with time due to advances in early diagnosis and supportive care for infants with SCID, donor type, the presence of infection, and subtype of SCID remain important determinants of outcome. Studies of 10-year survival in 699 infants with SCID in Europe and 5-year survival in 240

infants with SCID in North America confirm excellent survival of 90% and 94%, respectively, after matched sibling donor HCT. Outcomes after mismatched related, unrelated adult volunteer, and umbilical cord blood HCT have improved, although a clear advantage of one alternative donor versus another has not been demonstrated. Mismatched related donor HCT performed without conditioning may be associated with better survival than when conditioning is given.

Respiratory infections and older age at the time of transplant have long been associated with poorer outcome. Infants older than 3.5 months at the time of HCT who have never had infection or had infections that were amenable to treatment prior to HCT interestingly have similar survival to infants younger than 3.5 months at the time of HCT. Among infants who were not actively infected at the time of HCT, survival was very good even for alternative donor recipients. These results suggest that early diagnosis and protection of infection, i.e., through newborn screening, would improve survival significantly. The specific type of SCID also affects outcome: survival after HCT is better in patients with B⁺ than B⁻ SCID.

In infants with SCID, long-term T-cell reconstitution may be achieved in the absence of conditioning and the absence of engraftment of donor-derived stem cells, due to engraftment of committed lymphoid progenitors that seed the thymus. Consistent with this, donor T-cell chimerism and T-cell reconstitution after HCT are achieved in >90% of infants with SCID and the majority have a polyclonal repertoire. The durability of T-cell reconstitution in the absence of conditioning is variable, and some reports have indicated a progressive decline of thymic function after HCT for SCID. Such reports are supported by the finding that survivors after HCT performed with conditioning have higher T-cell counts and higher naive CD4⁺ CD45RA⁺ T-cell counts than those after HCT performed without conditioning. Reconstitution of humoral immunity after HCT for SCID is less uniform; for genetic subtypes that affect B-cell development or function, engraftment of donor B cells is typically required for humoral immune reconstitution. For example, inadequate B-cell function (requiring immunoglobulin-replacement therapy) is often observed in patients with γ c and JAK3 deficiency who remain with autologous B cells, due to intrinsic defects in the host B cells' response to γ c-dependent cytokines such as IL-4 and IL-21. The number of circulating NK lymphocytes often remains low in patients with γ c and JAK3 deficiency, and may contribute to the increased risk of warts.

Rates of acute GVHD (aGVHD) are generally low, ~20%, largely limited to recipients of alternative donor HCT. Patients with poor T-cell reconstitution are at risk for viral and opportunistic infections; autoimmunity (especially cytopenias and hypothyroidism) has been reported in 10% to 20% of these patients, particularly in those with cGVHD. Other long-term complications include nutritional problems, poor growth and development, and neurologic complications (mental retardation, motor dysfunction, sensorineural hearing deficits). Some of these complications are more common in certain subtypes, particularly growth in patients with Artemis-SCID and neurologic problems in patients with ADA deficiency.

Gene Therapy for SCID

Gene therapy, in which the gene of interest is introduced into the patient's own cells, is an attractive therapeutic option for SCID, in particular for infants who do not have an HLA-identical related donor. Expression of the normal copy of the gene in CD34⁺ stem cells confers a selective advantage to the gene-corrected cells during T-cell differentiation. Furthermore, there is no risk of GVHD. Gene therapy has been used successfully to correct SCID in patients with ADA deficiency and with X-linked SCID.

Since the year 2000, more than 70 patients with ADA-deficient SCID have been treated with gene therapy worldwide. Published reports from Milan (Italy), London (United Kingdom) and the United States have collectively described 26 patients who received autologous CD34⁺ progenitor cells transduced with gammaretroviral

Therapeutic Approach to Severe Combined Immune Deficiency

- HSC transplantation is the mainstay of treatment. Optimal survival is achieved when the transplant is performed early in life. This is now possible with newborn screening.
- Transplantation for SCID can be performed without conditioning, due to the profound absence of T cells and inability to reject. Thus, the bone marrow of a fully HLA-matched sibling can be infused without manipulation and without giving any conditioning to the baby. GVHD prophylaxis is also not necessary. Haploidentical bone marrow from a parent can also be infused without conditioning but must first be T-cell depleted.
- Such transplants without conditioning can result in T-cell reconstitution that lasts for decades. In the case of a matched sibling graft, initial T-cell reconstitution is rapid, generally within the first 1–3 months, due to proliferation of mature T cells. In the case of a haploidentical graft, mature T cells are removed and thus 4–6 months is required for HSC to develop and emerge from the thymus as mature T cells.
- Without conditioning, only a low number of donor-derived long-lived HSCs engraft, and this may lead to lack of donor B-cell reconstitution and lack of humoral immunity. With conditioning, donor HSCs are more likely to engraft and give rise to donor B cells. Currently, matched unrelated donor transplants are performed with conditioning.
- Enzyme replacement may be used in patients with adenosine deaminase deficiency. Gene therapy has offered promising results; however, it is also associated with increased risk of leukemic proliferation due to insertional mutagenesis.

vectors expressing the ADA complementary (c)DNA. All are alive, with sustained production of gene marked T, B and myeloid cells, and the majority of patients have been able to stop ERT. In all trials, engraftment of gene-corrected stem cells has been facilitated by the use of a reduced-intensity chemotherapy regimen with low-dose busulfan.

Twenty patients with X-linked SCID were treated by gene therapy using a gammaretroviral vector in Paris and London at the turn of the century, without chemotherapy conditioning. Eighteen patients are alive, and 17 of them show normalization of T-cell count and function, with sustained thymic output, diversified T-cell repertoire, and ability to mount antigen-specific T-cell responses. In a few cases, improvement of humoral immunity has also been observed. However, leukemic T-cell proliferation due to insertional mutagenesis was observed in 5 out of 20 patients. A modified self-inactivating gammaretroviral vector based on the previously mentioned parent vector has now been reported to be efficacious in nine patients with X-linked SCID in a multicenter trial. Preliminary evidence from this trial suggests that deletion of viral enhancers has decreased expansion of clones bearing insertion sites near lymphoid protooncogenes, suggesting an improved safety profile with regard to leukemogenesis. Self-inactivating lentiviral vectors based on HIV are being developed and/or tested in both ADA and X-linked SCID.

OTHER COMBINED IMMUNODEFICIENCIES

Defects of TCR Signaling

Several forms of combined immune deficiency are caused by genetic defects that affect molecules involved in TCR signaling. In particular, the T lymphocyte-specific protein tyrosine kinase (Lck) associates with CD4 and CD8 molecules and mediates phosphorylation of CD3 chains upon TCR engagement. The Zeta-associated protein of 70 kDa (ZAP-70) tyrosine kinase phosphorylates the CD3 chains, thus promoting downstream TCR signaling. RHOH is an atypical Rho GTPase that participates in receptor-induced signaling in hematopoietic cells. The IL-2-inducible tyrosine kinase (ITK) is a member of the thymic epithelial cell (TEC) family of nonreceptor tyrosine kinases, and modulates the strength of the TCR-induced

signal. The serine-threonine protein kinase 4 (STK4) protein induces the transcriptional coactivation of target genes involved in cell proliferation and survival, and is involved in the control of cell death.

At variance with typical forms of SCID, genetic defects of TCR signaling are characterized by residual number and/or function of T cells, consistent with partially preserved thymic architecture and function. Since the thymus of these patients is not empty, the use of chemotherapy is required to facilitate engraftment and T-cell differentiation with donor-derived cells. The immunological phenotype of ZAP-70 deficiency in humans is characterized by a virtual lack of CD8⁺ lymphocytes; the number of CD4⁺ cells is preserved, but they are unable to proliferate in response to mitogens and antigens. In contrast, both CD4⁺ and CD8⁺ lymphocytes are absent in *Zap70*^{-/-} mice.

Both RHOH and STK4 deficiencies are characterized by a reduced number of naive T cells, an increased proportion of effector memory T cells (including CD8⁺ cells with an “exhausted” CD45RA⁺CCR7⁻ phenotype), and defective lymphocyte proliferation. CD4 lymphopenia and low levels of CD4 and CD8 surface expression have been reported in one patient with LCK deficiency. Progressive CD4 lymphopenia is also commonly seen in patients with ITK deficiency.

All of these forms of impaired TCR signaling are inherited as autosomal recessive traits. Clinically, patients with impaired T-cell signaling present with recurrent, often severe, infections. Cutaneous viral infections are especially common in patients with RHOH and STK4 deficiency. The clinical phenotype of ZAP-70 deficiency is often undistinguishable from SCID; in a few cases, hypomorphic *ZAP70* mutations have been associated with Omenn syndrome. Severe lung disease and a high risk of EBV-driven lymphoproliferation are a hallmark of ITK deficiency. Autoimmune manifestations have been observed in several patients with these disorders. Prevention of infections is based on antimicrobial prophylaxis and use of intravenous immunoglobulins; however, ultimate treatment requires HCT.

Coronin-1A Deficiency

Coronin-1A is involved in reorganization of the actin cytoskeleton that allows egress of thymocytes to the periphery. While complete deficiency of coronin-1A in humans is a cause of SCID, hypomorphic mutations have been associated with severe naive T-cell lymphopenia, oligoclonal expansion of activated T cells, and increased risk of EBV-driven lymphoproliferation.

HLA Class II Deficiency

Expression of HLA class II molecules on the surface of thymic epithelial and dendritic cells is essential to promote positive selection of CD4⁺ lymphocytes. HLA class II deficiency includes a group of autosomal recessive disorders in which mutations in transcription factors (*CIITA*, *RFXAP*, *RFX5*, and *RFXANK*) that regulate HLA class II gene expression result in profoundly reduced numbers of CD4⁺ lymphocytes. The clinical phenotype consists of recurrent infections since infancy. Treatment is based on antimicrobial prophylaxis, regular use of immunoglobulins, and HCT. Persistence of CD4 lymphopenia is often observed after HCT, because transplantation of hematopoietic stem cells does not correct defective expression of HLA class II molecules on the surface of TECs, causing defective positive selection of CD4⁺ lymphocytes.

HLA Class I Deficiency

Presentation of antigens in association with MHC class I molecules is important for thymic development of CD8⁺ lymphocytes and for the development of antigen-specific cytotoxic T-cell responses. In addition, HLA class I molecules also modulate the function of NK

cells that express several HLA class I-binding molecules. HLA class I molecules are assembled and loaded with peptides in the endoplasmic reticulum by transporter associated with antigen presentation (TAP) proteins (TAP1 and TAP2) and the TAP binding or Tapasin protein (TAPBP). Mutations of *TAP1*, *TAP2*, or *TAPBP* cause defective expression of HLA class I molecules, which is associated with a severe reduction in the number of circulating CD8⁺ TCRαβ⁺ lymphocytes. NK cells expressing killer inhibitory receptors may not receive HLA class I-dependent inhibitory signals, and hence may mount cytotoxic responses to uninfected cells, causing inflammatory lesions in the lungs and in the skin. There is no definitive treatment for this disease, and management is based on supportive care.

CD40 Ligand and CD40 Deficiencies

CD40 ligand (CD40LG) is expressed by activated CD4⁺ cells. Interaction of CD40LG-expressing CD4⁺ cells with B lymphocytes that constitutively express CD40 delivers a signal for B-cell proliferation and class-switch recombination in the presence of appropriate cytokines (see Fig. 51.2). Furthermore, interaction between CD40LG-expressing CD4⁺ lymphocytes and CD40⁺ dendritic cells and macrophages promotes secretion of IL-12, and thus enables the development of Th1 responses against intracellular pathogens.

The *CD40LG* gene is located on the X chromosome (at Xq26). Males with *CD40LG* mutations suffer from a combined immunodeficiency characterized by recurrent infections, often caused by opportunistic pathogens. *P. jiroveci* pneumonia classically occurs in the first year of life, but may occur at any age. *Cryptosporidium parvum* infection may cause chronic watery diarrhea and lead to sclerosing cholangitis. Chronic or intermittent neutropenia has been frequently observed. Patients with CD40LG deficiency are also uniquely prone to tumors of the liver and biliary tract.

Levels of serum IgG and IgA are markedly reduced or undetectable; IgM may be normal or increased, and for this reason the disease is also known as *X-linked hyper-IgM syndrome*. The number of memory B cells is also markedly reduced.

In vitro activation of T cells with phorbol myristate acetate and ionomycin fails to induce expression of CD40LG on the surface of CD4⁺ cells, whereas other activation markers (e.g., CD69) are normally expressed.

The prognosis is severe. Death may occur early in life secondary to infections, or during late childhood and young adulthood due to severe liver disease and tumors. Clinical management consists of continuous prophylaxis of *Pneumocystis* infection with TMP-SMZ, regular use of intravenous immunoglobulins, and hygiene measures to limit the risk of exposure to *Cryptosporidium*. HCT is the only definitive cure, with survival of ~70% reported in Europe. Preexisting pulmonary disease and *Cryptosporidium* infection are risk factors for less favorable outcome.

CD40 deficiency is a very rare autosomal recessive disorder, whose clinical and immunological phenotype is indistinguishable from CD40LG deficiency (see Fig. 51.2). The diagnosis is based on the lack of expression of CD40 on the surface of circulating B lymphocytes. Management is as for CD40LG deficiency.

Defects of NF-κB Signaling

The nuclear factor kappa-B (NF-κB) signaling pathway is ubiquitous to all tissues and stages of development, playing critical roles in cell proliferation, oncogenesis, cell survival, and inflammatory responses. Several genetic defects affecting activation of NF-κB have been described that result in combined immune deficiency variably associated with extra-immune manifestations. Hypomorphic mutations in the *IKBKG* gene, which encodes for the NF-κB essential modulator (NEMO; also known as *IKK-γ*), the regulatory subunit of the IκB kinase complex, are inherited as an X-linked trait and represent the prototype of disorders of NF-κB signaling. Complete lack of NEMO expression is embryonically lethal in males; females who are

heterozygous for null NEMO mutations suffer from incontinentia pigmenti. Typically, males with NEMO deficiency present with ectodermal dysplasia and immunodeficiency (EDA-ID). The phenotypic manifestations of EDA-ID are largely restricted to epithelial tissues and the immune system, with sparse hair, shiny skin, lack of sweat glands and other appendages, and rare conical-shaped teeth. There is often frontal bossing and a characteristic facies. Typical infections are caused by bacteria, including sepsis and meningitis, especially *Streptococcus pneumoniae*, *Staphylococcus*, and *Haemophilus influenzae*; DNA viral infections such as CMV and herpes simplex virus (HSV); and atypical mycobacterial infection. Pneumocystis and other opportunistic infections may also occur. Inflammatory colitis is a frequent manifestation of immune dysregulation. Lymphedema and osteopetrosis have been reported in some patients. Occasionally, manifestations of ectodermal dysplasia may be modest or even absent, thus adding to phenotypic heterogeneity. Immunological abnormalities include variable defects in T-cell proliferation to mitogen and antigens, hypogammaglobulinemia with normal or high IgM, defective antibody production (especially against polysaccharides), and impairment of NK-cell cytotoxicity. Finally, monocytes from patients with NEMO deficiency fail to elaborate inflammatory cytokines such as tumor necrosis factor (TNF) α in response to stimulation by a variety of Toll-like receptor ligands. A similar clinical and immunological phenotype is observed in patients with autosomal dominant EDA-ID caused by gain-of-function mutations of the *IKBA* gene. In these patients, the mutated IKB α protein cannot be phosphorylated at residues that are critical for its degradation. This prevents release of the cytoplasmic components of NF- κ B, which cannot translocate to the nucleus and mediate transcription of target genes.

Aside from supportive therapy with intravenous immunoglobulin replacement, antibiotic prophylaxis and treatment of infections, HCT for these disorders has been used with variable success. Because of the role of NF- κ B signaling in nonhematopoietic tissues, certain manifestations of the disease, such as colitis, may not be uniformly ameliorated by HCT.

Mutations of the *IKBKB* gene are responsible for an autosomal recessive disease, characterized by a SCID-like phenotype without ectodermal dystrophy. Patients lack regulatory T cells and TCR $\gamma\delta^+$ T cells. The *MAP3K14* gene encodes for NIK, a component of the noncanonical NF- κ B signaling pathway. Patients with NIK deficiency suffer from recurrent infections. Immunological abnormalities include reduced T-cell proliferation, hypogammaglobulinemia with reduced number of total and switched memory B cells, and NK deficiency.

The CARD11–BCL10–MALT1 complex regulates NF- κ B signaling. Deficiency of any of these proteins causes combined immune deficiency with increased susceptibility to infections. T-cell proliferation is impaired. Defective antibody responses are observed in patients with BCL10 and CARD11 deficiency; the latter condition is also characterized by an increase in the proportion of transitional B cells.

DOCK2 Deficiency

The dedicator of cytokinesis (DOCK) proteins are atypical guanine exchange factors containing a phosphatidylinositol (3,4,5)-triphosphate (PIP3) binding domain and a Rho-family GTPase binding domain with guanine exchange factor activity. DOCK2 is predominantly expressed in various hematopoietic cell lineages (including T, B, NK, and NKT lymphocytes, as well as granulocytes and other myeloid cells), and is activated in response to engagement of the TCR, BCR, and chemokine receptors. DOCK2 activation allows formation of GTP-Rac1, thereby promoting reorganization of the cellular cytoskeleton, and intracellular signaling. DOCK2 deficiency is an autosomal recessive combined immunodeficiency characterized by increased susceptibility to severe infections starting early in life. Severe varicella has been reported in multiple patients. T-cell lymphopenia, with marked reduction of naive T cells and impaired T-cell proliferation, defective antibody responses, reduced NK cell function,

poor migration of T and B lymphocytes in response to chemokines, NKT-cell deficiency, and markedly reduced secretion of interferon-alpha (IFN- α) by plasmacytoid dendritic cells represent the major immunological abnormalities. Low TREC levels at birth have been reported in two patients. The prognosis is very severe, but definitive cure may be achieved with HCT. Use of systemic IFN- α may help in the treatment of severe viral infections.

DOCK8 Deficiency

DOCK8 deficiency is an autosomal recessive combined immunodeficiency characterized by severe and recurrent infections, particularly systemic and cutaneous viral infection (molluscum contagiosum, HSV-1 and HSV-2, human papillomavirus), allergic manifestations (early-onset eczema, food allergies) with elevated serum IgE, impaired humoral immunity (with frequent sinopulmonary infections), and increased risk for squamous cell carcinoma and lymphoma. Large intragenic deletions account for the majority of the mutations. Affected patients have low numbers of naive CD8 T cells, and accumulation of CD8 memory cells with an “exhausted phenotype”. A profound impairment in the generation of CD8 $^+$ memory T cells in response to influenza or other viral infections has been reported. Humoral immunity is also compromised, with loss of germinal center B cells and defective immunoglobulin affinity maturation. The disease has a severe prognosis, with considerable mortality. HCT represents the only definitive treatment. Use of systemic IFN- α may ameliorate manifestations of severe cutaneous viral infection.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is an X-linked disorder, characterized by thrombocytopenia with small-sized platelets, eczema, and immunodeficiency. Autoimmune manifestations are common, and there is an increased risk of hematologic malignancies (primarily non-Hodgkin lymphoma, sometimes EBV driven). The estimated incidence is 1 in 100,000 births. The defect is due to mutations in the *WAS* gene, which encodes for an intracytoplasmic protein (WAS protein [WASp]) expressed in hematopoietic cells and involved in cytoskeleton reorganization and immune synapse formation. Deficiency of WASp results in impaired T-cell activation, poor production of antibodies, particularly to carbohydrate antigen, defective NK function, impaired phagocytic cell migration, and defective antigen presentation, thus explaining the immunodeficiency of the disease.

The clinical phenotype may range from typical and severe WAS to isolated thrombocytopenia; milder phenotypes are often associated with residual expression of WASp. Rarely, mutations occurring in the GTPase binding domain of the protein results in a hyperactive form of WASp, resulting in X-linked neutropenia and myelodysplasia without thrombocytopenia, eczema, or immunodeficiency.

Boys with WAS typically present in infancy with bleeding, prompting the discovery of low numbers of platelets with a low mean platelet volume. Bleeding manifestations can range from petechiae and bruising, to severe gastrointestinal and intracranial hemorrhages. Eczema can be mild to severe. Common infections in WAS patients include otitis, sinusitis, pneumonia, and cellulitis. Viral infections (especially from herpesviruses, including CMV, EBV, and HSV-1) and opportunistic infections, such as *P. jiroveci* pneumonia, are also frequent. Approximately 40% of patients with WAS develop autoimmunity, including autoimmune hemolytic anemia, autoimmune thrombocytopenia, thyroiditis, colitis, vasculitis, nephropathy, and arthritis. In addition to thrombocytopenia, typical laboratory findings include inability to mount responses to polysaccharide antigens, low or absent isohemagglutinin titers, high IgE, and poor proliferation of T cells when stimulated with anti-CD3 antibody. Other immune findings are more variable, including progressive T lymphopenia with age, low IgM, and high IgA. Analysis of WASp expression and demonstration of *WAS* gene mutations confirm the diagnosis.

Supportive treatment for WAS consists of monitoring and treatment for bleeding, antimicrobial prophylaxis, immunoglobulin-replacement therapy, and treatment of eczema and autoimmune manifestations with immunosuppressive drugs. Splenectomy can be effective in many to correct thrombocytopenia, but leads to increased risk of sepsis.

Allogeneic HCT (typically with myeloablative regimens) for WAS has become standard at many institutions, and may be indicated early in life, especially in patients with severe mutations that abrogate protein expression.

HCT is usually associated with robust T-cell engraftment, whereas some patients develop mixed chimerism in the B and myeloid lineages, indicating differential requirement for normal WAS protein to promote lineage-specific development or survival. Poor myeloid chimerism is associated with the risk of persistent thrombocytopenia, and mixed chimerism favors autoimmune manifestations.

Survival after HCT for WAS is influenced by donor type and age at transplantation. Optimal results, with approximately 90% survival, are obtained after HCT from an HLA-identical sibling donor. Results of HCT from matched unrelated donors are superior if the transplant is performed at a young age (<5 years), but are good overall even when the transplant is performed later in life. However, mixed chimerism may be associated with increased risk of autoimmunity, and low myeloid chimerism with persistence of thrombocytopenia.

Because outcome after HCT is not uniformly good and many patients lack matched related or unrelated donors, somatic gene therapy is an attractive treatment option for WAS. In a first trial, 10 boys with WAS were treated with gene therapy by transduction of CD34⁺-selected peripheral blood stem cells using a murine leukemia virus-based gammaretroviral vector after low-dose busulfan conditioning. Immune reconstitution was attained in nine patients; however, seven of these developed leukemia due to insertional mutagenesis. More recently, gene therapy for WAS has been performed using a self-inactivating lentiviral vector. Results show good immune reconstitution and improved safety (with no leukemic events reported); however, the platelet count, although increased, remains abnormally low in most patients.

COMBINED IMMUNODEFICIENCIES WITH OSSEOUS DYSPLASIA

Cartilage hair hypoplasia (CHH) is an autosomal recessive disorder characterized by short-limbed dwarfism, hair abnormalities, increased risk of bone marrow dysplasia, malignancies and Hirschsprung disease, and a variable degree of immunodeficiency. The majority of patients show susceptibility to bacterial and viral infections; however, some may present with SCID, Omenn syndrome, or selective deficiency of CD8⁺ cells. The disease is more common among certain ethnic groups (the Amish populations and the Finns), and is caused by mutations of the gene encoding for the untranslated RNA component of the ribonuclease mitochondrial RNA processing (*RMRP*) complex, which is involved in cleavage of ribosomal RNA, processing of mitochondrial RNA, and cell cycle control. Management of the immunologic problems in CHH depends on their severity. HCT may be indicated in cases with severe T lymphocyte defects.

Schimke immunoosseous dysplasia is an autosomal recessive disorder that also combines immunologic and skeletal abnormalities. These children have short stature, skeletal dysplasia, renal dysfunction and T-cell immunodeficiency caused by mutations in the *SMARCA1* gene.

OTHER COMBINED IMMUNODEFICIENCIES

Mutations of ICOS, a molecule expressed by activated T cells, were initially thought to cause a common variable immune deficiency (CVID)-like phenotype, but have more recently been shown to cause combined immune deficiency, with recurrent infections of the respiratory and gastrointestinal tracts, and autoimmunity.

Hepatic venoocclusive disease with immunodeficiency is an autosomal recessive condition caused by mutations of the *SP110* gene. In addition to liver disease, patients are highly prone to infections that are often sustained by opportunistic pathogens (CMV, *Candida*, *P. jiroveci*). Cerebrospinal leukodystrophy has been observed in several cases. The disease is rapidly fatal, unless treated by HCT.

Autosomal recessive combined immune deficiency with intestinal atresias is caused by mutations in the *TTC7A* gene, which encodes for a protein involved in maintaining cell polarity in epithelial cells. Variable, but often severe, lymphopenia and panhypogammaglobulinemia are typical immunological abnormalities. The prognosis is generally severe and is determined by the severity of the gastrointestinal involvement and of immune deficiency. Small-bowel transplantation is often necessary. In patients with profound immune deficiency HCT may be required; however, limited data are available on long-term outcome.

The cytidine triphosphate synthase 1 (CTPS1) protein is essential for lymphocyte proliferation. Patients with CTPS1 deficiency have a high risk of recurrent and chronic infections (especially those due to herpesviruses), and of EBV-related lymphoma.

A very high risk of EBV-induced lymphoproliferative disease is also observed in patients with CD27 deficiency, who may also present with signs of hemophagocytic lymphohistiocytosis (HLH). These patients lack memory B cells and often develop hypogammaglobulinemia after EBV infection.

Finally, EBV-associated lymphoma is a common manifestation in patients with magnesium transporter type 1 (MAGT1) deficiency. This condition is inherited as an X-linked trait. The number of naive CD4⁺ T cells is reduced, and expression of NKG2D, an important activating molecule, on the surface of CD8⁺ cytotoxic T cells and NK lymphocytes, is markedly decreased. HCT can correct the disease.

IL-21 and IL-21R deficiencies are inherited as autosomal recessive traits. Gastrointestinal manifestations with colitis and *Cryptosporidium*-associated cholangitis have been reported. A single patient with Kaposi sarcoma and OX40 deficiency has been reported.

DISORDERS WITH T CELL-MEDIATED IMMUNE DYSREGULATION

Along with generation of a diversified repertoire of T and B lymphocytes, purging of self-reactive cells is essential to maintain immune homeostasis and prevent autoimmune diseases. We have already reported how autoimmune manifestations are common in severe forms of immunodeficiency characterized by oligoclonal expansion of T lymphocytes (e.g., Omenn syndrome, complete atypical DGS) and in patients with defects of T-cell signaling. Here, we describe other forms of primary immunodeficiency with faulty control of central or peripheral T-cell tolerance.

Autoimmune Polyendocrinopathy Candidiasis Ectodermal Dystrophy Syndrome

Also known as *autoimmune polyglandular syndrome type 1* (APS1), autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED) is an autosomal recessive disorder characterized by autoimmune endocrine manifestations (hypoparathyroidism, Addison disease), candidiasis, and nail dystrophy. The disease is caused by mutations of the autoimmune regulator (*AIRE*) gene, which encodes for a transcription factor expressed by medullary TECs (mTECs) where it regulates expression of tissue specific antigens that are presented to nascent T cells, thereby promoting clonal deletion of self-reactive T lymphocytes, or their conversion to natural regulatory T cells (nTreg cells).

In patients with APECED, mucocutaneous candidiasis usually develops first (in infancy or early childhood), followed by autoimmune hypoparathyroidism with hypocalcemia and adrenal failure. Around 15% to 20% of patients may develop insulin-dependent

diabetes. Other autoimmune manifestations (hepatitis, ovarian failure) are also common. Hyposplenism has been reported in one study. Candidiasis may reflect elevated levels of antibodies to IL-17 and IL-22, which play an important role in the defense against *Candida* spp.

Management of patients with APECED is based on regular follow-up and search for autoantibodies, which should be repeated every 6 months. Hormone-replacement therapy is indicated for the endocrinopathies. Aggressive management and prevention of candidiasis is important to avoid persistent or recurrent infections that may favor development of squamous cell carcinoma.

Immune Dysregulation Polyendocrinopathy Enteropathy X-Linked Syndrome

Immune dysregulation polyendocrinopathy enteropathy X-linked (IPEX) is an X-linked disorder of systemic autoimmunity. Males with IPEX syndrome present early in life with skin rash, intractable watery diarrhea, insulin-dependent diabetes mellitus, lymphadenopathy, splenomegaly, and failure to thrive. Other autoimmune manifestations include thyroid disease, nephropathy, cytopenias, and vasculitis. In addition, patients with IPEX show elevated levels of IgE.

IPEX is caused by mutations of the *FOXP3* gene, which encodes for a transcription factor that plays a critical role in the development and function of regulatory T (Treg) lymphocytes. These cells have suppressive functions; they have a distinctive phenotype (CD4⁺ CD25^{hi} FOXP3⁺) and normally represent 5% to 15% of CD4⁺ circulating lymphocytes. Most patients with IPEX lack Treg cells; activated self-reactive T lymphocytes infiltrate target tissues and secrete cytokines, causing tissue damage.

IPEX has a severe prognosis. Death often occurs within the first few years of life due to severe malabsorption, failure to thrive, metabolic derangement, or because of severe infections secondary to immune suppression. Use of immunosuppressive drugs (steroids, sirolimus, tacrolimus, rituximab) is necessary to treat the disease. However, the only definitive treatment is allogeneic HCT. Mixed chimerism is sufficient to control the disease; therefore, reduced-intensity conditioning has been used with good results.

CD25 and STAT5B Deficiencies

IL-2 plays an important role in T lymphocyte proliferation and in immune homeostasis. Upon binding to the high-affinity IL-2 receptor, IL-2 promotes phosphorylation and nuclear translocation of the transcription factor signal transducer and activator of transcription (STAT)5, which drives expression of IL-2 target genes, including *FOXP3*. Autosomal recessive mutations of the *IL2RA* (CD25) gene, which encodes for the α chain of the IL-2 receptor, cause a disease that is associated with IPEX-like manifestations (lymphadenopathy, hepatosplenomegaly, autoimmune cytopenias, inflammatory bowel disease) and increased susceptibility to severe viral infections. The number of circulating T cells may be normal or slightly reduced, and in vitro proliferative response to mitogens is decreased. The patients' T cells produce reduced amounts of the immunosuppressive cytokine IL-10 upon in vitro activation. HCT represents the only definitive treatment.

Autosomal recessive mutations of the *STAT5B* gene cause a syndrome characterized by autoimmunity (especially cytopenias and autoimmune hepatitis), eczema, severe and/or recurrent infections, lymphocytic interstitial pneumonia, and growth hormone (GH)-insensitive dwarfism. The latter reflects the critical role played by STAT5 in the cellular response to GH. Affected patients have a low number of circulating T and NK lymphocytes and Treg cells, and in vitro proliferative responses to mitogens are reduced. In contrast, IgG levels are often elevated. Aggressive treatment of infections, use of immunosuppressive drugs to treat autoimmune manifestations, and regular monitoring of pulmonary function are the mainstay of treatment.

Cytotoxic T Lymphocyte Antigen 4 Deficiency

Cytotoxic T lymphocyte antigen 4 (CTLA4) is a surface molecule expressed by conventional and regulatory T cells. It competes with CD28 for binding to CD80/CD86 molecules expressed by antigen-presenting cells. However, in contrast to CD28, CTLA4 delivers a suppressive signal that limits T-cell activation. Heterozygous loss-of-function mutations of CTLA4 cause a condition characterized by lymphoid infiltrates in the lung, gastrointestinal tract, and the brain (simulating lymphoma), autoimmune cytopenias, hypogammaglobulinemia, lymphopenia, accumulation of activated T cells, and decreased Treg cell function. The disease is inherited as an autosomal dominant trait with incomplete penetrance. Treatment is based on use of CTLA4-Ig (abatacept) and sirolimus. HCT may be considered in severe cases.

Lipopolysaccharide Responsive Beige-Like Anchor Protein Deficiency

Deficiency of the lipopolysaccharide responsive beige-like anchor protein (LRBA) is inherited as an autosomal recessive trait and causes a combined immunodeficiency with prominent immune dysregulation affecting mostly the gastrointestinal tract (with severe chronic diarrhea and failure to thrive) and the lungs. Autoimmune cytopenias are also common. Typical immunological abnormalities include hypogammaglobulinemia and a variable degree of lymphopenia, with increased proportion of activated T cells. The disease shares some clinical and immunologic manifestation similarities with CTLA4 deficiency. Indeed, LRBA binds to CTLA4 and allows endosomal trafficking of the latter to the cell membrane. In the absence of LRBA, CTLA4 is targeted to the lysosomal compartment where it is degraded. Consistent with this, Treg cells from patients with LRBA deficiency have low levels of expression of CTLA4 and FOXP3, and the actual number and function of Treg lymphocytes are impaired. Treatment with CTLA4-Ig (alone or in combination with sirolimus) may be beneficial.

Defects of Calcium Flux

T lymphocyte activation and homeostasis depend on calcium mobilization. In particular, TCR-induced activation results in release of Ca²⁺ from the endoplasmic reticulum stores, followed by Ca²⁺ entry through the Ca²⁺ release-activated channels (CRAC) located in the cell membrane. Mutations of *STIM1* (which encodes for a sensor of endoplasmic reticulum calcium stores) and of *ORAI1* (which encodes for CRAC) cause severe immunodeficiency in which T-lymphocyte generation in the thymus is not affected, but peripheral T cells are functionally impaired. Autoimmunity and nonprogressive myopathy are distinguishing features of these disorders.

Autoimmune Lymphoproliferative Syndrome

Interaction between Fas (CD95) on activated T and B lymphocytes, and Fas ligand (FASLG) on activated T cells triggers the extrinsic pathway to activation of the caspase cascade, culminating in apoptosis. In addition, cellular stress (including cytokine deprivation) may activate the intrinsic pathway of apoptosis, leading to disruption of mitochondrial membrane permeability, release of cytochrome c, activation of caspase 9 and apoptosis. Defects of Fas- or mitochondrial-dependent apoptosis are responsible for autoimmune lymphoproliferative syndrome (ALPS), characterized by early-onset, chronic (>6 months), nonmalignant lymphoproliferation, autoimmunity, and increased risk of lymphoma.

The majority of patients with ALPS carry heterozygous dominant-negative mutations in the *FAS* (CD95, *TNFRSF6*) gene (ALPS-FAS). Somatic mutations of the *FAS* gene are the second most common cause of the disease (ALPS-sFAS). More rarely, ALPS is caused by

mutations of the *FASLG* gene (ALPS-FASLG), of caspase 8, caspase 10, Fas-associated death domain (FADD) protein, or by somatic activating mutations of N-RAS or K-RAS. Finally, autosomal recessive deficiency of protein kinase C (PRKCD), which plays an important role in regulating cell survival and apoptosis, also causes an ALPS-like disease with B-cell lymphoproliferative disease.

Lymphoproliferation, manifesting as lymphadenopathy, splenomegaly, or hepatomegaly, is the most common clinical manifestation, with a trend toward progressive remission in adulthood. More than 70% of ALPS patients develop autoimmune disease—most commonly immune cytopenias, less frequently organ-specific autoimmunity. There is an increased risk of malignancies, especially EBV-associated non-Hodgkin lymphoma. Patients with PRKCD deficiency often present SLE-like manifestations, with nephropathy and antiphospholipid antibody syndrome.

An immunologic signature of ALPS is the increased number of DN circulating T lymphocytes that express the $\alpha\beta$ form of the TCR, but do not express CD4 or CD8 molecules. There is defective in vitro apoptosis of lymphocytes through the Fas-mediated or intrinsic pathway (depending on the genetic variant). Elevated levels of soluble Fas ligand, vitamin B12, and IL-10, Hypergammaglobulinemia, and anti-phospholipid antibodies are often present in patients with ALPS-FAS. By contrast, patients with PRKCD deficiency have low levels of IgG and an increased proportion of CD5⁺ B cells. Patients with caspase 8 deficiency, FADD deficiency, and PRKCD deficiency have recurrent infections. The number of DN T cells may be normal in patients with *NRAS* or *KRAS* mutations.

Treatment is based on immunosuppression (with steroids, rituximab, mycophenolate mofetil, or sirolimus) and surveillance against lymphoma. Splenectomy may improve cytopenias; however, relapse of autoimmunity has been observed in 50% of the splenectomized patients. Furthermore, severe, invasive bacterial infections have been reported in 30% of splenectomized patients, and the mortality rate for invasive bacterial infection after splenectomy is as high as 13.3%.

Other Conditions With Immune Dysregulation

Gain-of-function mutations of the *STAT1* gene cause a variable clinical phenotype ranging from chronic mucocutaneous candidiasis to increased occurrence of viral, fungal, and bacterial infections, to autoimmunity.

Gain-of-function mutations of the *STAT3* gene cause increased STAT3 signaling and enhanced Th17 differentiation, with lymphoproliferation and solid-organ autoimmunity. The number of Treg cells is reduced.

Deficiency of ITCH, an E3 ubiquitin ligase that regulates activation of phospholipase C γ 1 (PLC γ 1), causes multiple autoimmune manifestations (enteropathy, thyroiditis, type 1 diabetes, hepatitis), interstitial lung disease, dysmorphic features, and developmental delay.

Defects of IL-10 and IL-10R are responsible for very early onset inflammatory bowel disease.

Mutations of the tripeptidyl-peptidase II (*TPP2*) gene cause severe autoimmune hemolytic anemia, variable lymphoproliferation, and recurrent infections. Accelerated senescence of lymphoid cells and hypergammaglobulinemia are observed.

DEFECTS OF CELL-MEDIATED CYTOTOXICITY

Mechanisms of immune defense against viral infections are largely dependent on responses mediated by CD8⁺ cytotoxic T lymphocytes (CTLs) and NK lymphocytes. Multimers of perforin, a protein contained in cytolytic granules, form pores through which CTL and NK cells release cytotoxic proteins (granzyme B, granulysin) into virus-infected target cells, causing activation of caspases and apoptosis. In resting CTLs and NK lymphocytes, cytotoxic proteins are contained in endosomal secretory lytic granules. Following interaction of CTLs or NK cells with the target cell, vesicles

containing lytic granules are transported and dock and fuse with the cell membrane, permitting release of cytotoxic proteins into the target cells.

Hemophagocytic Lymphohistiocytosis

Defects in the intracellular transport and release of cytolytic granules are responsible for various forms of familial HLH, including deficiency of Munc13-4 (required to prime vesicles), syntaxin 11 and Munc18-2 (both of which promote vesicle fusion with the cell membrane), and perforin. In these disorders, infections (mostly caused by viruses) trigger an uncontrolled immune response mediated by CD8⁺ T lymphocytes and NK cells that secrete large amounts of IFN- γ , which activates macrophages. Fever, liver, and spleen enlargement, lymphadenopathy, profound cytopenias, hypoalbuminemia, coagulopathy, high levels of ferritin and triglycerides, and immune activation (with increased levels of soluble CD25) characterize these acute episodes, which may lead to multiple-organ failure and death. The diagnosis of these familial forms of HLH is facilitated by flow cytometric analysis of surface expression of CD107a (a protein normally contained in endosomal vesicles) upon in vitro activation of cytotoxic T cells and NK cells. Defective expression of CD107a is observed in patients with Munc13-4, Munc18-2, and syntaxin 11 deficiencies. By contrast, this test is normal in patients with perforin deficiency, in which reduced or absent expression of perforin can be easily demonstrated by flow cytometry.

HLH Associated With Pigmentary Dilution Disorders

Typical features of HLH are also observed in some pigmentary dilution disorders. In particular, Chediak-Higashi syndrome (CHS) is an autosomal recessive disease due to mutations of the *LYST* gene, which encodes for a protein involved in the sorting of proteins to secretory endosomes. This defect affects not only cytotoxic lymphocytes (accounting for FHL-like clinical features), but also melanocytes (that are unable to transfer melanin to keratinocytes and other epithelial cells) and peripheral neurons. Clinical features of CHS include partial albinism (with silvery hair), progressive peripheral neuropathy, recurrent bacterial infections, and mild tendency to bleeding. Neutropenia is often present and may cause bacterial infections. Giant lysosomes can be identified in circulating leukocytes.

Griscelli syndrome type 2 (GS2) is caused by mutations of the *RAB27A* gene, which encodes for a protein involved in docking of secretory granules of cytotoxic lymphocytes and melanocytes to the cell membrane. Accordingly, patients with GS2 present with HLH and hypopigmentation. The diagnosis is facilitated by the demonstration of large clumps of pigment distributed irregularly along the hair shaft, and by reduced expression of CD107a on the surface of CD8⁺ and NK lymphocytes upon in vitro activation.

Hermansky-Pudlak syndrome type 2 is an autosomal recessive disorder caused by mutations of the *AP3B1* gene, which encodes for the β component of the AP-3 complex, involved in sorting of transmembrane proteins to secretory lysosomes. Clinical manifestations include partial albinism, nystagmus, prolonged bleeding, recurrent bacterial and viral infections, and increased risk of HLH. Pigmentary abnormalities, neutropenia, platelet dysfunction (with absence of dense granules and reduced platelet aggregation), and defective cytotoxic activity account for the clinical manifestations of the disease.

Irrespective of the nature of the genetic defect, HLH therapy is based on the prompt and aggressive treatment of underlying infections and immunosuppression to curtail macrophage activation. Administration of humanized anti-IFN- γ monoclonal antibodies may block continuous activation of the immune system and induce remission. Ultimately, definitive treatment is based on allogeneic HCT from a matched related or unrelated donor, and the best results are obtained using reduced-intensity conditioning. Mixed chimerism is sufficient to correct the immunologic abnormalities.

X-Linked Lymphoproliferative Disease

In normal individuals, primary infection with EBV causes infectious mononucleosis, a self-limiting disease. EBV establishes latency in B lymphocytes, salivary glands, and some epithelial cells, and is maintained under control by CD8⁺ CTLs, and NK lymphocytes. Males with X-linked lymphoproliferative disease type 1 (XLP1) are uniquely susceptible to life-threatening complications of EBV infections. XLP1 is caused by mutations of the *SH2D1A* gene, which encodes for a small adaptor molecule, SLAM-associated protein (SAP). In the absence of SAP, cytotoxic responses to EBV-infected cells are markedly reduced. Persistence of EBV triggers continuous activation of CD8⁺ CTLs that release high amounts of IFN- γ , ultimately resulting in a macrophage activation syndrome. In addition to HLH, patients with XLP1 are also at high risk of B-cell lymphoma. SAP is also important for the function of follicular helper T cells (T_{FH}), which promote maturation of antibody responses. Consistent with this, XLP1 males often develop hypogammaglobulinemia with a lack of memory B lymphocytes. Finally, XLP1 is also associated with impaired development of NK T (NKT) lymphocytes. Flow cytometric analysis of SAP expression and mutation analysis at the *SH2D1A* locus confirms the diagnosis.

A minority of patients with XLP carry defects in another gene (*BIRC4*) that encodes for the X-linked inhibitor of apoptosis (XIAP). Consistent with this, lymphocytes from patients with this disease (XLP2) show increased susceptibility to activation-induced apoptosis. Compared with XLP1, patients with XLP2 have a higher incidence of HLH (with or without EBV infection), but do not show increased risk of lymphoma. Severe inflammatory bowel disease has been reported in several patients. Hypogammaglobulinemia is often present. Flow cytometric analysis of XIAP expression and mutation analysis at the *BIRC4* locus are used to confirm the diagnosis.

Both XLP1 and XLP2 are life-threatening disorders. Administration of immunoglobulins may be beneficial; however, the only curative approach is HCT.

DEFECTS OF B-CELL DEVELOPMENT AND FUNCTION

The previous section covered defects that predominantly affect T lymphocyte development and/or function. This section covers primary immunodeficiencies in which abnormalities of B-cell development and/or function predominate (see Figs. 51.2 and 51.3).

Diagnostic and Therapeutic Approach to Cytotoxicity Defects

- Primary immunodeficiency with defects of cell-mediated cytotoxicity include a heterogeneous group of disorders characterized by increased susceptibility to severe viral infections.
- Typical clinical features include high fever, liver and spleen enlargement, lymphadenopathy, coagulation defects, abnormalities of liver function, and cytopenias after viral infections.
- Two major groups of cell-mediated cytotoxicity defects include familial forms of HLH (fHLH) and X-linked lymphoproliferative disease. In the former, diagnosis is based on demonstration of abnormal cytotoxic function of T and NK lymphocytes. Defective expression of CD107a on activated lymphocytes or reduced expression of perforin may help define the nature of the underlying disorder causing fHLH.
- Prompt recognition and treatment of the underlying infection is essential. Immunosuppression is also required to block exaggerated inflammatory responses. However, the only curative approach to defects of cell-mediated cytotoxicity is represented by hematopoietic cell transplantation. Mixed chimerism is sufficient to allow immune reconstitution. This goal can be achieved with reduced intensity conditioning, with a lower risk of treatment-related toxicity.

X-Linked Agammaglobulinemia

X-linked agammaglobulinemia (XLA), also known as *Bruton's agammaglobulinemia*, is the most common monogenic cause of failure of B-cell development. Males with XLA lack circulating B cells, caused by mutations of the Bruton's tyrosine kinase or *BTK* gene, which encodes for a tyrosine kinase involved in signaling through various receptors, including the pre-B-cell receptor (pre-BCR) and the BCR. Impaired signaling through the pre-BCR causes a severe, but incomplete, block at the pre-B-cell stage in the bone marrow (see Fig. 51.2).

Clinical manifestations of XLA include recurrent sinopulmonary infections (pneumonia, bronchitis, sinusitis, otitis), particularly with encapsulated organisms such as pneumococcus and *Haemophilus influenza*, bacterial skin infections (cellulitis, impetigo, pyoderma gangrenosum, perirectal abscess), and sepsis with *Pseudomonas* or *Staphylococcus*. Symptoms typically begin after 3–6 months of age when maternally derived antibodies disappear. The proportion of circulating B cells is markedly reduced (typically 0.05% to 0.3% of lymphocytes) and there is profound deficiency of all immunoglobulin isotypes. Milder mutations that are permissive for BTK protein expression are associated in vivo with higher levels of serum IgM and later age at diagnosis. Neutropenia, secondary to severe infections, is observed in approximately 10% to 25% of patients; typically, it resolves with antibiotics and immunoglobulin-replacement therapy.

In addition to bacterial infections, patients with XLA are uniquely susceptible to enteroviral infections (including chronic meningoencephalitis) caused by poliovirus, coxsackie virus, and others. However, such complications have become rare after the introduction of optimal doses of immunoglobulin-replacement therapy. Patients with XLA are also at higher risk of infections caused by *Mycoplasma* and *Ureaplasma* species, which affect the joints, prostate, or lungs; and *Giardia lamblia*, causing protracted diarrhea and malabsorption. An increased incidence of lymphoma, colorectal cancer, and gastric adenocarcinoma has been reported in XLA.

Therapy is based on life-long regular administration of immunoglobulins intravenously or subcutaneously, and on prompt and aggressive treatment of infections. With this regimen, survival approaches that of the general population. Antibiotic prophylaxis may be beneficial, but its role has not been firmly established. Patients on immunoglobulin-replacement therapy should be monitored for side effects and adverse reactions, and for liver and renal function.

Autosomal Recessive Agammaglobulinemia

While the majority of agammaglobulinemia cases are caused by the X-linked form, about 15% of cases are presumed to be autosomal recessive (see Fig. 51.2). Mutations of the immunoglobulin μ heavy chain gene (*IGHM*) are the second most common cause of agammaglobulinemia. Other cases are caused by defects in other components of the pre-BCR/BCR complex including the signaling moieties Ig α (CD79A) and Ig β (CD79B), and $\lambda 5$ (IGLL1), the surrogate light chain that pairs with Vpre-B, and the scaffold protein BLNK, which brings BTK into the signaling complex. Finally, congenital agammaglobulinemia may also be caused by mutations of the *PIK3R1* gene, causing complete loss of the p85 α subunit of phosphatidylinositol 3-kinase (PI3K), and to heterozygous, dominant-negative mutations of the *TCF3* gene encoding for the transcription factor E47.

Common Variable Immunodeficiency

CVID is the most common primary immunodeficiency severe enough to require treatment, with a prevalence estimated to be 1 in 25,000 to 1 in 30,000 Caucasians, and accounting for approximately 10% to 20% of humoral immunodeficiencies. While a growing number of genetic defects have been found to be associated with a CVID phenotype, these defects account for a minority of cases. The

Fig. 51.3 GENETIC DEFECTS ASSOCIATED WITH COMMON VARIABLE IMMUNODEFICIENCY. Schematic of cell surface molecules expressed on B cells and their ligands, highlighting those in which defects have been shown to be associated with CVID. *Ag*, Antigen; *APRIL*, a proliferation-inducing ligand; *BAFF*, B-cell-activating factor; *BAFFR*, B-cell-activating factor receptor; *BCMA*, B-cell-maturation antigen; *DC*, dendritic cell; *HSPG*, heparin sulfate proteoglycan; *ICOS*, inducible T-cell costimulator; *ICOS-L*, inducible T-cell costimulator ligand; *Ig*, immunoglobulin; *IL-4*, interleukin 4; *IL-10*, interleukin 10; *PC*, plasma cell; *TACI*, transmembrane activator and calcium modulator and cyclophilin ligand interactor; *TI-2*, T-cell-independent type 2.

“variable” nature of the clinical manifestations of CVID patients could reflect genetic heterogeneity, but also refers to distinct clinical and immunological features that distinguish subgroups of CVID patients. However, the most common genetic variant described to date (mutations in transmembrane activator and calcium modulator and cyclophilin ligand interactor [TACI]) can be found in asymptomatic individuals, and more likely represents a predisposition to CVIDs than primary cause. Thus, the genetic causes of the majority of cases of CVIDs remain obscure and are not clearly monogenic in nature.

Diagnostic criteria for CVIDs were established in 1999 by consensus of European and Pan-American societies, and include the presence of hypogammaglobulinemia (<2 standard deviations below the mean for age of IgG, IgA, and/or IgM) and the lack of specific antibody responses in individuals with onset of symptoms >2 years of age, for whom other causes of humoral immunodeficiency have been ruled out. The number of circulating B cells detected is variable. Specific antibody responses should be assessed for more than one antigen. Because an increasing number of gene defects causing hypogammaglobulinemia early in life have been identified, many experts would recommend limiting the diagnosis of CVID to patients in whom symptoms appeared at >4 years of age.

Consistent with the antibody deficiency, CVID patients have recurrent bacterial infections of the respiratory tract, sepsis with encapsulated organisms, and infections from *Ureaplasma urealyticum*, *Giardia* species and enteroviruses. However, variable derangement of T-cell numbers and function often results in noninfectious manifestations, including autoimmunity, lymphoid infiltration or proliferation, and malignancy. In one survey only 26% of CVID patients had infections as the only manifestation of disease. Autoimmune cytopenias are quite common (~12%) and may be the presenting feature.

Other autoimmune complications include rheumatoid arthritis, systemic lupus erythematosus, hypothyroidism, vitiligo, psoriasis, diabetes, and autoimmune gastritis with pernicious anemia. Polyclonal lymphocytic granulomatous infiltrates are common and may involve the lungs, liver, or gut (causing enteropathy that is resistant to gluten withdrawal). Finally, both lymphoid (non-Hodgkin lymphoma, chronic lymphocytic leukemia) and nonlymphoid (gastric cancer) malignancies are more frequent in CVID, although the latter may be related to *Helicobacter pylori* infection.

Replacement of immunoglobulins and treatment and prevention of infection remains the mainstay of management of CVID. Immunosuppression may be needed for inflammatory and autoimmune manifestations. Disease manifestations such as autoimmunity, polyclonal lymphocytic infiltrative disease, enteropathy, and malignancy have differential and increasing impact on survival (relative risk of death 2.5, 3.0, 4.0, and 5.5, respectively), while patients with solely infectious manifestations have equivalent survival to the general population. Treatment with HCT has been performed with limited success, and often in the context of consolidative treatment for lymphoproliferation.

Immunophenotyping, genotyping, and recently genome-wide association studies have been performed in an attempt to subcategorize the heterogeneous group of CVIDs into pathobiologically relevant groups. In large part the associations have not been sufficiently robust to direct diagnosis or clinical management, and underscore the genetic heterogeneity of the disease. B-cell subphenotypes most common among CVID patients include a severe reduction in switched memory B cells (CD19⁺CD27⁺IgD⁻); some patients manifest expansion of transitional B cells (CD19⁺CD24^{hi}CD38^{hi}), expansion of CD21^{low}CD38^{low} B cells (the latter thought to play a role in autoimmunity), or reduction in CD4 T-cell number.

Genetic Variants Associated With CVIDs

A few genes have been reported to be associated with CVID (see Fig. 51.3), including transmembrane activator and CAML interactor (TACI; *TNFRSF13B*), *CD19*, *CD81*, *CD20*, *CD21*, B-cell activating factor receptor (BAFF-R; *TNFRSF13C*), *NFKB1*, and *NFKB2*. TACI is a TNF receptor superfamily member, which is expressed at high levels on activated B cells and marginal zone B cells, and binds two ligands, BAFF and APRIL. Like other TNF receptor superfamily members, TACI assembles as a trimer or higher order multimer. Heterozygous and homozygous mutations in TACI have been documented in 10% to 15% of CVID patients; however, they are also found at a lower frequency in the general population. Thus, the presence of TACI mutations is considered to be a predisposing factor to CVID, rather than a disease-causing factor.

Mutations in *CD19*, *CD81*, and *CD21*, which are all components of the B-cell coreceptor, have been reported in few individuals. These defects do not affect B-cell development but impair signaling, causing hypogammaglobulinemia, low number of switched memory B cells, and poor antibody response to T-independent antigens.

CD20 is a surface molecule involved in B-cell development and plasma cell differentiation. Autosomal recessive *CD20* deficiency is characterized by recurrent infections, low serum IgG, with normal or elevated IgA and/or IgM.

BAFF-R deficiency is very rare. It has variable clinical presentation, with CVID-like features or even absence of symptoms. Laboratory findings include hypogammaglobulinemia, low numbers of circulating B cells and a defective proportion of memory B cells, and normal antibody response to T-dependent antigen but a defective response to carbohydrate antigens.

A variable clinical phenotype has been also reported in patients with haploinsufficiency of the p50 subunit of NF- κ B (encoded by the *NFKB1* gene), causing defective signaling through the canonical NF- κ B signaling pathway. In addition to recurrent infections and progressive lung disease, patients often present with autoimmunity (hemolytic anemia, thyroiditis, alopecia) and lymphadenopathy. However, genotypically affected individuals may also remain asymptomatic even through adulthood. Heterozygous mutations of the *NFKB2* gene (affecting mostly the noncanonical NF- κ B signaling pathway) cause recurrent infections (especially due to HSV, varicella-zoster virus [VZV], and *Giardia*), central adrenal insufficiency, hypopituitarism, alopecia, trachyonychia, and growth deficiency. Hypogammaglobulinemia, a low number of memory B cells, Treg lymphocytes, T follicular helper (Tfh) cells, and NK lymphocytes have been demonstrated.

B-CELL-INTRINSIC DEFECTS OF CLASS-SWITCH RECOMBINATION

Maturation of the antibody response is marked by class-switch recombination (CSR) and by somatic hypermutation (SHM). With CSR, the μ heavy chain is replaced by other Ig heavy chains. With SHM, mutations are introduced in the Ig V region, allowing affinity maturation. Following CD40LG–CD40 interaction and activation of the NF- κ B signaling pathway, expression of activation-induced cytidine deaminase (AID) and of uracil-DNA glycosylase (UNG) occurs in germinal center B lymphocytes (see Fig. 51.3). AID acts on the DNA of Ig heavy chain switch regions and converts cytidine to uridine, which is recognized and removed by UNG. The abasic sites are cleaved by a DNA endonuclease. DNA repair then brings together two different switch regions, allowing CSR.

Mutations in AID and UNG are inherited as autosomal recessive traits. Patients suffer from recurrent bacterial infections. Autoimmune manifestations have been observed in several patients. Circulating B cells are present, but there is a severe reduction of all Ig isotypes with the exception of IgM, which is often elevated. Lymphadenopathy is common and is associated with expansion of germinal centers. Somatic hypermutation is severely compromised in patients with

Diagnostic and Therapeutic Approach to Defects in Humoral Immunity

- Defects in humoral immunity may be caused by intrinsic defects in B-cell development and function, or caused by combined immunodeficiency disorders where lack of T-cell help is the primary cause of B-cell dysfunction.
- Age-specific norms must be used for children. Immunoglobulin (Ig)G levels at birth reflect the maternally transferred antibody, which nadir between 2 and 6 months, then progressively rise with age. IgA and IgM levels rise continually with age until the teenage years.
- Based on enumeration of T, B and natural killer cells, X-linked agammaglobulinemia (XLA; absence of B cells) can be rapidly ruled out.
- The finding of hyper-IgM with low IgG should prompt a work-up for CD40L deficiency, CD40 deficiency, activation-induced cytidine deaminase (AID), and uracil-DNA glycosylase (UNG). The likelihood of each of these is of course different depending on gender and family history. It is important to note that CD40L deficiency may present with a normal IgM.
- The diagnosis of common variable immunodeficiency disorders (CVIDs) should only be made once other causes have been ruled out, and should be made with caution, if at all, in children under 4 years of age. Disorders such as XLA, autosomal recessive agammaglobulinemia, various hyper-IgM syndromes, and XLP should be specifically considered and ruled out. Other diseases that may masquerade as CVID include other combined immunodeficiencies, cystic fibrosis, HIV, and conditions leading to Ig loss such as protein-losing enteropathy. Medications may mimic the symptoms of CVID. Finally, in adults hypogammaglobulinemia may herald the development of thymoma or lymphoid malignancies, and therefore may be secondary to evolving neoplasia.
- Treatment of XLA and the hyper-IgM syndromes other than CD40L deficiency is long-term intravenous Ig replacement, which is very effective.
- Experts disagree on whether CD40L deficiency should be treated with early HSCT, and currently there are no clear predictors to determine who is likely to suffer from opportunistic infections. A patient with CD40L deficiency who has developed cryptosporidium infection and sclerosing cholangitis generally has a much worse outlook with HSCT.
- Treatment of CVID with HSCT is generally reserved for those with an alternate requirement for allogeneic transplant such as lymphoid malignancy or lymphoproliferation, which requires continual immunosuppression.

AID deficiency, and follows an abnormal pattern in patients with UNG deficiency.

Treatment is based on regular administration of Igs, as well as prompt recognition and therapy of infections.

Defects in CSR have also been reported in patients with mutations in *INO80* (encoding for a chromatin remodeling complex) and *MSH6* (involved in the DNA mismatch repair pathway). The latter group of patients is at increased risk of cancer.

Other Immunoglobulin Defects

Gain-of-function mutations of the *PIK3CD* gene (encoding for the p110 δ catalytic component of PI3K) cause an immunodeficiency characterized by nodular lymphoid hyperplasia, progressive lung disease with bronchiectasis, chronic or recurrent herpesvirus viremia (CMV, EBV, VZV, HSV), and hepatosplenomegaly. There is an increased risk of lymphomas, which are not necessarily associated with EBV infection. The immunologic phenotype includes CD4 lymphopenia, a reduced proportion of naive T cells, expansion of effector memory and “exhausted” CD8⁺ T cells, defective T-cell proliferation, variable Ig levels (often with low IgG2), reduced proportion of memory B cells, and poor antibody responses. In these patients, increased PI3K signaling causes hyperactivation of the AKT–mammalian target of rapamycin (mTOR) pathway, shifting the

intracellular metabolism of lymphoid cells towards glycolysis and thereby deranging lymphocyte function and differentiation.

A very similar clinical and laboratory phenotype has been observed in patients with heterozygous mutations of the *PIK3RI* gene (encoding for the p85 α regulatory subunit of PI3K), which permits expression of a mutated p85 α protein lacking the p110 δ -interacting domain. Treatment with rapamycin, to reduce mTOR activation, may be beneficial in both conditions. An alternative strategy, currently under investigation, is based on the use of PI3K inhibitors.

HISTIOCYTIC DISORDERS

Michael B. Jordan and Alexandra Hult Filipovich

The histiocytic disorders comprise a broad grouping of hematologic and immunologic diseases united by the observation that monocyte/macrophages or dendritic cells appear to be prominently involved in disease pathophysiology. The term *histiocyte* refers to phagocytic cells, historically identified on tissue sections but now more precisely defined as cells of the monocyte/macrophage lineage (Fig. 52.1). The ontogeny of these cells continues to be actively studied and debated, and their role(s) in pathogenesis is an active area of investigation. The characteristic cells seen in various histiocytic lesions can, in general, be differentiated by a variety of functional and phenotypic markers. The modern classification of the histiocytoses mirrors this biology (Table 52.1). Although malignant disorders involving monocyte/macrophages or dendritic cells were originally included in this classification, this chapter focuses solely on nonmalignant disorders in this category.

Of the dendritic cell-related histiocytoses, the most clinically common and prominent one is Langerhans cell histiocytosis (LCH). This chapter also briefly discusses other dendritic cell-related histiocytic disorders, including juvenile xanthogranuloma (JXG); Erdheim–Chester disease (ECD); and sinus histiocytosis with massive lymphadenopathy (SHML), also referred to as *Rosai-Dorfman disease* (RDD).

The prominent monocyte/macrophage-related histiocytic disorder, hemophagocytic lymphohistiocytosis (HLH), is discussed in detail later in this chapter. In HLH, activated macrophages, activated T cells, and defective natural killer (NK) cells are the dysfunctional interactive partners.

Table 52.1 lists a currently accepted classification of histiocytic disorders. These disorders are a diverse grouping, ranging from benign skin lesions to rapidly life-threatening systemic disorders. Tables 52.2 and 52.3 list clinical features and commonly used pathologic markers or features that may be used to help distinguish some of these disorders. The clinical diversity of histiocytic disorders is underscored by recent discoveries related to their pathogenesis. Studies dating to the late 1990s have demonstrated that HLH (at least in its familial form) is a unique immune-regulatory disorder. LCH is another disorder, historically considered to be nonmalignant. However, demonstrations of clonality as well as genetic abnormalities of B-Raf now demonstrate that LCH is a benign neoplasm despite its variable clinical phenotype. The pathogenesis of less common dendritic cell- and macrophage-related histiocytic disorders are still unknown.

LANGERHANS CELL HISTIOCYTOSIS

LCH is the most common of the histiocytoses. The central cell of LCH, the Langerhans dendritic cell, was first described in 1868 by 21-year-old Paul Langerhans. Between 1893 and 1920, Hand, Schüller, and Christian described the various nonfatal presentations of LCH, which include bony lesions, skin rash, and diabetes insipidus (DI). Letterer and Siwe (1924 and 1933, respectively) added to the list of clinical presentations by describing cases with liver and spleen involvement in infants and toddlers. These disorders were later grouped under the term *histiocytosis X* (denoting the uncertainty about disease pathogenesis) by Lichtenstein. It was eventually theorized by Nezelof (1973) that histiocytosis X is caused by a proliferation of pathologic Langerhans cells. At present, the term *LCH* has been adopted to refer

to all of the varied manifestations of this protean disorder. It is now well recognized that LCH can present at any time in life from the neonatal period to old age. LCH lesions may spontaneously regress or repeatedly “reactivate”, contributing to long-term disabilities such as DI or a neurodegenerative disease. Life-threatening forms of LCH, previously referred to as *Letterer–Siwe disease*, typically present in infancy and clearly require intensive therapy and sometimes salvage treatment such as allogeneic bone marrow transplantation (BMT) to cure the children.

Epidemiology

The incidence of LCH has been estimated to be between 5 and 15 cases per million children, per year. The incidence of LCH in adults is believed to be lower than in children but is likely underestimated because of a lack of recognition of LCH in adult medicine. Notably, LCH does not appear to have significant geographic or ethnic predilections. Although families with multiple cases of LCH have been reported, these kindreds are extremely rare. One notable clinical or epidemiologic association reported thus far involves an unexplained coincidence of both LCH and leukemia (of various subtypes) in rare patients.

Pathobiology

The understanding of the pathobiology of LCH is currently undergoing significant evolution, driven by new insights into both normal and disease-associated Langerhans cells. Over the years, LCH has been classified as a neoplasm, a reactive disorder, or an aberrant immune response. LCH cells are pathologic in that they bear heterogeneous characteristics not normally identified in healthy Langerhans cells that are typically resident in the skin. The granulomatous lesions of LCH, which can be found in nearly any organ, represent an accumulation of normal inflammatory cells, including eosinophils, lymphocytes (especially T cells), and macrophages, in addition to the LCH cells. The clinically benign behavior of most cases, including spontaneous remissions and lack of aggressive disease evolution with recurrences, as well as the benign histopathologic appearance of lesions, have suggested a nonmalignant etiology. The failure of many laboratories to culture pathologic Langerhans cells has reinforced this impression. Thus, LCH has been hypothesized to be a reactive or immunologic disorder by many. On the other hand, lesional Langerhans cells have been demonstrated by several investigators to be clonal. This observation, combined with the clinical utility of antineoplastic drugs, has bolstered the opinion that LCH may be a neoplastic disorder.

Several reports in the last 5 years of highly prevalent B-Raf mutations in lesional Langerhans cells have again shifted thinking and strongly support a neoplastic etiology. The mutation in question (*BRAF* V600E) is well described in both malignant melanomas and in benign nevi, among other neoplasms. This mutation leads to activation of the extracellular signal-related kinase (ERK) pathway. More recently, additional mutations associated with the ERK pathway activation have been described in LCH patients. Along with these disease-specific findings, understanding of the biology of normal Langerhans cells has advanced. Cutaneous Langerhans dendritic cells have been shown to arise from in situ precursors,

Fig. 52.1 DEVELOPMENT OF CELLS OF THE MONOCYTE/MACROPHAGE LINEAGE. *CFU-DL*, Colony-forming unit–dendritic Langerhans cell; *CFU-GM*, colony-forming unit–granulocyte-macrophage; *CFU-M*, colony-forming unit–macrophage.

TABLE 52.1 Classification of Histiocytic Disorders: Benign Disorders of Varying Biologic Behavior

A. Dendritic cell related	
Langerhans cell histiocytosis	
Juvenile xanthogranuloma and related disorders including:	
• Erdheim–Chester disease • Solitary histiocytomas with juvenile xanthogranuloma phenotype • Secondary dendritic cell disorders	
B. Monocyte/macrophage related	
Hemophagocytic lymphohistiocytosis: familial and sporadic	
Secondary hemophagocytic syndromes	
• Infection associated • Malignancy associated • Autoimmune associated	
Sinus histiocytosis with massive lymphadenopathy (Rosai–Dorfman disease)	
Solitary histiocytoma of macrophage phenotype	

but during inflammation or stress, to arise from circulating myeloid precursors. Therefore, a picture is emerging in which the acquisition of mutation(s), such as *BRAF* V600E, in myeloid precursors may cause a neoplastic proliferation of a terminally differentiated clone that colonizes a distinct anatomic location. Similar to a cutaneous nevus, this neoplasm is a benign one because lesional cells are not fully transformed. Thus, recent findings support the hypothesis that LCH is a benign hematopoietic neoplasm, or a hematopoietic “mole”. Thus far, there has been no compelling insight into why LCH has such diverse manifestations, ranging from solitary to widely disseminated disease.

Clinical Manifestations

Clinical involvement with LCH can be highly variable but most often involves bony lesions (present in ≈80% of cases), which may be

painful or painless; the latter is common with skull lesions. Skin involvement, typically papulosquamous lesions, often affecting the scalp (and frequently mistaken for cradle cap, seborrhea) is reported in 30% to 60% of patient series. Soft tissue swelling, often in proximity to bony lesions, external ear drainage, enlargement of lymph nodes and thymus, and gum hypertrophy with premature eruption of baby teeth are also well-recognized manifestations. More serious systemic involvement occurs when there is hepatosplenomegaly, liver dysfunction, lung scarring, and hematopoietic failure with or without intestinal involvement. The latter findings are more typical of the widely disseminated form of LCH seen in young infants, which carries a high mortality rate.

Bony Involvement

Solitary or multifocal bony lesions are found predominantly in older children and young adults, usually within the first three decades of life. Such lytic bone lesions are commonly referred to as *eosinophilic granuloma* because of their pathologic appearance. The incidence of bone lesions peaks between 5 and 10 years of age. Solitary or multifocal eosinophilic granuloma (with or without involvement of other organ systems) represents approximately 60% to 80% of all instances of LCH. Patients with systemic involvement frequently have bone lesions in addition to other manifestations of disease. Patients often cannot bear weight and may have tender swelling caused by tissue infiltrates overlying the bone lesions. Radiographically, the lesions are sharply marginated, round, or oval, and usually have a beveled edge on radiography that gives the appearance of depth. Hand–Schüller–Christian disease, referring to the triad of bony involvement, skin lesions, and DI, is most commonly described in younger children aged 2–5 years. It represents 15% to 40% of these patients, although this type of involvement can be observed in patients of all ages. Signs and symptoms include bony defects with exophthalmos, with a tumor mass in the orbital cavity being characteristic. This condition usually occurs owing to involvement of the roof and lateral wall of the orbital bones. In addition, teeth may be lost because of gum infiltration or mandibular involvement (Fig. 52.2).

TABLE 52.2**Clinical Features of the Non-Langerhans Cell Histiocytosis, Nonhemophagocytic Lymphohistiocytosis Histiocytoses**

Diagnosis	Ages	Lesions (n)	Appearance	Common Sites	Natural History
JXG	0–18 years (median, 2 years)	Single:multiple 9:1 (disseminated in <6 months)	Reddish progressing to yellow brown	Head and neck	Gradual involution
Giant JXG	Young	Single	>2 cm	Upper extremity or back	Involution
Systemic JXG (4% of JXG)	(3 months*)	Single, multiple	Almost 50% have no skin lesions	Subcutis, liver, spleen, lung, CNS, iris	May involute (4–10% fatal)
Adult XG	18–80 (35 years*)	Single	Same as JXG	Upper body	No involution
BCH	Young child	Few, multiple	Reddish-tan papules	Head and neck	Involution or progression to XG
GEH	Young adult	Disseminated	Reddish-tan papules in crops	Face, trunk, arms	Involution or progression
XD	Young adult	Disseminated	Yellow/reddish-brown plaques and nodules	Eyelids, mucosae, viscerae, CNS	Slow involution or progression
PNH	40–60 years	Disseminated	Xanthoma, nodules	Skin, subcutis	Progression to disfigurement
MRH	>40 years	Multiple	Pink/reddish-brown or yellow	Head, extremities with erosive polyarthritis	Progression
SHML	Wide age range (20 years*)	Mainly systemic	Firm indurated papules	Cervical adenopathy, 80% “B” symptoms, extranodal (43%)	Exacerbations and remissions (5–11% fatal)
ECD	7–84 years (53 years*)	Mainly systemic	Xanthelasma, xanthoma	Long-bone sclerosis, retroperitoneal fibrosis	Highly fatal

*Approximate median age of presentation.

BCH, Benign cephalic histiocytosis; CNS, central nervous system; DI, diabetes insipidus; ECD, Erdheim–Chester disease; GEH, generalized eruptive histiocytosis;

JXG, juvenile xanthogranuloma; MRH, multicentric reticulohistiocytosis; PNH, progressive nodular histiocytosis; SHML, sinus histiocytosis with massive lymphadenopathy; XD, xanthoma disseminatum.

Adapted from Weitzman, Egeler, eds: *Histiocytic Disorders of Children and Adults*. Cambridge, 2005, Cambridge University Press.

The most frequent sites of skeletal involvement include the flat bones of the skull, ribs, pelvis, and scapula. There may be extensive involvement of the skull, with irregularly shaped, lucent lesions giving rise to the so-called *geographic skull*. Long bones and lumbosacral vertebrae, usually the anterior portion of the vertebral body, are

involved less frequently. Involvement of the vertebral bodies may lead to collapse (*vertebra plana*) as the principal or only presenting manifestation. In such cases, the diagnosis may be problematic, although biopsy is typically not advisable unless a soft tissue mass is present. In long bones, growth of lesions in the medullary cavity leads to pressure that may result in erosion through the cortex, stimulating the formation of periosteal new bone accompanied by soft tissue extension. The differential diagnosis includes Ewing and osteogenic sarcoma, bone lymphoma, benign bone tumor and cyst, and infection. Involvement of the wrists, hands, knees, feet, or cervical vertebrae is less common. Orbital involvement may result in vision loss or strabismus caused by optic nerve or orbital muscle involvement, respectively, and may mimic preseptal cellulitis. Oral involvement commonly affects the gums, palate, or both. Erosion of the lamina dura gives rise to the characteristic “floating tooth” seen on dental radiographs. The entire mandible may be involved (see Fig. 52.2), with loss of bone leading to diminished height of the mandibular rami. Erosion of gingival tissue causes premature eruption, decay, and tooth loss. Parents of affected children, particularly infants, frequently report precocious eruption of teeth when, in fact, the gums are receding, leading to exposure of immature dentition. Chronic otitis media caused by involvement of the mastoid and petrous portion of the temporal bone, leading to otitis externa is common.

Cutaneous Involvement

Cutaneous involvement by LCH is both common (occurring in 20–40% of patients) and highly variable. The rash is typically a scaly seborrheic, eczematoid, sometimes purpuric rash involving the scalp, ear canals, abdomen, and intertriginous areas of the neck, face, trunk, and groin (Fig. 52.3). The rash may be maculopapular or nodulopapular. Ulceration may result, especially in intertriginous areas, and

Fig. 52.2 COMPUTED TOMOGRAPHIC SCAN OF A DESTRUCTIVE LANGERHANS CELL HISTIOCYTOSIS ZYGOMATIC LESION IN A CHILD.

Fig. 52.3 SKIN INVOLVEMENT IN LANGERHANS CELL HISTIOCYTOSIS. (A) Diffuse maculopapular rash. (B) Hemorrhagic scalp rash. (C) Erythematous, “raw” rash typically seen in skin folds such as in the axilla or groin.

may be painful. Mild, isolated cutaneous involvement is relatively common in young infants. Rarely, LCH may present as deep subcutaneous skin nodules only (formerly described as *Hashimoto–Pritzker syndrome*), typically in young infants.

Involvement of Other Organ Systems

A subset of infants and toddlers with LCH have involvement of the spleen, liver, or bone marrow (BM), usually in addition to prominent skin involvement and variable bony disease. This clinical phenotype, previously referred to as *Letterer–Siwe disease*, is the most severe manifestation of LCH and the only form that is likely to be life threatening. Involvement of the BM, usually as evidenced by cytopenias, is an especially poor prognostic factor. Of note, unlike with other tissues, biopsy of the BM in these patients does not typically reveal an obvious infiltrate with CD1a⁺ cells but rather tends to have a dysplastic appearance. Liver involvement may be severe, leading to significant cholestasis, hypoproteinemia, and diminished synthesis of clotting factors.

LCH can have a strictly nodal presentation, not to be confused with SHML, also known as RDD. This presentation is characterized

by significant enlargement of multiple lymph node groups with little or no other signs of disease. Thymic involvement is relatively common in children with multisystem involvement. Pancreatic and thyroid involvement has also been reported. Gastrointestinal tract disease has rarely been identified. It is sometimes associated with severe symptoms of diarrhea, malabsorption, and hypoproteinemia.

Isolated pulmonary involvement is usually seen in young adults in their third or fourth decades of life, and occasionally in adolescents. It may follow a severe and often chronic debilitating course; patients may present with pneumothorax. Cigarette smoking has been strongly implicated in primary pulmonary histiocytosis. In contrast, pulmonary involvement in younger patients with systemic disease frequently is mild, although fulminant pulmonary disease may occur. Findings on chest radiographs vary from a diffuse infiltrate consistent with bilateral interstitial pneumonia to a “honeycomb lung” appearance (Fig. 52.4).

Other Clinical Features

DI affects 5% to 40% of patients with LCH, depending on the report. Most instances of DI occur in children who present with

systemic disease and involvement of the orbit and skull. Fewer than one-third of children who ultimately develop DI have polydipsia and polyuria as presenting symptoms of LCH. Most cases of DI present within 4 years of diagnosis. DI is caused by infiltration by Langerhans cells and macrophages into the hypothalamus with or without involvement of the posterior pituitary gland (Fig. 52.5). DI may occur at any time during the course of LCH. Patients should be instructed to report signs of DI as soon as they develop because dehydration and electrolyte imbalance may be quite serious. In addition, definitive documentation of DI with measurement of serum and urine electrolytes and osmolality before and after a several-hour water deprivation period should be performed. Vasopressin levels can be measured to document a deficiency. The effectiveness of LCH treatment for reversal of new-onset DI is controversial.

Short stature has been found in up to 40% of children with systemic LCH. Chronic illness and steroid therapy are believed to play an important role in this phenomenon. However, short stature also may be a consequence of anterior pituitary involvement and growth hormone deficiency, which can occur in up to half of patients with initial anterior pituitary dysfunction. Other endocrine manifestations include hyperprolactinemia and hypogonadism caused by hypothalamic infiltration.

A severe complication or manifestation of LCH is the development of a delayed central nervous system (CNS) neurodegenerative

syndrome. This CNS involvement is typically seen in children who had classic lytic bony involvement or soft tissue mass lesions in or around the CNS years earlier. Delayed CNS involvement is typically diagnosed after a prolonged, sometimes insidious, decrease in school function. Magnetic resonance imaging (MRI) reveals diffuse or polymorphic lesions involving the white matter of the cerebellum, pons, and cerebral hemispheres. Limited biopsy studies have revealed an inflammatory infiltrate, predominated by CD8⁺ T cells. Such findings suggest that this form of CNS involvement is analogous to a paraneoplastic syndrome. However, the timing (usually years after disease resolution) and the lack of concurrently active LCH in most patients are unique to this syndrome. Currently, there are no agreed upon diagnostic criteria for CNS LCH, but neurologic involvement (as evidenced by neuropsychiatric testing) with or without MRI findings is essential. Of note, although abnormal MRI findings (with white matter lesions) may precede clinical manifestations, such findings do not always correlate with clinical disease (even in retrospect). Lesions involving the CNS itself or bony lesions of the skull base and facial bones (but not the calvarium or mandible) are thought to confer the greatest risk for subsequent development of this complication.

Laboratory Manifestations

LCH is the most common and prominent of numerous dendritic cell-related histiocytic disorders. Tables 52.2 and 52.3 list the clinical and pathologic features that help to describe and distinguish LCH from other, much rarer, histiocytic disorders (as well as HLH and SHML, discussed in the next section). The typical histologic appearance of LCH varies with the age of the lesion examined (Fig. 52.6). The Langerhans cell is the essential diagnostic feature in the histology of LCH. Early lesions often are locally destructive, with proliferation and accumulation of phenotypically and functionally immature Langerhans cells. Mitoses usually are not present in great numbers, but when found are of no known prognostic significance. Multinucleated giant cells are commonly noted. Other inflammatory cells, such as granulocytes, eosinophils, macrophages, and lymphocytes, are also present. Giant cells and macrophages may be phagocytic and, over time, may accumulate cholesterol. As lesions mature or show signs of regression, fewer Langerhans cells are present, and development of fibrotic reaction is less. The diagnosis of LCH relies on the immunohistochemical identification of the presence of Langerhans cells by cell surface CD1a or by the presence of Birbeck granules by electron microscopy in biopsied lesions. Pathologic criteria for the diagnosis of LCH have been established and were formalized by the Histiocyte Society in 1987. With the availability of antibodies to CD1a for use in routinely processed paraffin-embedded specimens, electron

(C) Cell with a central longitudinal nuclear groove, giving the cell a coffee bean appearance. (D) Immunohistochemical stain for CD1A showing the histiocytic cells are positive. (E) Some cases of Langerhans histiocytosis are associated with prominent eosinophilia. Another term for such cases is *eosinophilic granuloma*. (F–H) Juvenile histiocytosis. Histologic features of juvenile xanthogranuloma vary. (F) In this case, low-power magnification shows a dome-shaped lesion with an attenuated epidermis. (G) At higher power, the bulk of the lesion is composed of a proliferation of histiocytes with abundant pink cytoplasm. Sometimes these histiocytes show more vacuolization or xanthomatization. (H) Scattered Touton-type giant cells are present.

microscopy is rarely needed. Of note, CD1a⁺ Langerhans cells are known to accumulate at the sites of inflammation and may be seen at the margins of malignant lesions. Thus, care should be taken that an adequate biopsy specimen has been obtained to observe the full context of a putative lesion.

Unlike with many malignancies, there are no predictive pathologic features that may define “favorable” or “unfavorable” histology. Although patients are grouped based on their organ system involvement, untreated patients generally do not progress to a different grouping. Within a few months after presentation, it will become apparent that the lesions seen initially are limited to the skeleton or were the “heralding lesion(s)” of diffuse systemic involvement. When cutaneous involvement is the only obvious presenting sign, several months may be required to determine the ultimate extent of disease.

Patients who are suspected to have LCH or who have a new biopsy-proven diagnosis of LCH should have a screening positron emission tomography (or plain radiography and bone scan, although this has been demonstrated to be less sensitive) to help determine the extent of disease involvement. All patients should be evaluated with a complete blood count, chemistries including liver function tests, coagulation workup, and urine osmolality. Dental examination and radiographs should also be considered. The occurrence of cytopenias, particularly thrombocytopenia, in the presence of liver or spleen involvement may be diagnostic of BM involvement.

Differential Diagnosis

The differential diagnosis of LCH depends on the clinical presentation and is typically clarified with a tissue biopsy. Skin involvement frequently mimics seborrheic dermatitis, albeit with a severe or refractory course. Immunodeficiency syndromes or viral infection must be considered as well. The differential diagnosis of bony lesions, although typically quite distinctive, may include bone cyst, lymphoma,

sarcoma, or metastatic solid tumor. Chronically draining ears from temporal bone involvement is often diagnosed as chronic otitis media. Liver and spleen involvement must be distinguished from leukemia and storage diseases.

Prognosis

The prognosis of patients with LCH is largely determined by the nature of their disease presentation and their response to initial therapies. In general, the only patient population with significant mortality rates are those with visceral, or so-called “risk organ”, involvement (e.g., liver, spleen, or BM). Furthermore, the international Histiocyte Society conducted a clinical trial (LCH-II) that identified the response after an initial 6 weeks of therapy with weekly vinblastine and daily prednisolone as the single most important factor in predicting mortality in patients with risk organ involvement. Of the approximately 79% of patients who responded to initial therapy, 94% were alive at 5 years, but only 11% of the nonresponders survived. These important data suggest that alternative therapies should be tested early during the course of therapy for patients with poor early responses. Based on early clinical trials, a staging system was developed for the LCH-III trial that is being further modified in the LCH-IV trial.

Therapy

A generally accepted standard for initial treatment of patients with LCH is use of an appropriate amount of the least toxic therapy to treat the disease. In patients with potentially morbid or life-threatening disease at presentation or in those who develop morbid or life-threatening disease during the course of treatment, alternative and sometimes more aggressive treatment should be implemented. This

approach emphasizes the need for treatment protocols based on careful prognosis-based risk stratification. Whether more intense upfront therapy in lower risk patients can reduce disease sequelae, such as DI, CNS degeneration, sclerosing cholangitis, or disease recurrence, is currently under evaluation. For the majority of patients with localized or limited systemic disease, the goal of therapy should be minimizing loss of function and preventing cosmetic deformity. Seborrhea-like dermatitis of the scalp may improve with use of a selenium- or phenol-based shampoo. Topical steroids can be effective, but prolonged exposure or use on the face should be avoided. Topical nitrogen mustard has been used for problematic focal skin lesions. In patients with particularly refractory and extensive skin involvement, psoralen ultraviolet A can be effective. These topical therapies have not been studied in clinical trials.

Surgery and Radiotherapy

Patients with disease involving a single bone can usually be managed with local therapy. This most often involves surgical curettage for patients whose lesions are in easily accessible, noncritical locations. Complete “cancer operation” resections are not considered necessary and should be avoided to reduce cosmetic and orthopedic deformities, as well as loss of function. Local soft tissue disease (e.g., scalp, thymus, lymph nodes) generally recurs despite surgery; thus, additional treatment with antiinflammatory or cytoreductive drugs is usually required. Because of concerns about the development of secondary malignancies, systemic therapy is usually favored over radiation. However, local radiotherapy is indicated under certain circumstances; for example, when patients are at risk for visual or hearing loss, skeletal deformity, spinal cord injury, or severe pain when systemic therapy is not rapidly effective.

Chemotherapy

Historically, drugs used in therapy for classic malignant diseases have been used for the systemic or local treatment of LCH. A variety of drugs, including vinblastine, vincristine, cytarabine, nitrogen mustard, cyclophosphamide, procarbazine, chlorambucil, etoposide, methotrexate, corticosteroids, and 6-mercaptopurine (6-MP), have been used, alone or in combination, with variable success. Therapeutic advances for LCH in recent years have largely come from international cooperative trials conducted by the Histiocyte Society. The Histiocyte Society is currently opening the next international trial, LCH-IV, which has strata allowing for the enrollment of all patients with LCH, either as a treatment or as a registry study. For patients not enrolled on LCH-IV, detailed treatment recommendations are available on the Histiocyte Society’s website (<http://www.histio.org>).

A reasonable therapeutic approach to systemic therapy is to observe patients with limited, single-system disease who respond to local (i.e., surgery, radiation) or nonsystemic (i.e., topical steroids) therapy and look for signs of disease resolution. If persistent symptomatic lesions or evidence of progressive disease is seen, systemic treatment should be pursued. Patients with disease that is localized to skin, bone, and lymph nodes (defined as “nonrisk” organs) generally have a good prognosis and may require only minimal treatment. Extensive refractory skin disease may warrant systemic therapy with low-dose oral methotrexate, vinblastine–prednisone, or low-dose cytarabine, or with topical therapy such as nitrogen mustard.

Multisystem disease or multifocal bony disease usually warrants treatment with systemic chemotherapy. The current standard of care is a risk-adapted approach, largely using vinblastine, prednisone, and 6-MP, based on the LCH-III trial. This approach has evolved in a stepwise fashion from previous multicenter trials conducted by international groups (DAL-HX 83/90 protocols [Austria, Germany, Switzerland, The Netherlands], LCH-I, and LCH-II). All of these protocols were risk adapted and were based on different combinations of prednisone, vinblastine, etoposide, methotrexate, and 6-MP. The

Histiocyte Society has stratified patients with LCH into “low-risk” (LR) and “high-risk” (HR) groups based on outcomes related to the extent and location of the LCH lesions. LR patients include patients with skin, bone, lymph node, and pituitary involvement. Patients with liver, spleen, or BM involvement usually have a worse prognosis and are considered higher risk. Children with lung LCH, without involvement of other HR organs, are generally not considered to be HR. Additionally, LR patients believed to have lesions that may increase their future risks of CNS degenerative disease (lesions within the CNS, skull base, or facial bones) are designated as “CNS risk”.

Alternative treatment has not been standardized for patients with recurrent or refractory disease. Patients with recurrent disease (i.e., disease that reappears after a period of remission) often respond well to the drugs with which they initially were treated. Several studies, including an international phase II trial, have demonstrated significant activity of 2-chlorodeoxyadenosine (2-CdA) against recurrent and refractory LCH. In addition, the combination of 2-CdA and high-dose cytarabine has been used in refractory, high-risk patients. However, recent reports suggest that clofarabine may be a superior agent for salvage treatment of refractory LCH compared with historical experience (although no direct comparison has been conducted). Finally, a recent report, by Simko et al has demonstrated that upfront use of cytarabine monotherapy is associated with excellent response rates, and may avoid the toxicities of prednisone/vinblastine-based regimens.

Long-Term Follow-up

Retrospective analysis of “CNS risk” patients treated with only surgery, steroid injection, radiation therapy, or a single chemotherapy drug have a 40% incidence of DI. If they receive vinblastine and prednisone for 6 months the incidence of DI is 20%. Complications of developing DI include a significant incidence of anterior pituitary hormone deficiencies or neurodegenerative syndrome. Patients with neurodegenerative syndrome may have ataxia, dysarthria, dysmetria, and learning and behavior difficulties. The diagnosis may be aided by brain MRI, in which T2 hyperintense signals in the cerebellum, basal ganglia, or pons may be present, but such abnormalities do not always correlate with clinical disease or vice versa. Treatment with intravenous immunoglobulin (IVIG) or low-dose cytarabine has anecdotally resulted in stabilization of these symptoms.

A retrospective analysis by Willis et al of 71 patients from a single institution followed for a median of 8.1 years from diagnosis revealed the presence of significant late sequelae in 64% of patients followed for more than 3 years. Skeletal defects were found in 42%, dental problems in 30%, DI in 25%, growth failure in 20%, sex hormone deficiency in 16%, hypothyroidism in 14%, hearing loss in 16%, and CNS dysfunction in 14%. The risk of malignancy in patients with LCH undergoing radiation and chemotherapy is well documented. Thus judicious use of radiotherapy, avoidance of potentially carcinogenic chemotherapeutic agents, and good supportive care are recommended. Leukemia in LCH patients treated with etoposide as a single agent and in combination with other agents has been reported. Because etoposide was not shown to be any more effective than vinblastine in both the LCH-I and LCH-II trials for patients without risk organ involvement, there does not appear to be reason to include this leukemogenic agent in the treatment of these patients with newly diagnosed LCH.

Another serious late effect of LCH is sclerosing cholangitis, which may lead to secondary biliary cirrhosis and liver failure. Sclerosing cholangitis may develop years after successful therapy for LCH and does not typically signify disease recurrence. The only successful treatment of sclerosing cholangitis has been liver transplantation. Other late complications of LCH are pulmonary cyst formation, fibrosis, and chronic pneumothoraces. No effective treatment is available, and progression to cor pulmonale and respiratory failure may occur. Lung transplantation has been used for treatment of such patients. Thus, all patients with LCH require long-term follow up.

In addition to late malignancies, patients should be monitored for signs of long-term disabilities, including cosmetic, orthopedic, and cutaneous deformities that may lead to loss of function and emotional disorders, loss of permanent dentition, endocrinologic disorders and growth failure, hearing impairment, CNS abnormalities and neurocognitive function, sclerosing cholangitis with biliary cirrhosis, and pulmonary fibrosis and cor pulmonale.

Future Directions

The treatment of LCH has undergone significant refinement over the past decade. However, therapy remains empirically defined. With the recent insights into the pathophysiology of LCH, such as B-Raf mutations, new possibilities for more intelligently designed, targeted therapies are conceivable. Trials are ongoing for the assessment of B-Raf and Mek inhibitors in pediatric solid malignancies. It is expected that pilot trials in patients with LCH will commence in the near future. Future clinical trials for such targeted therapies will likely focus on patients with therapy-resistant risk organ involvement because these children have the least satisfactory outcomes.

JUVENILE XANTHOGRANULOMATOUS DISEASE

JXG (or more broadly, the full spectrum of juvenile xanthogranulomatous diseases) is a dendritic cell-related histiocytic disorder. JXG most commonly affects infants and young children, and presents as a solitary or a few “fleshy nodules”. These red-yellowish, benign-appearing lesions are sometimes mistaken for molluscum. However, when biopsied, these lesions reveal a distinctive pathology (see Fig. 52.6). Multinucleated, Touton giant cells are usually found, and lesional histiocytes are positive for CD14, CD68, CD163, factor XIIIa, and fascin, suggesting that they are dermal dendrocytes. The cells are usually negative for CD1a, S100, and the plasmacytoid monocyte antigen CD123.

JXG most commonly presents as a single skin lesion in infants and young children. The lesions are nodular and usually yellowish to reddish purple. Lesions may vary significantly in size and number but are often several millimeters to 1 cm in size and solitary. However, in some patients the lesions become widespread and quite disfiguring (Fig. 52.7). Furthermore, JXG may become systemic, involving multiple organs, including the liver, lungs, heart, and CNS. CNS involvement can present with seizures, hemiplegia, and increased intracranial pressure. Patients diagnosed with JXG, particularly multifocal JXG, may benefit from screening computed tomography scans to rule out disseminated involvement, particularly if clinical history suggests this. However, regardless of clinical symptoms, all patients with JXG should have ophthalmologic examination to rule out anterior chamber involvement and prevent potentially blinding complications.

Cutaneous JXG lesions usually resolve over several months and require no treatment. Of note, residual pigmented areas may persist indefinitely even after lesions have regressed. In patients in whom JXG becomes systemic and involves multiple organs, systemic chemotherapy similar to that for patients with LCH has been used. In patients who do not respond to initial treatment with vinblastine and steroids, use of other agents, such as methotrexate, steroids, and 2-CdA, has led to responses, according to anecdotal reports.

ERDHEIM-CHESTER DISEASE

ECD is a rare, non-Langerhans form of histiocytosis first described in 1930 with a wide range of manifestations. The number of new cases has dramatically increased over the past 10 years because of the better recognition of this condition. The natural evolution is variable, but the prognosis in the absence of effective therapy is poor.

Fig. 52.7 EXTENSIVE JUVENILE XANTHOGRANULOMATOUS DISEASE IN AN INFANT.

ECD is seen most commonly in patients aged 50 years or older. It usually presents with xanthoma-like skin nodules and bilateral lower limb bone pain. Patients with more disseminated disease may have cardiopulmonary insufficiency; renal failure caused by characteristic retroperitoneal and perinephric infiltrative or constrictive changes; and CNS involvement manifested by ataxia, DI, and altered mental status. They may also have periorbital involvement with exophthalmos and impingement on the optic nerves. The disease may be progressive and fatal. The pathophysiology of ECD has been mysterious, although a plasma cytokine profile consisting of elevated interferon- α (IFN- α), interleukin-12 (IL-12), monocyte chemoattractant protein-1, IL-4, and IL-7 in these patients suggests a systemic immune perturbation. Recently, mutations in *BRAF* similar to those in LCH have been identified as the likely initiating event in these patients, although why ECD develops uniquely compared with LCH remains a mystery.

First-line treatment for ECD has consisted of IFN- α . However, a recent report of excellent response to a B-Raf inhibitor may change this standard of care. Other effective treatments have been limited, although responses have been observed with steroids, vinblastine plus steroids, methotrexate, 2-CdA, and bisphosphonates, in addition to IFN- α . Autologous hematopoietic BMT has been reported as a therapeutic modality.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

In the broad classification of histiocytic disorders (see Table 52.1), HLH is categorized as a monocyte/macrophage-related histiocytic disorder. HLH derives its name from its sometimes distinctive pathology (hemophagocytosis), in which macrophages appear to be widely infiltrating tissues and engulfing blood and BM cells in a nonspecific fashion. However, HLH is best conceptualized as an immune regulatory disorder, which is characterized by clinical signs and symptoms of extreme inflammation and the development of cytopenias, hepatitis, and CNS dysfunction, which are severe and life threatening. Indeed, it has recently been proposed that the name of this disorder should be changed to “hyperinflammatory lymphohistiocytosis” (also HLH).

HLH was first described as a familial disease by Farquhar and Claireux in 1952, which they named “familial hemophagocytic

TABLE 52.4**Diagnostic Criteria for Hemophagocytic Lymphohistiocytosis, Established for the Conduct of the Hemophagocytic Lymphohistiocytosis-2004 Trial**

The diagnosis of HLH may be established by:^a

- A. A molecular diagnosis consistent with HLH: Pathologic mutations of *PRF1*, *UNC13D*, *Munc18-2*, *Rab27a*, *STX11*, *SH2D1A*, or *BIRC4* or
- B. Five of the eight criteria listed below are fulfilled:
 1. Fever $\geq 38.3^{\circ}\text{C}$
 2. Splenomegaly
 3. Cytopenias (affecting at least two of three lineages in the peripheral blood)
 4. Hemoglobin $< 9 \text{ g/dL}$ (in infants < 4 weeks: hemoglobin $< 10 \text{ g/dL}$)
Platelets $< 100 \times 10^3/\text{mL}$
Neutrophils $< 1 \times 10^3/\text{mL}$
 5. Hypertriglyceridemia (fasting $\geq 265 \text{ mg/dL}$) or hypofibrinogenemia ($\leq 150 \text{ mg/dL}$)
 6. Hemophagocytosis in BM, spleen, lymph nodes, or liver
 7. Low or absent NK cell activity
 8. Ferritin $> 500 \text{ ng/mL}$
 9. Elevated soluble CD25 (soluble IL-2 receptor α)

^aAdditionally, in the case of familial HLH, no evidence of malignancy should be apparent.

BM, Bone marrow; HLH, hemophagocytic lymphohistiocytosis; IL-2, interleukin-2; NK, natural killer.

reticulosis". Through the years, the syndrome of HLH has been recognized as both a sporadic and familial disorder, and in various clinical contexts. Although we prefer to lump each of these clinical variations into a single syndrome (HLH), the medical literature has used a plethora of names: familial erythrophagocytic lymphohistiocytosis, viral-associated hemophagocytic syndrome, and malignancy-associated hemophagocytic syndrome, among others. Furthermore, macrophage activation syndrome (MAS), the systemic inflammatory syndrome observed in association with rheumatologic disorders, is likely a variant of HLH syndrome because both "classic" HLH and MAS have similar clinical phenotypes and appear to share some underlying mechanisms. The International Histiocyte Society formally adopted the name of HLH in 1998 and defined criteria for its diagnosis, which were updated in 2004 (Table 52.4).

Epidemiology

The true incidence and prevalence of HLH are unknown and remain difficult to ascertain accurately. The diagnosis of HLH is challenging because of its variable presentation and the many nonspecific clinical features it shares with other disease processes. HLH is considered to be rare, but increasing awareness and recognition of the syndrome is leading to more frequent diagnoses. Currently, it is estimated that the autosomal recessive forms of familial HLH have a prevalence of 1 in 50,000 live births. A recent report estimated the incidence of HLH in tertiary care pediatric hospitals at 1 case of HLH per 3000 inpatient admissions. Because of the typically autosomal recessive nature of familial HLH, this disorder is reported to occur more frequently in isolated populations or kindreds with consanguinity.

Pathobiology

The immunologic basis of HLH was long suspected because of its inflammatory nature and the finding of cytotoxic deficiencies and other immune abnormalities in patients with HLH. The first confirmation that HLH is an immunodeficiency came in 1999 with the discovery of perforin mutations in affected patients. However, unlike other immunodeficiencies, the principal clinical characteristic of

HLH is one of intense, prolonged systemic inflammation rather than unusual or severe infections. Although this inflammation may be triggered by infection or vaccination, the inflammation itself (and not apparently the sometimes benign or transient infection) appears to drive the clinical features of HLH. Thus, familial HLH appears to be a deficiency of immune regulation. Animal studies have begun to detail how this immune regulation functions and how deficiencies may lead to HLH. In brief, cytotoxic lymphocytes kill not only infected cells but also antigen-presenting cells (APCs). These APCs promote T-cell activation during infection. This persistence of activating signals leads to excessive or prolonged acute T-cell activation. Abnormal T-cell activation, in turn, leads to activation of macrophages and the development of disease pathology. In animal models, IFN- γ appears to be the critical nexus between T-cell activation and disease development. In several published series, IFN- γ appears to be elevated in patients with HLH. However, clinical data appear mixed, and it remains uncertain whether IFN- γ is critical for HLH development in all patients. An underlying lesion of immune regulation and the associated pathophysiology is less clear in apparently sporadic cases of HLH, sometimes referred to as *secondary HLH*. However, the traditional dichotomy between primary (familial) HLH and secondary HLH (associated with infections, malignancy, or autoimmunity) is becoming increasingly murky.

HLH may present in a variety of clinical contexts and with a variety of etiologic associations. Patients in the primary HLH category are those with clear familial inheritance or known genetic causes, are usually infants or younger children, and are thought to have fixed defects of cytotoxic function (although this is not always the case). These patients have a clear risk of HLH recurrence and will generally not survive long term without hematopoietic cell transplantation (HCT). Although HLH in these patients can be associated with infections (e.g., cytomegalovirus [CMV] or Epstein-Barr virus [EBV]) or vaccination, the immunologic trigger is often not apparent. The term "secondary HLH" generally refers to older children (or adults) who present without a family history or known genetic cause for their HLH. These patients typically have concurrent infections or medical conditions that appear to trigger their HLH, such as EBV infection, malignancy, or rheumatologic disorders. The list of triggering stimuli for both familial and apparently nonfamilial HLH is extensive. Patients with presumed secondary HLH are sometimes reported as having immune studies, including NK cell function, that normalize with disease resolution, although in the authors' experience this is variable or unclear. Although the mortality rate from HLH may be significant, the risk of recurrence in cases of secondary HLH is poorly defined. Recurrence of HLH in the absence of autoimmune disease or malignancy is generally considered to be good evidence that a patient has primary HLH, regardless of the other clinical features. In the absence of a known genetic defect or family history, it is often not possible to make an initial diagnosis of "primary" or "secondary" HLH. Further obscuring this dichotomy, a recent report by Zhang et al described a large series of adults with HLH who were found to have genetic mutations typically seen in children with familial HLH.

A variety of genetic causes of familial HLH have been identified, all either autosomal recessive or X-linked (Table 52.5). Most of these genetic lesions affect a biologic pathway referred to as *granule-dependent*, or *perforin-dependent*, *cytotoxicity* (Fig. 52.8). This pathway is used by T cells and NK cells to kill target cells, typically those infected by viruses. When triggered, specialized lysosomal granules containing perforin, granzymes, and other proteins are released, leading to apoptotic death of target cells. The first genetic lesions identified in patients with HLH were mutations in *prf1*, the gene encoding the protein perforin. *Prf1* mutations account for about 15% to 20% of HLH in certain geographic areas and are known as familial HLH 2 (FHL2). FHL2 has mild and severe phenotypes that correlate with the degree of mature perforin protein that is produced. Abnormalities of granule formation, mobilization, and extrusion are also identified as causes of HLH. Munc13-4, a protein essential to the exocytotic process, is mutated in FHL3. FHL3 has a worldwide distribution and accounts for 15% to 20% of all heritable HLH.

Fig. 52.8 MECHANICS OF CYTOTOXIC FUNCTION REVEALED BY HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS-ASSOCIATED GENE MUTATIONS. Hemophagocytic lymphohistiocytosis-associated genetic abnormalities (in the indicated genes) may affect granule-dependent lymphocyte cytotoxicity by impairing trafficking, docking, priming for exocytosis, or membrane fusion of cytolytic granules. The function of this pathway may also be severely impaired by loss of functional perforin, the key delivery molecule for proapoptotic granzymes. Diverse mutations in this pathway all give rise to similar clinical phenotypes (albeit of variable severity). Lyst (the gene affected in Chediak-Higashi syndrome) is not portrayed because its function is not entirely clear, although it appears to play an important role in the maintenance of normally sized (and functional) cytolytic granules. CTL, Cytotoxic T lymphocyte; NK, natural killer, SNARE, soluble *N*-ethylmaleimide-sensitive fusion attachment receptor protein. (Adapted from Jordan MB, Allen CE, Weitzman S, Filipovich AH, McClain KL: *How I treat hemophagocytic lymphohistiocytosis*. Blood 118:4041, 2011.)

However, recent discoveries of previously unappreciated intronic mutations in this gene may expand the proportion of patients with FHL3. FHL4 is caused by mutations in the protein syntaxin 11, a member of the soluble *N*-ethylmaleimide-sensitive fusion attachment receptor protein family of proteins, which is necessary for the fusion of cytotoxic vesicles with the plasma membrane to release their granules. Mutations in the syntaxin-binding protein 2, also important for this process, have been designated FHL5. The genetic defect responsible for FHL1 has not been identified, and no mutations in granzyme proteins have been associated with HLH.

Two X-linked causes of HLH are known. The first, called “X-linked lymphoproliferative syndrome 1” (or XLP1), is caused by

defects in SH2D1A or SAP. This disorder is a complex one characterized by lymphoproliferation, hypogammaglobulinemia, excess risk of lymphoma, and development of HLH. It appears to share some of the pathophysiology with classic familial HLH, although other abnormalities (of B cells and other cells) make this disorder distinctive. The second X-linked cause of HLH, sometimes called “XLP2” (although this is disputed), are abnormalities of a gene/protein called baculoviral inhibitor of apoptosis protein repeat-containing protein 4 (BIRC4)/X-linked inhibitor of apoptosis protein (XIAP). The apparently unique pathophysiology of HLH caused by XIAP deficiency is not understood. Other immunodeficiency syndromes caused by defects in lysosomal trafficking have been linked to life-threatening episodes of HLH. These include Chediak-Higashi syndrome, Griscelli syndrome, and Hermansky-Pudlak syndrome, type II.

Taken together, the nine genetic disorders described above still account for fewer than half of the diagnosed cases of HLH in children, including many familial cases still awaiting molecular definition. Until recently, it was widely believed that symptoms of HLH triggered by genetic causes arose during infancy and early childhood. With the more widespread availability of genetic testing, it is apparent that the first significant episode of HLH can occur throughout life from prenatal presentations through the seventh decade of life. Distinctions between primary (genetically determined) and secondary (acquired) forms of HLH become increasingly blurred together as new genetic causes are identified and patients who develop HLH beyond early childhood or in the contexts of EBV infection or autoimmune disease are being found to share some of the same genetic etiologies.

Clinical Manifestations

The classic presentation of HLH consists of prolonged, hectic fevers (usually present for 1–2 weeks before diagnosis), hepatosplenomegaly, and cytopenias. Neurologic symptoms are common and distinctive features of these patients; these include symptoms of irritability, ataxia, hypotonia or hypertonia, evidence of increased intracranial pressure, meningismus, depressed mental status, cranial nerve palsies, and seizures. Standard diagnostic criteria have been defined by the Histiocyte Society for the conduct of the now closed HLH2004 trial (see Table 52.4). Although imperfect, these criteria are widely accepted for the diagnosis of HLH. However, because HLH is a clinical syndrome, it may present in many forms, including fever of unknown origin (FUO); hepatitis or acute liver failure; and sepsis-like, Kawasaki-like, and primary neurologic abnormalities. Not all of the HLH diagnostic criteria may be present initially, so it is important to follow clinical signs and laboratory markers of pathologic inflammation repeatedly to identify the trends. Typical clinical features seen in patients with HLH, grouped by organ system, are described in the following text.

Prolonged Fever

FUO is a very common diagnosis on general pediatric wards, and differentiating HLH from other causes of FUO may be challenging. In one series, patients ultimately diagnosed with HLH presented with fevers above 102°F for a median of 19 days (range: 4–41 days). In patients with FUO, cytopenias, highly elevated ferritin (>3000 g/dL), or sCD25 significantly above age-adjusted normal ranges generally suggest that a complete HLH diagnostic evaluation should be pursued.

Liver Disease and Coagulopathy

Most patients with HLH have variable evidence of hepatitis at presentation. HLH should be considered in the differential diagnosis of acute liver failure, especially if lymphocytic infiltrates are noted on biopsy. Autopsy evaluation of the liver has shown chronic persistent

hepatitis with periportal lymphocytic infiltration in the majority of patients. Neonates with HLH may present with hydrops fetalis and liver failure. Most patients have evidence of disseminated intravascular coagulation (DIC) and are at high risk for acute bleeding. Furthermore, patients with HLH caused by degranulation defects may have intrinsic platelet dysfunction.

Bone Marrow Failure

Anemia and thrombocytopenia occur in more than 80% of patients at the time of presentation with HLH. The cellularity of BM aspirates varies from normocellular to hypocellular or hypercellular. The prevalence of hemophagocytosis in association with HLH diagnosis ranges from 25% to 100%. Although hemophagocytosis in BM is associated with HLH, the morphologic phenomenon may also be induced by more common events, including blood transfusions, infection, autoimmune disease, and other forms of BM failure or causes of red blood cell destruction. Despite the nomenclature of HLH, diagnosis of HLH should never be made or excluded solely on the presence or absence of hemophagocytosis. Infiltration of BM or liver by CD163⁺ macrophages, along with global clinical evaluation, may distinguish HLH from other causes of hemophagocytosis.

Skin Manifestations

Patients may have a variety of skin manifestations, including generalized maculopapular erythematous rashes, generalized erythroderma, edema, panniculitis, inflamed papular lesions, petechiae, and purpura. The incidence of skin manifestations ranges from 6% to 65% in published series with highly pleomorphic presentations. Some patients may present with features suggestive of Kawasaki disease, including erythematous rashes, conjunctivitis, red lips, and enlarged cervical lymph nodes. Rashes may correlate with lymphocyte infiltration on skin biopsy, and hemophagocytosis may also be found.

Pulmonary Dysfunction

Patients may develop pulmonary dysfunction that leads to urgent admission to the intensive care unit. In a review of the radiographic abnormalities in 25 patients, 17 had acute respiratory failure with alveolar or interstitial opacities, with fatal outcomes in 88% of those cases.

Brain, Ophthalmic, and Neuromuscular Symptoms

More than one-third of patients present with neurologic symptoms, including seizures, meningismus, decreased level of consciousness, cranial nerve palsy, psychomotor retardation, ataxia, irritability, or hypotonia. The cerebrospinal fluid (CSF) is abnormal in more than 50% of HLH patients with findings of pleocytosis, elevated protein, or hemophagocytosis. MRI findings are highly variable and include discrete lesions, leptomeningeal enhancement, or global edema, and images correlate with neurologic symptoms. Retinal hemorrhages, swelling of the optic nerve, and infiltration of the choroid have been reported in infants with HLH. Diffuse peripheral neuropathy with pain and weakness secondary to myelin destruction by macrophages may also occur.

Laboratory Manifestations

Laboratory manifestations are a critical component of diagnosing HLH. Biochemical abnormalities noted on clinical laboratory assessment include anemia, thrombocytopenia, neutropenia, elevated liver transaminases, hyperbilirubinemia, hypofibrinogenemia, coagulation abnormalities, hypoalbuminemia, hyponatremia, hypertriglyceride-

mia, elevated soluble CD163, elevated soluble CD25 (sCD25; also called “soluble IL-2 receptor”), and hyperferritinemia. Specialized immunologic testing may reveal low or absent NK cell or cytotoxic T lymphocyte function (although this is not always seen), low levels of perforin or other disease-associated proteins (e.g., SAP or XIAP), and decreased degranulation (observed with mutations affecting granule trafficking). Additionally, pathologic examination of BM biopsy, liver biopsy, CSF, spleen or lymph node, or even occasionally peripheral blood may reveal hemophagocytosis and infiltration with CD163⁺ macrophages and activated T cells (Fig. 52.9). Examination of CSF reveals pleocytosis, elevated protein, and elevated neopterin levels with CNS involvement. Brain MRI often reveals polymorphic white or grey matter abnormalities in such cases.

Elevations in sCD25 are a particularly useful and notable laboratory feature of HLH. In the authors' experience, this marker is dynamically associated with “active” HLH, and patients with active HLH rarely, if ever, have normal levels of sCD25. Of note, the interpretation of soluble IL-2 receptor levels must be undertaken with care because normal levels change with age and the method of analysis. Despite a few small reports of increased soluble IL-2 receptor levels in sepsis, significant elevations of this marker are rarely observed outside the context of HLH. However, the clinical utility of sCD25 is often compromised by delays because most institutions must send patient samples to referral laboratories. Because of its ready availability in most hospitals, the serum ferritin level can serve as an important adjunct to the decision-making process. The HLH diagnostic guidelines define a cutoff at greater than 500 µg/L, which may be observed in sepsis or other hyperinflammatory conditions. Ferritin levels in HLH are usually dramatically higher, with some series finding mean levels near 45,000 µg/L. A recent review of elevated ferritin values at a large pediatric academic tertiary care hospital demonstrated that a ferritin level greater than 10,000 was 90% sensitive and 96% specific for HLH.

Differential Diagnosis of Hemophagocytic Lymphohistiocytosis

Because HLH presents as an inflammatory syndrome, the differential diagnosis of this disorder is a broad one. Infection must be considered as either a mimic of HLH or as an underlying trigger of the disorder. The list of infections reported as associated with HLH is extensive. If the patient presents with acute multiorgan failure, then sepsis is generally considered first before a diagnosis of HLH is considered. Viral infections, including EBV, CMV, dengue, and severe influenza, should always be considered and treated. Protozoan infections, including malaria, toxoplasmosis, and leishmaniasis, may be a consideration in endemic areas. Visceral leishmaniasis, in particular, may be clinically indistinguishable from primary HLH. In addition to infectious disorders, rheumatologic disorders, including systemic onset juvenile idiopathic arthritis (soJIA) and Kawasaki syndrome, should be considered. Finally, as either a mimic or trigger, malignancy should be considered, particularly lymphoma and leukemia.

Diagnosis

Because of the severe nature of this disorder and the existence of disease-altering therapies, it is crucial to identify patients early in their course. The Histiocyte Society established diagnostic criteria for the HLH-2004 trial, which is widely used for patients not treated in this trial, using both clinical and laboratory findings (see Table 52.4). Laboratory verification of a known genetic defect confirms the diagnosis independent of the presence or absence of any clinical signs or symptoms. However, genetic diagnosis is not usually available in a timely fashion for patients with acute clinical presentations. In the absence of a genetic diagnosis, five of the eight clinical criteria must be met to make a diagnosis. It is important to note that NK cell dysfunction is only present in about 50% of patients with HLH. Additionally, hemophagocytosis may not be present early in the HLH

Fig. 52.9 (A–F) Familial hemophagocytic lymphohistiocytosis. Illustrations from a 3-month-old girl who presented with diarrhea, pancytopenia, hepatomegaly, and liver failure. Bone marrow (A and B) showed left-shifted granulopoiesis and increased histiocytes, which at high power (C and D) were undergoing prominent phagocytosis of erythrocytes, platelets, and other cells. Liver biopsy sample (E) showed a lymphohistiocytic infiltrate also associated with hemophagocytosis (F). The patient was shown to harbor a mutation of the perforin gene in exon 2. (G–J) Sinus histiocytosis with massive lymphadenopathy (Rosai–Dorfman disease). Low-power magnification of the biopsy sample (G) shows a mottled appearance of the lesion caused by dark areas containing small lymphocytes and lighter areas containing histiocytes. At higher magnification (H), the histiocytes have abundant pale cytoplasm with scattered cells within. This is emperipolesis, a process of cells traveling through the cytoplasm but not apparently becoming phagocytized or degraded. Note the plasma cells in the background. The emperipolesis can be better visualized with a CD68 stain for histiocytes (I). This process delineates the cell boundary and the cells within the histiocyte cytoplasm. The emperipolesis can also be seen on a Wright-stained touch preparation (J).

disease process; therefore, serial assessments may be required if that diagnostic criterion is to be met.

Therapy

Without therapy, survival of patients with active familial HLH is historically reported to be approximately 2 months. The first international treatment protocol for HLH was organized by the Histiocyte Society in 1994 and led to reported survival of 55%, with a median follow-up of 3.1 years. The HLH-94 protocol, as illustrated in Fig. 52.10, included an 8-week induction therapy with dexamethasone, etoposide, and intrathecal methotrexate. The principal goal of induction therapy is to suppress the life-threatening inflammatory process that underlies HLH. At the end of 8 weeks, patients are either weaned off therapy or transitioned to continuation therapy, which is intended only as a bridge to transplantation.

The Histiocyte Society opened a new trial in 2004, HLH-2004, which is now closed. The major modifications from HLH-94 were to move cyclosporine dosing to the beginning of induction and add hydrocortisone to intrathecal therapy. Results of this trial are not reported at this time. An alternative approach to etoposide-based regimens with comparable survival was published as a single-center retrospective experience over 14 years, in which all patients were treated with corticosteroids and antithymocyte globulin (ATG), followed (rapidly) by HCT. Until this immunotherapy approach can be compared with etoposide–dexamethasone in the setting of a clinical trial and until the results of the HLH-2004 study are published, the standard of care therapy for patients not enrolled in a clinical trial should be based on HLH-94.

Fig. 52.10 INDUCTION THERAPY FOR HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS. Based on the HLH-94 study, this approach should be considered standard of care for all patients not enrolled in clinical trials based on published evidence of efficacy. Etoposide is dosed as 150 mg/m² per dose. Alternatively, for patients weighing less than 10 kg, consideration may be given to dosing etoposide as 5 mg/kg per dose. Dexamethasone (Dex.) is dosed as indicated and may be given orally or intravenously, although the latter is preferred at therapy initiation. IT MTX/HC should be given to patients with evidence of CNS involvement as early as lumbar puncture may be safely performed (which may vary from the diagram) and dosed as follows: age younger than 1 year, 6/8 mg (MTX/HC); age 1–2 years, 8/10 mg; age 2–3 years, 10/12 mg; and age older than 3 years, 12/15 mg. Weekly intrathecal therapy is generally continued until at least 1 week after resolution of CNS involvement (both clinical and cerebrospinal fluid indices). CNS, Central nervous system; IT MTX/HC, intrathecal methotrexate and hydrocortisone. (Adapted from Jordan MB, Allen CE, Weitzman S, Filipovich AH, McClain KL: How I treat hemophagocytic lymphohistiocytosis. *Blood* 118:4041, 2011.)

Often, the principal challenge for treating patients with HLH is making a timely and accurate diagnosis. It is critical to search for and treat underlying triggers of HLH and institute specific antimicrobial therapy. Rituximab is often helpful in controlling EBV infection. IVIG is an appropriate adjunct for most viral infections. If the patient is stable and not severely ill, consideration can be given to treating the underlying trigger with disease-specific therapy with or without corticosteroids and close follow-up. However, in most cases, an aggressive therapeutic approach is warranted and may reasonably be initiated before obtaining final results for all diagnostic studies. Specifically, HLH therapy should not be withheld while awaiting results of genetic testing because our understanding of HLH-associated gene defects remains incomplete and testing typically takes weeks to complete. With the exception of autoimmune disease and malignancy, initial therapy for patients with suspected familial or reactive HLH does not differ.

Induction Therapy

The current standard of care consists of a decrescendo course of etoposide and dexamethasone with or without intrathecal therapy (see Fig. 52.10). Ideally, critically ill patients should be treated at facilities familiar with care of cancer and BMT patients. It is important to initiate therapy promptly even in the face of unresolved infections, cytopenias, or organ dysfunction. After starting therapy, patients should be monitored closely for signs of improvement as well as potential complications and toxicities, and therapy may need to be customized. For patients who respond well, with resolution of symptoms and normalization of inflammatory markers, therapy may be weaned per protocol. However, dexamethasone doses and etoposide frequency may need to be increased in response to disease reactivation (see [Salvage Therapy](#) section later). Deterioration of liver function and blood counts as well as steady increases in serum ferritin, sCD25, and sCD163 tests may signal relapse of HLH disease activity. If patients do not display at least a partial response within 2 to 3 weeks of therapy initiation, salvage therapy should be considered. Recurrence of fever and increased inflammatory markers after an apparent response should also prompt a careful search for opportunistic infection.

Central Nervous System Disease

Patients may present with CNS involvement or may have recurrent disease as treatment doses are being tapered. All patients should receive a careful neurologic examination, lumbar puncture, and brain MRI, even if they are asymptomatic, as soon as they can be safely performed. Changes in mental status at any time during therapy should be investigated urgently. Patients with proven CNS involvement should be treated with weekly intrathecal methotrexate and hydrocortisone until CSF abnormalities and symptoms normalize. The risk of posterior reversible encephalopathy syndrome (PRES) appears to be significant during induction therapy. Although the etiology of PRES is incompletely understood, it is more frequent in settings of hypertension and is also associated with cyclosporine use. Blood pressure should be aggressively managed during induction. Because CNS involvement suggests a familial etiology and because this disease feature is associated with substantial risks for long-term morbidity, HCT should be considered for patients with this complication.

Supportive Care

Supportive care guidelines for patients on therapy for HLH should be similar to standard practice for patients undergoing HCT, including acute care nursing, *Pneumocystis jirovecii* prophylaxis, fungal prophylaxis, IVIG supplementation, and neutropenic precautions. Any new fever should be evaluated for HLH reactivation, as well

as opportunistic infection, and empiric broad-spectrum antibiotic therapy should be initiated. Because of inflammation, consumptive coagulopathy, and intrinsic platelet defects in some patients, they are at very high risk of spontaneous bleeding. The authors aim to maintain platelet count greater than $50 \times 10^9/L$ and do not recommend prophylactic heparin, which is sometimes used in acutely ill patients. Platelets, fresh-frozen plasma, cryoprecipitate, and occasionally activated factor VII are required for acute bleeding.

Continuation Therapy

Patients who can be weaned off of dexamethasone and etoposide without recurrence, recover normal immune function, and have no identified HLH-associated gene defects may stop therapy after the 8-week induction course. HCT is generally recommended in patients with age younger than 2 years, CNS involvement, recurrent or refractory disease, persistent NK cell dysfunction, or proven familial or genetic disease. Continuation according to HLH-94 consists of pulses of dexamethasone and etoposide (etoposide, 150 mg/m^2 every 2 weeks alternating with dexamethasone $10 \text{ mg/m}^2/\text{day}$ for 3 days every 2 weeks). Cyclosporine may be added in patients with stable blood pressure and adequate liver and kidney function. Patients on continuation therapy should proceed to HCT as quickly as possible because of the ongoing risks of infection, disease reactivation, or leukemia or myelodysplastic syndrome related to prolonged use of etoposide.

Salvage Therapy

A significant number of patients with HLH either fail to respond adequately to current therapies or relapse before HCT. Approximately 50% of patients treated in the HLH-94 study experienced a complete resolution of HLH, 30% experienced a partial resolution, and approximately 20% died before HCT. Notably, most deaths occurred during the first few weeks of treatment and may reflect either preexisting morbidities or primary refractory disease. Although it is hoped that some patients will fare better with more prompt diagnosis of HLH, others remain unresponsive to standard therapy. Initial treatment with ATG (thymoglobulin, rabbit ATG) has been reported to give higher complete response rates, but partly because of higher relapse rates, long-term outcomes do not appear superior. Although current therapy is effective, there is a need for new treatments for patients with refractory HLH. At present, there are few data regarding potential second-line therapies. Case reports exist describing the use of infliximab, daclizumab, alemtuzumab, anakinra, vincristine, and other agents as salvage therapies for HLH. A recent report found that alemtuzumab has significant activity against refractory HLH in a larger series of patients. Although refractory HLH appears to have a dismal prognosis, approximately 70% of patients in this series survived. Because of its immunoablative qualities, alemtuzumab should be used with caution and by those with experience caring for profoundly immune compromised patients. CMV reactivation and adenoviremia were frequent complications of this therapy. In contrast to refractory patients, those patients who initially respond well to standard therapy but then relapse as treatment is tapered or withdrawn often respond to reintensification of therapy with standard agents. Because of the variability in patient responses, a critical aspect of initial or salvage therapy is close monitoring of the patients for improvement and potential toxicities such as BM suppression or infection.

Hematopoietic Cell Transplantation

Because the time to transplant is a factor in morbidity and mortality from the disease, a donor search should begin at the time of diagnosis even though the precise etiology of HLH (e.g., genetic defect) has not yet been defined. Generally, HCT is recommended in cases of documented familial HLH, recurrent or progressive disease despite

intensive therapy, and CNS involvement. Long-term disease-free survival after HCT was approximately 50% to 65% before the year 2000, regardless of whether a matched sibling or closely matched unrelated donor was used. Most patients transplanted during that era succumbed to “transplant-related” complications during the first 100 days after infusion. A significant proportion of fatal complications involved inflammatory conditions termed *acute respiratory distress syndrome*, *veno-occlusive disease*, and *multisystem organ failure, unspecified*. In rare cases, residual HLH was identified at autopsy despite the use of myeloablative conditioning therapy.

During the past decade, the use of reduced-intensity conditioning (RIC) regimens before HCT has been investigated after encouraging results from an institutional series. Most cases of RIC pretreatment have included alemtuzumab and demonstrated superior early post-transplant survival. In a single-center analysis directly comparing HCT outcomes after myeloablative conditioning versus RIC, a statistically significant improvement was observed after RIC conditioning, with all patients surviving at 6 months after transplant. At present, published data regarding outcome of RIC transplants using umbilical cord blood is not sufficient to draw conclusions regarding safety or efficacy. Donor choice should also take into account the possibility of an occult predisposition to HLH in siblings of patients without identified gene defects. Much remains to be learned and refined regarding the optimal application of alemtuzumab as well as other agents used before HCT. The timing of pretransplant alemtuzumab impacts the probability of graft-versus-host disease, mixed chimerism, and, in rare cases, rejection. Other factors, such as donor source, human leukocyte antigen match, cell dose, and patient condition with regard to HLH disease activity at time of conditioning, may all play roles in determining the likelihood of success after RIC HCT.

Patients with CNS HLH need close posttransplant follow-up. The authors recommend examination of CSF within 100 days of HCT even in asymptomatic patients. Follow-up MRIs are recommended if pretransplant abnormalities were present. In some patients with mixed or full hematopoietic donor chimerism, HLH disease activity in the CSF can be effectively treated with intrathecal therapy during the early posttransplant months. CNS disease is subsequently controlled as donor immune reconstitution progresses.

Prognosis

Significant strides have been made in the treatment of HLH, with survival now generally ranging from 50% to 70%. In children with nonfamilial HLH, overall survival has been reported at 72%, but only 20% of the patients did not require HCT. Survival is increased in children, irrespective of genetic status, who receive HSCT from matched rather than unmatched donors. RIC pretransplant regimens appear to further decrease mortality. The best outcomes in HSCT are seen in children who have a rapid and complete response to pretransplant therapies and who do not exhibit significant neurologic involvement. Prompt initiation of HSCT in familial patients after disease remission is obtained is also likely to increase survival. Patients with significant neurologic involvement may experience severe and permanent sequelae even if they survive.

MACROPHAGE ACTIVATION SYNDROME

MAS is the name commonly given to a severe, potentially fatal inflammatory condition seen in the context of rheumatologic disorders such as soJIA or systemic lupus erythematosus (SLE). The syndrome of MAS shares many similarities with classic HLH, and many investigators view it as a special form of HLH, suggesting that the name may be changed to rheumatologic HLH (or R-HLH). The main manifestations of MAS include fever, hepatosplenomegaly, lymphadenopathy, severe cytopenias, serious liver disease, and coagulopathy consistent with DIC. Hemophagocytosis is often (although not always) seen in the BM of patients with MAS. The true incidence of MAS may be underestimated because relatively mild cases of MAS often remained

unrecognized. Recent evidence suggests that mild subclinical MAS occurs in as many as one-third of patients with active soJIA and may be the first manifestation of soJIA. Infections or change in medications may precede the diagnosis of MAS; in most patients, MAS is triggered by a flare-up of the underlying rheumatologic disease. Published observations suggest that as in HLH, MAS patients have profoundly depressed NK cell function, sometimes associated with abnormal perforin expression, and these abnormalities are associated with specific perforin and Munc13-4 polymorphisms.

Diagnosis and Treatment

There are no validated diagnostic criteria for MAS, and early diagnosis is often difficult. A recent consensus conference has developed expert-based *classification* criteria for MAS, although these have not been validated as *diagnostic* criteria in clinical trials. Thus, in a patient with persistently active underlying rheumatologic disease, a fall in the erythrocyte sedimentation rate (ESR) and platelet count, particularly in combination with persistently high C-reactive protein and increasing levels of ferritin, should raise a suspicion of impending MAS. The diagnosis of MAS is usually confirmed by the demonstration of hemophagocytosis in the BM. Assessment of the levels of sCD25 and sCD163 in serum may help with the timely diagnosis of MAS. Although mild elevation of sCD25 has been reported in many rheumatic diseases, including JIA and SLE, a several-fold increase in the levels of sIL2R α in these diseases is highly suggestive of MAS. The application of the HLH diagnostic criteria to systemic JIA patients with suspected MAS is problematic. Some of the HLH markers, such as lymphadenopathy, splenomegaly, and hyperferritinemia, are common features of active systemic JIA itself and therefore do not distinguish MAS from a conventional systemic JIA flare. Patients with systemic JIA often have increased white blood cell and platelet counts, as well as serum levels of fibrinogen as a part of the inflammatory response seen in this disease. Therefore, when they develop MAS, they reach the degree of cytopenias and hypofibrinogenemia seen in HLH only at the late stages of the syndrome when medical management becomes challenging. This is even more problematic for the diagnosis of MAS in patients with SLE in whom autoimmune cytopenias are common and difficult to distinguish from those caused by MAS.

Early recognition of this syndrome and immediate therapeutic intervention to produce a rapid response are critical. Prompt administration of more aggressive treatment in these patients may, in fact, prevent development of the full-blown syndrome. To achieve rapid reversal of coagulation abnormalities and cytopenias, most clinicians start with intravenous methylprednisolone pulse therapy (30 mg/kg for 3 consecutive days) followed by 2–3 mg/kg/day divided in four doses. After normalization of hematologic abnormalities and resolution of coagulopathy, steroids are tapered slowly to avoid relapses of MAS. Commonly, however, MAS appears to be corticosteroid resistant, with deaths being reported even among patients treated with massive doses of steroids. Parenteral administration of cyclosporine A has been shown to be highly effective in patients with corticosteroid-resistant MAS. The utility of biologic drugs in MAS treatment remains unclear. Although tumor necrosis factor-inhibiting agents, biologics that neutralize IL-1 and IL-6, have been reported to be effective in occasional MAS patients, other reports describe patients in whom MAS occurred while they were receiving these agents. Based on some success with IVIG administration in virus-associated HLH, this treatment might be effective in MAS triggered by viral infection. If MAS, however, is driven by EBV infection, rituximab, a monoclonal antibody that depletes B lymphocytes (the main type of cells harboring the EBV virus) may be considered.

Future Directions

As an alternative approach to etoposide-based approaches for the treatment of HLH, ATG–prednisone has been used for a number of

years in some centers. These two approaches appear to have unique strengths and weaknesses. Although a significant number of patients fail to respond adequately or completely to etoposide-based regimens, ATG-based regimens are complicated by relatively frequent and early relapse (median time to relapse reported by Ouachee-Chardin et al, 5.5 weeks). Thus, a rational combination of these approaches may improve outcomes by increasing initial responses and maintaining them until HCT can be obtained. Currently, a multicenter clinical trial called *hybrid immunotherapy for HLH* (HIT-HLH) is underway in North America, testing the potential of this idea. A sister trial is being conducted in Europe. In this approach, ATG and etoposide are incorporated into one regimen, but the etoposide dose intensity is decreased to minimize potential myelosuppression. No data are available yet regarding the usefulness of this approach. Alternative strategies using anticytokine antibodies for induction therapy are also being developed.

Although HLH appears to be a disease of excessive immune activation, the ideal form of immune suppression and antiinflammatory therapy remains unknown. Although somewhat responsive to corticosteroids and clearly responsive to anti-T-cell serotherapy, such as ATG or alemtuzumab, HLH remains difficult to treat. However, newer, targeted therapies, based on insights from animal models, are on the horizon. A new drug (currently designated NI-0501), a monoclonal antibody targeting IFN- γ , is being tested in a clinical trial in patients with HLH. It is likely that such targeted therapies will eventually supersede current approaches.

SINUS HISTIOCYTOSIS WITH MASSIVE LYMPHADENOPATHY OR ROSAI-DORFMAN DISEASE

First described in 1969, SHML, or RDD, is clinically characterized as a benign, frequently chronic, painless massive lymphadenopathy usually involving cervical lymph nodes and, less frequently, axillary, hilar, peritracheal, and inguinal nodes. Extranodal disease is present in approximately 30% of patients. The upper respiratory mucosa is involved in 20% of patients, bone in 25%, and orbit or eyelid in 10%. Occasionally, there is involvement of the skin, CNS (meninges), lung, liver, and kidney. Ocular manifestations, such as uveitis, have been observed. Although SHML is a histologically reactive and molecularly polyclonal disorder, significant morbidity and death have been associated with massive tissue invasion of the liver, kidney, lung, brain, and other critical structures. In these instances, the disease may have a rapid downhill course.

Eighty percent of patients are diagnosed in the first or second decade of life; however, the disorder also can affect elderly adults. Typically, patients are of African descent; the incidence of SHML is greatest in Africa and the West Indies. Males and females are equally affected.

Laboratory evaluation frequently reveals an elevated ESR, moderate polyclonal hypergammaglobulinemia, anemia, and granulocytosis. Subtle abnormalities of immune indices may also be seen. Involved lymph nodes (see Fig. 52.9) show marked sinusoidal dilation with proliferation of foamy histiocytes within the sinuses (see E-Slide VM03962). Eosinophils are usually low in number, but plasma cells are abundant. A characteristic finding, referred to as *emperipolesis*, demonstrates lymphocytes surrounded by the membranes of histiocytes as observed best by electron microscopy. The proliferating histiocytes appear to be macrophages. These large, pale cells show variable expression of S100. They can be distinguished from Langerhans cells found in the lymph nodes of patients with classic LCH by the absence of CD1a or Birbeck granules, the presence of α 1-antichymotrypsin, and the absence of CD1a expression.

The etiology of RDD is unknown, but disordered immune regulation has been proposed as a significant contributor. It was originally thought that RDD represented an unusual response to herpesviruses, but this has not been confirmed. Although patients are frequently febrile, infectious agents are not commonly implicated, and the fever is presumed to be a manifestation of systemic disease.

Disease manifestations can subside over several months to years. Of 215 cases in a patient registry, 21% had complete resolution of disease. However, 14 patients died. Five died of "immunologic" causes, such as severe hemolysis; three died of infections; and six probably died as a direct consequence of disease infiltration. As the disease resolves, extranodal disease regresses before nodal disease. Corticosteroids, vinblastine, and low-dose cyclophosphamide are sometimes effective; however, the results with these agents have been inconsistent. A recent report has found that (similar to refractory LCH) clofarabine may be a highly active agent in patients with SHML who require systemic therapy. Attempts at treatment should be reserved for special circumstances, such as tracheal or epidural compression, or invasion of other vital structures, as well as for significant cosmetic disfigurement. Local excision may be useful in selected patients, although the lesions may reappear.

LYSOSOMAL STORAGE DISEASES: PERSPECTIVES AND PRINCIPLES

Edward H. Schuchman and Melissa P. Wasserstein

The lysosomal storage diseases (LSDs) are a diverse group of inherited disorders caused by the defective function of specific lysosomal proteins (Table 53.1). Originally described by de Duve and colleagues,¹ lysosomes are ubiquitous organelles required to metabolize macromolecules. This includes molecules internalized by cells through the process of endocytosis, as well as those produced during the natural turnover of endogenous cell components (autophagocytosis). More than 50 hydrolytic enzymes have been found within the lysosome, as well as several membrane-embedded transport proteins, ion pumps, and other specialized components. Unique to the lysosome is a highly acidic pH, and the enzymes and proteins found within this organelle have evolved to optimally function within this unique environment. Hers² was the first to describe enlarged and abnormally shaped lysosomes in a patient with Pompe disease (α -glucosidase deficiency), thus delineating the first LSD. To date, more than 50 disorders have been attributed to defective lysosomal proteins. Most are inherited as autosomal recessive traits, although two are X-linked (Fabry disease and mucopolysaccharidosis [MPS] type II [Hunter disease]). In general, LSDs are categorized according to the type of macromolecule(s) that accumulate (e.g., lipidoses, mucopolysaccharidoses). The pathophysiology of these diseases is directly related to these accumulating material(s), although as the diseases progress many secondary abnormalities also occur. There is also considerable cell and organ specificity among the LSDs that is directly related to the location and function of the specific macromolecules affected.

PATHOBIOLOGY OF LYSOSOMAL STORAGE DISEASES

Biology of the Lysosome and Lysosomal Enzymes: Basic Principles

Lysosomes are formed through the fusion of enzyme-containing vesicles produced in the trans-Golgi network (TGN) with other vesicles such as endosomes or autophagosomes. Central to the formation of a mature lysosome is the establishment of an acidic pH. Mature lysosomes have a pH below 5, which is maintained by proton pumps found within the lysosomal membrane. Acidification of the compartment is required for proper activation of the hydrolytic enzymes and the release of macromolecules from their membrane receptors, providing access to the fully active hydrolytic enzymes. Although lysosomes have been historically considered discrete organelles, it is now known that the lysosomal system is highly dynamic and consists of a series of digestive vesicles with varying pH, hydrolytic enzyme activities, and cellular location.³

Lysosomal function requires the coordinated action of acidic hydrolases, acidification machinery and membrane proteins. It has recently been discovered that the diverse genes/gene products involved in lysosomal function belong to a gene network—the coordinated lysosomal expression and regulation (CLEAR) network—and are transcriptionally regulated by the lysosomal “master gene” *TFEB*.⁴ Transcription factor EB (TFEB) positively regulates the expression of other genes required to form lysosomes, controls the number of lysosomes, and promotes degradation of lysosomal substrates. Key to the formation of the lysosome is the delivery of the hydrolytic enzymes to the acidified vesicles in the TGN. This is accomplished

through a series of specific targeting mechanisms unique to these proteins⁵ (see later and box on [Lysosomal Protein Biosynthesis and Sorting](#)).

Coincident with the addition of the β -*N*-acetylglucosamine moiety is the addition of a phosphate group to this sugar by the enzyme *N*-acetylglucosaminyl-1-phosphotransferase. This modification is essential for targeting of most lysosomal enzymes, and mutations in the gene encoding this enzyme lead to a severe LSD (I-cell disease) characterized by the abnormal targeting and secretion of many lysosomal enzymes.⁶ The glucosaminyl residues are subsequently cleaved, exposing terminal mannose-6-phosphate (M6P) residues on the oligosaccharides. Importantly, for any given lysosomal enzyme the oligosaccharide chains may be highly heterogeneous, containing varying amounts of M6P, sialic acid, and glucosaminyl sugars.

In addition to targeting the enzymes to lysosomes, the oligosaccharide side chains also participate in the tertiary structure and folding of the proteins, and are in many cases necessary for their activity. Proteolytic processing within the lysosome also may be required for activity, as well as assembly into macromolecular “scaffolds” that may include protective and/or activator proteins. These events are driven, at least in part, by the low pH of the organelle. Finally, although most lysosomal enzymes use the M6P targeting system, it is also important to recognize that non-M6P targeting systems have been described and may function alone or in combination with M6P.⁷ For example, the lysosomal membrane proteins (LIMPs or LAMPs) are sorted to the lysosomal membrane through tyrosine residues located near the carboxyl-terminal end of the proteins.

Pathogenesis of Lysosomal Storage Diseases: General Concepts

The majority of LSDs result from mutations in genes encoding individual lysosomal enzymes, leading to the intralysosomal accumulation of the enzyme’s substrate. A small number of the diseases also result from mutations in genes encoding defective transport proteins that reside within the lysosomal membrane, or by the defective function of other nonhydrolytic enzymes required for lysosomal enzyme biosynthesis (e.g., I-cell disease). The type of macromolecules that accumulate distinguishes two main categories of LSDs: i.e., those that accumulate mucopolysaccharides (mucopolysaccharidoses; MPS diseases), and those that accumulate lipids (lipidoses; see Schulze et al⁸ and Giugliani et al⁹ for reviews). Several carbohydrate storage diseases have also been described.¹⁰ With only a few exceptions (e.g., Wolman disease), the lipid substrates stored in the LSDs share a common structure that includes a ceramide backbone (2-*N*-acyl-sphingosine, i.e., the sphingolipids). More than 100 sphingolipids are known with diverse function,¹¹ and their abnormal accumulation in the LSDs results in a wide range of physiologic, morphologic, and clinical manifestations. For example, progressive lysosomal accumulation of glycosphingolipids in the central nervous system (CNS) leads to neurodegeneration, abnormal neurite sprouting, and synapse deterioration, whereas storage of these lipids in visceral cells can lead to organomegaly, skeletal abnormalities, pulmonary infiltration, and many other manifestations.

**TABLE
53.1****Examples of Lysosomal Storage Diseases**

Category	Disease	Protein Abnormalities
Lipidoses	Fabry	α -Galactosidase A
	Farber	Acid ceramidase
	Gaucher (types 1, 2, and 3)	β -Glucosidase
	GM ₁ gangliosidosis	β -Galactosidase
	GM ₂ gangliosidosis	β -Hexosaminidase A and B
	Tay–Sachs	
	Sandhoff	Arylsulfatase A
	Metachromatic leukodystrophy	
	Niemann–Pick	
	Types A and B	Acid sphingomyelinase
Mucopolysaccharidoses	Type C	
	Type 1	NPC1
	Type 2	NPC2/HE1
	Wolman disease (cholesterol ester storage disease)	Acid lipase
	MPS I (Hurler and Scheie)	α -Iduronidase
Other	MPS II (Hunter)	Iduronidase sulfatase
	MPS III (Sanfilippo)	
	Type A	Heparan <i>N</i> -sulfatase
	Type B	<i>N</i> -Acetyl- α -D-glucosaminidase
	Type C	Acetyl-CoA- α -glucosaminide acetyltransferase
	Type D	<i>N</i> -Acetylglucosamine-6-sulfate sulfatase
	MPS IV (Morquio)	
	Type A	Galactosamine-6-sulfatase
	Type B	β -Galactosidase
	MPS VI (Maroteaux–Lamy)	<i>N</i> -Acetylglucosamine-4-sulfatase (arylsulfatase B)
	MPS VII (Sly)	β -Glucuronidase
	MPS IX	Hyaluronidase
	Aspartylglycosaminuria	Aspartylglycosaminidase
	Cystinosis (Fanconi syndrome)	Cystinosis
	Fucosidosis	Fucosidase
	I-cell (ML-II)	<i>N</i> -acetylglucosamine-1-phosphotransferase
	Pompe	α -Glucosidase
	Mannosidosis	α -Mannosidase
	Schindler	α -Galactosidase B

Lysosomal Protein Biosynthesis and Sorting

All lysosomal enzymes are cotranslationally *N*-glycosylated in the rough endoplasmic reticulum (ER) through the en block transfer of carbohydrate chains from a lipid intermediate (dolichophosphate). After completion of this process they generally undergo additional proteolytic processing and are assembled into transport vesicles for delivery and further processing in the cis-Golgi apparatus. At this stage, most proteins destined for the lysosomes contain only branched mannosyl oligosaccharide chains that terminate with short-chain α -glucosyl moieties. During transport through the Golgi apparatus they acquire additional, complex oligosaccharide modifications that result in their sorting to lysosomes. A series of glycosyl hydrolases and transferases within specific regions of the cis-, mid-, and trans-Golgi participate in these sequential modifications. For example, in the cis-Golgi, α -glucosidases and α -mannosidases remove terminal glucose and mannose residues, respectively, to produce mannose-terminated core oligosaccharides. Within the mid-Golgi, additional sugars are added, including β -*N*-acetylglucosamine and β -galactoside. The addition of terminal sialic acid residues occurs in the trans-Golgi.

For the MPS diseases, the mucopolysaccharides (also known as *glycosaminoglycans* [GAGs]) are the primary accumulating macromolecules and are found predominately within connective tissues. The accumulation of these materials results in severe cartilage and bone abnormalities that affect the skeletal system, trachea, and other organs. In some cases the CNS may also be affected, particularly in diseases where the GAG heparan sulfate accumulates.

In general, the storage pattern of a substrate in an LSD patient is dependent on the normal distribution of the molecule in the body, and this tissue-specific storage pattern is responsible for the organ-specific pathology. For example, in Hurler syndrome (MPS type I), two GAGs, dermatan and heparan sulfate, accumulate and result in severe skeletal and neurologic manifestations. In contrast, in Maroteaux–Lamy disease (MPS type VI), only dermatan sulfate accumulates. Because this latter GAG is not normally found in the brain, CNS manifestations do not occur in MPS VI. Similarly, in Tay–Sachs and Sandhoff diseases, the deficiencies of β -hexosaminidase A, or β -hexosaminidases A and B, respectively, results either in primary CNS disease or in combined CNS and visceral disease caused by the different accumulated substrates. Whereas β -hexosaminidase A cleaves the glycosphingolipid (ganglioside) GM₂, which is very abundant in the brain, β -hexosaminidase B primarily cleaves sialic acid-containing gangliosides and globosides. Globosides, in particular, are synthesized in visceral tissues, resulting in visceral storage in Sandhoff disease.

Although the primary pathogenic mechanism leading to most LSDs is well understood (i.e., genetic lesions result in primary protein defects and the accumulation of specific substrates), in recent years the complexity of these diseases has been recognized. For example, although GAGs are the primary accumulating macromolecules in the MPS diseases, other compounds, including the neural-specific glycolipids (gangliosides), also accumulate and contribute to disease pathology. In the lipidosis Niemann–Pick disease (NPD) type C, the primary protein defect affects cholesterol transport, although sphingolipids also accumulate and are responsible, in part, for the cellular

dysfunction and cell death. In fact, an approved therapy for NPD type C, Miglustat (see later), is based on the principle of reducing ganglioside storage in the brain rather than correcting the primary cholesterol transport defect.¹² Similarly, in NPD types A and B, the sphingolipid sphingomyelin is the primary accumulating substrate, although cholesterol storage also is a major contributory factor.

Indeed, for any individual LSD the pattern of macromolecule accumulation may be extremely heterogeneous and, importantly, also may be tissue and cell specific.¹³ Although the mechanism(s) leading to this heterogeneous storage pattern is not always known, it presumably relates to a global dysfunction of the lysosomal system, providing a connection between seemingly distinct metabolic pathways.

As the macromolecules accumulate, the lysosomes become distended and destabilized, and may eventually fail to carry out their normal functions related to phagocytosis and autophagocytosis. In turn, this may result in cell dysfunction, senescence, and/or death. In addition, because of the progressive cell and organ disease that occurs in the LSDs, inflammatory pathways are frequently activated in an attempt to repair the damage. However, because the inflammatory cells themselves are dysfunctional, the diseases progress and the inflammatory changes may become chronic. Inflammation is therefore also an important contributory factor to the pathogenesis of LSDs. For example, in the MPS diseases GAG storage is known to activate the Toll-like receptor 4 signaling pathway, leading to the release of tumor necrosis factor- α (TNF- α) and other inflammatory cytokines.¹⁴ TNF- α , in turn, causes elevation of the toxic lipid ceramide within cartilage cells (chondrocytes), contributing to cell death. Treatment of animal models of MPS with anti-TNF- α drugs alone has resulted in the reduction of chondrocyte death and substantial clinical benefits, demonstrating the importance of inflammation in these diseases.^{15,16}

GENETICS AND DIAGNOSIS OF LYSOSOMAL STORAGE DISEASES

All LSDs except for two, Fabry disease and MPS type II (Hunter disease), are inherited as autosomal recessive traits. Fabry and Hunter diseases are inherited as X-linked recessive traits. Most mutations causing individual LSDs result in single amino acid changes in the enzyme's polypeptide chain, resulting in absent or defective function. The genes encoding most lysosomal proteins have been cloned, and there is no obvious clustering of these genes within the genome. In some cases, nonfunctional pseudogenes also have been described, which may or may not be transcribed or translated into a nonfunctional protein. Although there is no clustering of the lysosomal genes, most exhibit coordinated transcriptional behavior and are regulated by TFEB.^{4,17} In the LSDs TFEB is often translocated from the cytoplasm to the nucleus to "turn on" expression of other lysosomal proteins and enhance lysosomal biogenesis. This is a mechanism by which cells try to compensate for lysosomal dysfunction. However, because the newly formed lysosomes in these diseases will retain the same primary metabolic defect, this may lead to amplification of the disease pathology.

The mutated proteins in LSD patients may be stable and delivered to lysosomes (albeit with reduced catalytic function), or may be unstable with only partial or absent delivery to lysosomes. The effects of the individual mutations may also be cell and tissue specific depending on the normal expression pattern of the enzymes. In general, heterozygous "carriers" of single mutations in a lysosomal gene do not develop clinical symptoms of the disorder, except in the X-linked disorders. For example, in Fabry disease X-inactivation patterns can lead to clusters of cells without enzyme activity, and female individuals carrying one α -galactosidase A mutation may develop disease-related pathology.¹⁸ In addition, one lysosomal gene, *SMPD1* encoding acid sphingomyelinase (ASM), is known to be "paternally imprinted" (i.e., preferentially expressed from the maternal chromosome), suggesting that type A and B NPD individuals who inherit "severe" *SMPD1* mutations on the maternal chromosome may be more severely affected than those who inherit the same

mutations from the paternal chromosome.¹⁹ This also suggests that some type A and B NPD carrier individuals with maternally derived mutations might exhibit clinical or laboratory manifestations of the disorder, and there is at least one report documenting very low serum high-density lipoprotein levels in such carrier individuals.²⁰

Diagnostic assays for patients suspected of having LSDs generally rely on the measurement of specific enzymatic activities in isolated leukocytes, cultured fibroblasts, or transformed lymphoblasts. For some disorders, carrier identification and prenatal diagnosis are available as well. However, because detection of the individual enzyme activities is often complex (e.g., uses nonnatural substrates, detergents, and other specific assay conditions), it is recommended that the enzymatic confirmation of suspected cases be carried out in specialized laboratories experienced in these methods. In addition, because in most LSDs leukocytes and skin fibroblasts are not the clinically relevant cell types, these assay methods are at best indirect measures of the defective lysosomal protein's function at the pathologic sites. For this reason, predicting the clinical outcome from these *in vitro* measurements is generally not reliable.²¹ For example, cells from patients with the infantile, neurologic form of ASM-deficient NPD (type A) and the later-onset, nonneurologic form (type B) often have similar residual enzymatic activities, although their clinical course is markedly different. This likely reflects the function of the individual mutant ASM polypeptides in the brain. Numerous other examples exist for other LSDs as well, posing a unique challenge for predicting phenotypic outcomes in newly diagnosed patients.

As already noted, many genetic abnormalities have been identified for most of the individual LSDs. For most diseases, multiple mutations have been found, and the majority of these are unique (i.e., private) to individual families. However, for some LSDs there are specific populations that may have recurrent mutations caused by founder effects and/or consanguinity, facilitating the use of DNA-based screening methods for the detection of the LSD. This has been most effectively translated into clinical use in the Ashkenazi Jewish population, in which relatively small number(s) of mutations account for several LSDs.²² This has led to the establishment of a DNA-based "Jewish Genetic Disease" screening panel and the population-based identification of carrier individuals for the same disorder. Such individuals are referred for genetic counseling to assist with family planning and pregnancy outcome choices. The implementation of such screening has led to a dramatic reduction in the incidence of some diseases within this population (e.g., infantile Tay-Sachs disease), and will likely lead to the prevention of other disorders as well. The rapid evolution of cost-effective, high-throughput sequencing methods is also likely to open other populations and disorders to these DNA-based screening approaches.²³ However, it is important to note that the functional consequences of most DNA abnormalities on the protein function have not been confirmed, and thus DNA-based methods alone should not be used to predict clinical outcomes in patients unless the biochemical consequences of these abnormalities are fully established. In general, confirmation of a suspected LSD case should be accomplished by both enzymatic and DNA-based studies, and in only rare cases are these laboratory tests useful to predict clinical outcomes.

THERAPY OF LYSOSOMAL STORAGE DISEASES: AN OVERVIEW

Since the first recognition that LSDs resulted from the defective function of lysosomal proteins, the concept of simply "replacing" the missing protein in individual patients was put forward.²⁴ This concept was further strengthened in the 1970s by the identification of the M6P-targeting system for lysosomal enzymes and the finding that the secreted forms of many lysosomal enzymes could be rapidly internalized, or "taken up", by cell surface M6P receptors and delivered into the lysosomal system.²⁵ Today, the principle underlying the treatment of most LSDs remains the replacement of the missing or defective protein. This can be accomplished by stem cell transplantation, protein (enzyme) replacement therapy, or gene therapy. In some cases,

treatments have also been developed that are either aimed at slowing the accumulation of undegraded materials (substrate reduction therapy [SRT]) or enhancement of the mutant protein function (chaperone therapy).

The majority of the clinical experience using cell-based therapy in LSDs comes from bone marrow transplantation (BMT).²⁶ Bone marrow has several advantages as a cell source, including the fact that it contains multiple stem and progenitor cell lineages that can lead to the repopulation of various organs and tissues. However, aggressive immunosuppressive preconditioning is required to achieve effective engraftment in the transplanted patients, leading to high morbidity and, in some cases, mortality. In addition, graft-versus-host disease may occur. These deleterious effects can be severe and may lead to clinical complications in patients that are worse than the disorders themselves. The availability of cord blood repositories and improved transplant methods has reduced these risks, but the possibility of high morbidity remains.

In LSD patients who have successfully undergone BMT and achieved a high level of engraftment, the clinical results have been variable. A number of factors account for this. First, repopulation after BMT is not uniform throughout the body, and depending on the organ systems affected in the patients, clinical improvement may or may not occur. For example, the hematopoietic system is particularly amenable to BMT repopulation, but the skeletal system (cartilage and bone) is not. In the nervous system some transplanted bone marrow-derived cells may cross the blood–brain barrier and repopulate the CNS, but the number of these cells is small and the repopulation efficiency low.²⁷ A second factor accounting for the variable clinical results after BMT is the age at which the transplant is undertaken. Many of the disease manifestations that occur in LSDs lead to permanent tissue damage (e.g., fibrosis, apoptosis) and are not reversible. Thus, not only must efficient engraftment be achieved after transplantation, but the procedure must also be undertaken before irreversible damage sets in, often in early childhood.

Other than BMT, liver transplantation has been undertaken in several LSDs, also with variable success.²⁸ Because the liver is a natural secretory organ, the concept underlying liver transplantation is that even partial repopulation of this organ with healthy cells will lead to secretion of these proteins into the circulation and widespread metabolic cross-correction. As with BMT, however, the uptake and distribution of the secreted enzymes will be limited by physiologic barriers (e.g., the blood–brain barrier) and dependent on the vascular supply to the tissue. Unlike BMT, there will no circulating stem cells available for organ engraftment other than in the liver. It is also of interest that early attempts at cell therapy for LSDs used amniotic cells for transplantation. Although the engraftment of these cells was extremely low and the clinical outcomes poor, these studies represented the first embryonic stem cell-based approach for these disorders.

Simultaneous with the development of cell and organ transplantation for LSDs, investigators also began to isolate and study the normal lysosomal proteins involved in the individual LSDs and to explore the idea of protein (enzyme) replacement therapy (ERT). Because this work originated before the development of recombinant DNA technology, it relied on discarded human materials as the enzyme source, usually urine or placentas. “Proof-of-principle” for this approach was first documented by Neufeld and colleagues,²⁹ who showed in an elegant series of studies that metabolic cross-correction of MPS cells could be achieved by coculture of these cells with normal cells or by replacing the media in MPS cells with “conditioned” media obtained from the normal cells. In addition, at around the same time methods of quantifying the levels or residual enzymatic activities in the LSDs were being developed, and there was also an early recognition that very low levels of functional enzymatic activities in the individual LSDs could have an important impact on the clinical presentation of the individual patients. This suggested that low levels of enzyme uptake were likely required to achieve metabolic cross-correction *in vivo*.

The first short-term clinical experience with ERT took place in the early 1970s by Brady, Desnick, and others.³⁰ These early studies revealed (1) that the enzymes were generally well tolerated, (2) that

the half-life of the enzymes in the circulation was short lived, and (3) that the sugar moieties on the enzymes had an important influence on their clearance from the circulation. In general, enzymes with terminal sialic acid residues had longer half-lives in the circulation than those with exposed mannose or M6P residues.

Despite these early successes, the further development of ERT was limited by the inability of the academic-based research laboratories to produce enough of the highly purified enzymes for long-term treatment studies. In addition, due to the very low numbers of diagnosed patients at that time, there was little or no commercial interest in these diseases. In the 1980s, a small biotechnology company (Genzyme, Cambridge, Massachusetts) took on this challenge and began to commercially prepare β -glucocerebrosidase, the enzyme deficient in Gaucher disease, from human placentas. This led to the first long-term experience with ERT in patients with non-neurologic (type 1) Gaucher disease.³¹ Importantly, the purified enzyme was chemically modified to expose terminal mannose residues, leading to preferential uptake by macrophages, the primary cellular site of pathology in this disease.

The results of ERT in type 1 Gaucher disease were life changing and included remarkably reduced liver/spleen size and improved hematologic findings. Although the therapy required biweekly intravenous infusions, it led to substantially improved quality of life and was approved by the international regulatory authorities. Based on this remarkable success, over a dozen companies are now involved in the development of ERTs and other therapies for LSDs. In addition, widespread efforts have been undertaken to diagnose patients, including the recent implementation of newborn screening for these disorders. These efforts have revealed that LSDs are more common than originally thought, and it is estimated that they may occur in up to approximately 1 in 7000 live births, and could be even more enriched in some regional, ethnic, and/or disease populations.

By the early 1990s, DNA technologies had evolved to the point where human recombinant β -glucocerebrosidase could be produced in genetically engineered Chinese hamster ovary (CHO) cells, and this eventually replaced the use of placental enzyme. Currently, recombinant LSD enzymes are being produced in various sources, including CHO cells, transformed human cells, plants, and chicken eggs.

Based on the outstanding success in Gaucher disease, ERTs have now been developed for seven other LSDs, including Fabry disease (α -galactosidase), Pompe disease (α -glucosidase), and several of the MPS disorders (MPS I, II, IV and VI). Several others are also under development. With these developments came the recognition that the effects of ERT were disease specific and could be complicated by immune reactions to the infused recombinant proteins. For example, in contrast to the readily accessible hematopoietic system in Gaucher disease, in other LSDs the major cellular targets for ERT (e.g., podocytes in the kidney, myocytes in the muscle, chondrocytes in the cartilage) do not readily take up the intravenously delivered enzymes, either because they do not express the proper cell surface receptors or do not have a sufficient vascular supply. In addition, the costs of these therapies are extremely high, placing a very high burden on reimbursement systems.

These realizations have led researchers to explore other therapies as well, work that has been greatly aided by the development of animal models for most of the LSDs.³² Considerable early effort was directed towards gene therapies, which have been extensively evaluated in the animal model systems.³³ Numerous clinical and pathologic improvements have been obtained, although the translation of these gene therapy technologies into the clinic has been slow because of safety concerns and issues with large-scale vector production. Recently, the first gene therapy clinical trials for LSDs have been approved in Europe, and over the next decade the evaluation of this approach in several of the individual diseases should be forthcoming.

Other investigators have sought alternative therapeutic approaches for these diseases, focusing on inhibiting the production of substrate in order to reduce accumulation (SRT). For example, Miglustat (OGT 918, *N*-butyl-deoxynojirimycin; trade name: Zavesca) is a low-molecular-weight compound that inhibits glucosylceramide

synthase, the enzyme that catalyzes the first step in the biosynthesis of glucosylceramide and other glycosphingolipids. Miglustat is an orally administered compound that has been shown to effectively decrease organ volume and improve hematologic parameters in patients with type 1 Gaucher disease.³⁴ However, gastrointestinal side effects are fairly common with oral treatment, so the use of Miglustat has been limited to Gaucher disease patients for whom ERT is not suitable. Miglustat is also used in patients with type C NPD, which causes progressive and severe neurologic disease.¹² Most patients with type C NPD have mutations in an integral membrane protein involved in cholesterol transport (NPC1). However, because NPC1 is a nonsoluble transporter, protein-replacement therapy is not a therapeutic option at the present time. Using animal models, investigators showed that the neurologic pathology in type C NPD was associated with the secondary accumulation of a particular glycolipid, GM₂ ganglioside. Based on this finding, studies were carried out using Miglustat to inhibit glycolipid biosynthesis, resulting in reduction of GM₂ storage and partial neurologic improvements. Clinical trials of Miglustat in type C NPD patients revealed stabilization or improvement of some clinical markers.

Another small-molecule approach under development for the LSDs is based on the use of enzyme-specific inhibitors that can act as “chaperones” of the corresponding mutant proteins, thereby facilitating their delivery to lysosomes and enhancing their residual enzymatic activities. Such “chaperone” therapy is currently being evaluated in clinical trials for several LSDs. Numerous other approaches also have been or are being evaluated in the various LSD animal models, including targeting of inflammatory pathways and stem cell-based therapies, and in the future patients should have access to various therapeutic choices. As with ERT, the effects of these individual therapies are likely to be disease and organ specific, and it is expected that in the future effective treatment of LSD patients will require a combination of these approaches.

HEMATOLOGIC MANIFESTATIONS OF LYSOSOMAL STORAGE DISEASES

Hematologic findings are associated with several LSDs, but in two, Gaucher disease and NPD (types A and B), hematologic abnormalities are among the common presenting features. Hematologic findings should be considered in the differential diagnosis of both disorders, and patients with Gaucher disease or NPD may be seen by hematologists to manage their symptoms. In the next section the hematologic features of these disorders are discussed, as well as several other relevant issues related to hematologic manifestations and LSDs.

Gaucher Disease: β -Glucosidase Deficiency

Cells of the monocyte–macrophage system are the primary sites of pathology in this disorder. In general, these cells are enriched for lysosomes and highly active in phagocytosis. As such, disruption of lysosomes may have a profound effect on their function. An important diagnostic hallmark of Gaucher disease is the presence in a variety of tissues of lipid-filled cells derived from the monocyte–macrophage system, referred to as *Gaucher cells*. These cells are readily evident in the bone marrow, but can also be seen in blood smears and histologically in other tissues, including liver, spleen, lung, and others. As the disease progresses, the deposition of Gaucher cells in these organs increases.

Bleeding is a common presenting symptom of patients with Gaucher disease and is primarily caused by thrombocytopenia. The major sites of bleeding are mucocutaneous, including epistaxis, easy bruising, and gingival hemorrhage. Thrombocytopenia in Gaucher disease is generally thought to be caused by splenic sequestration of platelets. Spleen enlargement is present in all symptomatic patients and is a common presenting sign of the disease. Splenic enlargement in Gaucher disease may be massive, up to 75-fold normal.³⁵

Some patients with type 1 Gaucher disease have excessive bleeding that is disproportionate to their platelet counts and coagulation profiles. Abnormal platelet function has been described in patients with type 1 Gaucher disease with abnormal bleeding tendencies.³⁶ These defects have been attributed to defects in platelet adhesion as well as aggregation. Coagulation deficiencies, particularly low factor levels of factor XI, have also been described.³⁷ Because both factor XI deficiency and type 1 Gaucher disease are relatively common in the Ashkenazi Jewish population, this finding may reflect concurrence of the two disorders. However, a report describing Egyptian type 1 Gaucher disease patients with deficiencies in factors II, V, VII, VIII, X, XI, and XII supports the concept that the coagulopathy is not limited to Ashkenazi Jewish patients and may have a distinct pathophysiology.³⁸ In fact, many patients with Gaucher disease have significant deficiencies (less than 50%) of multiple coagulation factors.³⁷ This is associated with elevations of coagulation activators, suggesting ongoing activation of the coagulation cascade with a resultant consumption of coagulation factors.³⁸

Anemia in patients with Gaucher disease is usually mild but occasionally may be severe and can be associated with leukopenia. These findings are also probably attributable to sequestration of cells in the spleen, as well as dysfunctional bone marrow production of cells as the disease progresses. The mainstay of treatment for the hematologic abnormalities in Gaucher disease is ERT. ERT typically produces a remarkable improvement in the platelet count, hemoglobin, and white blood cell count, as well as a reduction in spleen size.²⁴ ERT may also partially improve the coagulation profile.³⁸

In patients with massive splenomegaly, splenectomy is often approached as a treatment option with the expectation that it will improve the platelet count and reduce the risk of splenic rupture. However, the spleen is an important reservoir for storage material, and its removal can displace lipid deposition to other organs, accelerating the rate and severity of disease.

Types A and B Niemann–Pick Disease: Acid Sphingomyelinase Deficiency

The hematologic findings in types A and B NPD are similar to those in Gaucher disease and may include thrombocytopenia and anemia. Splenic enlargement is also a common presenting feature of this disorder, and sequestration of cells in the spleen is thought to be the underlying cause of the low platelets, low hemoglobin, or leukopenia (Fig. 53.1A and B). Some patients with type B NPD have excessive bleeding without significant thrombocytopenia or coagulopathy. Frequent and prolonged epistaxis can be particularly problematic and in some extreme cases may require cauterization, packing, and blood transfusions.

As with Gaucher disease, a primary cellular site of pathology in types A and B NPD is the monocyte–macrophage system, and the characteristic pathological cells are referred to as *Niemann–Pick cells*. These can be distinguished from Gaucher cells by an experienced pathologist, but are frequently misclassified or not recognized, resulting in misdiagnosis. They are also readily evident in blood smears, bone marrow, and other organs, and increase as the disease progresses. As noted above, there is another form of NPD (type C) that is caused by primary defects in cholesterol transport. These patients may also present with mild hematologic findings and an enlarged spleen, although in general the hematologic findings are less severe than in patients with types A and B NPD (see Fig. 53.1C and D).

Fabry Disease: α -Galactosidase Deficiency

Unlike Gaucher and NPD diseases, in Fabry disease the monocyte–macrophage system is not primarily affected. In this disorder, the primary site of accumulation of glycolipids occurs in the vascular endothelial and smooth muscle cells that surround blood vessels. As such, constriction of blood vessels occurs, leading to skin lesions, strokes, and kidney dysfunction. It is noteworthy that several of the

Fig. 53.1 (A) Typical histopathology (hematoxylin and eosin staining) of a liver section from a patient with type B NPD. Note the lipid-filled macrophages (Niemann–Pick cells) that are characteristic of this disorder. (B) Micrograph of the bone marrow from the same patient with type B NPD showing the presence of an NPD cell, as well as a sea-blue histiocyte. Both cells may be characteristically found in the bone marrow of these patients. (C) Bruising that may be seen in type B NPD and is associated with thrombocytopenia. (D) Chest radiograph of a patient with type B NPD showing the diffuse reticulonodular interstitial changes in this disorder. *NPD*, Niemann–Pick disease.

accumulating glycolipids in Fabry disease also are blood group lipids. For example, a number of blood group B glycolipids may contain terminal α -galactosyl moieties, and patients with Fabry disease who have blood groups B and AB will accumulate four glycolipid substrates as opposed to those with A or O blood groups, who will only accumulate two. The clinical consequence of this differential accumulation of blood group lipids in Fabry disease is not clearly understood.

Sea-Blue Histiocytosis and Lysosomal Storage Diseases

Sea-blue histiocytes are lipid-laden macrophages detectable by May–Giemsa staining of the bone marrow, blood cells, or other organs (see Fig. 53.1B). The appearance of these cells may be secondary in many disorders, but for the LSDs they are principally associated with NPD, Gaucher, Fabry, or ceroid storage diseases. For NPD and Gaucher disease specifically, there are several reports in the literature of patients with these disorders being misdiagnosed with primary sea-blue histiocytosis and only later being found to have the primary lysosomal enzyme defect.³⁴ Thus, the appearance of sea-blue histiocytes should be considered as part of the differential diagnosis of these disorders.

CONCLUSIONS AND FUTURE DIRECTIONS

The LSDs comprise a diverse group of genetic disorders that may present from infancy through adulthood. Most LSDs are caused by single enzyme deficiencies, but these single protein defects can result

in a complex array of metabolic abnormalities, leading to a wide range of clinical presentations. The pathophysiology of individual LSDs depends on the specific cells and tissues in which these metabolic abnormalities occur. Phenotypic heterogeneity among patients may be caused by different mutations in the enzyme-encoding genes, resulting in varying levels of residual enzyme activity. Hematologic abnormalities occur in several LSDs, although two diseases, type 1 Gaucher disease and types A and B NPD, primarily affect cells of the monocyte-macrophage system, and hematologic complications can be common and severe in some cases. Several treatment options are available for some of the LSDs, including ERT, and in the case of Gaucher disease ERT is very effective at correcting the hematologic findings. ERT is also under development for type B NPD. Other treatment options, including small molecule and antiinflammatory approaches, also are actively being developed for many LSDs, and in the future most LSD patients are likely to be treated by a combination of these methods. These efforts, together with the development of population-wide enzyme and DNA-based screening for the LSDs, should lead to better medical management and improved quality of life for most patients.

INFECTIOUS MONONUCLEOSIS AND OTHER EPSTEIN-BARR VIRUS-ASSOCIATED DISEASES

Carl Allen, Cliona M. Rooney, and Stephen Gottschalk

The initial clinical descriptions of primary Epstein-Barr virus (EBV) infections are credited to Filatov and Pfeiffer at the end of the 19th century. Pfeiffer coined the term *glandular fever*, which described an illness consisting of fever, malaise, sore throat, and lymphadenopathy. In 1920, Sprunt and Evans introduced the term *infectious mononucleosis (IM)* to describe a series of patients with fatigue, fever, lymphadenopathy, and prominent mononuclear lymphocytosis (Fig. 54.1). Serologic diagnosis of IM became available in the 1930s with the heterophile agglutination test developed by Paul and Bunnell and later modified by Davidson.

The identification of EBV as the causative agent of IM was impeded for many years by the inability to transmit the disease to animals or to grow the virus *ex vivo*. In 1958 Burkitt described a lymphoma in African children and investigators suspected an infectious etiology because the lymphoma's geographic distribution pattern coincided with the African mosquito belt.¹ In 1964 Epstein, Achong, and Barr described herpesvirus-like particles in tumor biopsies from patients with Burkitt lymphoma (BL). Werner and Gertrude Henle developed an indirect immunofluorescent antibody assay to this new virus, now called *Epstein-Barr virus*, and showed that patients with BL, as well as 90% of American adults, had antibodies against EBV. In 1965 the Henles documented seroconversion to EBV of an individual who presented with clinical symptoms of IM. This initial observation was corroborated by larger studies confirming the association of EBV and IM.

Since then, EBV has been linked to a heterogeneous group of diseases (see box on [EBV-Associated Clinical Syndromes](#)).² EBV was the first human virus implicated in oncogenesis, and the biology of the virus has been studied extensively on a cellular and molecular level.² Because primary EBV infection is a self-limiting disease in almost all individuals, therapeutic strategies have focused on the treatment of rare, potentially fatal EBV-associated diseases. Over the last two decades, successful immunotherapeutic approaches have been developed for EBV-associated malignancies, using either monoclonal antibodies or the adoptive transfer of EBV-specific T cells.^{3,4}

BIOLOGY OF EPSTEIN-BARR VIRUS

EBV belongs to the family of herpesviruses, which has almost 100 members. Membership is based on the architecture of the virion that is 120 to 300 nm in size and contains (a) a core of linear, double-stranded DNA, (b) an icosahedral capsid with 162 capsomers, (c) an amorphous material between the capsid and envelope designated tegument, and (d) an envelope containing viral glycoproteins. Besides EBV, designated human herpesvirus 4, seven other herpesviruses have been isolated from humans: herpes simplex viruses 1 and 2, cytomegalovirus (CMV), varicella-zoster virus, human herpesvirus 6, human herpesvirus 7, and the Kaposi sarcoma-associated herpesvirus (KSHV, human herpesvirus 8). Herpesviruses are further divided into subfamilies to reflect evolutionary relatedness and similar biologic properties. EBV and KSHV belong to the human gamma herpesvirus subgroup and have a limited tissue tropism to B and T lymphocytes and certain types of epithelial cells. Several variants of EBV have been identified by genomic polymorphisms. Initially, two EBV types were distinguished by sequence changes in EBV nuclear

antigens 2 and 3 (EBNA2 and EBNA3). However, using polymorphisms in the latent membrane protein 1 (LMP1), further subtypes have been described. EBV strains vary by geography and have not been linked to a particular EBV-associated disease.

PRIMARY EPSTEIN-BARR VIRUS INFECTION

Primary EBV infection usually occurs through the oropharynx, where mucosal epithelial cells and/or B cells become productively infected (Fig. 54.2). Infection of B cells by EBV is initiated by binding of the dominant viral glycoprotein gp350/220 to CD21, the C3d complement receptor; subsequent cell entry is mediated by a complex of three viral glycoproteins, gH, gL, and gp42. Gp42 binds to HLA class II, which functions as a coreceptor, and gH is most likely involved in virus-cell fusion. The entry of EBV into epithelial cells may occur through multiple mechanisms because the majority of epithelial cells are CD21 negative. After viral entry, the capsid is dissolved and the EBV genome is transported into the nucleus where it circularizes. Infection of epithelial cells results in lytic or abortive infection, whereas B-cell infection results predominantly in latency, the lytic infection also occurs, resulting in the release of infectious virus into the saliva and other secretions. During primary infection, EBV establishes lifelong latency in B cells and it is estimated that 1 to 50 cells per 1×10^6 B cells in the peripheral circulation are infected with EBV. The number of latently infected B cells within a person remains stable over years; however, intermittent reactivation of EBV in B cells into the lytic cycle at mucosal sites is probably responsible for the observed shedding of infectious virus into the saliva of asymptomatic carriers (Fig. 54.2).

Although EBV can infect any B cell and express the full spectrum of latency proteins, studies suggest that only infection of naive B cells results in persistent infection (Fig. 54.2). EBV infection pushes the naive B cell into a memory state independent of an antigen-dependent germinal center (GC) reaction by upregulation of cytosine deaminase, which induces both class switching and somatic hypermutation. The former also requires the expression of EBV-encoded LMP1, a constitutively activated CD40 molecule, or CD40 ligation, most likely provided by GC T helper (Th)3 cells that can provide T-cell help for B-cell differentiation by provision of CD40 ligand, interleukin (IL)-4, and IL-10 while preventing antigen-dependent effector T-cell-mediated B-cell elimination by expression of transforming growth factor (TGF)- β . This reaction occurs within the lymph node (see E-Slide VM03965) and also involves downregulation of latency proteins and expression of latency type II. On exit from the lymph node, expression of latency proteins is completely inhibited. In this way infected B cells can evade immune elimination. By contrast, primarily infected memory B cells enter and remain in latency type III and are rapidly eliminated by effector T cells and therefore do not contribute to virus persistence.

LATENT EPSTEIN-BARR VIRUS INFECTION

During latent infection, EBV persists episomally in resting memory B cells. Initially, it was thought that EBNA1 and LMP2 were

Fig. 54.1 PROMINENT MONONUCLEAR LYMPHOCYTOSIS IN MONONUCLEOSIS. Low power (A) illustrates the leukocytosis, mainly due to activated lymphocytes (B and C), which are contrasted with a normal small lymphocyte (D) and a monocyte and granulocyte (E). The large reactive lymphocytes are frequently confused with monocytes because of their morphologic resemblance and the term *mononucleosis*. Monocytes usually have a finer, lacy chromatin and a gray cytoplasm with small granules and vacuoles when compared with the large activated lymphocytes.

Fig. 54.2 INFECTIOUS LIFE CYCLE OF EPSTEIN-BARR VIRUS. *EBV*, Epstein-Barr virus; *EBNA*, Epstein-Barr nuclear antigen; *LMP*, latent membrane protein.

Multiple sclerosis

expressed in memory B cells; however, more recent studies indicate that the majority of infected cells do not express viral proteins and of the almost 100 viral proteins, only EBNA1 is expressed during memory B-cell division (Fig. 54.2).² This extremely limited expression of viral proteins allows EBV to persist long term despite a robust cellular EBV-specific immune response.

Three other distinct types of EBV latency have been characterized in a heterogeneous group of malignancies (Fig. 54.3). Latency type III, which can be readily produced by infecting B cells in vitro with EBV, is expressed in lymphoblastoid cell lines (LCL). These cells express the entire array of nine EBV latency proteins: EBNA1, -2, -3A, -3B, and -3C, EBNA leader protein (LP), and the two viral membrane proteins LMP1 and LMP2. This pattern of EBV gene expression characterizes the EBV-associated lymphoproliferative diseases (EBV-LPD) that occur in individuals severely immunocompromised by solid organ or hematopoietic stem cell transplantation (SOT, HSCT), congenital immunodeficiency, or human immunodeficiency virus (HIV) infection. Latency type II is the hallmark of EBV-positive Hodgkin disease (HD), non-Hodgkin lymphoma (NHL), as well as nasopharyngeal carcinoma (NPC). EBV proteins expressed in these malignancies are EBNA1, LMP1, and LMP2. In addition, BARF1 is expressed in subsets of latency type II associated malignancies. In latency type I, found in EBV-positive BL, only

Fig. 54.3 EBV-LATENT GENE EXPRESSION AND IMMUNOGENICITY OF COMMON EBV-ASSOCIATED MALIGNANCIES. *EBV*, Epstein-Barr virus; *EBNA*, Epstein-Barr nuclear antigen; *LP*, leader protein; *NK*, natural killer. For an explanation of symbols, see Fig. 54.2. *Not all lymphomas are latency type III. **Gastric adenocarcinoma can also express latency type II genes.

EBNA1 is expressed. However, variants in which all EBNAs are expressed in the absence of LMP1 have also been described. Latency type I or latency type II is found in EBV-associated gastric adenocarcinoma. While grouping EBV-associated malignancies according to their dominant gene expression profile provided a useful framework for understanding EBV-driven oncogenesis, more recent studies using comprehensive gene expression array profiling have demonstrated expression of lytic cycle genes in BL, or expression of lytic cycle and latency III genes in NPC.^{5,6}

The EBV proteins expressed during type III latency are involved in the transformation and growth of EBV-infected B cells. EBNA1 binds to the origin of replication of the latent viral genome and is responsible for the maintenance of the EBV episome in host B cells. EBNA2 upregulates the expression of the viral proteins LMP1 and LMP2 and cellular proteins that contribute to transformation. EBNA3A and EBNA3C are essential for EBV-induced B-cell transformation, and although EBNA3B is not essential for transformation, it is highly conserved and therefore must provide a survival function in vivo. EBNA-LP cooperates with EBNA2 in the induction of viral and cellular genes. LMP1, a viral oncogene, behaves like a constitutively activated CD40 molecule and is essential for EBV-mediated B-cell transformation. LMP2 mimics an activated B-cell receptor (BCR) allowing for long-term B-cell survival in the absence of antigen. In addition, it prevents the reactivation of EBV into the lytic phase of infection.

Besides EBV proteins, small nonpolyadenylated viral RNAs termed *EBERs 1* and *2* and the BamHI-A rightward transcripts (*BARTs*) are expressed in all forms of latency. In addition, the expression of at least 17 distinct EBV-derived microRNAs has been reported. The *EBERs* are the most abundant viral RNAs in latently infected cells. They enhance the oncogenic phenotype of EBV-transformed cells but are nonessential for EBV-mediated transformation. The expression pattern of the microRNAs depends on the latency type, and it is therefore likely that they play an important role during the life cycle of the virus.

IMMUNE RESPONSE TO EPSTEIN-BARR VIRUS

Healthy individuals mount vigorous humoral and cellular immune responses to primary EBV infection.⁷ Although antibodies to the viral membrane proteins neutralize virus infectivity, the cellular immune response is essential for controlling virus-infected cells during both lytic and latent phases.

Humoral Immune Responses

Heterophile Antibodies

Heterophile antibodies, originally described by Paul and Bunnell, are present in 90% to 95% of EBV infections at some point during the illness. However, in infants and children under the age of 4 years with primary EBV infection, heterophile antibody responses are often not detected. Heterophile antibodies are IgM antibodies, which agglutinate erythrocytes from different species including bovine, camel, horse, goat, and sheep. EBV-induced heterophile antibodies have no reactivity against guinea pig kidney cells in contrast to naturally occurring antibodies (Forssman antibodies) or antibodies present in patients with serum sickness and other conditions.

In addition to heterophile antibodies, cold agglutinins directed preferentially against the anti-I antigen on red cell membranes are frequently detected in the sera of patients with IM; however, hemolytic anemia is rare. Other antibodies (including anti-I, anti-N, Donath-Landsteiner antibodies, platelet antibodies, and anti-smooth muscle antibodies) have been described.

Epstein-Barr Virus-Specific Antibodies

EBV-specific antibody responses are detected with immunofluorescence assays developed in the first decades of EBV research. EBV antibodies are directed against (a) EBNA, (b) early antigen (EA), (c) the membrane antigen (MA) expressed on the surface of cells late in the lytic cycle, and (d) the viral capsid antigen (VCA) expressed within cells late in the lytic cycle. Each antigen is a composite of several distinct viral proteins, and attempts have been made to replace the aforementioned assays with tests using specific viral proteins; however, no single test has attracted widespread use.

VCA-IgM and -IgG antibodies are usually present at the onset of clinical symptoms because of the prolonged viral incubation period (Table 54.1). VCA-IgM antibodies are a good marker for an acute infection because they rapidly disappear within 4 to 8 weeks. VCA-IgG antibodies persist for life and are commonly used to document prior EBV infection. IgG antibodies against EA are present at the onset of the clinical illness in approximately 70% of patients. EA antibodies are divided into methanol-sensitive (anti-D) and methanol-resistant (anti-R) antibodies, and the majority of EA antibodies detected are anti-D antibodies. The presence of anti-D antibodies is

TABLE 54.1 Frequently Determined Epstein-Barr Virus–Specific Antibodies

Antibody Specificity	Positive in IM (%)	Time of Appearance in IM	Persistence	Comments
Viral Capsid Antigen				
VCA-IgM	100	At clinical presentation	4–8 weeks	Highly sensitive and specific; of major diagnostic utility
VCA-IgG	100	At clinical presentation	Lifelong	Useful for documentation of past EBV infection
Early Antigen (EA)				
Anti-D	70	Peaks 3–4 weeks after onset	3–6 months	Correlates with disease severity; seen in patients with NPC
Anti-R	Low	2 weeks to several months after onset	2 months to >3 years	Occasionally seen with unusually severe cases; seen in patients with African Burkitt lymphoma
EBNA	100	3–4 weeks after onset	Lifelong	Presence excludes primary EBV infection

EBV, Epstein-Barr virus; IM, infectious mononucleosis; NPC, nasopharyngeal carcinoma.

Modified from Schooley RT: Epstein-Barr virus (infectious mononucleosis). In Mandell GL, Bennett JE, Dolin R, editors: *Principles and practice of infectious diseases*, Philadelphia, 2000, Churchill Livingstone, p 1599.

consistent with recent infection, because titers disappear after recovery. IgG antibodies to EBNA appear late in the course of almost all cases of EBV infection and persist throughout life; their presence early in a suspected case of primary EBV infection excludes the diagnosis. Aberrations in this pattern of serum reactivity are observed in many EBV-associated diseases and will be discussed under the specific disease sections. For example, the absence of EBNA antibodies despite previous EBV infection is one of the serologic markers suggestive for chronic active EBV infection.

Cellular Immune Responses

In normal individuals, primary EBV infection often results in a massive expansion of activated, antigen-specific T cells. Using tetramer technology to enumerate antigen-specific T cells, it has been documented that the CD8⁺ T-cell response may be dominated by T cells specific for a limited number of epitopes, as seen with T-cell responses against other herpesviruses. T cells specific for epitopes derived from immediate early and several early EBV proteins of the lytic cycle are dominant during the acute phase of IM, and long-term persistence of EBV-specific, CD8⁺ T cells has been documented after primary EBV infection. As many as 5.5% of the circulating CD8⁺ T cells in a healthy virus carrier may be positive for a single EBV epitope, illustrating how persistent EBV infection can influence the composition of the host's T-cell pool. Besides EBV-specific CD8⁺ T cells, EBV-specific CD4⁺ T cells play an important role in the control of EBV infections, and EBNA1-specific CD4⁺ T cells have been implicated in the control of newly infected B cells. As for CD8⁺ T-cell responses, there is a marked hierarchy of immunodominance, with the majority of CD4⁺ T cells being specific for EBNA1 and to a lesser extent EBNA3C.

EBSTEIN-BARR VIRUS VACCINE DEVELOPMENT

At present there is only limited experience with human EBV vaccines.⁸ Four vaccine studies have been conducted in healthy donors in the prophylactic setting using recombinant vaccinia virus encoding the major viral glycoprotein gp350 (1), recombinant gp350 protein (2), or an EBNA3A peptide. While vaccination with gp350 induced neutralizing antibodies, and in one study prevented the clinical picture of IM, these vaccines did not significantly reduce the incidence of EBV infection. Also no reduction in the incidence of EBV infection was observed with the EBNA3A peptide vaccine. Additionally, a recombinant gp350 protein was evaluated in patients with chronic kidney disease prior to kidney transplantation. Although the vaccine induced transient neutralizing antibodies, it did not reduce the incidence of EBV-LPD posttransplant. Newer vaccines consisting

of gp350-ferritin complexes that induce significantly higher titers of neutralizing antibodies in preclinical models have been developed, but require testing in humans.

Vaccine strategies in the therapeutic setting for the immunotherapy of EBV-associated malignancies should seek to elicit or boost the EBV-specific cellular immune response against EBV latency. Individuals likely to benefit from this approach are EBV-seronegative patients scheduled to undergo SOT or patients who have an EBV-associated malignancy with a low tumor burden or are in remission (see box on **EBV-Associated Malignancies**). Three vaccine studies have been conducted in patients with EBV-positive NPC. In two studies patients with advanced disease were vaccinated with either dendritic cells (DCs) loaded with peptides derived from LMP2 or DCs transduced with an adenoviral vector encoding full-length LMP2 and an inactive form of LMP1. Administration of DC vaccines was safe, and a transient increase in the frequency of LMP2-specific T cells was observed on the DC/peptide vaccine trial. However, the clinical benefit in both studies was limited. Thus future studies should focus on DC vaccines with greater potency administered to subjects with less tumor burden. In another phase I clinical study, after frontline therapy, patients with NPC were vaccinated with a modified vaccinia virus Ankara encoding the c-terminal portion of EBNA1 and LMP2 (MVA-EL). Induction of CD4⁺ and CD8⁺ antigen-specific T-cell responses was observed in the majority of patients after vaccination, and a phase II clinical study is in progress. In addition, a clinical study combining MVA-EL with a PD-L1-specific checkpoint monoclonal antibody (pembrolizumab) is in the planning phase. Lastly, a recombinant adenovirus vaccine encoding LMP2 was evaluated in patients with NPC. While vaccine

Epstein-Barr Virus (EBV)–Associated Malignancies

Malignancy	EBV Frequency
Hodgkin disease	~40%
Non-Hodgkin lymphomas	
Burkitt lymphoma	20–95%
Diffuse large B-cell lymphoma and CD30 ⁺ Ki-1 ⁺ anaplastic large cell lymphoma	10–35%
Lymphomatoid granulomatosis	80–95%
T-cell-rich B-cell lymphoma	20%
Angioimmunoblastic lymphoma	>80%
T-cell, natural killer (NK)-cell, and T/NK-cell lymphomas	30–90%
Nasopharyngeal carcinoma	>95%
Gastric adenocarcinoma	5–10%
Pyothorax-associated lymphoma	>95%
Leiomyosarcoma in immunocompromised patients	>95%

administration was safe, no data are available if the vaccine boosted LMP2-specific T-cell responses.

INFECTIOUS MONONUCLEOSIS

Epidemiology

EBV infections occur worldwide and in most populations 90% to 95% of adults have antibodies against EBV. Depending on geographic and socioeconomic factors, there is a wide variation in the age of primary EBV infections. Early, asymptomatic primary EBV infection occurs in individuals from lower socioeconomic groups and in third world countries. In higher socioeconomic groups in industrialized countries, the age of primary infection is often delayed until the second decade of life and clinically apparent IM is more prevalent.

Humans are the only source of EBV. EBV is present in the saliva of patients with IM. A majority of EBV-positive adults shed virus into their saliva, and this percentage is increased in immunocompromised patients such as SOT recipients. EBV is viable outside the body for 2 weeks at 4°C but is susceptible to drying; the virus has not been recovered from environmental sources, suggesting that close contact is needed for viral spread. The incubation period of IM is estimated to be 30 to 50 days.

Clinical Manifestations

Primary EBV infection in infants and young children is either asymptomatic or accompanied by mild, nonspecific symptoms and signs such as fever, upper respiratory tract infection, pharyngitis with or without tonsillitis, and cervical lymphadenopathy. In contrast, approximately 50% of adolescents and young adults present with the clinical picture of IM. Frequently, a prodrome consisting of fatigue, malaise, and low-grade fever is present for 1 to 2 weeks. Prominent pharyngitis with exudative tonsillitis is often the cardinal sign of IM; other signs and symptoms are listed in Table 54.2. The adenopathy in IM most commonly affects the posterior cervical lymph nodes, although diffuse adenopathy can occur. The enlarged lymph nodes are not fixed, may be tender to palpation, and lack overlying skin erythema. Hepatomegaly is uncommon; however, splenomegaly develops in more than 50% of patients and is more prominent in the second to fourth week of the illness. Skin manifestations include a faint, morbilliform rash reminiscent of rubella and less commonly erythema multiforme and erythema nodosum. Most patients with primary EBV infection have symptoms for 2 to 4 weeks and recover without significant complications or sequelae.

Complications of Primary Epstein-Barr Virus Infections

The incidence of complications associated with primary EBV infection is low, although any organ system can be affected.

Hematologic Complications

Patients with IM may present with a wide range of hematologic findings besides the atypical lymphocytosis (Fig. 54.4). These include anemia, neutropenia, thrombocytopenia, and rare cases of aplastic anemia.

Anemia

Autoimmune hemolytic anemia occurs in approximately 3% of patients with IM. It presents in the first 2 weeks of the illness, and

TABLE 54.2 Clinical Manifestations of Infectious Mononucleosis

Manifestation	Percentage (Range)
Symptoms	
Sore throat	82 (70–88)
Malaise	57 (43–76)
Headache	51 (37–55)
Anorexia	21 (10–27)
Myalgias	20 (12–22)
Chills	16 (9–18)
Abdominal discomfort	9 (2–14)
Signs	
Lymphadenopathy	94 (93–100)
Pharyngitis	84 (69–91)

Palatal enanthem	11 (5–13)
Rash	10 (0–15)
Jaundice	9 (4–10)

Modified from Schooley RT: Epstein-Barr virus (infectious mononucleosis). In Mandell GL, Bennett JE, Dolin R, editors: *Principles and practice of infectious diseases*, Philadelphia, 2000, Churchill Livingstone, p 1599.

Fig. 54.4 PERIPHERAL BLOOD SMEAR IN INFECTIOUS MONONUCLEOSIS. (A) Low power shows moderately high white blood cell count and high number of reactive, or “atypical” lymphocytes. (B–G) Higher power illustrates spectrum of lymphoid morphology, including small resting lymphocyte (B) for comparison, large granular lymphocyte (C), atypical forms (D–F), also referred to as “reactive” lymphs, and circulating plasma cell (G).

the majority of patients recover within 1 to 2 months. Patients usually have a positive direct Coombs test. Most common anti-I antibodies are present; however, anti-I, anti-N, and Donath-Landsteiner antibodies have also been reported. In addition to hemolysis, IM-associated anemia can be caused by erythroblastopenia.

Neutropenia

Mild, self-limiting neutropenia is a common finding during the first 4 weeks of the disease. However, severe neutropenia associated with fatal bacterial infections has been reported.

Thrombocytopenia

Mild thrombocytopenia ($50,000$ to $150,000/\text{mm}^3$) is a common finding in patients with IM. It usually occurs within the first 2 weeks of presentation and resolves within 2 months. Severe thrombocytopenia with overt bleeding is rare; however, death from intracranial hemorrhage has been described. The etiology of the thrombocytopenia is not completely understood, and a variety of explanations have been suggested. Because bone marrow examination shows normal or increased numbers of megakaryocytes, peripheral platelet destruction is most likely due to the presence of antiplatelet antibodies or platelet pooling and destruction within an enlarged spleen.

Splenic Rupture

Splenic rupture occurs predominately in males, with an incidence of 1/1000 to 1/3000 (Fig. 54.5). The incidence of rupture is highest in the second and third week of illness and can be the first sign of IM. Clinical symptoms include abdominal pain or pain referred to either shoulder. Because abdominal pain is an unusual symptom of uncomplicated IM, a splenic rupture should be strongly considered in IM cases when abdominal pain is reported. Although it is a life-threatening complication, with current management the mortality rate is very low.

Neurologic Complications

Neurologic complications develop usually during the first 2 weeks of IM and may be the only manifestation of IM. EBV infection can cause a wide spectrum of neurologic diseases, including encephalitis, meningitis, Guillain-Barré syndrome, acute transverse myelitis, and peripheral neuritis. Patients with neurologic complications have an excellent outcome, with most patients recovering completely.

Other Organ Involvement

Although symptomatic heart disease with IM is uncommon, in one cohort of patients, unspecific ST- and T-wave abnormalities were found in 6% of patients. Renal involvement manifested as microscopic hematuria, and proteinuria is seen in 10% to 15% of patients; however, significant renal dysfunction is rare. Airway compromise due to hypertrophy of the adenoids and tonsils or mucosal inflammation and edema is uncommon but potentially fatal.

Diagnosis

Atypical lymphocytosis is the cardinal hematologic finding in IM (Fig. 54.4). It develops during the first week of the illness and peaks between the second and third week. Atypical lymphocytes represent 60% to 70% of the total white cell count, which ranges between $12,000/\text{mm}^3$ and $18,000/\text{mm}^3$. In general, the atypical lymphocytes are large and vary in size. Nuclei are large and eccentrically placed; the cytoplasm is basophilic, and vacuoles are often present. The variable morphologic pattern of atypical lymphocytes in IM distinguishes them from the monotonous appearance of immature leukemic blasts. Atypical lymphocytosis is not pathognomonic for IM and is associated with other diseases such as acute viral hepatitis, CMV infections, mumps, toxoplasmosis, rubella, roseola, and drug reactions.

The diagnosis of EBV infection depends on serologic testing. Tests for heterophile antibodies, including the monospot test and slide agglutination tests, are routinely available. The results of these tests are often negative in children less than 4 years of age, but they identify 90% of cases in older children and adults. Of the available EBV-specific serologic tests, VCA-IgM antibodies are most commonly determined to diagnose primary EBV infection in heterophile-negative IM cases; determining antibodies against EA may also be helpful (Table 54.1). VCA-IgG antibodies are positive during acute infections as well as the convalescent period. The presence of anti-EBNA antibodies excludes an acute infection. Isolation of EBV from throat washings is feasible; however, it is of little diagnostic value because 10% to 20% of healthy adult EBV carriers may shed the virus.

Differential Diagnosis

In the majority of cases, the diagnosis of IM is straightforward. The differential diagnosis includes streptococcal and nonstreptococcal pharyngitis, acute infections with CMV, human herpesvirus 6,

Fig. 54.5 RUPTURED SPLEEN FROM PATIENT WITH INFECTIOUS MONONUCLEOSIS. (A and B) Sections from the spleen show increased white cells in the red pulp. These correspond to the proliferating activated lymphocytes seen in the blood. (C) The lymphocytes can infiltrate into the splenic trabeculae, weakening the integrity of the spleen and making it more prone to rupture.

hepatitis viruses, and toxoplasma. Depending on the presentation, other diseases may be considered such as HIV, rubella, and leukemia or lymphoma.

Treatment

Supportive therapy should include rest and analgesia in the acute stage of IM. Contact sports should be avoided until the patient has fully recovered and the spleen is no longer palpable. The use of corticosteroids is not indicated for uncomplicated IM; however, a trial of corticosteroids is warranted in patients with marked tonsillar inflammation and hypertrophy resulting in impending airway obstruction. Although acyclovir reduces EBV shedding into oral secretions, treatment of IM with acyclovir has resulted in no clinical benefit.

OTHER EPSTEIN-BARR VIRUS ASSOCIATED DISEASES

Most individuals recover from the acute phase of primary EBV infection with no long-term sequelae. However, a minority of patients with intrinsic defects in immune function may respond with potentially lethal uncontrolled pathologic inflammation with fever and multisystem organ failure, meeting diagnostic criteria for hemophagocytic lymphohistiocytosis (HLH). Others may develop chronic active EBV infections (CAEBV) with persistent fever, arthralgia, myalgia, and lymphadenopathy, or develop lymphoproliferative and/or malignant disorders. In addition to primary immunodeficiencies that result in failure to control EBV infection, there is an increasing group of gene defects associated with complex or acquired immune dysfunction (ATM, WAS, PIK3CD, PIK3R1, CTPS1, STK4, GATA2, MCM4, FCGR3A, and CARD11) that predispose not only to complications of EBV infection but also other viruses, bacteria, and/or fungi.⁹

Hemophagocytic Lymphohistiocytosis

HLH is a syndrome characterized by uncontrolled inflammation (see Chapter 52). Diagnostic criteria defined by the Histiocyte Society reflect the clinical features of pathologic immune activation, including persistent fever, splenomegaly, cytopenias, hyperferritinemia, decreased fibrinogen or increased triglycerides, hemophagocytosis (in bone marrow, spleen, or lymph nodes), increased soluble IL-2 receptor α , and decreased or absent natural killer (NK) cell function. The diagnosis of HLH can also be established by a pattern of familial inheritance or proven gene defects. It was first characterized as an inherited disorder in infants in the 1950s, referred to as “familial hemophagocytic reticulosis.”

Gene defects resulting in impaired cytotoxic NK- and T-cell function have been associated with autosomal recessive inheritance of HLH, including PRF1 (familial (f)HLH-2), UNC13D (fHLH-3), STX11 (fHLH-4), STXPB2 (fHLH-5), Munc18-2, Rab27a (Griscelli syndrome, type 2), LYST (Chédiak-Higashi syndrome), AP3B1 (Hermansky-Pudlak syndrome, type II), ITK, CD27, and MAGT1 (XMEN syndrome).¹⁰ EBV infection may trigger HLH in patients with any form of familial disease. Gene defects are identified in only 50% of patients with family history consistent with inherited HLH. Therefore, although a diagnosis “primary” or “familial” HLH may be proven, it is impossible to exclude. Familial HLH commonly presents in young children, but there are reports of new onset of HLH in adults as old as 62 years with mutations in HLH-associated genes. Patients with familial HLH typically require prompt treatment with chemotherapy and immune suppression (etoposide/dexamethasone) followed by HSCT.¹¹ Without therapy, survival of patients with active familial HLH is approximately 2 months. The first international treatment protocol for HLH organized by the Histiocyte Society in 1994 reported long-term survival of over 50%. More recently, survival rates of greater than 90% have been reported with reduced intensity conditioning regimens.¹²

The term secondary HLH generally refers to older children (or adults) who present without a family history or known genetic cause for their HLH. EBV is a common trigger for “secondary HLH,” ranging from inflammation that resolves spontaneously to unrelenting disease requiring HSCT. Differentiating infectious mononucleosis from EBV-associated HLH (EBV-HLH) is challenging. Clinical criteria for HLH should be evaluated in patients with persistently high cell-free EBV genome copy numbers in plasma, persistent symptoms of inflammation, or severe symptoms. Patients who initially meet clinical criteria for HLH may occasionally improve spontaneously. Patients with less severe presentations may also respond to corticosteroids, intravenous immunoglobulins or cyclosporine. However, in patients with progressive or severe disease, early initiation (within 4 weeks of onset of symptoms) of etoposide is associated with significant improvement in survival.¹³ Because it can eliminate EBV-infected B cells, rituximab may be a beneficial addition to other therapies in patients with progressive EBV-HLH.¹⁴ Some patients with apparently self-resolving HLH after primary EBV infection later develop recurrent HLH requiring immunochemotherapy and HSCT. Therefore it remains important to follow patients beyond resolution of initial symptoms. Alemtuzumab has also been reported to be effective in patients with recurrent or refractory disease.¹¹ Early clinical data also support the use interferon (IFN)- γ monoclonal antibodies in patients with refractory HLH.

X-Linked Lymphoproliferative Diseases

X-Linked Lymphoproliferative Disease 1

Mutations or deletions in SH2D1A (Src homology 2 domain protein 1A) results in X-linked lymphoproliferative disease (XLP1; Duncan disease), an immunodeficiency characterized by fatal IM meeting the diagnostic criteria for HLH, agammaglobulinemia, or B-cell lymphoma. SH2D1A interacts with SLAM (signaling lymphocyte activation molecule), which plays a central role in the stimulation of B and T cells. SH2D1A controls several distinct key T-cell signaling pathways, and mutant SH2D1A does not bind SLAM, suggesting that it is a natural SLAM inhibitor. SAP association with SLAM receptors is crucial for development of normal NK T cells, formation of normal GCs, and NK- and T-cell killing of EBV-infected B cells. T cells from patients with XLP1 are also resistant to apoptosis by radiation-induced cell death (RICD). Immune hyperactivation induced by primary EBV infection may be due to specific defects in NK⁺ and CD8⁺ T-cell cytotoxicity rather than from decreased or absent cytotoxic proteins. Resistance to apoptosis may exacerbate the inflammatory response due to persistence of ineffective activated NK and T cells.

Following infection with EBV, XLP1 patients mount a vigorous, uncontrolled polyclonal expansion of T and B cells. Infiltrating T cells cause extensive tissue destruction of the liver and bone marrow, resulting in death in 50% of XLP1 patients during primary EBV infection. Approximately 30% of patients have acquired hypogammaglobulinemia and 25% of patients develop malignant B-cell lymphomas that are often extranodal, involving the intestinal ileocecal region. It is important to realize that some patients with SH2D1A mutations may only present with hypogammaglobulinemia mimicking common variable immunodeficiency, and a diagnosis of XLP1 should be considered when more than one male patient with hypogammaglobulinemia is encountered in the same family. Patients with fulminant immunologic responses to primary EBV infection may be treated with HLH treatment strategies (steroids and etoposide) and/or rituximab. However, the only curative therapy for XLP1 is HSCT.

X-Linked Lymphoproliferative Disease 2

A second X-linked immune deficiency characterized by recurrent HLH (with or without EBV infection) is XLP2, caused by BIRC4 mutations and XIAP deficiency.¹⁵ Unlike patients with XLP1, those

TABLE 54.3**Classification of Chronic Active Epstein-Barr Virus (EBV) Infection**

EBV-Infected Lymphocyte	Geography	Clinical Symptoms		Clinical Course
		General	Skin	
B cell	Predominant in Western hemisphere	Fever, adenopathy, organomegaly, hepatic, cardiac, or pulmonary dysfunction	None	Chronic
T cell	Predominant in Asia: Japan, Taiwan, Korea Also in Native Americans: in Mexico, Central and South America		Hydroa vacciniforme	Risk for aggressive lymphoma/leukemia
NK cell			Hypersensitivity to mosquito bites	

with XLP2 have less pleiotropic clinical manifestations. It rarely results in lymphoproliferation or lymphoma and may be more accurately characterized as “X-linked familial HLH.” XIAP is a ubiquitously expressed member of a family of proteins defined by baculovirus IAP repeat (BIR) domains that inhibit apoptosis through inhibition of caspases. The mechanism of XIAP-induced HLH remains uncertain. Paradoxically, unlike in cases of XLP1, in which lymphocytes are resistant to apoptosis, XIAP deficiency in XLP2 confers increased sensitivity to RICD. The clinical manifestations of HLH in XLP2 patients with primary EBV infections appear less severe than in patients with XLP1. However, data remain insufficient to make specific therapy recommendations for XLP1 versus XLP2 or other forms of familial HLH.

Chronic Active Epstein-Barr Virus

CAEBV represents a range of clinical manifestations resulting from persistent, uncontrolled infection of B, T, and/or NK cells by EBV (Table 54.3).¹⁶ Inability to control infection is likely due to defects in cytotoxic immune function. CAEBV has considerable pathologic and clinical overlap with HLH, and immune dysfunction is likely due to a variety of causes. Early descriptions of CAEBV primarily reported disease in Asian patients, and almost all cases were due to proliferation of EBV-infected T or NK cells. A recent review of several centers in the United States found a predominance of B cell–associated CAEBV in the Western hemisphere.

To establish the diagnosis of CAEBV, patients must have (a) signs and symptoms for at least 6 months and (b) an abnormal EBV serology with high antibody titers of VCA-IgG and EA-IgG, and little or no antibodies against EBNA. Affected individuals may also have measurable EA-messenger-RNA or EBV-DNA in the peripheral blood, serum, or affected tissues. The life-threatening form of CAEBV is characterized by high fevers, hepatosplenomegaly, and extensive lymphadenopathy, followed by hepatic, cardiac, or pulmonary dysfunction. These patients have very high EBV-VCA titers and EBV-DNA levels in their peripheral blood. Although EBV usually resides in B cells, in severe CAEBV, either T or NK cells are often infected, predisposing the patient to lethal T-cell or NK-cell lymphomas. Severe, often fatal CAEBV is more common in Japan, whereas mild/moderate CAEBV is more common in the Western hemisphere and is predominantly associated with B-cell infection. These patients do not have XLP-associated SH2D1A or BIRC4 mutations, and while the etiology of CAEBV remains poorly understood a recent study demonstrated that GATA2 deficiency is associated with CAEBV and hydroa vacciniforme. Severe allergy to mosquito bites is associated with EBV-infected NK cells, whereas hydroa vacciniforme is associated with EBV-infected T cells. The proposed classification scheme of CAEBV-associated lymphoproliferative disease (LPD) includes three categories: (1) polymorphic LPD without clonal proliferation of EBV-infected cells, (2) polymorphic LPD with clonality, and (3) monomorphic LPD (T- or NK-cell lymphoma/leukemia)

with clonality.¹⁷ In the 2016 WHO Classification of mature lymphoid, histiocytic, and dendritic neoplasms LPDs associated with EBV-infected T cells are classified as systemic EBV-positive T-cell LPDs of childhood; LPDs associated with EBV-infected NK cells, as hydroa vacciniforme-like lymphoproliferative disorder.

Although sporadic clinical improvements of mild/moderate CAEBV have been reported after infusion of IL-2, high-dose immunoglobulin, antiviral drugs, tumor necrosis factor (TNF)- α antibodies, or steroids, the only curative option for severe CAEBV is HSCT. Survival rates vary between 50% and 95%, with better outcomes for patients who (a) are transplanted early after diagnosis, (b) have fewer complications before transplant, and (c) have received a reduced intensity.¹⁸ Besides HSCT, the adoptive transfer of autologous EBV-specific T cells has been explored in five patients with mild or moderate CAEBV. Infusion of EBV-specific T cells resulted in resolution of fatigue, malaise, fever, lymphadenopathy, and splenomegaly lasting for 6 to 36 months. For severe CAEBV in which EBV resides in the T- or NK-cell compartment, the use of EBV-specific T cells has been investigated anecdotally. For example, we have infused donor-derived LMP2-specific T cells with a good partial response as judged by decreasing EBV-DNA load.

Oral Hairy Leukoplakia

Oral hairy leukoplakia (OHL) develops frequently, although not exclusively, in patients who are HIV-positive. It is a nonmalignant hyperplasia of epithelial cells, and most patients present with white, corrugated lesions on the tongue. Besides IM, OHL is the only EBV-associated disease in which active viral replication is apparent, and multiple strains are often present within the same lesion. Inhibiting EBV replication in vivo with antivirals such as valacyclovir results in resolution of OHL. However, after valacyclovir treatment, EBV replication recurs in normal tongue epithelial cells, indicating that productive EBV replication is necessary but not sufficient to induce OHL.

Multiple Sclerosis

Multiple sclerosis (MS) is a rare inflammatory demyelinating disease of the central nervous system. MS is triggered by a combination of genetic as well as environmental factors. The role of EBV in the pathogenesis of MS has been studied for the last 30 years.¹⁹ While the vast majority of EBV-seropositive individuals do not develop MS thereby questioning an association with EBV, the incidence of EBV seropositivity is higher in MS patients than healthy controls. In addition, individuals who have IM as their clinical presentation of primary EBV infection, have a higher incidence of MS. Lastly, increased or decreased cellular immune responses to EBV antigens have been reported in MS patients. If this dysregulation of EBV-specific cellular immune responses contributes to the pathogenesis

of MS is the subject of active investigation. Based on findings from these studies, EBV-targeted approaches might be explored in the future.

Epstein-Barr Virus–Associated Malignancies

Over the past decades, EBV has been associated with a heterogeneous group of malignancies.¹⁵ Each year 200,000 cases of EBV-positive malignancies are diagnosed worldwide, with gastric carcinoma being the most common, followed by NPC, and lymphoma. Although there is strong circumstantial evidence linking EBV to these malignancies, the potential causative relationship between EBV and these tumors remains to be firmly established. The following section focuses on EBV-LPD, HD, NHL (including BL), and NPC (Figs. 54.6 and 54.7). All EBV-associated malignancies are associated with viral latency, and spontaneous viral replication occurs at a very low frequency. Because antiviral agents, like acyclovir, only prevent viral replication and do not affect latency, these agents are of limited therapeutic value.

Lymphoproliferative Disease

EBV-LPD develops in patients with congenital or acquired immunodeficiencies, including severe combined immunodeficiency, XLP,

HIV infection, and immunosuppression in SOT recipients (Fig. 54.6, A, B) or HSCT.²⁰ Besides EBV and a dysfunctional cellular immune system, genetic alterations in B cells have also been implicated in the pathogenesis of posttransplant LPD, especially in SOT recipients, including microsatellite instability, DNA hypermethylation, aberrant somatic hypermutation, and mutations in specific genes such as *MYCC*, *BCL-6*, *N-ras*, and *p53*. Most cases of EBV-LPD are lymphomas of B-cell origin, histologic high-grade NHL of the immunoblastic or undifferentiated large cell type that respond poorly to cytotoxic therapy. In the setting of SOT, the reported incidence of EBV-LPD ranges from 1% to 25%, with the highest risk in seronegative recipients, patients receiving intensive immunosuppressive therapy, and patients receiving grafts with a high lymphoid content. After HSCT the incidence of EBV-LPD varies with the transplant regimen and may be as high as 25%. Risk factors for the development of EBV-LPD include the use of stem cells from an HLA-mismatched family member or closely HLA-matched unrelated donor, T-cell depletion of the donor cells, intensive immunosuppression, and an underlying diagnosis of primary immunodeficiency. The incidence is much lower when methods that also deplete B cells are employed. The onset of EBV-LPD seems to be preceded by a large increase in virus load as well as the proliferation of EBV-infected B cells. Frequent monitoring of the EBV-DNA load in peripheral blood is a valuable diagnostic test for early detection of EBV-LPD after HSCT or SOT. However, it remains a subject of debate which is the optimal sample (whole blood, isolated peripheral blood mononuclear cells, plasma)

Fig. 54.6 EXAMPLES OF EPSTEIN-BARR VIRUS–POSITIVE LYMPHOID MALIGNANCIES. Post-transplant lymphoproliferative disorder (PTLD), Hodgkin lymphoma, and large B-cell lymphoma. PTLD in the duodenum of a 15-month-old (A) with history of liver transplant. (B) The PTLD was classified as a polymorphic type and was EBV-positive. Hodgkin lymphoma (C) and EBV-positive Reed-Sternberg cells (D). Large B-cell lymphoma (plasmablastic type) in an HIV-positive patient (E), diffusely EBV-positive (F). Note, all EBV studies are in situ hybridizations for EBV mRNA, EBER.

Fig. 54.7 FURTHER EXAMPLES OF EBV-POSITIVE MALIGNANCIES. (A–E) Burkitt lymphoma and nasopharyngeal carcinoma. Low power of Burkitt lymphoma showing the classic “starry sky” appearance (A) and higher power illustrating the highly proliferative lymphoma cells (B), which are uniformly EBV positive (C). Nasopharyngeal carcinoma (D) with EBV-positive cells (E) demonstrated by in situ hybridization for EBV mRNA.

for EBV DNA quantitation. Lastly, the threshold level of EBV-DNA suggestive of impending EBV-LPD varies according to the PCR method of quantifying viral DNA. However, it should be emphasized that not all patients with high EBV-DNA levels, especially those with an SOT, develop EBV-LPD. Several distinct patterns of EBV latent gene expression have been identified in the memory B cells of high-load EBV carriers, with type III latency conferring the highest risk for EBV-LPD development. Besides EBV-DNA levels, determining the frequency of EBV-specific T cells or the functionality of T cells in patients with high EBV-DNA load might also assist in identifying patients who are at increased risk for developing EBV-LPD. In addition, host factors such as polymorphisms in the promoter regions of cytokines have been implicated in increasing the risk for developing EBV-LPD. Thus an elevated EBV-DNA load can lead to early diagnosis of EBV-LPD, with consequent reductions in mortality and treatment-related morbidity, although additional results such as clinical signs and symptoms, as well as radiographic findings, must be taken into account before therapy is initiated (Fig. 54.8).^{21,22}

Treatment of Lymphoproliferative Disease

A variety of treatment approaches have been explored for EBV-LPD (Fig. 54.9). These include reduction or withdrawal of immunosuppression, conventional chemotherapy, and radiation for localized disease, monoclonal antibodies, adoptive transfer of T cells or EBV-specific T cells, and autologous or allogeneic HSCT for refractory cases. Other potential strategies include eradication of EBV episomes using chemotherapeutic agents like hydroxyurea. Several groups are also developing small molecule inhibitors that block the DNA-binding site of EBNA1, which is critical for EBV episome maintenance.²³ Inducing the lytic cycle of EBV so that the lymphoma cells

Fig. 54.9 TREATMENT STRATEGIES FOR EPSTEIN-BARR VIRUS-ASSOCIATED LYMPHOPROLIFERATIVE DISEASES (EBV-LPD). For an explanation of symbols, see Fig. 54.2. *IVIG*, Intravenous immunoglobulin; *LP*, leader protein.

become sensitive to ganciclovir is another therapeutic options. Lastly, in SOT recipients simple withdrawal of immune suppression can result in the regression of localized EBV-LPD by allowing recovery of the suppressed cellular immune system. This approach is limited by the risk for graft rejection, and it is not useful after HSCT because of the profound immunosuppression and the risk for inducing graft-versus-host disease (GVHD).

Monoclonal Antibody Therapy

The CD20 monoclonal antibody rituximab is currently widely used as prophylaxis and as therapy for EBV-LPD. A comprehensive review

of the literature that included articles and abstracts published between 1999 and 2008 reported that the use of rituximab as preemptive therapy prevented the development of EBV-LPD in 90% of 341 HSCT recipients, while therapy was associated with a response rate of 63% in 126 HSCT patients.²⁴ However, response rates varied widely, likely reflecting heterogeneity in patient populations and the fact that early diagnosis and treatment leads to better outcomes. For EBV-LPD after SOT, a recent multicenter analysis of 80 patients reported that rituximab-based therapy had a 3-year progression-free survival of 70% compared with 21% for patients treated without rituximab.³ Half of the patients treated with rituximab also received chemotherapy, most of them having bulky disease and a high International Prognostic Index. A recent prospective multicenter study suggests that sequential therapy of rituximab followed by chemotherapy results in excellent disease control and overall survival. However, at present it remains unclear for which group of patients rituximab monotherapy is sufficient. Retrospective studies have identified risk factors including extralymphatic disease, high LDH, low albumin, and poor performance status, but these risk factors need to be validated in prospective studies.²⁵ In summary, rituximab has led to a dramatic improvement in outcome of EBV-LPD. However, rituximab does not restore the cellular immune response to EBV, which may be crucial for the long-term control of EBV-mediated B-cell proliferation. EBV-infected B cells may therefore increase with B-cell recovery, and EBV-LPD may recur. Although rare, the recurrence of CD20-negative lymphomas with the use of rituximab has been reported. Patients who fail to respond to chemoimmunotherapy strategies may respond to high-dose chemotherapy followed by autologous HSCT or adoptive T-cell therapies.

T-Cell Therapies

Donor T-cell infusions have been used successfully to treat EBV-LPD post-HSCT transplantation but carry the inherent risk for GVHD. One strategy to prevent GVHD after T-cell infusion is the administration of polyclonal EBV-specific T cells.²⁶ Initially, donor-derived EBV-specific T cells were generated *ex vivo* by repeated stimulation with autologous LCLs. Clinical studies in HSCT recipients have shown that these cells are safe, do not cause significant GVHD, reconstitute EBV-specific cellular immunity, and are effective as prophylaxis and therapy for EBV-LPD. In SOT recipients who develop EBV-LPD, donor-derived T cells are of limited value, because the tumor almost always arises in recipient B cells, and donor T cells are unlikely to survive in the recipient's hematopoietic system. Initial studies using autologous EBV-specific T cells for the treatment or prevention of EBV-LPD after SOT have shown promising results but need further investigation.

Although donor-derived EBV-specific T cells have potent clinical activity post-HSCT, their generation using LCLs as antigen presenting cells is a lengthy process, requiring 6 weeks to establish LCLs, then at least 4 weeks for T-cell expansion, followed by 2 weeks for quality control testing. Thus, several groups have developed strategies to rapidly select or generate EBV-specific T cells. Rapid selection strategies rely on the use of HLA-peptide multimers or Streptamers, or so-called interferon (IFN)- γ capture, in which T cells that secrete IFN- γ in response to antigen stimulation are selected. While these selection procedures require no or only limited (>24 hours) *ex vivo* culture, they require a leukopheresis product. In addition, HLA-peptide multimer or streptamer selection require knowledge of a particular epitope and is restricted to the selection of CD8⁺ T cells. Our group has therefore focused on rapid expansion protocols in which virus-specific T-cell products are activated and expanded for 10 days with overlapping peptide libraries spanning the viral antigens of interest in the presence of cytokines. Resulting cell lines are polyclonal and contain CD4⁺ and CD8⁺ T cells recognizing MHC class I as well as class II restricted viral antigens. EBV-specific T cells were generated as part of multivirus-specific T-cell product, and were effective in five patients with EBV-LPD or EBV viremia. In addition, banked “off the shelf” third-party EBV-specific T cells are actively being explored for the therapy of EBV-LPD as a single or as part of a multivirus-specific T-cell product.²⁷ Although third-party EBV-specific T cells did not

persist long-term post infusion, they have significant anti EBV-LPD activity, supporting the development of third-party banks for the therapy of EBV-LPD in the transplant setting.

Epstein-Barr Virus-Positive Hodgkin Disease and Non-Hodgkin Lymphomas

EBV is associated with HD as well as NHLs in immunocompetent patients (see [Chapters 74, 83](#)). An increased incidence of EBV-positive diffuse large B-cell lymphomas has been seen in older adults.²⁸ All EBV lymphomas are associated with the virus latent cycle ([Fig. 54.3](#)).² The majority of immunocompetent patients with EBV-associated lymphomas are latency type II and express EBNA1, LMP1, and LMP2, except for BL, which is latency type I and only expresses EBNA1.

Hodgkin Disease

HD is a malignant neoplasm of lymphoreticular cell origin, and 40% to 50% of cases in immunocompetent individuals are associated with expression of EBV-derived antigens in malignant Hodgkin and Reed-Sternberg (HRS) cells and their variants ([Fig. 54.6, B, C](#)). EBV-positive HD is more commonly seen in young children and in less developed countries. EBV association with HD differs by histologic subtype, being highest with the mixed-cellularity subtype. Evidence linking EBV to the pathogenesis of HD includes the findings that (a) every HRS cell in an EBV-positive tumor mass carries the virus, and (b) the EBV genome is clonal, indicating that the malignant HRS cells originated from a single EBV-infected cell. In addition, LMP1, one of the EBV proteins expressed in HRS cells, activates the transcription factor nuclear factor kappa-B (NF- κ B), which is thought to play an important role in the HD pathogenesis. EBV-positive HD patients also differ in their antibody response to the major EBV-associated antigens in comparison with healthy controls. The overall outcome of EBV-positive and EBV-negative HD is similar; with combination chemotherapy and radiation, the prognosis is excellent for low-stage disease, and overall survival rate for advanced-stage disease is between 65% and 80% (see [Chapter 75](#)). Depending on age and histologic subtype, the presence of EBV might be associated with better survival.

Non-Hodgkin Lymphomas

NHLs expressing type II latency include diffuse large B-cell lymphoma (DLBCL), CD30⁺ Ki-1 anaplastic large cell lymphoma (ALCL) of B-cell type, T-cell-rich B-cell NHLs and lymphomatoid granulomatosis (see [Chapter 76](#)). The association of these lymphomas with EBV varies, ranging from 10% to 95%.

EBV-associated NK/T-cell lymphomas include extranodal NK/T-cell lymphoma (nasal type), angioimmunoblastic lymphoma, and large granular lymphocyte (LGL) leukemia/lymphoma (NK- or T-cell type). Between 30% and 100% of these lymphomas are EBV-positive, expressing a type II latency pattern. In addition, CAEBV of NK/T-cell type has been associated with fulminant forms of lymphoma, more than 95% of which are positive for EBV. The overall outcome of EBV-associated NHL depends on histologic subtype and risk factors present at diagnosis, but most are high-grade malignancies with an unfavorable prognosis using current treatment modalities, which are described in detail in [Chapters 79 to 85](#).

Adoptive Immunotherapy for Epstein-Barr Virus-Positive Hodgkin Disease and Non-Hodgkin Lymphomas in Immunocompetent Individuals

In contrast to EBV-LPD only a limited number of EBV-derived antigens (EBNA1, LMP1, and LMP2) are present in EBV-positive HD and NHL. Initial studies with patient-derived, LCL-generated

EBV-specific T cells demonstrated their safety, but infused T cells had limited antitumor activity against HD and NHL in comparison to EBV-LPD. This lack of efficacy could be due in part to immunosuppressive factors secreted by lymphoma cells or may simply be quantitative in that the method used for EBV-specific T-cell generation produces T-cell lines that are dominated by clones reactive to viral proteins not expressed in latency type II lymphoma. To improve T-cell efficacy methods to expand T-cell specific for the EBV proteins LMP1 and LMP2 expressed in latency type II lymphoma and to genetically modify the expanded T cells to render them resistant against inhibitory cytokines have been developed. We conducted two clinical studies with LMP1/2 (LMP)-specific T cells in patients with EBV-positive HD and NHL.²⁹ The initial trial targeted LMP2 alone and the subsequent LMP1 and LMP2. On both trials combined, 50 patients received LMP-specific T cells. Of 29 patients who received these cells as adjuvant therapy, 28 remained in remission for a median of 3.1 years. Thirteen out of 21 patients infused with active disease had objective clinical responses with 11 patients being complete. While LMP-specific T cells had clinical activity, generation required not only LCLs but also recombinant adenovirus vectors encoding LMP1 and LMP2. After having developed an LMP-specific T-cell production process that is devoid of LCLs and recombinant adenovirus vectors, these cells are currently being tested in clinical studies. To evaluate if rendering LMP-specific T cells resistant to the immunosuppressive lymphoma environment enhances their antitumor activity, we focused on targeting TGF- β , which promotes tumor growth, limits T-cell effector function, and activates inhibitory, regulatory T cells. These detrimental effects of TGF- β can be overcome by modifying T cells to express a dominant negative TGF- β receptor (DNR), which lacks its intracellular signaling domain. DNR expression blocks TGF- β signaling and restores T-cell effector function in the presence of TGF- β . Initial testing in humans indicate that DNR-modified LMP-specific T cells benefit patients who failed therapy with unmodified cells. For a detailed discussion on cell therapy with conventional or genetically modified T cells targeting non-viral antigens for hematologic malignancies see [Chapters 98 and 100](#). In addition to genetically modifying T cells to enhance their antitumor activity, combining the adoptive transfer of T cells with monoclonal antibodies that block immune checkpoints, such as PD-1/PD-L1, hold the promise to enhance their antitumor activity. This approach has not been tested in humans; however, clinical studies are currently being planned.

Epstein-Barr Virus-Associated Non-Hodgkin Lymphoma in HIV Patients

Patients infected with HIV are at high risk to develop NHL. The incidence increases with age, and the male-to-female ratio is approximately 2:1. Depending on certain histologic features, the EBV association ranges from 30% in systemic HIV-related BL (HIV-BL) to 70% to 80% in HIV-related immunoblastic lymphoma (HIV-IBL), and virtually all cases of primary central nervous system lymphoma (PCNSL) are EBV-positive. In biopsies of EBV-associated HIV-NHL, there is considerable variation in the number of EBV-positive cells, and the pattern of EBV latent gene expression varies among tumor types as in immunocompetent individuals ([Fig. 54.6, E, F](#)). In HIV-infected patients, the development of EBV-associated HIV-NHL is preceded by a loss of functional EBV-specific T cells, suggesting that strategies to boost the endogenous EBV-specific T-cell response might prevent lymphomas. Restoring CD4⁺ T-cell counts in patients with HIV with highly active antiretroviral therapy (HAART) has decreased the incidence of PCNSL and HIV-NHL. The clinical experience with T-cell therapy for EBV-associated HIV-NHL is limited.

Burkitt Lymphoma

BL is a high-grade malignant small noncleaved B-cell lymphoma. Histology usually reveals a “starry-sky” pattern resulting from

numerous benign macrophages that have ingested apoptotic tumor cells ([Fig. 54.7A–C](#)). Although almost all endemic BLs in equatorial Africa are associated with EBV, the virus has been implicated less often in sporadic cases, and in the United States only 20% of BL are EBV positive. In developing countries, an intermediate type of BL has been described, both in its clinical presentation and association with EBV, which varies from 25% to 80%. As with NPC and HD, there is strong circumstantial evidence linking EBV to BL. The EBV genome is clonal as in other EBV-associated malignancies. The majority of BLs carry a translocation between the long arm of chromosome 8, the site of the MYCC oncogene (8q24), and the Ig heavy chain region on chromosome 14, t(8;14). Although the t(8;14) translocation is seen in endemic as well as sporadic BLs, the exact location of the chromosomal breakpoints on chromosome 8 and 14 differ. Other chromosomal translocations seen in BLs are between MYCC and the κ -light chain locus on chromosome 2, t(2;8), or the λ -light chain locus on chromosome 22, t(8;22).

Current treatment strategies rely on intensive chemotherapy, and overall survival depends on extent of disease at presentation, being 90% to 100% for local and 60% to 70% for advanced disease. The prospect for the development of an EBV-specific immunotherapy for BLs is problematic because lymphoma cells evade the immune system by downregulating the expression of EBV latency antigens, cell adhesion molecules, and MHC class I molecules. EBNA1, the only EBV protein expressed in BL, autoregulates its own translation and inhibits HLA class I presentation because of an internal glycine-alanine repeat region. However, the characterization of EBNA1-specific CD4⁺ T cells, as well as rare CD8⁺ T cells that can recognize BL through EBNA1, has provided impetus to explore the role of CD4⁺ T cells in the control and therapy of BL. In addition, EBNA1-specific CD4⁺ T cells had potent antitumor activity in a murine model of BL. As discussed in the EBV-LPD section, induction of the lytic EBV cycle is another attractive EBV-targeted approach for BL.

Nasopharyngeal Carcinoma

NPC arises from the epithelial cells of the nasopharynx. The WHO classifies NPC into keratinizing squamous cell carcinoma (type 1), nonkeratinizing carcinoma (type 2), and undifferentiated carcinoma (type 3, most common). Type 2 and 3 carcinomas are associated with EBV ([Fig. 54.7D, E](#)); however, environmental and genetic factors play an important role in oncogenesis, because the incidence of NPC varies 50- to 100-fold from Southern China to Western countries. EBV was initially linked to NPC by the observation that patients had elevated levels of VCA-IgG, VCA-IgA, and EA-IgG antibodies. Further studies showed that EBV-DNA is present in every tumor cell of type 2 and 3 carcinomas with remarkable consistency. As in HD, the EBV episome in an individual tumor is clonal.

EBV antibody responses have been used to follow tumor burden in patients with NPC; in addition, VCA-IgA antibodies and antibodies against EBV DNase are predictive for NPC in high-risk populations. More recently, detection of EBV-DNA in serum by different PCR methods has shown to be useful for the diagnosis, prognosis, and monitoring of patients with NPC. Most patients with NPC are treated with radiation. Other modalities such as surgery, chemotherapy, and combined approaches may be appropriate in selected circumstances, but a detailed discussion is beyond the scope of this chapter. In NPC, as for EBV-positive lymphomas, only a limited number of EBV latent antigens are expressed. Three therapeutic vaccine studies targeting LMP2, LMP1 and LMP2, or EBNA1 and LMP2 have been conducted, and the results of these trials were discussed in the earlier section EBV Vaccine Development.

The adoptive transfer of autologous EBV-specific T cells is being actively explored. Several groups have reported that the infusion of T cells is safe and has resulted in clinical responses, especially in patients with locoregional disease. In addition, EBV-specific T cells, given as adjuvant after chemotherapy, resulted in a significant increase in 3-year overall survival in comparison to historical controls, who

only received chemotherapy.³⁰ A pivotal, randomized clinical study to validate these findings is in progress.

FUTURE DIRECTIONS

Since its discovery in 1964, EBV has been linked to a heterogeneous group of diseases. EBV was the first human virus implicated in oncogenesis, and the biology of the virus has been studied extensively on a cellular and molecular level. Over the last two decades immunotherapeutic approaches targeting EBV have been developed for EBV-associated malignancies and later phase clinical studies are currently in progress. Although adoptive transfer of T cells so far has been more successful than vaccines, novel, more potent vaccines have been developed that await testing in humans. Combinatorial therapies, for example combining EBV-targeted immunotherapy with antibodies that block immune checkpoints, are starting to be evaluated in clinical studies and hold the promise to improve outcomes. In the next 5 years, rationally designed small molecule inhibitors will be tested for the first time in humans that block the DNA binding site of EBNA-1 with the potential to eradicate EBV. Lastly, whole exome sequencing will continue to identify genes that are associated with life-threatening complications of EBV infections, providing clues into their pathogenesis and novel therapeutic interventions.

PROGRESS IN THE CLASSIFICATION OF HEMATOPOIETIC AND LYMPHOID NEOPLASMS: CLINICAL IMPLICATIONS

Mohamed E. Salama and Ronald Hoffman

Defining and classifying tumors of the hematopoietic and lymphoid tissue accurately is a core requirement for providing optimal treatment to patients with hematologic malignancies. Precise definitions and terminologies are prerequisites for the precise classification of hematologic malignancies. A reproducible classification that is based on consensus definitions and terminologies is fundamentally essential for proper medical practice and the advancement of medical knowledge. Generally, such classifications should be based upon clinically distinct, nonoverlapping disease entities that can be grouped together based on shared distinguishable clinical features, as well as phenotypic and molecular markers which allow for reproducible laboratory testing, clinical outcomes, and responses to therapeutic agents. Traditionally, preliminary attempts at disease classification are initiated by the personal experience of experts, and then evolve after many years or even decades of controversy and exhaustive debate. Subsequently, classification schemes change when new scientific discoveries are validated.

Following many years of controversy, a collaborative project of members of the European Association for Haematopathology and the Society for Hematopathology, along with advice from clinical hematologists and oncologists, resulted in the World Health Organization (WHO) Classification of Tumours of Haematopoietic and Lymphoid Tissues.^{1,2} This WHO classification, which is the first true worldwide consensus classification of hematologic malignancies, is based on the principles initially defined in the “Revised European-American Classification of Lymphoid Neoplasms” (REAL) from the International Lymphoma Study Group (ILSG).³ The most recent WHO classification (4th edition) was formulated in a series of meetings by two clinically advisory committees: one for myeloid neoplasms and other acute leukemias, and one for lymphoid neoplasms.⁴ The current WHO classification, which addresses new developments related to disease definitions, nomenclature, grading, and clinical relevance, provides the basis for an approach to hematopoietic and lymphoid neoplasm classification that employs morphology, immune phenotype, genetic features, and clinical features to define diseases.⁴ The relative importance of each of these components varies among diseases and is dependent on the current state of knowledge. Morphologic assessment remains a key element of the diagnostic evaluation and classification of hematologic malignancies, as many diseases have characteristic diagnostic features. Morphologic evaluation also remains a decisive step for prioritization of ancillary testing choices that may include phenotyping, as well as molecular or genetic testing. Immunophenotypic studies such as flow cytometry and immunohistochemistry are used routinely to identify the lineage of the benign or malignant process, and often are necessary to reach a definitive diagnosis. In several lymphoid and myeloid neoplasms a specific diagnosis can be facilitated by genetic or molecular abnormalities (e.g., *CCND1* in suspected mantle cell lymphoma [MCL] or *BCR/ABL* for chronic myeloid leukemia [CML]). In addition, some abnormalities can serve as prognostic markers in several diseases (e.g., *TP53*). However, many entities still lack defining genetic or molecular abnormalities.

In some conditions rendering an accurate diagnosis requires knowledge of clinical features such as a patient’s age and previous therapy, as well as the anatomic site and/or extent of disease. Although most of the disease entities described in the WHO classification

represent distinct entities, some categories are not as clearly defined and are regarded as provisional entities. In addition, borderline categories have been created for cases that do not clearly fit into one category; thus well-defined categories can remain homogeneous while borderline cases can be further studied and characterized. Furthermore, the WHO classification stratifies hematologic neoplasms according to lineage into three main groups: myeloid, lymphoid, and histiocytic/dendritic cells. In this chapter we provide a summary of neoplasms in these three groups, emphasizing changes that have had an effect on practice guidelines.

PROGRESS IN THE DIAGNOSIS AND CLASSIFICATION OF MYELOID NEOPLASMS

Clinical Implications

The myeloid neoplasms are a heterogeneous group of diseases. In general terms, they are clonal hematopoietic malignancies that can arise in or affect a single myeloid lineage (e.g., monocytic). Alternatively, they can be derived from a pluripotent progenitor cell and can affect multiple or even all myeloid cell types (erythroid, megakaryocytic, monocytic, neutrophilic, basophilic, eosinophilic, and mast cells). The myeloid neoplasms include chronic and acute diseases, along with diseases that evolve from an indolent process to a more aggressive state. As such, they can manifest as proliferative disorders, mostly involving primary mature hematopoietic elements; they can predominately affect immature or blastic cells; or sometimes they can be a combination of these two manifestations. The diseases can result in excess production of blood cells, or they can proliferate in the bone marrow (BM) and exhibit ineffective hematopoiesis, resulting in peripheral cytopenias. Because the diseases range from indolent to acute, they exhibit a wide variation in prognosis. Some disorders are fairly indolent and require only supportive care and transfusional support; others slowly progress but have no successful treatment option. Acute and life-threatening disorders are often curable, even within days or weeks after presentation, if appropriately managed. Accurate, timely diagnosis, and correct classification can have a tremendous impact on outcome.

The diagnosis of the myeloid neoplasms typically requires a multifaceted team approach that relies on cooperation among the clinician, laboratory personnel, and a skilled pathologist. The precise diagnosis requires compiling accurate historical data, clinical information, general laboratory findings, and carefully interpreted observations from the peripheral blood smear, bone core biopsy, and aspirate merged with information from immunophenotyping, cytogenetic analysis, and molecular studies (Table 55.1). Although in some cases a diagnosis can be made with a quick examination of the blood smear, with a single molecular test, or with a simple immunophenotype, in general, careful assessment of the total clinical picture gives the most accurate and clinically relevant diagnosis. Future routine diagnostic modalities may include next-generation sequencing, single-nucleotide polymorphism array karyotyping, gene expression arrays, and genome-wide epigenetic studies.

The myeloid neoplasms are grouped as different categories of diseases. These categories seem to be changing constantly, both in

TABLE 55.1 Components in the Routine Clinical Evaluation of Myeloid Diseases**Current**

- Accurate clinical history, including family history and physical examination findings
- General laboratory findings, including CBC, and other specific tests (e.g., EPO) when appropriate
- Evaluation of well-prepared and stained peripheral blood smear with 200 cell differential count
- Review of BM aspirate, including iron stain, and 500 cell differential count
- Evaluation of H&E sections of BM biopsy of sufficient length and reticulin stain
- Phenotyping studies, including cytochemical reactions (nonspecific and specific esterase reactions and myeloperoxidase) and flow cytometric analysis of peripheral blood or BM for phenotype of blasts or other cells when appropriate
- Cytogenetic analysis, including karyotype, and FISH for specific abnormalities when appropriate
- Single-nucleotide polymorphism array karyotyping
- Genetic analysis for particular genetic rearrangements or mutations, including gene sequencing when appropriate
- Next-generation sequencing

Potential Future Clinical Studies

- Gene expression arrays
- Genome-wide epigenetic studies

BM, Bone marrow; CBC, complete blood count; EPO, erythropoietin; FISH, fluorescence in situ hybridization; H&E, hematoxylin and eosin.

name and in the components of the disorders. However, refinements have led to an increased understanding of the clinical, pathologic, and genetic basis of the diseases and ultimately serve, or at least strive to, improve diagnosis, treatment and outcome. The current classification of myeloid neoplasms include the categories of myeloproliferative neoplasms (MPNs), acute myeloid leukemias (AMLs), myelodysplastic syndromes (MDS), and MDS/MPNs, which is a category with features that are intermediate between MDS and MPN (Table 55.2). This generally accepted classification system was derived from a number of earlier classification systems,⁵ and represents the working system of WHO as of 2008.^{4,6} The recent proposal to update the 2008 classification is based on the newer information from molecular testing modalities that further impact the classification and categorization of these neoplasms.⁷

The Myeloproliferative Neoplasms

The MPNs, formerly referred to as *myeloproliferative disorders* (MPDs), are a group of clonal multipotential hematopoietic stem cell disorders that have a proliferative nature, presenting frequently with hypercellular BMs, and an elevation of one or more myeloid cell types in the blood. The MPNs are insidious in onset and chronic in course but have a variable tendency to terminate in BM failure or acute leukemia.⁸ The MPNs include CML (Table 55.3), which illustrates how the elucidation of pathways involved in the molecular pathogenesis (i.e., dysregulation of *ABL1* tyrosine kinase [TK] signaling) can

TABLE 55.3 Tyrosine Kinase Involvement in Myeloproliferative Neoplasms

Disease	Tyrosine Kinase Involvement
Chronic myeloid leukemia, <i>BCR-ABL1</i> +	<i>ABL1</i> (100%)
Myeloid and lymphoid neoplasms with eosinophilia TK abnormalities	<i>PDGFRA</i> , <i>PDGFRB</i> , or <i>FGFR4</i>
Polycythemia vera	<i>JAK2</i> V617F (≈95%), <i>JAK</i> exon 12 (≈4%)
Primary myelofibrosis	<i>JAK2</i> V617F (≈50%), <i>MPL</i> W515 K/L (5–9%), <i>CALR</i> (35%)
Essential thrombocythemia	<i>JAK2</i> V617F (≈50%), <i>MPL</i> W515 K/L (≈1%), <i>CALR</i> (35%)
Chronic neutrophilic leukemia	<i>CSF3R</i> (83–90%)
Chronic eosinophilic leukemia, not otherwise specified	—
Mastocytosis	<i>KIT</i> D816V (≈95%)
MPN, unclassified	—
MPN, Myeloproliferative neoplasm; TK, tyrosine kinase.	

successfully lead to the rational targeted therapy (i.e., imatinib and other TK inhibitors).⁹

The MPNs also include *BCR-ABL1*–negative entities, essential thrombocythemia (ET), polycythemia vera (PV), and primary myelofibrosis (MF) (see Chapters 68–70). These MPNs share common features including multipotential hematopoietic stem cell origin, clonal proliferation, and chronic nature. Although they seem to be distinctive, they can present a diagnostic challenge, and they can have subtle and overlapping presentations. Recent discoveries in the underlying molecular pathology of these entities have demonstrated that, similar to CML and eosinophilic disorders, they too share TK signaling dysregulation, at least to some degree. This is attributable to an associated mutation in the TK, *JAK2* (*JAK2* V617F), which is present in about 50 to 95% of cases of Ph-negative MPNs. Variants of *JAK2* mutations involving exon 12 are also observed in 2% to 3% of PV patients. This association has led to significant revisions in the 2008 WHO criteria for diagnosis, but it also has raised questions as to how a single mutation can be associated with such heterogeneous phenotypic characteristics. Proposed revisions in 2016 WHO classifications for the diagnosis of the Ph-negative MPNs include suggested modifications of lower hemoglobin thresholds for PV. BM biopsy results and the presence of *JAK2* mutations will represent major criteria. A subnormal erythropoietin level will become a minor criterion, and the endogenous erythroid colony assay will no longer be included in the next revision of the WHO diagnostic criteria for MPNs.¹⁰ These changes are intended to capture patients with subtle presentations, such as those with masked PV. Experts also have recommended inclusion of mutations in calreticulin and the thrombopoietin receptor, *MPL*, which is identified in 20% to 30% of ET and MF cases, and the colony-stimulating factor 3 receptor mutations in the next revision.^{10–12}

JAK2 V617F inhibitors are among several agents under investigation for use in patients with MPNs. In 2011 the US Food and Drug Administration (FDA) approved ruxolitinib for the treatment of patients with intermediate or high-risk MF. Subsequently, the FDA also designated ruxolitinib as an orphan product, as it demonstrated potentially significant improvement in safety and efficacy over other available therapies for PV. A number of novel agents that target various pathways are currently being investigated and will be further discussed in detail later (see Chapters 68–70).

Chronic neutrophilic leukemia (CNL) and mast cell disease are currently included in the category of MPNs. CNL is now better defined with the integration of *CSF3R* mutation as a diagnostic tool, and is distinct from atypical CML.¹³

Mast cell disease is yet another disease related to abnormal TK signaling, in this case the *KIT* gene.¹⁴ Its classification system generally considers systemic mastocytosis and cutaneous mastocytosis as main entities but also includes a mast cell proliferation associated with clonal nonmast cell hematopoietic malignancies; this can be another myeloid malignancy or, less commonly, a lymphoid malignancy. With the advances of comprehensive mutational profiling, it is proposed that additional mutations in *SRSF2*, *ASXL1* and/or *RUNX1* identify a high-risk group of patients with *KIT* D816V⁺ advanced systemic mastocytosis.¹⁵ A more recently improved understanding of the cellular and molecular basis of eosinophilic disorders has translated into more biologically oriented classification schemes that carry therapeutic implications. Thus in 2008 the WHO established a semimolecular classification scheme of separately listed disease subgroups including “myeloid and lymphoid neoplasms with eosinophilia and abnormalities of platelet-derived growth factor receptors (PDGFRA, PDGFRB), or fibroblast growth factor receptor 1 (FGFR1)”, chronic eosinophilic leukemia (CEL), not otherwise specified (NOS), lymphocyte-variant hypereosinophilia, and idiopathic hypereosinophilic syndrome (see Chapter 71). Although quite uncommon, these are noteworthy because, similar to CML, they have also been found to be caused by dysregulation of TK signaling (caused by mutations in *PDGFRA*, *PDGFRB*, or *FGFR4*) and at least partially successfully treated with TK inhibitors.¹⁶

It is important to emphasize that diagnosis of the MPNs does not rest solely with the routine microscopic examination. The diagnostic work-up is more far-reaching and must include reviewing the clinical history and pertinent physical findings, as well as obtaining and assessing laboratory values, including recent complete blood cell counts. Examination of a well-prepared peripheral blood smear and both BM aspirate and biopsy specimens are still crucial. However, ancillary studies, such as cytogenetic and molecular analysis, as well as other more specific laboratory evaluations, are just as important in formulating the correct diagnosis, and in particular, in distinguishing MPNs from reactive myeloid proliferations. This is particularly true, for example, regarding the *JAK2* V617F or other driver mutations, and the impact not only on the diagnosis but also on the prognostication of MPNs.

The Acute Myeloid Leukemias

The historical and emerging classifications systems for AML dramatically illustrate the marked heterogeneity of these diseases. Despite this heterogeneity, however, to date a major breakthrough has not been made in the development of specific initial treatment for AML as an entity apart from acute promyelocytic leukemia. However, to a large extent this concept is changing as newer agents targeting molecularly or genetically defined AML have become available (e.g., FMS-like tyrosine kinase-3 [FLT3] inhibitors for FLT3-mutated cases).^{17,18} It is anticipated that the gap between the growing number of unique or genetically defined acute leukemia types and the somewhat limited treatment options may begin to close.

The French–American–British (FAB) classification of AML, introduced in 1976 with its subsequent revision in 1985, provided the first real framework for classifying the AMLs. It also provided fairly reproducible definitions of diseases. The classification was mainly based on morphologic and cytochemical features of the leukemic blasts in the BM. In general, the FAB scheme required that 30% of the BM-nucleated elements be blasts; then it further defined AML subtypes based on the presence of maturation in the granulocytic series, the presence of a monocytic component, and the presence of an erythroid component. Later, as immunophenotyping allowed for improved identification of myeloid precursors, acute megakaryoblastic leukemia and AML with minimal differentiation were added. The types of AML noted in the revised FAB scheme included one with minimal differentiation (M0), one without maturation (M1), one with maturation (M2), and acute promyelocytic leukemia (M3). Also included were a type with combined monocytic and myeloid (neutrophilic) components (M4), a pure monocytic or monoblastic

type (M5A, M5B), a type with a prominent erythroid component (M6), and a megakaryoblastic type (M7) (Table 55.4).

FAB classification provided a framework and defined criteria for different types of acute leukemia. However, leukemia-associated genetic changes, first recognized in the 1980s, seemed to provide more important prognostic information and did not always correlate well with the FAB-defined entities. As the cytogenetic abnormalities became more widely appreciated and their prognostic implications better understood, classification schemes based solely on the “favorable”, “intermediate”, and “adverse” prognostic cytogenetic findings were introduced and used along with or as an alternative to the FAB scheme (Table 55.4).

The AML WHO classification published in 2001 provided a different strategy from that used by the FAB in two important ways: it redefined AML as requiring only 20% blasts in the BM or blood, and it emphasized the importance of the associated cytogenetic abnormalities. The change in blast percentage came from the recognition that patients with 20% to 30% blasts, who previously were classified as having MDS (refractory anemia with excess of blasts in transformation [RAEB-T] in the FAB MDS classification), often had outcomes similar to those with AML and frequently required treatment as if they had been diagnosed with AML. Furthermore, the inclusion of cytogenetics recognized the important prognostic information associated with these abnormalities, as well as the fact that cytogenetics could point to the underlying molecular pathogenesis. As we learned from our experience with CML, this was critical in developing new drugs and treatment strategies. However, the WHO classification recognized that not all acute leukemias could be defined by cytogenetic abnormalities and that some needed to be defined either clinically or still based on morphologic findings. In this regard, the 2001 classification recognized four major subclasses of AML: AML with recurring cytogenetic abnormalities; therapy-related AML (subclassified further as those with etoposide treatment and those with a history of cytotoxic drug therapy or radiation); AML with multilineage dysplasia; and cases that did not fit into the other subclasses that are referred to as AML not otherwise categorized (Table 55.4).

A 2008 revision of the 2001 classification scheme emphasized risk-based stratification and made a number of changes (Table 55.4).⁴ In particular, it expanded the cytogenetic abnormality-associated cases to those with some less common translocations. It added provisional entities defined by mutations often occurring in cytogenetically normal cases, namely those with *NPM1* and *CEBPA* mutations. It combined the different types of therapy-related MDS/AML and renamed this category *therapy-related myeloid neoplasm* (t-MN). It also redefined the dysplasia-associated cases by allowing the cases to be identified by history (of previous MDS), morphology (with multilineage dysplasia), or by cytogenetics (with defined chromosomal changes associated with dysplasia). Additional categories were also added, including AML associated with Down syndrome, acute panmyelosis with MF, granulocytic sarcoma, and blastic plasmacytoid dendritic cell tumor. The 2008 classification eventually defined more than 25 different types of AML. The advent of newer technologies, such as single-nucleotide polymorphism array karyotyping and next-generation sequencing, facilitated the recognition of several relevant driver mutations.¹⁹ Molecular analysis for leukemic driver mutations, particularly in the cytogenetically normal AML subgroup (40% to 50% of AML patients), has been incorporated into routine clinical practice to assess disease progression and prognosis. Important mutations involve *FLT3*, *NPM1*, *KIT*, *CEBPA*, *TET2*, *DNMT3A*, and *IDH1*. Although the relevance of many of these mutations to prognosis is defined, some are still debated and their coexisting consequences are yet to be determined.

With the development of more sensitive analysis, the subclassification of AML patients has become more detailed. The proposed revisions to AML classification in 2016 remain largely unchanged for the entities of AML and NOS, with the exception of including the erythroid/myeloid subtype of acute erythroid leukemia with MDS. The 2016 revisions are expected to include recognition of new cytogenetic subgroups such as AML with BCR-ABL and

TABLE 55.4
Classification Schemes for the Acute Myelogenous Leukemias

French-American-British (FAB, 1985)	Cytogenetic	WHO (2001)	WHO (2008)	WHO (2016)

accompanied cryptic deletions of antigen receptors, particularly immunoglobulin heavy chain (IGH) gene rearrangement; this was recently shown to be specific for de novo disease.^{20,21} This update is also anticipated to include new and revised mutations subgroups. For example, AML with *RUNX1* mutations will include only de novo cases. AML with *CEBPα* will be heterozygous/double mutations (Fig. 55.1). In addition, *NPM1* and double mutations in *CEBPα* will trump multilineage dysplasia in de novo disease without MDS-related cytogenetics abnormalities other than del(9q). There will be a greater emphasis on the recognition of familial myeloid neoplasms, with an added classifications section.¹⁹ Overall, the 2016 WHO Classification of AML will have limited changes but will recognize the importance of mutations studies without making the classification overly complex.

The Myelodysplastic Syndromes

The earliest recognition of myelodysplastic disorders as a clinical entity came with the identification of long-standing and treatment-refractory anemia as occasionally representing a preleukemic disorder (see Chapters 60 and 63). MDS patients classically present with pancytopenias and a hypercellular BM with ineffective hematopoiesis and multilineage dysplasia, with or without an increase in blast cell numbers. Although this is fairly typical, it belies the wide pathologic spectrum of MDS, which includes cases that are diagnostically challenging, and which can be difficult to distinguish on one hand from benign causes of cytopenias in older adult patients, and on the other hand from AML and other more aggressive clonal myeloid neoplasms.

The FAB group proposed the first formal classification of MDS in 1982.⁵ In this classification scheme, the myelodysplastic disorders were divided into four subtypes based on increasing blast cell numbers or as chronic myelomonocytic leukemia (CMML). The four entities included refractory anemia (RA), refractory anemia with ring sideroblasts (RARS), refractory anemia with excess of blasts (RAEB), and refractory anemia with excess of blasts in transformation (RAEB-T). These entities differed mainly by the percentage of blasts seen in the

BM (Table 55.5). As noted earlier, in the FAB scheme AML was defined by the presence of 30% or more blasts in the blood or BM.

The FAB included CMML in the MDS category, although it was recognized that CMML differed in that it had a proliferative component with increased numbers of circulating monocytes. At times, leukocytosis was a predominant feature of the so-called *myeloproliferative type* of CMML, but this was considered to be a dysplastic form and was classified as a type of MDS when the white blood cell count was less than 13,000/ μ L.

The 2001 WHO classification of MDS resulted in significant changes to the classification of both MDS (Table 55.5) and AML (as discussed earlier). As mentioned previously, the most notable change was the reduction in the blast percentage required for a diagnosis of AML from 30% to 20%, leading to the elimination of the RAEB-T category. The 2001 classification also included a new subtype of MDS that, despite the lack of increased blasts (less than 5%), had a more aggressive course, probably owing to the presence of more pronounced multilineage dysplasia. This category was called *refractory cytopenia with multilineage dysplasia* (RCMD), and it comprised a substantial proportion of cases previously grouped in the low-grade RA and RARS categories. Although the recognition of RCMD served to deemphasize the importance of the blast percentage for prognosis, these classifications subdivided the RAEB category into two types, with 5% to 9% blasts (RAEB-1) and 10% to 19% blasts (RAEB-2), paradoxically emphasizing the prognostic significance of blast percentage in this category.

An additional significant change in the WHO 2001 MDS classification scheme included the exclusion of CMML from the MDS category, and the development of a separate nosologic group for CMML and other diseases in which there were features of both myelodysplasia and myeloproliferation at the time of diagnosis. These “overlap” disorders are mentioned briefly later.

Further refinements in the WHO classification scheme for MDS were made subsequently in 2008 (Table 55.5). These included expanding low-grade MDS from refractory anemia to refractory cytopenia with unilineage dysplasia (RCUD), thereby recognizing that the megakaryocyte or granulocyte lineage could be equally

Fig. 55.1 ALIGNMENT DATA OF INTEGRATIVE GENOMICS VIEWER FOR DOUBLE *CEBPα* MUTATIONS IDENTIFIED IN AN AML PATIENT. The *left* side shows c.63_64delinsA, p.Ser21fs, the *right* side shows c.914A>C, p.Gln305Pro. The *CEBPα* N-terminal frame-shift mutation (p.Ser21fs) is predicted to disrupt the normal function of *CEBPα*. The other *CEBPα* mutation (c.914A>C, p.Gln305Pro) is a C-terminal missense mutation that has been reported in AML patients. Double-*CEBPα* mutations (as seen in this patient) are found in 5% of patients with AML and are associated with a favorable outcome.⁴⁴ *CEBPα*-double mutant AML patients also had a significantly better overall survival at 8 years.

CMML			

AML, Acute myeloid leukemia; AR, Auer rods; BM, bone marrow; CMML, chronic myelomonocytic leukemia; FAB, French–American–British classification; MDS-U, myelodysplastic syndrome, unclassified; PB, peripheral blood; RA, refractory anemia; RARS, refractory anemia with ring sideroblasts; RAEB, refractory anemia with excess blasts; RAEB-T, refractory anemia with excess blasts in transformation; RCC, refractory cytopenia of childhood; RCMD, refractory cytopenia with multilineage dysplasia; RCUD, refractory cytopenia with unilineage dysplasia; RS, ring sideroblasts (% indicates percent RS of total nucleated erythroid precursors); WHO, World Health Organization classification.

affected. The 2008 WHO classification scheme also emphasized the key role of cytogenetic analysis in the diagnosis of MDS, particularly in cases with otherwise insufficient morphologic evidence to substantiate a diagnosis of MDS. This is reflected in the inclusion of the subtype MDS unclassified (MDS-U), defined by the presence of cytopenias, less than 1% peripheral blasts, less than 10% dysplastic cells in any lineage, and less than 5% BM blasts with the presence of specific cytogenetic abnormalities commonly associated with MDS. In addition, the WHO 2008 classification now includes “MDS with an isolated del(5q)” including the “5q minus syndrome.” This syndrome had been recognized for some time and is characterized typically by its presentation in middle-aged women with macrocytic anemia, splenomegaly, normal-to-elevated platelet counts, hypolobated megakaryocytes in the BM, and an isolated del(5q). The specific types of MDS have been increased and there are more than 10 different entities.

Although the basic diagnostic principles of the 2008 WHO classification of MDS are expected to remain unchanged in the 2016 WHO classification system, several changes to the classification are proposed. The proposed nomenclature changes include replacement of the terminology “refractory anemia” and “refractory cytopenia” with “myelodysplastic syndrome with single lineage dysplasia.” In addition, the proposed changes will incorporate considerations of the prognostic significance of gene mutations in MDS, revising the diagnostic criteria for MDS entities with ring sideroblasts based on the detection of *SF3B1* mutations, slightly modifying the cytogenetic criteria for MDS with isolated del(5q), reclassifying most cases of the erythroid/myeloid type of acute erythroleukemia, and recognizing the familial link in some cases of MDS.²² Flow cytometry immunophenotyping will be recognized as a useful ancillary technique in the evaluation of MDS,

however, its use will not be required in the diagnostic workup of MDS.²²

The Overlap Myelodysplastic/Myeloproliferative Neoplasms

In 2001 WHO introduced the overlap syndromes—that is, the MDS/MPNs (Table 55.6)—because at the time there was disagreement among committee members as to whether CMML was an MDS, as the FAB suggested, or an MPN, as a number of investigators suggested. This group of diseases was defined to include disorders that share features of the MPNs and of MDS at the time of initial presentation, but that do not fit well into either group. Some of the entities in the MPD/MPN category still are not well understood and may represent a disease in transition from MDS or MPN, although a case should not be placed in this category if initially diagnosed as MDS or MPN. However, without complete knowledge of the historical pathology of each individual patient, it is useful to have this category in order to construct a more reasonable classification. The overlap syndromes include CMML, including the juvenile type and juvenile myelomonocytic leukemia (JMML; see Chapter 63), in addition to “atypical” CML (atypical CML, *BCR-ABL1* negative) and an “unclassifiable” category that includes refractory anemia with ring sideroblasts and thrombocytosis (RARS-T). The MDS/MPNs share proliferative features in some cell lineages but also have dysplastic features, including ineffective hematopoiesis, in others. Similar to the MPNs, the overlap syndromes require a full evaluation of clinical and morphologic findings and evaluation of ancillary studies before a firm diagnosis can be rendered.

EVOLVING CONCEPTS IN CLASSIFICATION OF LYMPHOID NEOPLASMS

Hodgkin lymphoma was first described by Thomas Hodgkin in 1932 and is a distinct entity (Table 55.7) that can be distinguished from the majority of lymphomas that are designated non-Hodgkin lymphomas (NHL).⁴ Historically, different classification systems have been proposed for NHL (Table 55.8). Henry Rappaport utilized the histologic features and the architectural arrangement of the neoplastic cells and their cytology when developing a classification system in 1956, which became widely accepted. This system was created prior to the advent of modern immunology; as such, the Lukes–Collins classification in 1975 attempted to relate cell morphology to immunologic function. Subsequently in 1982, the Working Formulation for classifying NHL replaced the Rappaport and Lukes–Collins classification. This system had three groups based on patient prognosis: low, intermediate, and high grade. In 1994, the REAL classification implemented a new approach for classifying NHL, taking into account immunologic, genetic, and clinical features, and not solely relying on histopathologic characteristics of the tumor cells.³ In 2001, the WHO classification successfully provided a common language and was adopted as the standard for clinicians and investigators worldwide.¹ The modifications made in the 2008 classification are the result of a successful coordination between pathologists, clinicians, and biologists.⁴

REAL, Revised European-American Classification of Lymphoid Neoplasms; WHO, World Health Organization.

B-cell, T-cell, and NK-cell neoplasms often represent clonal expansion of these cells at certain developmental stages. Although B-cell neoplasms tend to mimic stages of normal B-cell development, some common B-cell neoplasms such as hairy cell leukemia do not conform to a normal B-cell differentiation stage. Additionally, some lymphomas show overt heterogeneity or lineage plasticity; consequently, the normal counterpart of neoplastic cells cannot be used as the sole basis for developing a classification system. The 2008 WHO Classification of Tumors of Hematopoietic and Lymphoid Tissues schema routinely employs a multiple-parameter approach that is based on clinical, morphologic, and biologic features, keeping in mind that a precise separation between entities is not possible in certain cases. Thus, the WHO recognized “gray zones” in which tumor cells may cross boundaries between currently used categories, such as the boundaries between classical Hodgkin lymphoma and primary mediastinal large B-cell lymphoma.⁴

In 2008 WHO expanded the classification of lymphoid neoplasms, with more consideration being given to disease definitions, nomenclature, grading, and clinical relevance. Since then, disease definitions have continued to evolve and expand, with new entities and variants being recognized. Both clinical and laboratory research findings provided new insights that are relevant to these emerging concepts.^{23,24} Current areas of development focus on early or in situ lesions, as well as definition of the earlier steps of neoplastic transformation, age as a disease-defining feature (e.g., diffuse large-cell lymphoma of the older adult; Table 55.9), and site-specific impact on disease definition. In addition, there was an emphasis on overlapping or borderline entities, with fuzzy demarcation of morphologic, molecular, and genetic characteristics as areas of diagnostic challenge.²³

Early Events in Lymphoid Neoplasms

Recent studies have identified additional clonal lymphoid lesions that share genetic and/or phenotypic properties with well-defined neoplasms such as chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL),^{25,26} multiple myeloma (MM), follicular lymphoma (FL) and MCL. However, these entities do not fulfill the

diagnostic criteria for these well-defined neoplasms, and many appear to have a limited potential for progression. Monoclonal gammopathy of undetermined significance (MGUS), monoclonal B-cell lymphocytosis (MBL), FL in situ, and MCL in situ are examples of such entities.

MGUS is considered an early form of its malignant counterpart MM, with an age-related increased incidence and a small but definitive risk of progression to MM at an annual rate of 1%. Recent reports have emphasized the significance of genetic profiling in MGUS for risk stratification, and support the view that progression from MGUS to MM results from the selection and expansion of multiple aberrant clones rather than a linear step-wise acquisition of specific genetic abnormalities.^{27,28} The International Myeloma Working Group (IMWG) 2010 guidelines recommend a MGUS risk stratification system, with periodic follow-up with serum electrophoresis for low-risk MGUS patients. However, patients with intermediate-risk and high-risk MGUS are suggested to undergo a baseline BM examination including cytogenetics and skeletal survey, and to be followed with serum electrophoresis studies twice in the first year following diagnosis and annually thereafter.²⁹

MBL has been diagnosed more frequently than previously reported; this is thought to be related to high sensitivity of flow cytometric analyses. MBL is defined as the presence of a circulating monoclonal B-cell population below $5 \times 10^9/L$, persisting for at least 3 months, in otherwise asymptomatic individuals. Based on clonal B-cell counts and clinical significance, MBL is now subdivided into high-count MBL ($0.5\text{--}5.0 \times 10^9/L$) and low-count MBL (less than $0.5 \times 10^9/L$).³⁰ High-count MBL progresses to CLL at an annual rate of 1% to 2%, with the clonal B-cell count at presentation being the greatest risk factor. The presence of palpable lymphadenopathy, organomegaly, and/or infiltration of lymphocytes within the BM (greater than 30% of nucleated cells) fulfills the International Workshop on Chronic Lymphocytic Leukemia (IWCLL) criteria for CLL, even in the absence of clonal lymphocytosis, while the WHO diagnosis of CLL/SLL is based upon the presence of extramedullary involvement. Current recommendations for management of CLL-like MBL include yearly monitoring with therapeutic intervention if clinically indicated. Low-count MBL, based on current data, is unlikely to progress to CLL and does not warrant clinical monitoring. MBL with an atypical CLL-like phenotype ($CD5^+$, bright $CD20$, $CD23^-$) could represent an early leukemic manifestation of MCL, and a thorough staging workup including fluorescence in situ hybridization (FISH) testing for $t(11;14)$ translocation is recommended.

FL in situ was initially described³¹ as the localization of atypical B cells that have $t(14;18)$ (IgH-B-cell lymphoma [BCL2]) translocation in the germinal centers of reactive-appearing lymph nodes with strong expression of $CD10$ and $BCL2$. The lymph node architecture is generally intact. The majority of cases of FL in situ do not progress to overt lymphoma, thus the alternate term “follicular lymphoma-like B cells of undetermined significance” was recently proposed. In the 2016 WHO classification revision, alternative term of in situ FL neoplasia is used in order to reflect the uncertain clinical significance of this entity. In situ FL neoplasia must be differentiated from partial involvement by low-grade FL, which usually shows partially effaced nodal architecture with enlarged, crowded follicles, and attenuated mantle zones. This distinction is clinically relevant, as partial involvement by low-grade FL is more likely to be associated with or progress towards overt FL.

Analogous to in situ FL neoplasia, incidental diagnosis of colonization of the mantle cuffs of reactive follicles by cyclin D1-positive B cells has been termed in situ mantle cell neoplasia (MCLIS). In these cases,³² cyclinD1 highlighted a small subset of B cells within the mantle zone, indicating low-level involvement by lymphoma. This peculiar pattern of cyclinD1 positivity encircling follicles is characteristic of an early or in situ MCL. The in situ variant of MCL is rare and exhibits cyclinD1 positivity within the innermost mantle zone B lymphocytes, and often is reserved for only partial encircling of follicles by MCL cells. In contrast, it has been proposed that full encircling of follicles by cyclinD1-positive cells should be interpreted as an early sign of involvement by MCL. This distinction is important as partial MCL is more likely than MCLIS to progress or coexist with advanced disease. Current management recommendations for MCLIS include whole-body imaging and unilateral BM biopsy (if indicated) to rule out a concomitant overt lymphoma. In the absence of overt disease, no treatment is required and careful follow-up is advised.

Age as a Disease-Defining Feature

The 2008 WHO classification introduced the concept of age as a defining feature in several disease categories.⁴ The entities of FL and nodal marginal zone lymphomas (MZLs) that present in the pediatric age group differ from their adult counterparts clinically and biologically. The pediatric variant of FL usually presents with localized disease and is of high histologic grade. These lymphomas lack translocations $t(14;18)$ and do not express $BCL2$ and have good prognosis, although the optimal management remains to be determined. Nodal MZLs in children also appear to have a low risk of progression. Pediatric nodal MZLs are clonal diseases characterized by marginal zone expansion with fragmentation of germinal centers

and progressive transformation of germinal center-like changes. Presentation with isolated cervical lymphadenopathy is common in pediatric nodal MZL. The WHO classification also recognizes two rare Epstein-Barr virus (EBV)-associated T-cell diseases: systemic EBV⁺ T-cell lymphoproliferative disease of childhood and hydroa vacciniforme-like lymphoma. These diseases occur almost entirely in children, primarily in those of Asian origin.

On the opposite spectrum of age-related lymphoproliferative disorders is EBV-positive diffuse large B-cell lymphoma (EBV+ DLBCL) of the older adult, which is among the newly included provisional entities in the 2008 WHO classification. The underlying immunologic deficit in this setting is believed to be immunosenescence, which is defined as the natural decay of the immune system as a consequence of aging. This entity also is defined histologically as malignant B-cell lymphoproliferation in people older than 50 years of age, without any known immunodeficiency or prior lymphoma diagnosis, and is associated with an aggressive clinical behavior pattern. Initial studies reported some overlap with classic Hodgkin lymphoma encountered in the older adult.²³ At present, there is a broader understanding than previously appreciated of the wide clinicopathologic spectrum of age-related EBV-positive lymphoproliferative disorder (LPD). This spectrum includes reactive lymphoid hyperplasia, polymorphic extranodal LPD (76% have EBV mucocutaneous ulcer), polymorphic nodal LPD and EBV+ DLBCL. Both polymorphic nodal lesions and EBV+ DLBCL are characterized by poor survival. In this clinicopathologic spectrum, histologic types are highly predictive of outcome; and small-volume disease, particularly in mucosal sites and skin (EBV mucocutaneous ulcer), which are associated with a good prognosis. It is important to keep in mind that although these lymphomas tend to cluster in the very young or the older adult age groups, they are not age restricted. Similarly, EBV+ DLBCL of the older adult can occur in a younger population.³³

Aggressive B-Cell Lymphoma, Borderline Entities and Site-Specific Categories

The 2008 WHO classification identified several subtypes of DLBCLs (Table 55.9). However, many DLBCLs lack pathologic, clinical, or other defining features that can be used to stratify them. Thus, these are designated DLBCL, NOS in the WHO classification. Stratification according to gene expression profiling as germinal center B-cell (GCB) versus activated B-cell (ABC) types has proven to have prognostic value. The GCB and ABC subtypes are now formally recognized in the 2016 WHO classification, despite the absence of a reproducible routine diagnostic test and the imperfect correlation of immunohistochemical surrogate markers with genomic studies.³⁴ Digital multiplexed gene expression utilizing formalin-fixed paraffin-embedded-derived RNA at a reasonable cost and turnaround time to classify B-cell lymphomas according to cell of origin is currently being validated as a routine clinical assay.^{35,36} The clinical need and utility of this designation is rising, with more studies suggesting that ABC versus GCB lymphomas exhibit differential sensitivity to certain drugs and therapeutic modalities.³⁴

In addition to the designation of DLBCL to ABC or GCB subtypes, next-generation sequencing technologies have unveiled the remarkable complexity of DLBCL. More important, it has become increasingly clear that these complexities represent lymphoma subtypes which are driven by very different intracellular oncologic signaling pathways and which can be differentially exploited for therapeutic benefit.³⁷ Recent studies have demonstrated the high frequency of abnormalities (i.e., noted in greater than 50% of DLBCLs) affecting histone/chromatin-modification enzymes, such as *CREBBP*, *EP300*, *MLL2*, and *EZH2*.³⁸ The role of therapeutic agents that target the epigenome has been suggested in DLBCL subgroups due to the variability in DNA methylation and its association with outcome.^{39,40}

Currently, the role of MYC and BCL2 proteins in DLBCL is an area of an active investigation. It is proposed that cases of DLBCL be evaluated for concurrent MYC and BCL2 dysregulation at diagnosis, in order to determine the presence of translocation/protein

overexpression. Patients with dual overexpression of MYC and BCL2 have a significantly poorer outcome compared with patients who express only one or neither protein. In addition, concurrent MYC and BCL2 translocation, known as *double-hit lymphoma*, indicates a subgroup of patients who are refractory to treatment and have a median survival of approximately 8 months.

The 2008 WHO classification emphasizes the importance of integrating morphologic, immunophenotypic, and molecular data to make a final diagnosis. This integration has refined our ability to diagnose several entities such as DLBCL and Burkitt lymphoma (BL). The 2008 WHO classification eliminated the variant category of atypical BL, which had been included in the 2001 WHO classification. Thus, a case with the typical BL phenotype (CD20⁺, CD10⁺, BCL2⁻) and genotype (so-called *MYC-simple* or *MYC/IG* in the absence of other major cytogenetic anomalies) may be classified as BL even if there is some variability in the morphology of the neoplastic cells. In addition, the 2008 WHO classification recognizes a group of high-grade B-cell lymphomas that are not readily classified as either BL or DLBCL. This provisional category is termed *B-cell lymphoma, unclassifiable*, with features that are intermediate between DLBCL and BL, including double-hit lymphomas.⁴ In the 2016 WHO classification DLBCL with MYC and BCL2 and/or BCL6 rearrangements will be included in a single category to be designated high grade B cell lymphoma (HGBL), with MYC and BCL2 and/or BCL6 rearrangements. The category of BCLU will be eliminated. Cases that appear blastoid or cases intermediate between DLBCL and BL, but which lack a MYC and BCL2 and/or BCL6 rearrangement, will be placed in the category of HGBL, NOS. The 2008 WHO classification recognizes another provisional category of B-cell neoplasms with features that are intermediate between DLBCL and classical Hodgkin lymphoma (CHL). These tumors occur predominantly in young men and appear to be more aggressive than either primary mediastinal large B-cell lymphoma or nodular sclerosis CHL. There are other settings in which the distinction between DLBCL and CHL is challenging. For example, some EBV-associated B-cell lymphomas may exhibit features that closely resemble or mimic CHL. The borderline category should be used sparingly but is appropriate when a distinction between CHL and DLBCL is not possible.⁴

Several aggressive B-cell lymphomas have a distinct immunoprofile or resemble a cell-specific stage of differentiation. These include plasmablastic lymphoma, ALK⁺ large B-cell lymphoma, human herpesvirus 8-associated malignancies, primary effusion lymphoma, and large B-cell lymphoma associated with multicentric Castleman disease. All of these entities resemble a stage of plasma cell differentiation. Other site-specific categories are primary DLBCL of the central nervous system and primary cutaneous DLBCL, leg type. Both primary central nervous system DLBCL and other DLBCLs arising in privileged sites, such as the testis, may exhibit distinctive biologic features. However, clinical features remain important in clinical management. Interestingly, primary central nervous system DLBCL has a distinctive gene expression signature that may continue to justify it as a separate entity.

Follicular Lymphoma Grading

Revisions to the 2008 WHO classification incorporated changes related to the grading of FL. Both grade 1 and grade 2 were combined in one category and designated “low-grade FL.” This revision was the result of questioning the clinical significance of separating grade 1 from grade 2 despite minimal differences in long-term outcome.⁴ In addition, several studies identified biologic differences between grades 3A and 3B, with the latter being more closely related to DLBCL. The separation of FL grade 3A from 3B is based on the absence of centrocytes in 3B; however, in routine practice this distinction is difficult. Further studies in this area are needed, as they may be helpful in increasing reproducibility of this distinction. According to the 2008 WHO classification, diffuse areas in grade 3 FL should be designated DLBCL, along with FL, as the bottom-line diagnosis.⁴

Peripheral T-Cell Lymphoma

Peripheral T-cell lymphomas (PTCLs) encompass numerous entities (Table 55.10) that are characterized by a poor prognosis, with the exception of histologic subtype “ALK-positive anaplastic large-cell lymphoma.” Most PTCLs lack distinct genetic or biologic features, and the mechanisms underlying the pathogenesis of these lymphomas are not yet fully understood. However, development of genomic high-throughput profiling techniques now allows us to extensively identify the molecular abnormalities present in these entities. The diagnosis of many cases is challenging even for expert hematopathologists, and more than a third of the cases cannot be further classified and consequently are relegated to a “waste basket” category PTCL-NOS. Other frequently encountered entities are angioimmunoblastic T-cell lymphoma (AITL), and anaplastic large cell lymphoma (ALCL). AITL and approximately 20% of PTCL-NOS⁴ show phenotypic features of T-cell follicular helper (Tfh) cells; and share a spectrum of genetic abnormalities such as *TET2* and *DNMT3A*, as well as mutations in the motility and adhesion gene *RHOA*.⁴¹

Despite morphologic and phenotypic similarities ALK⁺ ALCL is considered a distinct entity that must be distinguished from the entity of ALK⁻ ALCL given the clinical and biologic differences. In the 2016 update to the WHO classification, ALK⁻ ALCL are no longer provisional entities and strict criteria are required for the diagnosis of ALK⁻ ALCL because CD30 may be expressed in a variety of PTCL subtypes.

Three variants of primary cutaneous PTCL were introduced in the 2008 WHO classification; primary cutaneous gamma-delta T-cell lymphoma, primary cutaneous CD4⁺ small/medium T-cell lymphoma as a provisional entity, and primary cutaneous aggressive epidermotropic CD8⁺ cytotoxic T-cell lymphoma. Cutaneous gamma-delta T-cell lymphomas have a diverse histologic and clinical spectrum and may display a panniculitis-like pattern. However, this disease has a much poorer prognosis than subcutaneous panniculitis-like T-cell lymphoma, which is defined as a lymphoma exclusively of alpha-beta phenotype in the 2008 WHO classification. Primary cutaneous small/medium CD4⁺ T-cell lymphoma is another lymphoma with

TABLE 55.10 WHO Classification of Mature T-Cell and NK-Cell Neoplasms

- T-cell polymorphocytic leukemia
- T-cell large granular lymphocytic leukemia
- Chronic lymphoproliferative disorder of NK cells
- Aggressive NK-cell leukemia
- Systemic EBV-positive T-cell lymphoproliferative disease of childhood
- Hydroa vacciniforme-like lymphoma
- Adult T-cell leukemia/lymphoma
- Extranodal NK/T-cell lymphoma, nasal type
- Enteropathy-associated T-cell lymphoma
- Hepatosplenic T-cell lymphoma
- Subcutaneous panniculitis-like T-cell lymphoma
- Mycosis fungoides
- Sézary syndrome
- Primary cutaneous CD30⁺ T-cell lymphoproliferative disorders
- Lymphomatoid papulosis
- Primary cutaneous anaplastic large-cell lymphoma
- Primary cutaneous T-cell lymphoma
- Primary cutaneous aggressive epidermotropic CD8⁺ cytotoxic T-cell lymphoma
- Primary cutaneous small/medium CD4⁺ T-cell lymphoma
- Peripheral T-cell lymphoma, NOS
- Angioimmunoblastic T-cell lymphoma
- Anaplastic large-cell lymphoma, ALK-positive
- Anaplastic large-cell lymphoma, ALK-negative

ALK, Anaplastic lymphoma kinase; EBV, Epstein-Barr virus; NK, natural killer; NOS, not otherwise specified.

Tfh cell origin that presents commonly as an isolated lesion in the head and neck region.⁴² In the 2016 WHO classification a change in the terminology of this entity is proposed—to primary cutaneous small/medium CD4⁺ T-cell lymphoproliferative disease instead of lymphoma.

The 2008 WHO classification acknowledged that a variety of PTCLs can present with intestinal disease and that not all of these cases are associated with celiac disease. Intestinal involvement can be seen at presentation, and/or with progression, in extranodal NK/T-cell lymphoma as well as in some gamma-delta T-cell lymphomas. The WHO classification required more stringent criteria to establish a diagnosis known as *enteropathy-associated T-cell lymphoma*. Specifically, in order to make the diagnosis of enteropathy-associated T-cell lymphoma, evidence of celiac disease was required either at the genetic level, with the appropriate HLA phenotype, or histologically, in the adjacent uninvolved small bowel mucosa. A new variant, termed the *monomorphic variant of enteropathy-associated T-cell lymphoma*, or *type II*, was introduced into the 2008 WHO classification. Cases exhibiting this variant have some distinctive immunophenotypic and genotypic features. The tumor cells are CD8⁺ and CD56⁺, and *MYC* amplifications are present in a subset of cases. The monomorphic variant occurs in the setting of celiac disease but also occurs sporadically.⁴

Precursor Lymphoid Neoplasms

The lymphoblastic neoplasms are derived from precursor cells or blasts, most of which are precursor B and T-cell neoplasms that present as leukemia. However, the designation of lymphoblastic lymphoma is used when the neoplasm is confined to a mass lesion without or with only minimal blood or BM involvement. The WHO classification retains the convention that precursor neoplasms are designated *leukemia/lymphoma*. When distinction between leukemia and lymphoma is required for clinical protocol eligibility in presentation with a mass lesion and increased blasts in the BM, a threshold of 25% blasts is used as the defining feature of leukemia.⁴

The 2008 classification recognizes genetic features in the definition of some forms of B-lymphoblastic leukemia (B-ALL). One such example is Philadelphia chromosome-positive (Ph⁺) B-ALL, associated with *BCR-ABL1*, which is more common in adults than in children and is considered very high risk, regardless of other factors. Deletions and other alterations in the *IKZF1* (Ikaros) gene are adverse prognostic indicators in both Ph⁺ and Ph[−] patients with B-ALL. Another variant with distinctive clinical features at presentation is B-ALL/lymphoma with t(5;15)(q31;q32) (*IL3-IGH*). These patients present with a marked increase in eosinophils, which may mask a relatively small number of blasts in the BM—a diagnostic pitfall worthy of note. The ongoing and increasing complexity highlights the importance of clinicopathologic correlation and the value of ancillary studies in the classification and workup of patients with B-ALL.⁴³

T-lymphoblastic leukemia (T-ALL) is also associated with considerable genetic variability. Routine histopathology, flow cytometry immunophenotyping, conventional cytogenetic analysis, FISH, and/or clonality testing are usually adequate to establish the diagnosis. The most commonly involved genes include the HOX transcription factors. However, genotyping is recommended in the workup of the disease, although at this time it is not used as a criterion to define distinct entities.

DENDRITIC CELL AND HISTIOCYTIC NEOPLASMS: PRINCIPAL CONSIDERATIONS FOR DIAGNOSIS AND TREATMENT

Dendritic and histiocytic neoplasms are hematologic malignancies that have distinct yet variable clinical presentation, and together they make up less than 1% of the neoplastic process of the lymph node or soft tissue.⁴ However, the true prevalence of these disorders remains

TABLE 55.11 WHO Classification of Histiocytic and Dendritic Cell Neoplasms

- Histiocytic sarcoma
- Langerhans cell histiocytosis
- Langerhans cell sarcoma
- Interdigitating dendritic cell sarcoma
- Follicular dendritic cell sarcoma
- Fibroblastic reticular cell tumor
- Intermediate dendritic cell tumor
- Disseminated juvenile xanthogranuloma

uncertain because many have been recognized only recently. Several entities are recognized in the 2008 WHO classification of histiocytic and dendritic cell neoplasms (Table 55.11). Traditionally, these tumors are placed into two basic categories based on their derivation from either BM precursors or mesenchymal cells. Histiocytic sarcoma (HS), Langerhans cell histiocytosis (LCH), and interdigitating dendritic cell sarcoma (IDCS) are derived from BM precursors; while follicular dendritic cell sarcoma (FDCS), indeterminate dendritic cell sarcoma, fibroblastic reticular cell tumors, and disseminated juvenile xanthogranuloma are derived from stromal-derived dendritic cells or are mesenchymal in origin. Although divergent differentiation from marrow precursors is the normal histogenesis, hybrid and trans differentiation from lymphoid clones has been proposed in some entities.³⁹

Excisional biopsy is the preferred specimen choice from which to render the diagnosis of these disorders. Consultation with an experienced hematopathologist is often required, as morphologic review and an adequate battery of immunohistochemical stains are the most important elements in making an accurate diagnosis of these entities and in differentiating them from other, often-mistaken categories, most commonly NHLs. The rarity of these disorders is the major factor that makes this group of diseases difficult to accurately diagnose and challenging to treat. Advances of immunohistochemistry have contributed to an enhanced understanding of the biology of dendritic and histiocytic neoplasms, and have improved our ability to classify and diagnose these disorders. For example, in contrast to LCH, IDCS are usually positive for S100 but negative for CD1a and langerin (CD207). Unlike FDCS, IDCS do not express follicular dendritic cell markers such as CD21 or CD35.⁴

These entities can involve various organs, although most occur in the lymph nodes and skin, with a unifocal or solitary presentation, and are associated with a good prognosis with surgical resection. On the other hand, cases with disseminated disease have shown a poor outcome, although data on treatment options are limited. Nonetheless, chemotherapy and referral to a tertiary-care center should be considered for patients with these diagnoses. Large pooled analyses or clinical trials will be needed to better understand optimal treatment options of these rare disorders.

CONVENTIONAL AND MOLECULAR CYTOGENOMIC BASIS OF HEMATOLOGIC MALIGNANCIES

Vesna Najfeld

Dedicated to the loving memory of Eta Najfeld, MD, a Holocaust survivor and an amazing mother.

Over the past 60 years the cytogenetic analysis of hematologic malignancies has been an area of prolific growth. Chromosome studies and karyotype analysis provide information of both biologic and clinical significance. Refinements in cell culture methods and the application of chromosome banding techniques have advanced our understanding of disease-specific abnormalities, and molecular cytogenetic methods now have made possible the identification of genes involved at translocation breakpoints in specific chromosomal rearrangements. These advances in molecular cytogenetic methods permit mapping of structural rearrangements within a single gene and fundamentally contribute to our knowledge of the biology of leukemia. This evolution in our understanding of cancer genetics has resulted in distinct terminology (Table 56.1). Application of conventional and molecular cytogenetic methods has identified over 600 fusion genes involving over 250 different genes and approximately 1000 recurrent balanced translocations in human cancers. Relevance of these methods has played a pivotal role in the diagnosis, treatment, and prognosis of the hematologic malignancies. This chapter discusses specific cytogenetic events and delineates molecular phenotypes that are important to understand the molecular pathogenesis of hematologic malignancies and provides several genetic testing algorithms. The remarkable hypothesis put forward by Boveri at the turn of the 20th century—namely, that an abnormal chromosome pattern is intimately associated with the malignant phenotype of a tumor cell—has proven correct. Knowledge of the molecular cytogenetic phenotype of hematologic malignancies has led to innovative and specifically tailored treatments. The first example of such gene-targeted therapy has already been successfully applied to chronic myelogenous leukemia (CML).

METHODS

Fig. 56.1 shows the current cytogenomic methods used in detecting clonal chromosomal, gene or other genomic rearrangements and abnormalities in hematologic malignancies.

Cytogenetic Analysis

Cells arrested in metaphase are obtained by exposing marrow cells sequentially to mitotic inhibitors, hypotonic potassium chloride, and fixative. Chromosomes obtained from leukemic marrow are then subjected to the most widely used banding method, trypsin-Giemsa banding (Fig. 56.2). The criteria used to define clonal abnormalities are listed in Table 56.1 and described in the International System for Human Cytogenetic Nomenclature, 2013.

Fluorescence In Situ Hybridization Methods

Fluorescence in situ hybridization (FISH) is a molecular method that allows detection of the number, size, and location of DNA and RNA

segments within individual cells in a tissue sample. It is based on the ability of single-stranded DNA to anneal to complementary DNA. In hematologic disorders, the target DNA is the marrow or peripheral blood DNA present in interphase cells or the DNA of metaphase chromosomes that is fixed on a microscope slide. Other biologic material that may be involved in the leukemic process, such as spleen cells, ascites, and spinal fluid, are particularly useful for FISH studies. In lymphoma, the target DNA is present in lymph nodes, and FISH studies are performed on touch preparations, frozen sections, or paraffin-embedded tissue.

Fig. 56.3 shows four types of FISH probes that are used alone or in combination to determine both numeric and structural rearrangements: (a) centromere enumeration probes, which, as the name implies, are used most frequently in interphase nuclei for detection of numeric chromosome anomalies, (b) whole chromosome painting probes, which are used only on metaphase cells and are very useful in delineating complex rearrangements or the origin of a marker, derivative or ring chromosome, (c) subtelomeric probes, and (d) unique gene loci probes applied to both interphase and metaphase cells in single, dual, triple, or multiple colors to determine specific chromosomal rearrangements, deletions, or amplifications.

The four FISH probe strategies are used in probe design for detection of chromosomal translocations in hematologic malignancies (Fig. 56.4): (a) standard (conventional strategy), (b) extrasensitive strategy, (c) dual-fusion strategy, and (d) “breakapart strategy.” The first application of FISH technology for detection of chromosomal translocations in hematologic malignancy was when the *BCR-ABL1* hybrid gene was identified using two-color FISH in interphase cells as well as in metaphase marrow-derived CML cells. In the standard strategy for interphase evaluation of chromosomal translocation, a DNA probe comprising sequences mapped proximal to the breakpoint in one of the chromosomes involved in reciprocal translocations is combined with a differentially labeled DNA probe that includes sequences mapped distal to the breakpoint in the other chromosome. Positive nuclei for the translocation display one dual-color fusion signal, representing one of the derivative chromosomes generated by the translocation, and two single-color signals, one for each of the normal alleles. This standard FISH strategy has been used for detection of translocations in hematologic disorders at diagnosis.

For detection of minimal residual disease, the conventional strategy lacks specificity because cells with random spatial co-localization of normal signals with different colors, found at a frequency from 1% to 10% of scored nuclei, are seen as false positive. To minimize this problem, an extrasensitive method was developed in which a probe for one abnormal chromosome is designed to generate extra, smaller signals in positive nuclei. Hybridization using this strategy results in abnormal cells with co-localization of two signals in dual colors, an additional two signals in one single color and one signal in another single color. Application of the extrasensitive probe has been useful in discriminating between *BCR-ABL1* fusion-positive blast crisis of CML and de novo acute lymphoblastic leukemia (ALL).

A dual-fusion strategy was developed not only to minimize false-positivity but also to detect additional deletions at translocation breakpoints. The dual-color/dual-fusion strategy includes a probe set with DNA sequences that encompasses proximally and distally the translocation breakpoints on both chromosomes involved in the

**TABLE
56.1****Glossary of Cytogenetic, Fluorescence in Situ Hybridization and Genomic Terminology**

Aneuploidy	Abnormal chromosome number, either gain or loss.
Array CGH	A higher-level CGH technology that provides gene copy information.
Balanced translocation	Exchange of chromosomal material that creates no extra or missing DNA.
Banding	Set of dark and pale segments along the length of chromosomes, resulting from treatment with enzyme before staining. Each chromosome identified by its unique set of bands.
Breakpoint	Specific site on a chromosome containing a break in the DNA that is involved in chromosomal structural rearrangement, such as translocation or deletion.
Centromere	Constriction on the chromosome at the spindle site attachment. During cell mitosis two copies of the DNA in each chromosome are separated by shortening of the spindle fibers attached to opposite sides of the dividing cell. Position of the centromere determines whether the chromosome is metacentric (X-shaped; e.g., 1, 3, 19, 20), submetacentric (centromere positioned more toward the short arms; e.g., 2, 4, 5, 6–12, 16–18, X), or acrocentric (inverted V-shaped; e.g., 13–15, 21, 22, Y).
Centromere enumeration probe (CEP)	Highly repetitive α (or β) satellite DNA, located in the heterochromatin of the centromeric area of chromosomes. CEP targets repetitive α (or β) sequences and produces bright compact signals; particularly useful for detection of numerical loss or gain of chromosomes.
Comparative genomic hybridization (CGH)	Molecular cytogenetic technique that provides a copy-number karyotype at the chromosome and band level. Variety of arrays include disease specialized, chromosome arm specific, and others.
Chromosomal rearrangement	Aberration in which chromosomes are broken and rejoined.
Clonal abnormality	In cytogenetic analysis, two cells showing the same additional or structural abnormality or three cells with loss of the same chromosome. In FISH analysis, any abnormality present after the probe has been validated and normal reference range established, above the normal reference range.
Chromothripsis	A catastrophic DNA damage occurring during a single mitotic division Cytogenomics is the application of molecular biology to determine genomic copy number.
Deletion	Segment of chromosome that is missing (terminal) or segment of chromosome missing between two breakpoints (interstitial).
DNA sequence	Order of nucleotides in a DNA segment, usually displayed from the 5'-triphosphate (5' end) to the 3'-hydroxyl (3' end) nucleotides.
Driver mutation	This mutation affects the biology of cell.
Enhancer	DNA sequence that increases the rate of transcription.
Exon	Portion of gene that encodes protein.
Fiber FISH	Application of FISH technology to extended DNA or free DNA fibers.
FISH	Fluorescence in situ hybridization, a method for detection of the number and location of DNA sequences (genes) in tissue section or cell population.
Fluorochrome	Fluorescence molecule that, when conjugated to a molecule, binds to a hapten to facilitate detection of the chromosomal probe. By definition, a fluorochrome is a molecule that will become excited by the light of one wavelength.
Gene construct	Recombinant DNA containing a gene of interest surrounded by sequences engineered to promote a measure of its expression.
Gene map	Order of genes within a chromosome or entire genome.
Genotype	Genetic constitution, usually with reference to particular alleles at a locus.
Haploid	Half of a normal complement (i.e., 23 chromosomes).
Haploinsufficiency	Deletion or inactivation of one allele producing disease caused by inadequate activity of the remaining allele.
Hybrid gene	Fusion of two different genes as a result of a structural chromosomal rearrangement that functions as one transcriptional unit.
Hybridization	Method for rejoining (reannealing) complementary DNA or RNA strands.
Hyperdiploid	Additional chromosomes (e.g., 47 or 48 chromosomes).
Hypermetaphase FISH	Application of FISH to accumulated large number of metaphase cells.
Hypodiploid	Loss of chromosomes (e.g., 45 or 44 chromosomes).
I-FISH	Interphase fluorescence in situ hybridization, application of FISH to nondividing (resting) cells.
Interphase	Stage of mitosis in which the cell is not dividing.
Inversion	Structural chromosomal rearrangement as a result of two breaks occurring in the same chromosome. Paracentric inversion refers to both breaks occurring on the same side of the centromere. Pericentric inversion refers to breaks occurring on the opposite side of the centromere.
Isochromosome	Structural chromosomal rearrangement that consists of doubling of one of the two chromosome arms (connected by the centromere) and loss of the other arm.

Continued

**TABLE
56.1****Glossary of Cytogenetic, Fluorescence in Situ Hybridization and Genomic Terminology—cont'd**

Karyotype	Arrangement of metaphase chromosomes from a particular cell according to size and banding so that the largest chromosome is placed first and the smallest one last (see Fig. 56.2).
kb (kilobase)	Unit of DNA/RNA length = 1000 base pairs of DNA.
Kataegis	Kataegis is a recently discovered phenomenon in which multiple mutations cluster in a few hotspots in a genome. This region is often colocalized with regions of somatic genome rearrangements.
Locus	Unique location of a gene on a chromosome.
Locus (sequence)-specific probe (LSI)	Probe targeted to unique sequence region of the chromosome. Useful for localization of genes on normal chromosomes (gene mapping) and for detection of gene amplification, deletion, inversion, or translocation.
Marker chromosome	Chromosome whose morphology cannot be identified using banding method. Marker chromosomes are frequent in hematologic neoplasms.
M-FISH	Multicolor FISH karyotyping, which allows identification of 24 different human chromosomes (22 autosomes, and the X and Y chromosomes) (see text for details).
NGS	Next generation sequencing.
Nonsilent mutations	Mutations that alter the protein sequences.
Oncogene	Locus that is activated in association with tumor growth. One abnormal allele is sufficient to cause tumor formation or cancer.
SNP	Single nucleotide polymorphism.
Passenger mutation	Is usually a subclone and does not affect the biology of cell.
PCR	Polymerase chain reaction, by which individual gene segments are amplified through sequential cycles of polymerization, heat denaturation, and reannealing.
Pseudodiploid	Diploid number of chromosomes (46) accompanied by structural rearrangement.
Recurrent abnormality	Structural or numerical abnormality observed in multiple patients with the same or similar disease. Recurrent chromosome abnormalities in hematologic neoplasms have prognostic significance.
Telomeric probe	Used to detect repeated DNA sequences present at the end of the chromosome, which is called the telomere. Telomeric DNA contains 10–15 kb of TTAGGG repeats. Adjacent to the telomere is a region called the proximal subtelomeric region, and centromeric to it is a unique chromosome telomeric region. Chromosome-specific telomeric probes are useful for detection of cryptic translocations involving ends of chromosomes.
Translocation	Structural chromosome abnormality resulting from a break in at least two chromosomes with an exchange of material. In reciprocal or balanced translocation, no loss of chromosomal material occurs. In unbalanced translocation, loss of chromosomal DNA occurs.
Tumor suppressor gene	Locus that prevents tumor growth when at least one allele is functional. Loss of both alleles, first through constitutional and then through somatic mutation, is associated with tumor formation or cancer.
Whole chromosome painting probe (WCP)	Spans the entire length of chromosomal DNA sequences and, as the name implies, targets the entire length of DNA sequences. Useful for identification of complex or cryptic structural rearrangements as well as for identification of marker chromosomes.
Nomenclature	
p	= Short arm
q	= Long arm
+	When placed before the chromosome, denotes a gain of a whole chromosome (e.g., +8)
–	When placed before the chromosome, indicates a loss of a whole chromosome (e.g., –7); in rare situations, when placed after the chromosome, as in 5q–, indicates loss of a part of the long arms of chromosome 5
t	translocation
del	deletion
der	derivative
inv	inversion
i	isochromosome
mar	marker chromosome
con	connected
nuc ish	nuclear in situ hybridization
nuc ish 21q22 (D21S65X2)	two copies of D21S65 DNA segment on chromosome 21
nuc ish 9q34 (<i>ABL1</i> x2), 22q11.2 (<i>BCRx2</i>) (<i>ABL1</i> con <i>BCRx1</i>)	two <i>ABL</i> and two <i>BCR</i> loci, but one of each locus is juxtaposed on one chromosome as a result of t(9;22)

Cytogenomic methods and their resolutions

Fig. 56.1 CYTOGENOMIC METHODS AND THEIR RESOLUTIONS. See text for detailed descriptions of how these methodologies are applied for detection of genomic abnormalities in hematologic malignancies. (A) Conventional cytogenetic methods detects clonal numerical and structural chromosomal abnormalities on a single-cell level, at the level of 5–7 Mb. (B) Multicolor FISH method with 24 different colors is specifically useful to identify the origin of marker chromosomes, complex 3- or more-way translocations, origin of ring chromosomes, and other chromosomal abnormalities present in a complex karyotype such as those seen in myelodysplastic syndrome, lymphoma, and multiple myeloma. (C) Conventional CGH resolution at 2–5 Mb is not used frequently because other technologies have much higher resolution for detection of smaller genomic abnormalities. (D) In a routine tumor cytogenomic laboratory metaphase FISH method has many useful applications. It is the best method for mapping normal and abnormal genes to human chromosomes and therefore localizes genes that have changed their normal positions as a result of multiple chromosomal abnormalities, to determine terminal vs. interstitial deletions as well as to detect cryptic translocations and deletions. (E) As mentioned in the text, there are at least six different reasons to perform interphase FISH on nondividing cells from specimens of patients with hematologic malignancies. Interphase FISH is specifically useful for detection of minimal-residual disease with a diagnostic abnormality has been determined by conventional cytogenetics. (F) Fiber FISH is also used primarily in fine mapping but much more in a research setting than in clinical laboratory. (G and H) Array CGH with or without SNP is the molecular method for detection of small DNA changes at the resolution of a few hundred base pairs to 1 Mb. Addition of SNP array platforms allows for detection of acquired regional UPD. (I) Next generation sequencing is the most powerful method for detection of acquired somatic mutation at the single nucleotide level. Although not yet used routinely in clinical laboratories, the application of NGS to hematologic malignancies has revolutionized the current knowledge of many leukemic entities. *CGH*, Comparative genomic hybridization; *FISH*, fluorescence in situ hybridization; *NGS*, next generation sequencing; *SNP*, single-nucleotide polymorphism; *UPD*, uniparental disomy.

Fig. 56.2 NORMAL ARRANGEMENT OF CHROMOSOMES IN A KARYOTYPE FROM A BONE MARROW METAPHASE SHOWING A SLIGHTLY FUZZY MORPHOLOGY COMPARED WITH A NORMAL KARYOTYPE OBTAINED FROM PHYTOHEMAGGLUTININ-STIMULATED PERIPHERAL BLOOD CELLS.

Fig. 56.3 TYPES OF CHROMOSOMAL PROBES (SEE TEXT FOR DETAILS). (A) Pair of chromosome 12 (*left*) and interphase cell (*right*) after fluorescence in situ hybridization (FISH) study with centromere enumeration probe (CEP) showing two hybridization signals (*red*) in the centromeric area of chromosome and two tight signals in interphase cell consistent with disomy (normal copy number). CEP probes are most useful for detection of numerical abnormalities. (B) Hybridization with a whole chromosome 8 painting probe showing the hybridization signal (*green*) along the length of the entire chromosome 8 (*left*) and hybridization domains in interphase cell (*right*). Whole chromosome painting probes are useful for identifying unknown chromosomes in metaphase cells. (C) Target of locus-specific indicators are specific gene sequences such as P53 seen after hybridization as two small signals (*red*) on chromosome 17, band p13. The main applications of locus-specific indicator (LSI) probes are gene mapping, numerical enumeration in interphase cells, and detection of translocations. Telomeric probe, shown in green for the short arms of chromosome 17, are repetitive probes and are useful for detection of cryptic translocations involving ends of chromosomes. Chromosomes and nuclei are counterstained with DAPI (*blue*).

translocation. The sequences for each chromosome are labeled with a specific color, and the translocation generates fused signals in both derivative chromosomes. Positive nuclei exhibit two copies of fusion signals and one copy of each of the signals representing the normal alleles. Dual-color/dual-fusion probes are very useful in differentiating various leukemia and lymphoma-associated translocations.

Multiple translocation partners are well known for genes commonly associated with leukemia such as mixed-lineage leukemia (*MLL*) now known as *KMT2A*, the retinoic acid receptor α (*RARA*) gene, and the anaplastic lymphoma kinase (*ALK*) gene. The fourth FISH strategy, with breakpoint probes, was developed to address this issue. The breakpoint probe includes DNA sequences mapped proximally and distally to the breakpoint within a critical gene (the 3' end and the 5' end) labeled with two different fluorochromes. The fused fluorescence signals represent a normal gene, whereas nuclei with rearrangements within the target gene show one single-color signal and one for each derivative chromosome, regardless of which chromosome is the partner in translocation.

One of the most significant advances in diagnostic leukemia cytogenetics has been the application of interphase FISH. Interphase cytogenetics is the term used to describe detection of chromosomal

abnormalities in nondividing, interphase nuclei (Fig. 56.5). Six aspects of interphase FISH are particularly useful: (1) Interphase cytogenetics allows screening of a large number of cells. This permits investigation of hematologic malignancies with a low mitotic yield, such as chronic lymphocytic leukemia (CLL) or multiple myeloma (MM). (2) Interphase FISH permits detection of chromosomal rearrangements in peripheral blood samples, thus obviating the need for marrow aspiration. For instance, in CML, which rarely yields a large number of dividing cells in peripheral blood, conventional cytogenetics usually is uninformative. However, detection of *BCR-ABL1*, a molecular equivalent of the Philadelphia chromosome (Ph), in peripheral blood using interphase FISH provides reliable, fast, quantitative results (see the section on [Chronic Myelogenous Leukemia later in this chapter](#)). (3) Interphase FISH offers a quantitative assay for monitoring disease progression or detection of minimal residual disease after ablative chemotherapy or hematopoietic stem cell transplantation. (4) Use of specific probe sets allows detection of specific disease-associated abnormalities such as t(8;21), which denotes the M2 subtype of acute myeloid leukemia (AML), or t(15;17), which is associated with acute promyelocytic leukemia (APL), within 4 hours, allowing for timely and appropriate therapy. (5) Abnormalities can be detected accurately in archival specimens stored for up to 15 years. (6) Simultaneous use of interphase FISH and immunophenotyping is a powerful tool for investigation of lineage involvement in diseases such as myelodysplasia and to determine which cell population carries the specific chromosome abnormality. FISH nomenclature is described in the International System for Human Cytogenetic Nomenclature.

Higher resolution of chromosomal abnormalities can be achieved when fluorescently labeled probes are hybridized to extended DNA or free chromatin (chromatin strands released from their chromosomal scaffold) or free DNA fibers. This approach is termed *fiber FISH* (see Fig. 56.1F). The hybridized signals have the appearance of a "string of pearls" along the fiber rather than tight fluorescing spots observed in interphase cells. Although fiber FISH has limited clinical applicability because it requires special techniques of target DNA preparation on a glass slide, it has been successfully applied to map chromosomal breakpoints of the *cyclin D* gene in mantle cell lymphoma (MCL) and for detailed mapping of the breakpoint site region in the *BCL2* gene in follicular lymphoma (FL).

Multicolor karyotyping permits examination of the entire genome in a single analysis (see Fig. 56.1B, and Fig. 56.6). In 1996 it became possible to identify 24 different human chromosomes (12 autosomes and the X and Y sex chromosomes), each with a unique color, with the help of fluorochrome-specific optical filters. This method is called *multicolor FISH (M-FISH)*. When interferometer-based spectral imaging is used, the method is called *spectral karyotyping*. The starting point in both methodologies is the use of whole chromosome painting probes for each chromosome. Thus each chromosome is labeled with a different combination of fluorescent dyes. The fluorochrome colors are not distinct enough for the unaided human eye to distinguish the combination with which the chromosome is labeled. In M-FISH, images are sequentially obtained using five different fluorochrome-specific optical filters. A computer program combines the data and displays each chromosome as if it were stained with a distinct color. Spectral karyotyping is based on the use of an interferometer (used by astronomers to measure the light spectra of distant stars) to determine the full spectrum of light emitted by each stained chromosome. A computer program then displays all the chromosomes simultaneously, each with its own unique color. These methods are applied with increasing frequency to resolve complex karyotypes, to detect cryptic translocations in patients with a normal karyotype, and to define karyotypes with deletions. Their clinical use may be limited because the cost of equipment and probes is beyond what can be afforded by most clinical laboratories. The M-FISH technology cannot be used to discriminate structural intrachromosomal rearrangements such as duplications, deletions, and inversions.

Although the mBAND technique helps to analyze peri- and paracentric inversions in chromosomes this technique has rarely been used in clinical laboratory practice and it remains a research tool.

Fig. 56.4 FOUR DIFFERENT PROBE STRATEGIES FOR DETECTION OF CHROMOSOMAL TRANSLOCATIONS (SEE TEXT FOR DETAILS). (A) Normal cell after in situ hybridization with BCR (green) and ABL (red) showing a normal distribution of two red and two green single signals. (B) Conventional fusion strategy after in situ hybridization shows one fusion (yellow) signal representing derivative chromosome generated by the translocation and one single-color signal, red and green, for normal homologues in positive nuclei. (C) An extrasensitive fusion approach generates an extra small (red) signal, as well as a fusion signal (yellow) and one signal in single color (green and red) on normal homologues. (D) Dual-fusion strategy generates two fusion signals (yellow) on two derivative chromosomes and one single-color signal on each of two normal chromosomes. (E) Breakapart approach in a normal cell appears as two fusion signals (yellow). In this strategy, the 3' end and the 5' part of the gene are labeled in two colors. (F) When the rearrangement occurs, the normal chromosome shows co-localization of red and green (yellow) as a result of the proximity of the sequences on the chromosome, whereas abnormal derivative chromosomes each have one single red and single green signal, indicating that the rearrangement occurred between the two ends of the gene separating the green and red signals on two different chromosomes. The third-color probe (blue) can be used as an internal control (usually centromere enumeration probe) to determine the disomic number of chromosomes.

Comparative Genomic Hybridization and Next Generation Sequencing Methods

Another powerful method used for identifying the location of chromosomal gains, losses, deletions, or amplifications, without prior knowledge of the chromosomal target that may be altered, is comparative genomic hybridization (CGH) (see Fig. 56.1C). Briefly, isolated DNA from leukemic marrow or tumor tissue is labeled with a one-color fluorochrome (e.g., red), whereas DNA isolated from normal control tissue is labeled with a different color (e.g., green). These differently labeled DNAs are hybridized against each other in a competitive hybridization reaction onto normal metaphase spreads. Computer-assisted image analysis detects colors generated after hybridization, which indicate equal hybridization, relative excess, or deficiency of the target DNA (relative to control). The ratio of color intensity provides a “copy number” karyotype. Low resolution CGH, 5–10 Mb, has been successfully applied to study many leukemias, but its clinical use remains limited because it cannot detect balanced translocations, which are the hallmark of many hematologic malignancies. Nevertheless, CGH is an efficient approach to scanning the entire genome for variations in DNA copy number.

A particularly useful investigational approach is a “microchip array” in which labeled DNA or RNA from the sample of interest is hybridized with defined target sequences immobilized on a solid support. The advantage of this method is its ability to screen genes that are gained/amplified or deleted from the genome on a large scale

or, in the case of RNA, to learn whether such genes are expressed at a particular stage of disease. The first example of successful RNA application of the microchip array technique was the differentiation of AML from ALL based solely on gene expression. As shown in Fig. 56.1G, in the array CGH (aCGH) procedure, large-insert genomic clones, oligonucleotides, or single-nucleotide polymorphisms (SNPs) have replaced metaphase chromosomes used in the regular CGH. Array CGH is a higher-resolution CGH technology of approximately 5–50 kb, and provides diagnostic information for diseases associated with DNA dosage. It can also be used to discover previously unexpected sites of altered gene dosage associated with specific hematologic malignancy type. The concept of obtaining gene copy number from multiple genome locations in a single measurement has been used to characterize numerous hematologic malignancies over the last 15 years, and its clinical utility is demonstrated throughout this chapter. Nowadays, SNP arrays are also used that help to genotype few hundred to millions of SNPs to detect rare and common genomic rearrangements (see Fig. 56.1H). These arrays require hybridization of only the test sample onto the array, unlike aCGH, which relies on co-hybridization of test and reference DNA. At this time aCGH + SNP are frequently used together in one study. The most advanced genomic technologies currently known is the next generation sequencing or NGS (see Fig. 56.1I). Also known as massively parallel sequencing, these approaches use a range of techniques that enable sequencing of hundreds of thousands of nucleic acid molecules simultaneously. In order of complexity, these approaches include sequencing of gene panels, exome sequencing (protein-coding genes),

Fig. 56.5 SCHEMATIC REPRESENTATION OF CELL DIVISION. Most clinical FISH studies are performed on nondividing interphase cells, whereas conventional cytogenetics is performed at the metaphase stage of cell division. (Courtesy Dr. Ari Melnik, Cornell Medical Center, New York.)

transcriptome (expressed RNA), and sequencing the whole genome (WGS). These techniques have several arrays of several hundred thousand sequencing templates in parallel generating up to several hundred million short reads of DNA sequence per lane. The basic principle of NGS methods involves a process of DNA fragmentation, adapter ligation and immobilization of the fragments via the adapters to create libraries. The libraries then undergo a process of amplification, generating multiple copies of each DNA fragment which are then sequenced in parallel by a fluorescence- or chemiluminescence-based method, yielding billions of short sequence reads. These reads are then aligned to the human reference genome and highly efficient algorithms are used to perform the mapping of these complex genomes. Because of its cost effectiveness and enormous sequencing capacity, NGS is gradually changing the scenario of hematologic malignancy research by discovering disease-causing mutations, identifying novel drug targets, and implementing therapeutic individualization. Exome sequencing is a relatively inexpensive approach to identify protein-coding mutations, but has a major limitation in identifying structural genetic rearrangements, deletions and insertions of DNA, a hallmark of many hematologic malignancies. Exome sequencing is performed at a depth of 100–200-fold coverage of the haploid genome, which enables detection of mutations present in leukemic subclones, which is important in a study of relapse. Transcriptome sequencing involves sequencing of genes actively expressed and can be adjusted to selectively study RNA transcripts that encode proteins (mRNA), transcripts regardless of coding potential (RNA) or a variety of small and noncoding RNA transcripts. RNA sequencing is a highly informative approach and enables identification of

chromosomal rearrangements that result in the expression of chimeric fusion genes and sequence mutation detection. WGS usually involves sequencing leukemic and nonleukemic DNA of an individual. Although it is the most comprehensive modality, WGS may not identify all genetic alterations caused by variation in sequence coverage and difficulties in sequencing complex and GC-rich regions of the genome (including gene promoters).

These modern cytogenomic methods have increased the resolution at which chromosomal and gene rearrangements can be identified. Whereas in conventional cytogenetics the targets are whole chromosomes in metaphase spreads at a resolution of approximately 5 Mb, molecular cytogenetics methods may be used to analyze interphase nuclei at a resolution of 50 kb to 2 Mb or fiber FISH analysis of chromatin strands at a resolution of 5–500 kb. Moreover, the current resolution of aCGH is restricted only by clone size and by the density of clones on the array, some of which may contain resolution at the level of a single nucleotide.

Conventional cytogenetics, FISH, and aCGH along with NGS are complementary. Each has its own advantages and limitations in investigating genomic rearrangements of malignant cells. Although conventional cytogenetics is the comprehensive study of all chromosomes, it requires a large number of dividing cells, which, in some diseases, such as myelofibrosis, is difficult to obtain. Furthermore, many small deletions or structural rearrangements are beyond the microscopic level of detection. FISH is to be used in conjunction with conventional cytogenetics with both interphase and metaphase cells. It is a more sensitive method and detects rearrangements smaller than 1 kb. The main disadvantage of interphase FISH is that it

Fig. 56.6 Multicolor metaphase FISH of a bone marrow cell from a patient with myelodysplastic syndrome documenting 43,XY, -5, der(8)t(8;8)(p23;q11.2), der(14;16)(p12;p11.1), inv(15)(q21;q24), der(17)t(5;17)(p13;p13), -21 karyotype. The origin of t(8;8) and der(14;16) could not have been determined by conventional cytogenetic study alone.

cannot be used unless a known abnormality is suspected. When the abnormality is known, interphase FISH identify the clonal aberration at the single-cell level. Because of higher resolution and genome-wide analysis combined aCGH + SNP provides information of genomic changes in patients with a normal karyotype as well as acquired loss of heterozygosity, both important as a prognostic and a predictive tool. With the introduction of high throughput genomic technologies such as NGS, FISH-based chromosome level detection has gradually changed focus to genome-wide detection of single nucleotide and copy number variants that are common in leukemia. It is evident that identification of chromosomal aberrations by molecular cytogenomic techniques is important in detecting novel chromosomal rearrangements and genes involved in leukemogenesis. Understanding the basis of these techniques and their application is critical in the accurate diagnosis of hematologic malignancies.

Clonal Origin of Leukemia

The question of whether cell proliferation is monoclonal or polyclonal is fundamental to understanding the underlying etiology of hematologic malignancies. Markers of clonality are used to determine the origin of disease; to differentiate malignant from nonmalignant populations; to establish hematopoietic hierarchy, clonal evolution, and clonal remission; and to delineate steps involved in the multistep pathogenesis of hematologic malignancies.

The clonal origin of leukemias and lymphomas can be assessed by either intrinsic or extrinsic cellular markers. Intrinsic cellular markers

are specific for a cell population, arising either during normal differentiation or as a part of disease process. For instance, cell surface-associated immunoglobulin (Ig) markers such as the λ or κ light chain or idiotype and T-cell receptors (TCRs) can be useful for evaluating lymphoid diseases. Application of *IgH* markers demonstrated for the first time that MM was of clonal origin. Somatic cytogenetic alterations are useful intrinsic markers for identifying abnormal clones and following disease progression. Thus the observation of identical chromosome anomalies in different cells of the same tumor is evidence of clonality. Since the discovery of the Ph in 1960 it has been well established that nonrandom, recurrent chromosomal abnormalities characterize many hematopoietic malignancies. The finding of the Ph in different CML-derived hematopoietic cell lineages led to the hypothesis that CML originates in a single precursor cell that has a clonal development pattern. Moreover, the presence of additional recurrent chromosomal abnormalities in the Ph-positive clone (such as trisomy 8, duplication of the Ph, or trisomy 19) not only indicates the clinical progression of the disease to accelerated phase or blast crisis, but also demonstrates the subclonal evolution of the Ph-positive clone. Currently, disease-associated somatic genomic mutations, such as rearrangements of *KMT2A* (*MLL*), runt-related transcription factor gene (*RUNX1*), *ETV6*, *PML-RARA*, and many others, can be identified by polymerase chain reaction (PCR)-based assays, FISH assay, and novel aCGH and NGS technologies, and may serve, with or without conventional cytogenetics, as intrinsic markers of disease processes.

On the other hand, extrinsic marker systems use cellular mosaicism that is completely independent of the disease being studied and

Fig. 56.7 X-CHROMOSOME-LINKED ENZYME GLUCOSE-6-PHOSPHATE DEHYDROGENASE (G6PD) AS A MARKER TO INVESTIGATE CLONAL DEVELOPMENT OF HUMAN HEMATOPOIETIC DISORDERS. Early in embryogenesis, regions of all but one X chromosome are inactivated in each cell containing two or more X chromosomes. The choice of maternal versus paternal X chromosome for inactivation is random. Once the inactivation occurs, it is fixed and is stably transmitted to daughter cells during mitosis (Lyon hypothesis). Females who are heterozygous for the common B type and the less frequent A type, G6PD (localized on Xq27), are mosaic. This cellular mosaicism is used to study monoclonal versus polyclonal cell proliferation and development of malignant hematopoietic diseases. (Courtesy Dr. W Raskind, University of Washington, Seattle.)

is not restricted to the cell lineages. Individuals with Turner or Klinefelter syndrome are mosaic for XX or XY and monosomy X cells or XXY and XY cells, respectively. The mosaicism created by X-chromosome inactivation in females is much more widely applicable and has provided fundamental insights into the pathogenesis of hematologic malignancies. Original studies with X-linked glucose-6-phosphate dehydrogenase (G6PD) as a marker of clonality were based on the Lyon hypothesis, which asserts that early in embryogenesis, one X chromosome in females is inactivated in somatic cells and the activation status is stably transmitted to daughter cells during mitosis (Fig. 56.7). The choice of maternal versus paternal X-chromosome inactivation is random; however, once it occurs, it is maintained in all daughter cells. Random X inactivation occurs by embryonic day 6.5 around the start of gastrulation and results in a mosaic pattern that characterizes adult females. Therefore an adult female is a mosaic for two-cell populations, one expressing genes from an active X chromosome and the other expressing genes from the inactive X chromosome. Incidentally, mammalian X-chromosome inactivation is a mechanism that equalizes the dosage of X-linked genes between sexes. Although the exact mechanism of X-chromosome inactivation remains to be elucidated, the process of X inactivation starts with methylation of CpG islands. The inactivation process is believed to occur before differentiation of the embryonic stem cell into various cell lineages. Hematopoietic cells do not originate from a single embryonic stem cell but from several progenitors, thereby allowing for mosaic expression from both X chromosomes.

The observation that human females are heterozygous for the G6PD variant A and A⁻ and that two mosaic cell populations may be distinguishable by electrophoretic mobility was reported in the 1960s. The X-inactivation G6PD mosaic system was then applied to the study of clonality in human tumors (uterine leiomyomas) in 1964 by Gartler and Linden. In females who are heterozygous for the G6PD polymorphism and have malignant hematologic disorders such as CML, the finding of a single G6PD type in marrow or blood cells and both the A and B type G6PD in tissues not involved by the malignant process demonstrated that CML was of clonal origin and provided evidence that the malignant transformation occurred at the level of a stem cell common to most hematopoietic cell lineages. Additional studies with heterozygous G6PD females who had CML demonstrated that some CML-derived B lymphocytes had a single

G6PD type, but these clonal cells were Ph-negative; thus leukemic transformation predates development of the chromosomal abnormality. This observation provided evidence that CML has a multistep pathogenesis. Application of G6PD studies to hematologic malignancies demonstrated the clonal and stem cell origin for AML, ALL, Ph-negative myeloproliferative neoplasm (MPN), myelodysplastic syndrome (MDS), and CLL. G6PD studies were particularly useful in the investigation of red blood cells and platelets in hematologic malignancies because the absence of nuclei in these cells means they cannot be studied by cytogenetics or DNA analysis. Although it is now considered common knowledge that hematologic malignancies are characterized by clonal development, this understanding is greatly owing to what is now known as classic Fialkow's work, whose profound insight contributed much to current concepts and understanding.

Despite the importance of the G6PD approach, it is limited by the rarity of females who are heterozygous for the G6PD isoenzyme. An alternative and more extensive DNA-based X-chromosome clonal assay uses common polymorphic markers that are caused by changes in DNA methylation patterns that accompany inactivation of the X chromosome. These X-linked loci, such as phosphoglycerine kinase, hypoxanthine phosphoribosyltransferase, DXS25 (M27B), and human androgen receptor (HUMARA), have been subsequently extensively used in assessment of clonality, and now it is possible to identify clonal cell populations in virtually all females. DNA-based marker systems rely on a sequence polymorphism that has adjacent differences in methylation on the active and inactive X chromosomes. The inactive X chromosome is more highly methylated than its active homologue, but this is only true for certain regions of genes as 10% to 20% of X-linked genes escape inactivation and can be found both in clusters and in isolation. The most widely used HUMARA assay appears to maintain the stringent methylation differences. The number of CAG tandem repeats differentiates the maternal from the paternal X chromosome.

The DNA-based X-chromosome clonal assay is limited to females younger than 60 years because they usually have 1:1 distribution of two-mosaic-cell population. A ratio greater than 3:1 is found in women older than 60 years, probably as a result of stem cell kinetics influenced by X-linked genetic factors. When the ratio of two cell populations is greater than 3:1, this phenomenon is called a *skewed X-inactivation pattern*. With the HUMARA assay, acquired unequal

or skewed X-chromosome inactivation (excessive lyonization) is found in 35% to 40% of women older than 60 years. Thus X-chromosome-based clonality studies must incorporate age-matched controls. Despite the enormous contribution of clonality assays to the understanding of disease processes, they are usually performed in research investigations and are rarely used as diagnostic tools.

More recently acquired somatic mutations are detected using NGS, also known as high-throughput sequencing, the catch-all term used to describe a number of different modern sequencing technologies whereby millions of small fragments of DNA can be sequenced at the same time, creating a massive pool of data. This pool of data can reach gigabytes in size, which is the equivalent of 1 billion (1,000,000,000) base pairs of DNA.

Although NGS makes genome sequences handy, the data analysis and biologic explanations are still the bottle-neck in understanding leukemic genomes.

In Utero Mutations and Clonal Origin

The observation that monozygotic twins share identical but nonconstitutive and clone-specific fusion gene sequences (e.g., *ETV6-RUNX1*) in pediatric ALL provided the first unambiguous evidence (in 2003) that genetic lesions, generated by chromosomal translocation, arise in utero. These sophisticated series of studies initiated by Mel Greaves and his colleagues at the Institute for Cancer Research in London, have contributed for the past 13 years to a wealth of knowledge about founder mutations, subclonal development, clonal origin, and the evolution of disease. The initiating lesion and premalignant clone is shared by the twins as a consequence of intraplacental vascular anastomoses and blood cell chimerism. The twin data are endorsed by backtracking of prenatal-initiating genetic lesions in the archived blood spots, or Guthrie cards, of patients with ALL. These data were interpreted to suggest that *ETV6-RUNX1* is likely to be a critical initiating lesion for *ETV6-RUNX1*-positive ALL. However, such fusions are detectable in cord blood from newborn infants at rates approximately 100-fold higher than the incidence of ALL, suggesting an obligatory requirement for additional mutations in leukemia development. Over a period of 10 years these results were confirmed and in utero origin of *MLL*, *BCR-ABL1*, and *RUNX1-RUNX1T1* fusion rearrangements were documented, providing direct evidence for a prenatal origin of many childhood leukemias.

Results from genome sequencing of *ETV6-RUNX1* fusion region suggests it arises as a consequence of nonhomologous end-joining in the pro-B cell stage with possible self-renewal capacity to downstream B-cell precursors. Additional evidence was provided by screening for trisomies in stored cord blood and the data indicated that ~6% of enriched CD34⁺/CD19⁺ B lineage progenitors carry trisomies frequently seen in hyperdiploid childhood ALL. With novel SNP and other technologies, it has become apparent that ALL has multiple genome copy number variations (CNVs), mostly deletions and these CNVs are distinctive between a pair of twins, indicating a secondary, postnatal origin.¹

When genotyping sequencing combined with other molecular technologies of five pairs of monozygotic twins with concordant *ETV6-RUNX1*-positive ALL, Greaves and his colleagues demonstrated that all recurrent CNVs (32 in total) were different within twin pairs providing strong evidence that they are probably secondary mutations and postnatal in origin in both twins as well as in nontwins with ALL. Another two twin pairs who shared a monochromic placenta and had Ph-positive ALL, also studied by Greaves and his colleagues, provided confirmation for the previous observation that *BCR-ABL1* is not sufficient to cause Ph-positive leukemia. Twin A presented with ALL at age 3.8 years and twin B presented at age 4.1 years. Both had an identical *BCR-ABL1* fusion transcript and both received an allogeneic stem cell transplantation from the same human leukocyte antigen (HLA) identical sibling donor but 7 months later twin B died whereas twin A is in good health 8 years following the transplantation. SNP analysis revealed that twin A had a subclone with trisomies for chromosomes 4, 6, 9, 14, 17, and X, tetrasomy 21,

and a gain of 22q11.1–q11.23 region, whereas twin B had deletions of *EBF1* and *IKZF1*. These genotyping results provide direct evidence that rearrangements additional to *BCR-ABL1* are obviously postnatal in origin, they represent a subclonal evolution, and *BCR-ABL1* by itself is not sufficient for development of Ph-positive ALL.

These mutation-driven natural history studies provide evidence for sequential multistep pathogenesis with sequential accumulation of genetic changes, which may be linear through clonal succession as originally proposed by Peter Nowell in 1976, but as Greaves indicated, clonal evolution in most leukemia is rather complex and may represent also a branching structure, as predicted by Darwin.²

EARLY MUTATIONS IN LEUKEMOGENESIS AND AGE-RELATED CLONAL HEMATOPOIESIS

As indicated earlier and throughout the chapter, the progress of high-throughput sequencing has provided novel observations in the current understanding of the initial mutations in premalignant stem cells and the clonal development through the accumulation of genetic changes. For example, the evolving concept of the clonal origin of AML involves the mutation in the gene encoding DNA methyltransferase 3A, *DNMT3*.³ Approximately 22% of patients with AML have a mutation in *DNMT3* gene, localized on the short arms of human chromosome 2, 2p23. However, mutations of this gene are also described in other myeloid malignancies as well as in T cell leukemia/lymphoma. Deep sequencing of patients with AML showed that *DNMT3* mutations are typically found at higher frequencies than other accompanied mutations in AML, such as *NPM1*, *FLT3* or others, suggesting that they were among the first to arise. Two studies demonstrated that patients with AML and *DNMT3* mutations had the same mutation in T and B lymphocytes, indicating that in these patients the mutation had occurred in a primordial cell giving rise to all hematopoietic lineages, which may represent a “founder” clone population from which the AML leukemic population expands. Co-occurrence of *DNMT3* mutations in patients with chromosomal abnormalities such as t(15;17), inv(16), and t(8;21) (see later in the chapter) have not been described. In sharp contrast, approximately 60% of patients with *DNMT3* mutation also carry an *NPM1* mutation whereas only 13% of the patients with the wild type *DNMT3* carry *NPM1* mutations. These patterns imply a temporal acquisition of mutations in AML. Collectively these and other observations indicate that the *DNMT3* mutation is a primary mutation in premalignant stem cell whereas *NPM1* and *FLT3* are common secondary mutations in more differentiated cells that lead to an acute phase of disease, and combined, they may represent a distinct AML entity. It has been further documented that *DNMT3* mutant hematopoietic stem cells and their differentiated progeny persisted in the peripheral blood of these patients even when their AML is in remission following chemotherapy, indicating that at least some of these preleukemic ancestral cells are resistant to treatment. These studies have significant implications for the development of targeted therapies.

Clonal mosaicism for large chromosomal anomalies (duplications, deletions, and uniparental disomy [UPD]) using SNP microarray data from 50,000 subjects in the GENEVA study determined that clonal hematopoiesis is infrequent (<0.5%) from birth until 50 years of age after its frequency rapidly increases to 2% to 3% in the elderly. It has been estimated that individuals with clonal hematopoiesis have 10-fold higher risk of a subsequent hematologic malignancy. These age-related mutations were confirmed by analysis of mutation acquisition in hematopoietic stem cells, over time, through whole-exome sequencing of single hematopoietic stem cell-derived colonies, which showed that the total number of mutations in healthy individual stem cells increases with age. Moreover, sequencing of multiple elderly women provided evidence of clonal hematopoiesis based on X inactivation pattern and recurrent somatic mutation in *TET2* gene. Subsequent analysis of 182 additional elderly women with clonal hematopoiesis determined that more than 5% of these individuals had mutations in *TET2*. Most recent reports by Ebbert and his colleagues in USA on 17,182 persons and by Cross and his colleagues

in UK, suggests that peripheral blood of normal individuals showed clonal mutations in 9.5% of individuals between 70 and 79 years of age, 11.7% in individuals between 80 and 89 years of age and in 18.4% of individuals between 90 and 103 years of age. As in previous studies of healthy individuals, the majority of the mutations were in three genes, *DNMT3*, *TET2* and *ASXL1*, all known to occur in myeloid malignancies. The presence of mutations in these three genes is associated with an increase in the risk of hematologic malignancy.³ However, individuals with clonal hematopoiesis may live for many years and decades without hematologic malignancies though they are at increased risk as compared with those without mutations. These studies may explain the higher frequency of myeloid malignancies in the elderly population.

CHRONIC MYELOPROLIFERATIVE NEOPLASMS

The World Health Organization (WHO) characterizes MPNs as clonal stem cell disorders. CML has a unique place among hematologic malignancies and is described separately from the other Ph-negative MPNs.

Chronic Myelogenous Leukemia (see Chapter 67)

Knowledge of the origins of CML has accumulated over the last 56 years and serves as a classic example of molecular medicine at its best (Table 56.2). The Ph chromosome is the first example of a specific chromosomal abnormality associated with a malignant disease.⁴⁻⁵ *ABL1* and *BCR* genes are the first oncogenes localized at the site of a chromosomal breakpoint in t(9;22)(q34;q11.2). The *BCR-ABL1* fusion leads to a “hybrid” gene, resulting in the production of a dysregulated tyrosine kinase protein. Finally, imatinib mesylate, a specific tyrosine kinase inhibitor (TKI), was the first rationally designed targeted form of cancer therapy.

The Ph chromosome, named in honor of Philadelphia, the city of its discovery, was described for the first time in 1960. It represents a signature genomic rearrangement occurring in more than 95% of patients with CML. Approximately 3% of all pediatric leukemias are Ph-positive CML. The incidence in children increases with age and it is exceptionally rare in infants. The Ph chromosome results from a balanced translocation t(9;22)(q34;q11.2) (Fig. 56.8A–B). The Ph chromosome arises postzygotically, being found only in hematopoietic tissue. The findings of the Ph chromosome in myeloid cells, erythroid cells, eosinophils, monocytes/macrophages, basophils, and B lymphocytes, along with the absence of the Ph chromosome in cultured marrow fibroblasts, support the concept that the Ph chromosome results from a specific rearrangement in a multipotent hematopoietic stem cell and that it is an acquired rather than an inherited abnormality. Of interest, the Ph chromosome is rarely identified in T cells. T lymphocytes are long-lived cells and may antedate the development of CML. These observations combined with studies exploiting G6PD heterozygosity provide further evidence for the concept that CML is a clonal disease arising in a stem cell capable of differentiation into all hematopoietic cell lineages.

In a review of 1129 Ph-positive patients, the 9;22 translocation was identified in 1036 (92%) cases. Karyotypic analysis of marrow cells in patients with CML is a time-consuming task. However, it

demonstrates not only the presence of the Ph chromosome but also the presence of other chromosomal rearrangements (clonal evolution) of clinical significance.

The reciprocal nature of the Ph-positive translocation was confirmed when studies showed that its molecular consequence is the translocation of the *ABL1* gene from chromosome 9, band region q34, and subsequent fusion to the breakpoint cluster region (*BCR*) gene on chromosome 22, band q11.2 (Fig. 56.9). This creates a hybrid *BCR-ABL1* gene that is transcribed into a chimeric *BCR-ABL1* messenger RNA (mRNA) and translated into a specific chimeric protein.

Three major breakpoint locations along the *BCR* gene on chromosome 22 result in three chimeric proteins. They include P210^{BCR-ABL1}, P190^{BCR-ABL1}, and P230^{BCR-ABL1} and are associated with three distinct types of leukemia. P210^{BCR-ABL1} is found in the majority of patients with classic Ph-positive, *BCR-ABL1*-fusion-positive CML and approximately 30% of patients with Ph-positive ALL. Expression of P190^{BCR-ABL1} is seen in 20% to 30% of adults and 80% of children with Ph-positive ALL. Expression of P230^{BCR-ABL1} is associated with a rare indolent chronic neutrophilic leukemia variant and up to 1.6% of CML (approximately 50 patients in the worldwide literature have been described). Approximately 1% to 2% of Ph-positive patients with CML express both P21^{BCR-ABL1} and P190^{BCR-ABL1} and their response to TKI therapy is inferior to patients showing only P210^{BCR-ABL1}. The *BCR-ABL1* fusion is present in both standard and variant forms, in cases where chromosome 9 involvement is cytogenetically not detectable, and when a masked Ph is present. In the majority of patients, the fusion of *ABL1* and *BCR* takes place on chromosome 22 (Fig. 56.10 A–B). However, in a small group of patients the *BCR* gene is translocated to chromosome 9, and the fusion of the two genes is localized to 9q34. The prognosis of these patients may be inferior, but the number of reports is too small for a definitive conclusion. The *BCR-ABL1* fusion transcript is present in neutrophils, monocytes, eosinophils, erythrocytes, B cells, rarely in T cells, and in CD34⁺ cells and is associated with increased proliferation of CD34⁺ myeloid progenitor cells but not of other more mature myeloid precursors. These observations confirm the hypothesis that CML originates in a multipotent stem cell capable of differentiating to all hematopoietic cell lineages with the exception of T cells. These and other studies provide also evidence for the existence of clonal *BCR-ABL1* fusion-negative stage. The formation of *BCR-ABL1* and the Ph chromosome occurs in an already abnormal and genetically unstable clone of pluripotent hematopoietic cells. Thus it is the preexisting genetic instability that predisposes to formation of *BCR-ABL1* and in Ph⁺ chromosome. Once Ph chromosome formation occurs, it confers a further selective growth advantage over normal cells, resulting in overwhelming *BCR-ABL1*-positive, Ph-positive marrow cells at the time of diagnosis of CML.

In the 5% of patients with CML who are Ph-negative by cytogenetic studies, clonal and stem cell origin of these hematologic malignancies can still be demonstrated, and molecular analysis reveals the *BCR-ABL1* fusion in approximately 2% to 3% of these patients (Fig. 56.11). In the majority of Ph-negative patients, an *ABL1* insertion from chromosome 9 to 22q11.2 results in a *BCR-ABL1*-fusion product without reciprocal translocation of sequences from chromosome 22 to chromosome 9. Approximately 2% of patients truly are Ph-negative and *BCR-ABL* fusion-negative. These patients may not have CML but rather another MPN. The concept that the *BCR-ABL1* fusion plays a central role in the pathogenesis of CML is strongly supported by two lines of evidence: (a) retroviral transduction experiments in which P210^{BCR-ABL1} is expressed in murine marrow cells, resulting in a myeloproliferative disorder (MPD) resembling CML, and (b) the fact that imatinib, a TKI, selectively inhibits the *BCR-ABL1* fusion protein in mice and specifically inhibits the growth of human Ph-positive cells in vitro and in vivo. Although considered necessary, *BCR-ABL1* may not be initial or sufficient to cause the malignant transformation resulting in CML (see earlier clonal origin section).

Genomic PCR analysis can determine the exact breakpoints of DNA fusion products. Reverse transcriptase PCR (RT-PCR) and

TABLE 56.2 History of Discovery of Philadelphia Chromosome and BCR-ABL1 Fusion

1960	Philadelphia chromosome (Ph) is identified.
1973	Ph is t(9;22)(q34;q11.2).
1983	<i>ABL1</i> is translocated from chromosome 9 to chromosome 22.
1984	<i>BCR</i> is localized to 22q11.
1987	Ph ⁺ is <i>BCR-ABL1</i> fusion.

Fig. 56.8 (A) The karyotype of a female patient showing a balanced t(9;22)(q34;q11.2), also known as the Ph chromosome. (B) Isolated t(9;22) showing two-thirds of the long arms of chromosome 22 translocated to one homologue of chromosome 9.

Northern blot analysis allows detection of *BCR-ABL1* transcripts at the RNA level. Current FISH studies for detection of *BCR-ABL1* fusion at diagnosis use a dual-color *BCR-ABL1* ES probe or *BCR-ABL1* dual-fusion probe (Fig. 56.12, see also Fig. 56.6A–B). A triple-color *BCR-ABL1-ASS* probe is used for detection of deletions on both chromosomes 9 and 22 (see Fig. 56.12). Approximately 12% to 15% of patients with CML have large deletions adjacent to the Ph chromosome translocation breakpoint on the derivative 9 chromosome, and initial reports demonstrated inferior survival in these patients. These deletions are heterogeneous and may involve both chromosomes 9 and 22 (majority of cases), only chromosome 9 (8% of patients with deletions), or only chromosome 22 (4% of cases with deletions). Moreover, deletion size is variable, ranging from 0.5 Mb to greater than 10 Mb. A more refined study applying genomic SNP microarrays revealed three common deletion regions: (1) a 162-kb loss at 9q34, (2) a 138-kb deletion at 22q11.2, and (3) a 102-kb deletion at 22q11.2. It appears that the partial deletion of the *ABL1-BCR* fusion on derivative 9 chromosome occurs as a part of the same process as the formation of the *BCR-ABL1* translocation. Before imatinib therapy, these deletions were associated with an adverse

prognosis; however, in a study of 521 patients with CML, the cumulative incidence of complete cytogenetic responses and major molecular responses and the overall survival (OS) were comparable after 5-years of follow-up between CML patients with and without the del(9q).

At diagnosis, conventional cytogenetics remains the gold standard because the chromosome analysis will identify not only the t(9;22) but also other chromosomal abnormalities that may indicate accelerated or blast phase of the disease or clonal proliferation of Ph-negative cells.

Imatinib mesylate (Gleevec) has revolutionized therapy for CML and, for most patients, has transformed a deadly disease into a chronic disorder that is compatible with normal life. The standard method for monitoring a patient's response to therapy is conventional cytogenetic analysis of cells obtained from a marrow aspirate. In the phase III International Randomized Interferon and STI-571 (IRIS) study, 89% of patients had Ph-negative marrow aspirates as determined by conventional cytogenetics after 5 years of treatment. However, conventional cytogenetics has limited sensitivity. The degree of tumor load reduction is determined to be an important prognostic factor

Fig. 56.9 CURRENT FISH PROBE STRATEGIES FOR DETECTING BCR-ABL1 FUSION. Partial karyotype showing the Philadelphia chromosome as a result of $t(9;22)(q34;q11.2)$ (top row). The same chromosomes 9 and 22, as well as a bone marrow nucleus, after hybridization with BCR (green) and ABL1 (red) using an extrasensitive dual-color, single-fusion FISH strategy (second row). Chromosomes and a nucleus are counterstained with DAPI (blue). In the extrasensitive strategy, a part of ABL1 (red) remains on der(9) and is shown in interphase nucleus as a smaller red signal, whereas the normal-size ABL1 hybridization signal is seen on normal homolog 9. The other part of ABL1 is on the Ph chromosome and is seen co-localized with BCR as yellow in interphase nucleus. Therefore interphase nuclei will have one normal-size red signal, one smaller-size red signal, one normal-size BCR signal, and co-localization of BCR and ABL1, producing a yellow signal both in interphase cells and metaphase chromosomes. In the dual-color, dual-fusion strategy (third row), there are two co-localized signals on both der(9) and the Ph chromosome, as well as one red signal of ABL1 on chromosome 9 and one green signal of BCR on normal chromosome 22. In the triple-color, dual-fusion strategy, ASS gene (aqua) is added. It is used to determine whether sequences from der(9) are deleted at the time of the Ph formation. As shown in the fourth row, ASS is localized centromeric from ABL1 on 9q34, and in patients without deletion, ASS is present as two signals in nucleus and on the chromosome 9.

for patients with CML on therapy. Patients with CML without a discernible Ph chromosome detected by conventional cytogenetics analysis may still harbor up to 10^{10} leukemic cells.

Interphase FISH does not depend on the cycling status of cells, and use of double-fusion probes has reduced false-positive results to approximately 1%. However, if peripheral blood cells rather than marrow aspirate cells are used to monitor residual disease, the high percentage of *BCR-ABL1* fusion-negative lymphoid cells may under-represent the actual residual tumor load. In most direct comparison studies, interphase FISH of peripheral blood compared with conventional cytogenetics of marrow in patients who are treated with imatinib showed good correlations ($r = 0.91-0.97$). Real-time quantitative PCR (RQ-PCR) is by far the most sensitive method. It provides an accurate measure of the total leukemia cell mass and the degree to which *BCR-ABL1* transcripts are reduced by therapy, and it correlates with progression-free survival.

A

B

Fig. 56.10 (A) Complex Ph translocation. Top: A partial karyotype from a patient showing a three-way translocation $t(2;9;22)$ and (B) metaphase FISH (bottom) indicating that even in complex karyotype the fusion of *BCR* and *ABL1* takes place on the Ph chromosome or der(22) indicated in yellow.

The goal of therapy in CML is to achieve a molecular remission as measured by the reduction or elimination of *BCR-ABL1* transcripts. In the IRIS study, at 5-year follow-up, complete cytogenetic response combined with major molecular response at 12 months was associated with a 97% progression-free survival rate. This compares with an 89% progression-free survival for those with complete cytogenetic response but without a major molecular response. Current international recommendations for optimal molecular monitoring of patients receiving imatinib treatment includes an RQ-PCR assay expressing the *BCR-ABL1* transcript levels on an internationally agreed upon scale. The term *major molecular response* corresponds to $\leq 0.1\%$ *BCR-ABL1*, whereas the designation *complete molecular response* should be used only for patients with undetectable *BCR-ABL1*, where the limit of detection is confirmed to be at least ≈ 4.5 log reduction from baseline response. The two major obstacles to successful imatinib-based therapy for patients with Ph-positive, *BCR-ABL1* fusion-positive CML are the persistence of *BCR-ABL1* fusion-positive cells and relapse of the disease because of emergence of resistance to imatinib. Acquired resistance to imatinib treatment is manifested in two ways: amplification of *BCR-ABL1* fusion product (Fig. 56.13) and mutations in the ABL kinase domain. Currently, 100 different ABL1 kinase domain mutations have been described, although only about 15 are common and they account for more than 85% of all mutations detected.

Fig. 56.11. *BCR-ABL1* FUSION IN A PATIENT WITH THE Ph-NEGATIVE, NORMAL KARYOTYPE. *Left panel* shows a partial karyotype from three cells showing normal homologs 9 and 22. The *right panel* shows the *BCR-ABL1* fusion (yellow) on der(22) and diminished *ABL* (red) on der(9). The fusion has occurred as a result of *ABL1* insertion into *BCR* without apparent chromosomal translocation. Note an intact *ASS* (aqua) on both chromosomes 9.

Fig. 56.12 SCHEMATIC REPRESENTATION OF THE MOST FREQUENTLY USED *BCR-ABL* PROBES. Dual-color/single-fusion extrasensitive probe strategy, as indicated in text, uses a 650-kb probe in which two loci, *ABL* and *ASS*, both are labeled in red. *BCR-ABL* fusion-positive nuclei show three red signals: one small red signal on normal homologue 9, and a third red signal in fusion with *BCR*. When a triple-color probe is applied, the *ASS* locus usually is labeled in aqua and the *BCR-ABL* fusion-positive cells show two aqua signals, unless there is deletion of der(9). The most useful application of triple-color probe is documentation of deletion of derivative chromosome 9.

Patients with CML who cannot tolerate or are resistant to imatinib may benefit from the second and now third generation of TKIs, such as dasatinib, nilotinib, bosutinib, and ponatinib.⁷ These agents bind to the ABL kinase domain in a matter distinct from that of imatinib and thereby retain activity against nearly all imatinib-resistant mutations. Recent meta-analysis revealed ABL mutation rates with imatinib 9.7%, dasatinib 1.7%, and nilotinib 3.3%. The most common specific mutations were T315I, E255K, and M315I. T315I mutations constitute 58% of dasatinib-related mutations and 13% of imatinib related mutations. These mutations inhibit the binding of the TKIs, hindering the treatment of patients with CML. The introduction of ponatinib, a new formulation of TKI, has been shown to overcome resistance incurred by the T315I mutation (see Chapter 67).

Between 5% and 8% of patients undergoing treatment with imatinib will develop chromosomal abnormalities such as trisomy 8,

monosomy 7, del(20q), and other anomalies in *BCR-ABL1* fusion-negative cells. Imatinib may induce chromosomal abnormalities in *BCR-ABL1*⁺ cells. Alternatively, imatinib may uncover chromosomal abnormalities present before therapy after significant reduction of overlying Ph-positive cells (Fig. 56.14). Presence of +8 and other chromosomal anomalies in Ph-negative cells in patients treated with imatinib suggests that CML has a multistep pathogenesis and that clonal Ph-negative cells precede the development of the Ph-positive clone (Fig. 56.15). This important observation about the pathogenesis of CML demonstrates the power of conventional cytogenetics, even in the era of molecular assays, and should be used at least annually while patients are undergoing imatinib treatment. This hypothesis that clonal development occurs in Ph-negative cells before development of the Ph chromosome in the multistep CML pathogenesis was recently confirmed using NGS by targeting 25 genes

Fig. 56.13 EXAMPLES OF UNUSUAL Ph CHROMOSOME ASSOCIATED WITH IMATINIB RESISTANCE AND BLAST CRISIS OF CHRONIC MYELOGENOUS LEUKEMIA. (B) G-banding of dicentric Ph chromosome (*left*) $\text{dic der}(22)\text{t}(9;22)(\text{q}34;\text{q}11.2)$ and after FISH studies (*right*) showing two copies of BCR-ABL fusion. (C) G-banding of isodervative Ph, $\text{id}(22)\text{t}(9;22)(\text{q}34;\text{q}11.2)$ (*left*) and after FISH studies showing two copies of BCR-ABL fusion (*yellow*) on the end of both arms.

frequently mutated in myeloid disorders. Ph-negative clones were analyzed in 14 patients who developed clonal cytogenetic abnormalities in Ph-negative cells during TKI treatment. Mutations affecting the genes *DNMT3A*, *EZH2*, *RUNX1*, *TET2*, *TP53*, *U2AF1*, and *ZRSR2*, were detected in 43% of these patients. In two patients, the mutations were found also in corresponding Ph-positive diagnostic samples. Moreover, somatic mutations additional to *BCR-ABL1* are found in 33% of patients affecting *ASXL1*, *DNMT3A*, *RUNX1*, and *TET2* genes. When individual hematopoietic colonies were analyzed from patients with CML at diagnosis, most mutations were present in the Ph-positive cells. By contrast, deep sequencing of subsequent samples during TKI treatment revealed that one *DNMT3A* mutation occurs in Ph-negative cells that was also present in Ph-positive cells at diagnosis, strongly implying that *DNMT3A* preceded the formation of the *BCR-ABL1* rearrangement and provides support for the initial hypothesis (in 1980) that *BCR-ABL1* and the formation of the Ph chromosome are not initiating events in the pathogenesis of CML. Another example of clonal evolution in MPNs evolving over time is the co-occurrence of the *JAK2V617F* mutation and *BCR-ABL1*. These rare patients usually have a long (10–20 years) history of *JAK2V617F*⁺ polycythemia vera (PV) before *BCR-ABL1* and the Ph chromosome were formed. Single cell genotyping revealed both the *JAK2V617F* mutation and *BCR-ABL1* can occur concurrently in hematopoietic stem cells and that *JAK2V617F*⁺ mutation occurs before the acquisition of *BCR-ABL1*. The contribution of *BCR-ABL1* to disease progression appears to be greater than that of *JAK2V617F*, because these patients display a clinical phenotype that is consistent with CML rather than PV.

The mechanism of transformation to advanced-phase CML is heterogeneous and poorly understood. In blast crisis of CML, 80% to 85% of patients show karyotypic evolution, that is, new

Fig. 56.14 TWO DIFFERENT CELL POPULATIONS FROM A PATIENT TREATED WITH IMATINIB. One population shows $\text{t}(9;22)$ (*top row*, partial G-banded karyotype) and the BCR-ABL fusion signal (*yellow*, *second row*) as well as disomy 8 (*aqua*). In contrast, the second population shows trisomy 8 (*third row*, partial G-banded karyotype) in the BCR-ABL fusion-negative cells (*fourth row*), showing disomy for the *BCR* (*green*), *ABL* (*red*) as well as trisomy for chromosome 8 (*aqua*) (see text for details).

chromosomal abnormalities in very distinct patterns are present in addition to the Ph chromosome. The most common changes include gain of chromosome 8 (33%) or +19 (12%), gain of a second Ph chromosome (30%), $\text{i}(17\text{q})$ (20%), alone or in combination, to produce modal chromosome numbers of 47–50 (Fig. 56.16). In males, a loss of Y chromosome is frequently observed. Isochromosome 17q occurs almost exclusively in myeloid blast crisis. Others less frequently observed abnormalities include monosomies of chromosomes 7 and 17, and trisomies of chromosomes 17 and 21. In addition to these common karyotypic evolutions, additional chromosomal aberrations specific for AML—for example, $\text{t}(8;21)$ (Fig. 56.17), $\text{inv}(16)$, $\text{t}(3;21)(\text{q}26;\text{q}22)$, and most frequently, $\text{inv}(3\text{q})/\text{t}(3;3)$, resulting in the overexpression of *EVII*—have been observed. Simultaneous presence of $\text{t}(9;22)$ and $\text{inv}(3)$ at diagnosis or following TKI therapy appears to be associated with a lack of response to treatment

Fig. 56.15 HYPOTHETICAL MODEL OF MULTISTEP PATHOGENESIS OF Ph-POSITIVE CHRONIC MYELOGENOUS LEUKEMIA. The first detectable event is a clonal proliferation of cells that are capable of differentiating to all hematopoietic lineages. These cells are genetically unstable and give rise to BCR-ABL fusion and the Ph chromosome. The blast crisis is characterized by nonrandom abnormalities occurring in a genetically unstable Ph-positive clone. At least six events can be delineated. (Courtesy Dr. W Raskind, University of Washington, Seattle.)

Fig. 56.16 THE FOUR MOST FREQUENT ABNORMALITIES ASSOCIATED WITH THE BLAST CRISIS OF CHRONIC MYELOGENOUS LEUKEMIA. Duplication of the Ph chromosome (*top row*) is identified in about 30% of patients, trisomy 8 (*second row*) is found in 30%, isochromosome of the long arms of chromosome 17 (*third row*) is found in 20%, and gain of chromosome 19 (*fourth row*) is seen in approximately 12% of patients with blast crisis of chronic myelogenous leukemia.

and the clinical course is similar to that of cases with *inv(3)* without any other chromosomal abnormality. In patients treated with TKI, additional chromosomal abnormalities (ACAs) were classified into two groups based on their impact on survival. ACAs in the good prognostic group include trisomy 8, loss of Y chromosome, and an

Genetic Testing for Chronic Myelogenous Leukemia (CML)

At diagnosis of CML, perform quantitative cytogenetic analysis using the bone marrow aspirate, which is the *sine qua non* because peripheral blood cells rarely contain sufficient numbers of mitotic cells at the time of presentation. If the bone marrow aspirate is a "dry tap," perform interphase FISH using a *BCR-ABL1* extrasensitive dual-fusion color probe. To monitor patients with CML during therapy, use FISH to study blood or bone marrow to track changes in the percentage of cells with *BCR-ABL1* fusion at 3-month intervals. Once the patient is in complete cytogenetic and FISH remission, the consensus recommendation is to perform real-time quantitative polymerase chain reaction and to follow the patient at 3-month intervals until molecular remission is achieved. According to ELN 2013 recommendations, a single measurement of rising *BCR-ABL1* transcript numbers is not sufficient to change therapy, whereas two tests at 3 and 6 months, and supplementary tests in between, provide more support for the decision to change treatment. At relapse, perform a chromosome study to assess the karyotype of the malignant clone and to determine whether a new chromosomally abnormal clone has developed or a new subclone in the Philadelphia chromosome-positive clone.

extra copy of the Ph chromosome. The second group includes chromosomal abnormalities that are associated with a relatively poor prognosis including *i(17q)*, *-7/del(7q)* and *3q26.2* rearrangements. The concurrent presence of two or more ACAs conferred an inferior survival and can be categorized into the poor prognostic group. Complete cytogenetic remission for patients in accelerated phase or blast crisis CML treated with imatinib is rarely accompanied by a normal karyotype; however, 6% to 17% of these patients may have some cytogenetic response (see [box on Genetic Testing for Chronic Myelogenous Leukemia](#)).

High-resolution cytogenomic studies have demonstrated that in contrast to the chronic phase (which is characterized only by genomic imbalances in or around *BCR* and *ABL1*, specifically deletions), during the blast phase, many additional genomic imbalances occur. Using aCGH, 44 patients in chronic phase of CML as well as in 11 in myeloid and 1 in lymphoid blast crisis were investigated, and a spectrum of recurrent genomic imbalances was associated with disease progression, including losses at *1p36*, *5q21*, *9p21*, and *9q34* and gains at *1q*, *8q24*, *9q34*, *16p*, and *22q11*. Moreover, analysis of 78 CML patients in lymphoid blast crisis demonstrated a unique signature of genomic deletions within the Ig heavy-chain and *TCR* genes,

Fig. 56.17 SIMULTANEOUS DETECTION OF $t(9;22)$ AND $t(8;21)$ IN A PATIENT WITH BC-CML: A karyotype (left) from a patient with chronic myelogenous leukemia who failed three tyrosine kinase inhibitor treatments and progressed into blast crisis showing 46, XY, $\text{del}(4)(\text{q}31\text{q}33)$, $t(8;21)(\text{q}22;\text{q}22)$, +8, $t(9;22)(\text{q}34;\text{q}11.2)$, +15. Metaphase FISH studies (right panel) confirmed that in the BCR-ABL1 fusion-positive cells (middle row, yellow co-localization), the patient had RUN1-RUNX1 fusion as a result of $t(8;21)$ [yellow signals on $\text{der}(8)$ and $\text{der}(21)$] and a gain of chromosome 8 (top row) as well as trisomy 15 (bottom row) as shown using centromeric FISH probe specific for chromosome 15 (aqua).

indicating that their presence is essential for the development of a malignant clone with the lymphoid phenotype. The most common mutations in myeloid blast phase involve tumor suppressor gene *TP53* (about 25% of cases) and the *RUNX1* in about 40% of cases. In lymphoid blast crisis, 50% of patients have mutation in cycline-dependent kinase inhibitor *CDKN2A*. Recently, mutations in genes frequently found in Ph-negative MPNs such as *CBL*, *TET2*, *ASXL1*, and *IDH1/2* were also identified in patients in accelerated/blast phase. Moreover, deletions of *RB1*, gain of function mutations in *GATA-2* and *RAS* are just some of the spectrum of cytogenomic changes characterizing progression of CML. The current thinking is that progression of CML is the result of increased genomic instability combined with defective or insufficient ability to repair DNA.

Ph-Negative Chronic Myeloproliferative Neoplasms

Ph-negative MPNs are disorders arising in a single clone of multipotent precursor cells in which one or all myeloid lineages are abnormally amplified. Classic and more frequently encountered Ph-negative MPDs include PV, primary myelofibrosis, and essential thrombocytopenia (ET). Their cytogenetic and genomic profiles are described in Chapters 68, 70 and 71.

Less frequently encountered MPNs include chronic neutrophilic leukemia, hypereosinophilic syndrome/chronic eosinophilic leukemia, systemic mast cell disorders, atypical CML, and unclassifiable MPNs. Rare recurrent balanced abnormalities in atypical Ph-negative MPN generally involve the *PDGFRB* gene localized at 5q33, *FGFR1* gene on 8p11, and *PDGFRA* gene on 4q12. The best described are $t(5;12)(\text{q}33;\text{p}13)$, resulting in *ETV6-PDGFRB* fusion protein, and $t(8;13)(\text{p}11;\text{q}12)$, resulting in the *ZNF198-FGFR1* fusion gene. The disorder known as 8p11 myeloproliferative syndrome has been recognized and classified by WHO as belonging to the group of myeloid neoplasms associated with multilineage involvement characterized by chronic myelomonocytic leukemia with eosinophilia and an increased incidence (approximately 30%) of T-cell lymphoblastic lymphoma.

This disease is related to fusion genes between *FGFR1* located on 8p11 and various translocations fusing at least 14 different 5' partner genes to the 3' part of the *FGFR1* gene that encodes the tyrosine kinase domain (Table 56.3). They include *TPR* (1q25), *LRRFIP1* (2q37), *SQSTM1* (5q35), *FGFR10P* (6q27), *TRIM24* (7q34), *CUX1* (7q22), *PLAG1* (8q12), *CEP110* (9q33), *NUP98* (11p15), *FGFR1OP2* (12p11), *CPSF6* (12q15), *ZMYM2* (13q12), *MYO18A* (17q23), *HERVK* (19q13), and *BCR* (22q11) (Fig. 56.18). The most frequent translocation is $t(8;13)$, and cases with the submicroscopic deletion of the 5' part of the *FGFR1* gene have also been reported, similar to the formation of $t(9;22)$ with deleted sequences from $\text{der}(9\text{q})$ and/or 22q identified in CML. The presence of 8p11 abnormalities in both myeloid and lymphoid cells suggests its origin from a common stem cell.

In patients with chronic eosinophilic leukemia/hypereosinophilic syndrome the most frequent recurrent abnormality is the cryptic deletion on 4q12 as a result of *FIP1L1-PDGFRFA* fusion gene reported to occur at frequencies ranging from 3% to 56% (Chapter 71). The disparity in frequencies reflects differing levels of stringency criteria in the diagnosis of disorders with hypereosinophilia as well as different technologies used for detection of *FIP1L1-PDGFRFA* fusion. A most recent investigation of 376 patients with persistent unexplained hypereosinophilia revealed an 11% incidence of the *FIP1L1-PDGFRFA* fusion gene detected using highly sensitive RQ-PCR. Patients with *FIP1L1-PDGFRFA* fusion are characterized by male predominance, marrow fibrosis, increased number of mast cells, elevated serum tryptase levels, and a favorable response to low doses of imatinib. Most of these patients have a normal karyotype because a cryptic deletion of *CHIC2* locus on 4q12 which is only 800 kb in size. This abnormality is detectable using a more sensitive FISH technology and RQ-PCR in the majority of cases. Moreover, the most recent commercially available tricolor FISH probe will detect not only deletion 4q12 as a result of *FIP1L1-PDGFRFA* but also a rare *BCR-PDGFRFA* fusion resulting from the $t(4;22)(\text{q}12;\text{q}11.2)$ rearrangement (Fig. 56.19). Serial monitoring with RQ-PCR demonstrates exquisite sensitivity of *FIP1L1-PDGFRFA*-positive patients to low-dose

AL, Acute leukemia; ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; CEL, chronic eosinophilic leukemia; CML, chronic myelogenous leukemia; CMML, chronic myelomonocytic leukemia; CMPD, chronic myeloproliferative disorder; ET, essential thrombocytopenia; MF, myelofibrosis; MPD, myeloproliferative disorder; MPN, myeloproliferative neoplasm; PV, polycythemia vera; SM, systemic mastocytosis.

Fig. 56.18 (A) A partial karyotype from a patient diagnosed with Ph-negative myeloproliferative neoplasm showing $t(8;22)(p11;q11.2)$. (B) Six months later the patient developed hyperdiploid karyotype, acute lymphoblastic leukemia, and two copies of $t(8;22)$. (C) Interphase FISH confirmed a *FGFR1* (red)-*BCR* (green) fusion (yellow).

imatinib treatment. The *FIP1L1-PDGFR*A has been also detected in histopathologically defined cases of systemic mastocytosis with associated eosinophilia, and in cases of AML and T-cell lymphoblastic lymphoma associated with eosinophilia. In an Italian prospective cohort of 27 patients with *FIP1L1-PDGFR*A who were treated with imatinib, a complete hematologic response was achieved within 1 month and all patients became PCR negative for *FIP1L1-PDGFR*A after a median of 3 months (range 1–10 months). In contrast to CML, very few cases of acquired imatinib resistance have been reported. Those rare reported cases have a mutation in T674I within the ATP-binding domain of *PDGFR*A, analogous to the T315I mutation in CML.

Although translocations involving *PDGFRB* at 5q32 region have been identified with 22 different fusion partners, they are indeed very rare. Any patient with a 5q31–q33 chromosomal abnormality with or without eosinophilia should be investigated for *PDGFRB* rearrangements by FISH testing.

Once the *PDGFR*A, *PDGFRB*, and *FGFR1* rearrangements are excluded, the only other recurrent secondary abnormalities include

Fig. 56.19 BONE MARROW INTERPHASE NUCLEI AFTER FISH STUDIES USING TRICOLOR PROBE FOR CHROMOSOME 4, BAND REGION q12. The green color covers an approximately 750-kb region centromeric from *FIP1L1*. The red probe is telomeric of the *FIP1L1* gene. The aqua color probe begins between exons 15 and 16 of the *PDGFR*A gene and extends toward the 4q telomere. In normal nuclei, as shown here, the probe appears as two tricolor fusions because of close proximity of probes in interphase DNA. Patients with hypereosinophilic syndrome have fusion of *FIP1L1* and *PDGFR*A genes by interstitial deletion and produce one signal with green-aqua fusion and a missing orange signal. If the translocation involves the *PDGFR*A gene with loci on other chromosomes, the expected signal pattern is one orange-green fusion and one separate aqua signal.

Genetic Testing for Ph-Negative Myeloproliferative Neoplasms

At diagnosis, perform a real-time alleles-specific polymerase chain reaction for *JAK2V617F*, as well as mutational studies for *CALR* and *MPL*. Cytogenetic analysis of marrow cells is recommended for patients with essential thrombocythemia and polycythemia vera. Unstimulated peripheral blood can be used instead of marrow aspirate for patients with primary myelofibrosis. Perform FISH studies with *BCR-ABL1* for patients with thrombocythemia to exclude the diagnosis of chronic myelogenous leukemia. FISH studies can be performed when cytogenetics is uninformative for detection of the most frequent abnormalities: +8, +9, +9p, $del(13)(q14)$, and $del(20)(q11q13)$. A panel of five probes includes CEP9, *CDKN2A/B* at 9p21, D8Z2 as a centromeric probe for chromosome 8, *RBI* for deletion 13q, and *D20S108* for deletion of 20q12. For diagnostic purpose and to monitor treatment response in patients with hypereosinophilic syndrome, perform FISH using triple-color *FIP1L1* probe. For 5q32 rearrangements perform FISH with a *PDGFRB* FISH probe.

trisomy 8 and trisomy 21 (see [box on Genetic Testing for Ph-Negative Myeloproliferative Neoplasms](#)).

In the WHO 2016 classification, *mastocytosis* is no longer listed under Ph-negative MPN. These are rare and heterogeneous diseases characterized by accumulation of clonal mast cells in one or multiple organs. Mastocytosis can affect both children and adults. In most pediatric patients, the disease affects only the skin. In contrast, in most adult patients, the disease is systemic and chronic and almost invariably affects the bone marrow. These cases are called systemic mastocytosis. Over 80% of patients with systemic mastocytosis are characterized by *KIT* mutations, specifically in the activation loop of *KIT*, *KIT* D816V. *KIT* is encoded by a 21-exon-containing gene located on the long arms of chromosome 4, 4q12. Other rare *KIT* mutations have been described in adult and pediatric patients. The knowledge of the type and structure of *KIT* mutation is important because the A-loop mutations D816V/H/Y/N disrupt the structure of the receptor, leading permanently to an active conformation and resistance to imatinib. In patients with advanced systemic mastocytosis other mutations not infrequently include *TET2* (up to 39%), *SRSF2* (up to 36%), *ASXL1* (up to 21%), and *RUNX1* (23%). At diagnosis testing for *KIT* D816V in peripheral blood leukocytes,

using highly sensitive and specific PCR-based assays, is mandatory to determine the *KIT* allelic burden rapidly, which is now used as a gold standard for assessing disease burden.

MYELODYSPLASTIC SYNDROMES

The MDSs (see Chapter 63) are a clinically heterogeneous group of hematologic neoplasms with differing biology and clinical manifestations. They have in common a clonal origin, dysplastic cellular morphology, cytopenias, abnormalities of cellular maturation, and an increased propensity to develop acute leukemia (20%–40%). They predominantly occur in elderly people as a result of multistep pathogenesis. Cytogenetic studies can provide both diagnostic and prognostic information. A chromosomally abnormal clone can be detected in 50% to 60% of patients with de novo MDS and in approximately 90% of patients with therapy-related MDS. There appears to be a correlation between the frequency of chromosomal abnormalities and the severity of disease. Approximately 35% of patients with less aggressive MDS, such as refractory anemia and refractory anemia with ring sideroblasts, have clonal chromosomal rearrangements, whereas approximately 60% to 70% of patients with refractory anemia with excess blasts in transformation have such chromosomal abnormalities. A single or complex chromosomal abnormality may

be present initially, and evolutionary change may occur during the course of the disease. Even at diagnosis, complex genomic lesions involving five or more different chromosomes are not unusual. Despite heterogeneity of chromosomal defects (gain, loss, deletion, amplification, rare balanced translocations, transcriptional silencing via methylation or point mutation), the unifying concept of genetic instability in MDS is hemizyosity of specific genes or chromosomal regions. The most common chromosomal anomalies in MDS involve gain of 1q, del(5q)/-5, del(7q)/-7, trisomy 8, del(11)(q23), del(12p), +13/del(13q), t(11q23), del(12p), del(17p), del(20)(q11q13), +21, and idic(X)(q13).

In 2012 a new cytogenetic classification of MDS was established that includes five different risk groups⁸ (Fig. 56.20 and Table 56.4).

The clinical relevance and the power of conventional cytogenetics in MDS were recognized by the WHO, which documented a strong association between del(5)(q13q33) and 5q- syndrome. The 5q- syndrome is a unique subtype of low-risk MDS with a favorable prognosis, lack of other cytogenetic abnormalities, low rate of leukemic transformation, and more common occurrence in older adult females (see Fig. 56.20, second row).

Among patients who do not have 5q- syndrome (with or without other chromosomal abnormalities), interstitial deletions of the long arms of chromosome 5 occur in 10% to 15% of patients and are among the most frequent chromosomal abnormalities in MDS (see

Fig. 56.20 PROGNOSTIC SIGNIFICANCE OF THE RECURRENT CHROMOSOMAL ABNORMALITIES IN MYELODYSPLASTIC SYNDROME, ACCORDING TO THE NEW COMPREHENSIVE CYTOGENETIC SCORING SYSTEM.

TABLE 56.4 Recurrent Chromosomal Abnormalities in Primary Myelodysplastic Syndrome

Abnormality	Frequency (%)
–5 or del 5q	10–15
–7 or del 7q	10
trisomy 8	10–17

t(2;11)(p21;q23)	<1

Modified from Malcovati et al: *Blood* 122:2943, 2013.

Fig. 56.20, second row). The finding of del(5q) in CD34CD38⁺ cells indicates its occurrence in a stem cell capable of differentiating into myeloid and lymphoid cell lineages, which represents an early event in the pathogenesis of MDS. Data on 1432 patients with del(5q) show a significant amount of heterogeneity in breakpoints. FISH studies delineated a commonly deleted segment that is currently estimated to be 1.5 Mb in size, on 5q31.1. The clustering of genes responsible for growth and differentiation of hematopoietic cells at this site and recurrent nature of –5/del(5q) in MDS caused many investigators to speculate that (a) tumor suppressor gene(s) was/were located in the 5q31 or 5q22–23 band region. To date, the tumor suppressor gene responsible for MDS on 5q has yet to be identified. Because the mechanism causing the interstitial del(5q) is elusive, haploinsufficiency or inactivation caused by methylation, rather than a typical tumor suppressor gene, has been speculated to be involved in this process.

Patients with isolated del(5q) have a more favorable prognosis and live longer than patients with ACAs. Specifically, patients with del(5)(q13q31) live longer than patients with other 5q deletions, indicating that the type of 5q deletion may significantly affect prognosis and response to therapy. Indeed, lenalidomide therapy leads to a normal karyotype in 44% of 148 patients with interstitial del(5q). The effectiveness of lenalidomide has recently been elucidated and attributed to inhibition of haplodeficient gene *PP2A α* , a phosphatase, that plays an essential role in regulation of the G2/M checkpoint. Lenalidomide inhibits *PP2A*, which in turn causes P53 degradation and restores cell-cycle reentry.

In de novo MDS, isolated monosomy 7 or 7q deletion (see **Fig. 56.20**) occurs in 20% of patients. Frequently, chromosome 7 abnormalities occur with ACA, most commonly rearrangements of 3q or del(12p) (see **Fig. 56.20, third and fourth row**). Monosomy 7 is present in all MDS subtypes and is seen predominantly in males. In pediatric patients with constitutional disorders associated with a predisposition to develop AML including Fanconi anemia, congenital neutropenia, neurofibromatosis type 1, Down syndrome, or Kostmann syndrome, –7/del(7q) may be seen as an isolated abnormality. Therefore the question remains to whether these patients have genetic imprinting and preferentially lose chromosome 7. Unequivocal evidence exists that shows that preferential parental origin of the missing chromosome 7 does not occur; approximately half of the patients have loss of either the maternal or paternal homologue, excluding the genomic imprinting hypothesis. Embryonic origin of partial chromosome 7 deletion in monozygotic twins with juvenile chronic myelomonocytic leukemia has been reported. As shown in **Fig. 56.21**, acquired UPD of 7q is a known recurrent genomic rearrangement in

Fig. 56.21 ARRAY COMPARATIVE GENOMIC HYBRIDIZATION PLUS SINGLE-NUCLEOTIDE POLYMORPHISM FROM A PATIENT WITH MYELODYSPLASTIC SYNDROME AND NORMAL CHROMOSOME 7. Note acquired uniparental disomy (UPD) of the long arms of chromosome 7, known to be associated with worse prognosis.

MDS not detected cytogenetically and often detected in patients showing either a normal karyotype or other abnormalities.

According to the cytogenetic classification of MDS, patients with del(7q) as a single abnormality have a distinct clinicopathologic profile with an overall better prognosis than seen in patients with an isolated monosomy 7. Isolated del(7q) is more frequent in patients with less advanced forms of MDS according to the WHO classification or the International Prognostic Scoring System (IPSS). They have fewer blasts in the bone marrow than other cytogenetic groups and display a significantly superior survival when compared with patients with isolated monosomy 7. The presence of ACA in patients with del(7q) is associated with shortened OS (see **Fig. 56.20, third row**). Allele typing studies implicated three regions that are most frequently deleted: 7q22, 7q31.1, and 7q31.3. Cytogenetic results indicated that retention of 7q31 band may be associated with longer survival. Consequently, there is speculation that a putative myeloid suppressor gene(s) is located in the regions that are frequently deleted. Because prototypic tumor suppressor genes have not been identified in patients with 7q deletions, an alternative explanation may be haploinsufficiency whereby the level of protein is critical, or a complex of two cooperating proteins is affected as a result of inactivation caused by methylation.

Trisomy 8 (see **Fig. 56.20, third row**) is the third most frequent chromosomal abnormality in MDS. As a sole abnormality, it is found in 11% of patients with MDS and overall is found in 17% of patients. A significantly higher incidence of trisomy 8 occurs in males than in females. Trisomy 8 is present in all age groups of patients with MDS. Although trisomy 8 is detected in the hematopoietic stem cells of patients with MDS, a sizable fraction of stem cells are disomic but functionally abnormal, suggesting that the trisomy 8 acquisition is a secondary event. These findings provide evidence for a multistep pathogenesis of MDS, whereby gain of chromosome 8 is not an early event in the stepwise disease evolution. Although trisomy 8 carries an intermediate risk when detected at diagnosis, patients with MDS with trisomy 8 treated with the hypomethylating agent 5-azacitidine have a significantly better survival than patients with other chromosomal abnormalities.

The first series of patients with MDS or MDS/MPN associated with trisomy 11 as a sole abnormality or as a part of noncomplex karyotype was recently reported. This rare recurrent abnormality has an overall frequency of approximately 0.3% and is associated with a significantly inferior survival in patients with IPSS intermediate-risk

disease ($p = .0002$) but comparable to the poor-risk group ($p = .97$). Trisomy 11 is associated with clinical aggressiveness and represents a high-risk cytogenetic abnormality.

Deletions of 17p are seen in 3% to 4% of MDS and AML patients. These patients often display several other chromosomal rearrangements, including monosomy 17, isochromosome 17q (see Fig. 56.20, *third row*), and unbalanced translocations between chromosome 17 and another chromosome. Approximately 30% of these deletions are related to therapy. The extent of 17p deletion in all cases involves the *TP53* gene. There appears to be a close correlation between dysgranulopoiesis (e.g., pseudo-Pelger-Huet hypobulbation) and small vacuoles in neutrophils with 17p abnormalities and *TP53* deletion. The median survival of these patients is poor.

An isodicentric X chromosome in Xq13-idic(X) is a rare but recurrent abnormality that has been associated with refractory anemia with ringed sideroblasts. All MDS patients with idic(X)(q13) are females, most likely because the formation of idic(X) would result in nullisomy for Xq13-qter in males. The median age at the time of diagnosis is 73.5 years. The outcome of idic(X)-positive cases is variable; some investigators report aggressive and rapidly fatal disease and others a relatively favorable clinical course with survival for several years. The fact that idic(X) most often occurs as the sole cytogenetic abnormality suggests that it may in itself be sufficient for leukemogenesis. Using a high-resolution SNP array, the breakpoints on idic(X)(q13) were mapped into two distinct breakpoint clusters,

at approximately 70.9 Mb (five cases) and 72.1 Mb (seven cases) on the X chromosome. None of the 11 breakpoints occurred in a gene, strongly indicating that the idic(X)(q13) does not result in a fusion gene. Instead, the functional outcome of the abnormality confers a gene dosage effect because of the concurrent gain of Xpter-q13 and loss of Xq13-qter. This region of the X chromosome is enriched for repeated sequences and most likely, these repeats may facilitate the formation of idic(X). The isodicentric X chromosome was inactive in some patients and active in other patients; hence idic(X) appears to be leukemogenic regardless of X_a or X_i involvement.

Gain of 1q, usually in the form of an unbalanced translocation, is a recurrent abnormality in MDS and appears to be a marker of disease progression. Specifically, the gain of 1q in the form of jumping translocations either at diagnosis or the subsequent acquisition of jumping 1q translocations appears to be associated with imminent transformation to AML in patients after an average of 9 months (Fig. 56.22). Once acquired, the patient's prognosis tended to be dependent on the copy number of 1q, indicating that gain of jumping 1q translocations was associated with both disease progression and poor prognosis. In MDS, the average time to develop jumping 1q was less than 2 years. Treatment (azacitidine, chemotherapy, or stem cell transplant) may temporarily reduce or eradicate the clone, but the responses were not durable. These findings did not provide any common pattern as to the role of the partner chromosomes in unbalanced jumping 1q translocations. However, 81% of recipient

Fig. 56.22 GAIN OF LONG ARMS OF CHROMOSOME 1 IN MYELOYDYSPLASTIC SYNDROME AND MYELOPROLIFERATIVE NEOPLASM PATIENTS. Partial karyotypes in these six cases represent examples of gain or duplication of 1q. Trisomy 1q in the form of der(13) with an extra 1q is translocated to the terminal portion of the long arms of chromosome 13; (B) Gain of 1q in the form of der(6) whereby the entire long arms of 1 are translocated to the short arms of chromosome 6; (C) Two copies of der(6) resulting in tetrasomy 1q in a patient with an advanced myelodysplastic syndrome; (D) Duplication of region 1q12–q21 in a patient with essential thrombocytopenia; (E) Trisomy 1q translocated to the short arms of chromosome 9 resulting in a gain of 9p and 1q in a patient with polycythemia vera (PV) who transformed to myelofibrosis. This is a PV-specific and recurrent abnormality. (F) Trisomy 1q translocated to the terminal portion of the Y chromosome.

Fig. 56.23 CHROMOSOME 3 ABNORMALITIES IN MYELODYSPLASTIC SYNDROME (MDS). (A) A partial karyotype from a patient with MDS showing a recurrent $t(3;3)(q21;q26)$. In this rearrangement metaphase FISH showed on the left, *RPN1* (green) and a part of *MECOM* (red) gene on 3q21 giving an impression of a “yellow” signal because of their proximity on a metaphase chromosome. The right chromosome 3 shows *RPN1* (green) at 3q21, part of *RPN1* (green) and *MECOM* (red) on 3q26 as well as untranslocated *MECOM* translocated from the left chromosome 3 homolog. (B) An unusual chromosome 3 rearrangement in MDS showing a deletion of 3q11–q13 region, followed by inversion with two breakpoints at p21 and q21.2. All three genes *RPN1* (green), *MECOM* (red), and *BCL6* (yellow) remained in their normal loci.

breakpoints were localized in pericentric regions whereas the remaining 19% were telomeric fusions. Decondensation of pericentromeric heterochromatin of chromosome 1 together with centromere and repeat DNA sequences interspersed with histones and acetylated sequences may favor illegitimate recombinations leading to jumping 1q translocations. Moreover, exposure to azacitidine has been shown to be associated with alterations of pericentromeric heterochromatin of chromosome 1, as well as an increase in Alu DNA repeats. Hypomethylation of 1q12–21 pericentromeric region of chromosome 1 appears to be at least one aspect of copy number gains of 1q.

The most frequent rearrangement of chromosome 3 involves two bands on chromosome 3—band 3q21 and 3q26 simultaneously—which produces either $t(3;3)(q21;q26)$ or $inv(3)(q21;q26)$ (see Fig. 56.20, fourth row and Fig. 56.23). These chromosomal rearrangements are present in de novo and therapy-related MDS, as well as in AML and megakaryoblastic crisis of CML. The incidence of the 3q rearrangements is 2% to 5%. Characteristic clinical features include an elevated platelet count, marked hyperplasia with dysplasia of megakaryocytes, and a poor prognosis with minimal or no response to chemotherapy and a short survival. In addition to similar clinicopathologic features, patients with 3q21q26 share molecular heterogeneity in both the breakpoints and the expression pattern of the genes near these breakpoints (see Fig. 56.23 and Fig. 56.24). The chromosomal breakpoints, defined by FISH, in 3q26 are scattered over several hundred kilobases in either the 5' or the 3' region of the *EVII* gene, whereas the breakpoints in the 3q21 region are restricted to two smaller different genomic clusters approximately 100 kb downstream of the *RPN1* gene (see Figs. 56.23 and 56.24). *EVII* overexpression is observed in the majority of patients, but some patients with the 3q21q26 rearrangement do not have detectable *EVII* expression, and at least 9% of patients with AML without 3q26 abnormalities overexpress *EVII*. Therefore the poor prognosis of these patients may be independent of *EVII* expression, despite the fact that extensive 3q26 breakpoint FISH mapping of both metaphases and interphase nuclei suggests *EVII* involvement in numerous novel sporadic and recurrent 3q26 rearrangements. A fusion transcript of *RPN1-EVII* is rarely observed in patients with 3q21q26 rearrangements. Interestingly, functional genomic studies and allelic-specific analysis revealed experimentally that $inv(3)/t(3q)$ results simultaneously in haploinsufficiency of *GATA2* and upregulation of *EVII* as a result of rearrangements in noncoding regulatory sequences of these

genes, indicating the importance of mutations residing outside the coding exome.

A monosomal karyotype (MK), a new cytogenetic category, is defined as a karyotype showing two or more distinct autosomal chromosome monosomies or one single autosomal monosomy (excluding isolated loss of X or Y) in the presence of a structural abnormality (see Fig. 56.20, bottom row). Initial reports indicated that the MK in MDS, with or without monosomy for chromosomes 5 and 7, was prognostically worse than other complex karyotypes, although later reports could not confirm these results. The reason may be that treatment with azacitidine may have reduced the negative impact of MK in high-risk patients with MDS.

The clinical significance of loss of the Y chromosome, observed in 10% of patients with MDS and approximately 7% of older adult males without MDS, is undefined. Older adult males with MDS and loss of Y chromosome who achieve complete hematologic remission regain the Y chromosome in their marrow cells.

The prognosis of patients with MDS is very heterogeneous. In 1997, based on the cytogenetic abnormalities identified in 816 patients with MDS, as well as percentage of blasts and number of cytopenia, an IPSS was proposed.⁹ According to the IPSS, 86% of all cytogenetic findings can be explicitly classified according to their prognostic impact. The system is highly reproducible and very simple to use, but it has certain limitations. Moreover, in the remaining 14% of patients with cytogenetic abnormalities the chromosomal abnormalities had unknown prognostic significance (Fig. 56.25). This limitation underscores two major cytogenetic classification problems in MDS: the profound heterogeneity of acquired cytogenetic aberrations in MDS and the associated challenge of designing a comprehensive cytogenetic scoring system that predicts the prognostic impact of rare abnormalities. A new and comprehensive cytogenetic scoring system based on an international data collection of 2902 patients was recently proposed (see Fig. 56.20). Patients included were from the German-Austrian MDS Study Group ($n = 1193$), the International MDS Risk Analysis Workshop ($n = 816$), the Spanish Hematological Cytogenetics Working Group ($n = 849$), and the International Working Group on MDS Cytogenetics ($n = 44$) databases. In total, 19 cytogenetic categories were defined, providing clear prognostic classification for 91% of all patients. All abnormalities were arranged according to OS and development of AML to classify their prognostic impact. The abnormalities were classified into five prognostic subgroups: very good ($n = 81$) included $del(11q)$ and loss of Y chromosome (median OS, 61 months); good ($n = 1809$) included normal karyotype, $del(5q)$, $del(12p)$, and $del(20q)$ (all as single anomaly) and double abnormalities including $del(5q)$ (median OS 49 months); intermediate ($n = 529$) included $del(7q)$, +8, $i(17q)(q10)$, +19, +21, any other single abnormality, independent clones, and double abnormalities not harboring $del(5q)$ or $-7/del(7q)$ (median OS 26 months); poor ($n = 148$) included $inv(3)/t(3q)/del(3q)$, -7, and double abnormalities including $-7/del(7q)$ and complex (three abnormalities; OS of 16 months); and very poor ($n = 197$) included complex karyotypes with more than three abnormalities (OS of 6 months) (see Fig. 56.20). This new scoring system proposed should be viewed as a dynamic model, open to further refinement as the knowledge in karyotypic abnormalities of MDS continues to evolve.¹⁰

Cytogenetic and FISH studies have relatively similar sensitivities in detecting an abnormal clone among patients with MDS. A FISH test for targeted recurrent abnormalities in MDS should use probes to detect numerical and structural anomalies of chromosome regions 1q, 3q, 5q, 7, 7q31, 8, 11q, 12p, 13q, 17p, 20q, and 21. Occasional patients with normal karyotype show an occult neoplastic clone by FISH. On the other hand, using conventional cytogenetic studies, some patients exhibit a neoplastic clone that is not detected by FISH (see box on Genetic Testing for Myelodysplastic Syndrome and Fig. 56.20).

Familial MDS is very rare. However, a recent description of four families with telomerase mutations, both in the RNA component (TERC) and in the reverse transcriptase component (TERT), has raised the awareness of the pathologic role of telomerase mutations

Fig. 56.24 RING CHROMOSOMES IN MYELOYDYSPLASTIC SYNDROME (MDS) AND OTHER HEMATOLOGIC MALIGNANCIES. (A) Ring 3 of one homolog and deletion 3p and duplication 3q of another homolog 3 in a patient with MDS and a complex karyotype. (B) A gain of ring of chromosome 8 in a patient with acute lymphoblastic leukemia. Metaphase FISH revealed amplification of *FGFR1* (red) and *D8Z2* (green) and loss of chromosome 8 region telomeric from 8p12 and below centromere (green) resulting in almost total loss of 8p and 8q because *MYC* (aqua) at 8q24 was deleted in r(8). r(18) with breakpoints at p11 and q21 in a patient with acute myeloid leukemia at diagnosis. Metaphase FISH revealed that *SYT*, *MALT1* and *BCL2* were retained in the ring 18. (D) Two different ring 21, as revealed by multicolor FISH in a patient with hairy cell leukemia and a complex karyotype. (E) Ring 11 in a patient with MDS. (F) Two different ring 11 in a patient with multiple myeloma. Metaphase FISH revealed *MLL* amplification (yellow) but not amplification of *CCND1* (red), *IGH* (green), or centromere 11 (aqua). (G) ring of chromosome 7 in a patient with T-cell leukemia. *TCRB* and *TCRG* are localized at 7p14 and 7q34, respectively.

in development of MDS/AML. The telomerase activity of the mutations identified in the four of 20 families with familial MDS/AML was between 0% and 11% of the wild-type levels. Patients with telomerase mutations have short telomeres. The recognition of familial MDS/AML arising from constitutional mutations in *TERC* or *TERT* is important because these mutations probably act as disease initiating mutations. Moreover, subsequent generations present with increasingly more severe phenotypes at an earlier age so that each successive generation inherits progressively shorter telomeres, which increasingly promote genomic instability and may lead to earlier development of marrow failure, MDS, or AML. The recommendation is that inherited lesions always be considered in a young patient presenting with MDS, even in the absence of preexisting morphologic or hematologic abnormalities. Another constitutional abnormality that appears to predispose to MDS/AML is a deletion of band region q22.1–q22.2 of chromosome 21 with a complex phenotype (dysmorphic features, organ malformations, growth delay, and mental retardation), germline *RUNX1* deletion, and congenital thrombocytopenia. Three of nine reported patients subsequently developed MDS/AML.

Table 56.5 shows the acquired recurrent somatic mutations observed in patients with MDS. According to the European Leukemia

Net report 52% to 74% of patients with a normal karyotype have at least one genomic point mutation or MDS-related copy number change as detected by aCGH + SNP or genomic sequencing. When sequencing and cytogenetics were combined, 78% of MDS patients were found to have acquired genetic lesions. Most recently, Haferlach and colleagues screened MDS patients for known and putative mutations and deletions in 104 genes using targeted NGS and aCGH. They found 90% of patients harbored at least one mutation. Univariate analysis revealed that mutation in 25 genes had an effect on survival.

MDS is a disease of older people with a median age at diagnosis of 65–70; less than 10% of the patients are younger than 50 years. Using SNP array data from 50,000 subjects recruited for genome-wide association studies demonstrated that 0.5% of healthy individuals possessed genomic lesions. In contrast, recent whole-exome sequencing data of DNA from the peripheral blood of 17,182 persons showed clonal mutations leading to clonal outgrowth of hematopoietic cells in 10% of persons over the age of 70 years and in 18.4% among people aged 90–108 years. The most commonly mutated such genes were *DMT3A*, *TET2*, and *ASXL1*, which are frequent mutations in MDS and AML. These elderly people with clonal

Fig. 56.25 A GAIN OF *JAK2* IN A PATIENT WITH MYELODYSPLASTIC SYNDROME (MDS). A bone marrow karyotype (*left panel*) from a patient with MDS showing a 49, XY, add(9)(p12), +der(9)del(9)(p12p24)del(9)(q12q34)der(21)t(9;21)p21p24;p11, +der(21)t(9;21)(p21p24;p11)x2. FISH testing with *JAK2* (*top part*) and *CDKN2A* and centromere 9 (*bottom panel*) revealed 70% of cells to have a deletion of 9p, including *CDKN2A* and four copies of unrearranged *JAK2*, suggesting that in some patients with MDS the underlying mechanism may be a gain of *JAK2*.

TABLE 56.5 Recurrently Mutated Genes in Myelodysplastic Syndrome

Gene	Chromosomal Location	Frequency (%)	Prognosis
<i>SFRB1</i>	2q33.1	25–30	Favorable?
<i>TET2</i>	4q24	20–25	Neutral

Modified from Malcovati et al: *Blood* 122:2943, 2013.

Genetic Testing for Myelodysplastic Syndrome Disorder

The best genetic test at diagnosis is conventional cytogenetic studies. FISH for targeted loci is useful for some clinical situations, such as marrow samples lacking analyzable metaphases, or to follow the percentage of abnormal cells with known cytogenetic anomalies for patients undergoing treatment (see Fig. 56.20 for selection of appropriate fluorescence in situ hybridization probes). Integrating cytogenetics, FISH and microarray comparative genomic hybridization (CGH), particularly in patients with a normal karyotype, allows greater confidence in detection of genomic change fostering improved patient-specific management.

mutations in their peripheral blood did not have MDS or any other hematologic malignancy, indicating that age-related clonal hematopoiesis is a common premalignant condition and individuals with clonal mutations have an increased risk of developing hematologic malignancy.

ACUTE MYELOID LEUKEMIA

AML refers to a group of heterogeneous diseases with respect to clonality, molecular lesions, chromosomal aberrations, and response to treatment (see Chapter 59). Initially, using G6PD as a marker of clonality, it was determined that AML originates from a single clone and has a multistep pathogenesis. In adults, at the time of diagnosis all hematopoietic cell lineages are clonal. In children younger than 16 years, erythroid cells and platelets often are not part of the leukemic clone.

The application of nucleotide-polymorphism technologies has confirmed the clonal origin of AML and have further revealed that most, if not all, patients with AML evolve through a process of

constrained clonal evolution. Multicolor metaphase analysis, FISH, CGH arrays, SNP arrays, PCR arrays, and NGS have all greatly improved detection of subclones and established the concept of a clonal hierarchy in AML. To understand the branching evolution of AML development, each mutation must be placed in the context whether it is a “driver” versus “passenger” and an “initiation” versus “progression” event. Driver mutations directly affect the biology of the cell, whereas passenger mutations do not. Initiation mutations are present within the founding clone and are found in all AML cells. Progression mutations emerge during leukemic evolution, can be found as subclones, and exist in only a fraction of AML cells. Selection pressure, such as chemotherapy, can favor the elimination or outgrowth of different branches within the AML evolutionary hierarchy.

Modern genomic technologies have provided a better understanding of normal and leukemic hematopoiesis. A subset of AML cases evolves from a preceding clinically overt phase such as MDS by subclonal evolution with an increased number of genomic changes. The founder mutations present in preleukemic cells are retained in AML blasts, implicating them as putative initiating events and establishing clonal expansion as the first step in leukemogenesis. However, some recurrent leukemia-associated somatic mutations, such as *TET2*, have been also linked to multilineage clonal hematopoiesis in aging healthy individuals. For the majority of de novo AML without any prior clinical symptoms, the cell of origin, and biologic consequences of initiating mutations and order of subsequent mutations remain poorly understood. Recent evidence revealed that approximately 25% of adult AMLs are associated with *DNMT3A* mutations, which occurs in preleukemic hematopoietic stem cells before acquiring additional mutations such as *NPM1*. These initiating *DNMT3A* mutation-carrying cells persist during remission suggesting that preleukemic hematopoietic stem cells are resistant to induction chemotherapy and may represent a reservoir from which a future relapse develops.

Initial observations by the International Workshop on Chromosomes in Leukemia asserted that cytogenetic findings may serve as the single most important prognostic marker in AML; these observations were subsequently validated through studies conducted by the Medical Research Council (MRC), the Cancer and Leukemia Group B (CALGB), and the Southwest Oncology Group. Finally, in 2008, the WHO incorporated cytogenetic findings along with morphology, immunologic markers, and molecular genetics into their classification system. Cytogenetics is the most powerful independent prognostic factor in AML and provides the framework for risk stratification schemes that have been generally adopted to guide treatment approach. Based on karyotype status, two major groups of AML can be distinguished: (a) those with an abnormal karyotype, which accounts for approximately 52% of patients, and (b) those with a normal karyotype by conventional cytogenetics, which accounts for 48% of patients with AML.

Acute Myeloid Leukemia with a Normal Karyotype

Patients with AML with a normal karyotype who present between the ages of 16 and 60 years carry an intermediate prognosis. However, cytogenetically normal AML is highly heterogeneous at the molecular level, both mutations and overexpression of single genes have been identified, and their complex interactions are frequently refined to provide more accurate risk stratification. Within the normal cytogenetic category, 45% to 62% of patients with AML have nucleophosmin 1 (*NPM1*) mutations, 25% to 35% show *FLT3* mutations, 5% to 10% have *MLL* tandem duplications, and 8% to 15% have *CEBPA* mutations. The prognosis of patients with normal karyotype differs in the presence of each of these mutations (Table 56.6). Patients with *NPM1* mutations alone have a favorable prognosis, with 60% of patients living longer than 11 years. Even in patients age 70 or older, the presence of an *NPM1* mutation is an independent predictor of a more favorable outcome. More than 20 different mutations have been described in the C-terminal portion of the protein that lead to loss

TABLE 56.6 Gene Mutations in Patients with Acute Myeloid Leukemia and a Normal Karyotype

Gene	Chromosomal Location	Frequency (%) of Patients With Normal Karyotype	Prognosis
<i>NPM1</i>	5q35	45–62	Favorable, increased CR rates and prolonged OS in the absence of <i>FLT3</i> mutation
<i>FLT3-IDT</i>	13q12	25–35	Unfavorable, specifically when the mutant to WT allelic ratio is high
<i>FLT3-TKD</i>	13q12	7–10	Controversial
<i>CEBPA</i>	19q13.1	15	Favorable
<i>MLL-PTD</i>	11q23	10	Not known
<i>IDH1</i>	2q33.3	15–20	Most likely unfavorable
<i>IDH2</i>	15q26.1	20	Most likely unfavorable
<i>DNMT3A</i>	2p23.2	36	Most likely unfavorable
<i>TET2</i>	4q24	5	Likely unfavorable
<i>ASXL1</i>	20q11.21	9–10	Inferior outcome

CR, Complete remission; OS, overall survival.

of tryptophan residues and generation of a nuclear export signal that acts in concert to cause delocalization of *NPM1* from the nuclei to the cytoplasm. Because the functional integrity of *NPM1* is dependent on its ability to shuttle between the nucleus and cytoplasm, this ability is severely compromised in *NPM1*-mutated AML. *NPM1*-mutated AML is associated with distinctive biologic and clinical features including older age, female predominance, multilineage involvement, extramedullary disease, high blast percentages and increased white blood cell counts, and lack of CD34 expression. As an isolated molecular abnormality, *NPM1*-mutated AML is associated with a highly favorable prognosis, with complete remission (CR) rates between 70% and 80%. The most common mutation (type A, accounting for 75% of all mutations) generates an aberrant extra nuclear export signal. Although *NPM1* mutations are heterozygous, hetero/homodimerization with wild-type *NPM1* results in cytoplasmic mislocalization of both mutant and wild-type protein. This alteration in subcellular location perturbs normal *NPM1* function, including the mislocalization and stabilization of critical proteins such as the TP53 regulator p14ARF, and leads to transformation. This process also generates a distinct transcriptional signature in *NPM1* AML that facilitates the generation of leukemia. *NPM1* mutation is considered to be an early event in the pathogenesis of AML. In childhood AML with normal cytogenetics, *NPM1* mutations are relatively uncommon, occurring at a frequency of 8%.

In contrast, the presence of *FLT3* and *MLL* mutations are associated with an adverse prognosis, and coexistence of *FLT3* and *NPM1* does not improve the prognosis. Internal tandem duplications (ITDs) of the *FLT3* gene confer an increased risk for relapse and death when compared with patients without *FLT3*-ITD. Three types of *FLT3* gene changes are present, ITD of the juxtamembrane domain-coding sequence, a point mutation within the activation loop domain and the copy-neutral loss of heterozygosity. Although both mutations lead to the constitutive activation of the receptor, only presence of *FLT3*-ITD with high allelic ratio has been associated with an inferior outcome. This mutation initially develops as a heterozygous mutation and over time the *FLT3*-ITD blasts acquire copy-neutral loss of

heterozygosity resulting in homozygous mutated allele and high *FLT3*-ITD allelic ratio.

Intact functioning of the CCAAT/enhancer binding protein (*CEBPA*) gene is essential for normal granulocytic differentiation. It is a lineage-specific transcription factor that is required for the formation of committed myeloid progenitors from multipotent progenitor cells. *CEBPA* execute this function by coupling the direct transcriptional activation of myeloid-specific genes with the arrest of cell proliferation. *CEBPA* is an intronless gene whose mRNA can be translated into two different AUG codons to give rise to two distinct isoforms, p42 and p30. Only the p42 isoform of *CEBPA* can promote proliferation arrest. *CEBPA* mutations, leading to arrest of differentiation, are seen in 5% to 10% of de novo AML and in up to 15% of normal karyotype AML. Only mutations affecting both alleles, double mutations, confer superior survival as compared to single mutations. Concomitant *GATA1* and *WT1* mutations are seen more often in double mutants while *FLT3*-ITD, *NPM1*, *ASXL1*, and *RUNX1* are mutations more commonly associated with single mutations, possibly contributing to the poorer prognosis.¹¹

A rare but specific subset of adult AML can be defined by the cytogenetically cryptic *NUP98-NSD1* fusion gene that involves the nucleoporin gene 98 (*NUP98*) on chromosome 11p15, and the nonhomeobox gene *NSD1* present on chromosome 5q35. *NUP98* encodes a 98-kDa protein of the nuclear pore complex, and is known to fuse with at least 21 different fusion gene partners in chromosomal rearrangements in various hematologic malignancies. *NSD1* is thought to function both as a transcriptional co-activator and a co-repressor. Among 293 pediatric and 808 adult cytogenetically normal cases of AML the *NUP98-NSD1* fusion gene has been described in 16.1% of pediatric and 2.3% of adult AML cases. Apparently *NUP98-NSD1* has been shown to correlate with *FLT3*-ITD, which is associated with increased blast percentages.

TET2 proteins are necessary for the conversion of 5-methylcytosine to 5-hydroxymethylcytosine and play a role in demethylation processes within the cell. *TET2* mutations have been reported in 10% to 23% of patients with AML with a normal karyotype. The impact of *TET2* mutations on the prognosis and outcome remains poorly defined.

DNMT3A mutations, which affect the DNA methyltransferase enzymes and subsequent epigenetic modulation, have been described in about 27% to 33% of normal karyotype AML and are associated with a worse OS (see earlier sections on Clonal Origin and Early Mutations).^{12,13}

Currently, a newly diagnosed patient with AML and a normal karyotype should be checked for more common mutations such as *FLT3*, *NPM1*, *CEBPA*, *RUNX1*, *MLL-PTD*, or *EVII*, *TET2* and *DNMT3A*, which may have prognostic and possibly therapeutic implications. Patients with overexpression of other single genes should stay, until more data are collected, in a research setting of clinical trials (Table 56.6).

Acute Myeloid Leukemia with an Abnormal Karyotype

Among patients with an abnormal karyotype, 25% have balanced translocations and 27% showed unbalanced abnormalities or a complex karyotype.

The pretreatment karyotype in AML constitutes an independent prognostic determinant for attainment of CR and risk for relapse and survival. Four broad cytogenetic risk categories of AML are useful in clinical practice: favorable, intermediate, unfavorable, and unknown (Figs. 56.26 and 56.27 and Table 56.7). It is important to perform appropriate cytogenetic and FISH studies to establish the correct cytogenetic risk category.¹⁴ Table 56.8 lists 72 of approximately 250 recurrent chromosomal translocations in leukemia, including AML

Fig. 56.26 PROGNOSTIC CYTOGENETIC RISK CATEGORIES IN ACUTE MYELOID LEUKEMIA. Favorable prognosis includes *t*(8;21) and *ETO-AML1* fusion, *t*(15;17) and *PML-RARA* fusion, and *inv*(16) and rearrangements of *CBFβ* on 16q22. Trisomy 8 is associated with intermediate prognosis. Unfavorable cytogenetic risk categories include monosomy 5/*del*(5q), *-7/del*(7q), and translocations of 11q23 and *MLL*, represented here by *t*(6;11), and the Philadelphia chromosome.

Fig. 56.27 INTEGRATION OF CYTOGENETIC ABNORMALITIES AND MOLECULAR MARKERS TO REFINE RISK GROUPS IN ACUTE MYELOID LEUKEMIA. (Reprinted from Smith ML, Hills RK, Grimwade D: Independent prognostic variables in acute myeloid leukemia. *Blood Rev* 25:39, 2001; with permission.)

TABLE 56.7

Modification of European Leukemia Net Prognostic System in Acute Myeloid Leukemia

Prognostic Group	Subset	CR rate; relapse with 3+7 without HCT	Comments
Favorable	inv(16)/t(16;16) NK and NPM1+/FLT3 ITD-NK and CEBPA +/-	>80%–90%; 35%–40%	Outcome worse in older patients, with t-AML, KIT mutations, and poor response to initial therapy
Intermediate	Mutated NPM1 and FLT3-ITD (without adverse-risk genetic lesion), t(9;11)(p21.3;q23.3)/MLL-KMT2A Cytogenetic abnormalities Not in favorable or adverse group FLT3 ITD+	50%–80%; 50%–60%	Outcome worse in older patients, with t-AML, and poor initial response Outcome worse in older patients, with t-AML, and poor initial response
Adverse	–5, –7, 5q abn, 3q, 17p, 11q (other than 9;11), t(6;9), complex, monosomal karyotype, wild type NPM1 and FLT3-ITD, Mutated RUNX1, Mutated ASXL1 and mutated TP53, insufficient metaphases for analysis	<50%; >90%	Outcome worse in older patients, with t-AML, and poor initial response

CR, Complete remission; HCT, hematopoietic cell transplant; NK, normal karyotype, +/-, double mutation.

and excluding *MLL* translocations (see later) (see Fig. 56.26). Because of their specific association with distinct subtypes of leukemia, some AML-specific translocations have been incorporated into the WHO classification as criteria for subclassification of AML, including t(8;21), t(15;17), inv(16), and 11q23 rearrangements, regardless of the morphology or percentage of blast cells.

Two specific cytogenetic types of AML—t(8;21)(q22;q22) and inv(16)(p13q22) or t(16;16)(p13;q22) (see Fig. 56.27)—are called *core-binding factor (CBF)* AMLs and are usually grouped in clinical studies because of similarities between their molecular and prognostic features. However, the morphologic features of these two AML subtypes are very different, suggesting that individual approaches may enhance clinical benefits in future studies. Patients with t(8;21) exhibit large myeloid blasts with abundant basophilic cytoplasm, numerous azurophilic granules, and occasional Auer rods. Patients with 16q22 abnormalities show variable numbers of eosinophils, usually in increased numbers, in all stages of maturation. The immature eosinophilic granules are larger than normal and may contain purple-violet cytoplasmic granules. The t(8;21) subtype may be present alone, although 30% to 35% of patients also display loss of Y chromosomes in males and loss of X chromosome in females (see Fig. 56.26, top left). Another 20% of patients with t(8;21) have a deletion of 9q12–23, including a commonly deleted segment that spans 7 to 8 Mb. Trisomies for chromosomes 4 and 8 together with t(8;21) are observed in 6% to 10% of patients. Virtually all patients with t(8;21) achieve CR. Additional cytogenetic abnormalities, irrespective of their nature or complexity, do not have a deleterious effect on rates of remission, relative risk of relapse, and OS. The t(8;21)

interrupts two genes—*RUNX1* (*CBFA2*) on chromosome 21, band q22, in intron 5, and *RUNX1T1* (*ETO* [eight, twenty-one gene], on chromosome 8, band q22—and joins them to form a new chimeric gene on the abnormal der(8) chromosome. *RUNX1* is a gene on chromosome 21, also known as *CBFA2* because it encodes for a DNA-binding component of CBF and binds DNA through a specific sequence called the *runx domain*. The *RUNX1* gene locus on chromosome 21 spans 120 kb; the *RUNX1T1* gene on chromosome 8 is distributed over 87 kb.

The *RUNX1* gene has been identified in more than 39 chromosomal translocations in leukemia and plays a critical role during hematopoiesis (see different *RUNX1* chromosomal partners: <http://atlasgeneticsoncology.org/Genes/AML1ID52.html>). The fusion gene is located on the partner chromosome in the majority of *RUNX1* translocations. Its disruption is associated with the development of myeloid and lymphoid leukemias. Therefore *RUNX1* is viewed as a master regulatory switch that controls development of a definitive hematopoietic lineage. Moreover, the *RUNX1* transcription factor is critical for proliferation and differentiation of hematopoietic stem cells. Haploinsufficiency of *RUNX1* has been linked to a propensity to develop AML, and biallelic nonsense mutations in the *RUNX1* gene have been identified in the primitive AMLs of the French-American-British (FAB) M0 subtype. The *RUNX1T1* protein belongs to the ETO family of proteins involved in protein–protein interactions but not in protein–DNA interactions.

In the hybrid *RUNX1-RUNX1T1* protein, the C-terminus of *RUNX1* is replaced by the entire *RUNX1T1* protein. The main functional characteristic of *RUNX1-RUNX1T1* chimeric protein is

ACC/BC, Accelerated blast crisis; AL, Acute leukemia; aCML, atypical CML; ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; APL, acute promyelocytic leukemia; CBF, core-binding factor; CEL, chronic eosinophilic leukemia; CML, chronic myelogenous leukemia; CMML, chronic myelomonocytic leukemia; HES, hypereosinophilic syndrome; JMML, juvenile myelomonocytic leukemia; MDS, myelodysplastic syndrome; MLS, myelodysplastic syndrome; MPD, myeloproliferative disorder; MPN, myeloproliferative neoplasm; T-ALL, T-cell ALL; t-AML, therapy-related AML; t-MDS, therapy-related MDS.

its ability to bind DNA containing RUNX1 binding sites and thereby exert a dominant negative inhibition of the endogenous RUNX1 protein. The exact role of the RUNX1-RUNX1T1 fusion protein in determining the onset and progression of AML is not fully understood; however, accumulating evidence indicates that even a point mutation in the RUNX1 protein, responsible for assembling and organizing the machinery for hematopoietic gene expression at multiple sites in target genes, results in a block of differentiation of

myeloid progenitors to granulocytes. *RUNX1* mutations are present in 46% of patients with AML with the M0 subtype and in 80% of patients with AML with trisomy 13. As mentioned earlier, the *FLT3* gene is localized on chromosome 13, and quantitation of *FLT3* transcript levels is associated with a fivefold increase in patients with *RUNX1* mutations and trisomy 13 compared with patients without trisomy 13. The exact relationship between *FLT3* and *RUNX1* in leukemogenesis remains unknown. Multiple copies of *RUNX1*/

Fig. 56.28 DUPLICATION OF $t(8;21)$. Four copies of ETO-AML1 (*RUNX*) fusion (yellow) shown in two interphase cells (top) from a patient with acute myeloid leukemia and $t(8;21)$ (bottom) karyotype, as well as *ider(21)*. This formation is equivalent to the Ph duplication in the blast crisis of chronic myelogenous leukemia because of duplication of *der(21)* without accompanying $t(8;21)$.

RUNX1 fusion have been demonstrated (Fig. 56.28). The $t(8;21)$ is the most common translocation in pediatric patients with AML (10%–20%). Prenatal origin of $t(8;21)$ was established for approximately 50% of pediatric patients using Guthrie card analysis.

Although 60% to 70% patients with $t(8;21)$ achieve complete and long-term remission, monitoring minimal residual disease using $t(8;21)$ marker is important in identifying patients with a high risk for relapse. Multiparametric approaches, such as flow cytometry, RQ-PCR, and interphase FISH, are complementary methods and provide useful clinical information on relapse kinetics. It should be noted that 18% of healthy individuals have *RUN1-RUNX1* transcript by PCR and the fusion transcript has been detected in 40% of cord blood samples, suggesting that *RUNX1-RUNX1* by itself may not have overt leukemic manifestations.

In patients with 16q22 abnormalities such as *inv(16)(p13;q22)* and $t(16;16)(p13;q22)$, the marrow contains an increased percentage of abnormal eosinophils (Fig. 56.29). Combined May-Grünwald-Giemsa staining with FISH demonstrates that the abnormal eosinophils have *inv(16)* and are therefore part of the leukemic clone. Trisomy 22 is a frequent accompanying abnormality. Both *inv(16)* (see Fig. 56.26, top right) and $t(16;16)$ (see Fig. 56.29) are abnormalities of the *CBFβ* gene at 16q22 and are associated with M4Eo subtype, according to the FAB classification of AML. Both rearrangements result in fusion of *CBFβ* and *MYH11* (myosin heavy-chain) gene on 16p13. The exact role of the resulting hybrid protein, *CBFβ-SMMHC* (smooth muscle myosin heavy chain), is unknown, but it probably is involved in impaired hematopoietic differentiation. Both $t(8;21)$ and *inv(16)* rearrangements result in abnormal repression of CBF target genes. CBF is a heterodimeric transcription factor complex that consists of three distinct DNA-binding *CBFα* subunits *RUNX1*, *RUNX2*, and *RUNX3* and a common *CBFβ* subunit, which is non-DNA-binding. The binding affinity of *RUNX1* subunit to the DNA promoter sequences is significantly increased by association with *CBFβ*, which does not directly interact with DNA and protects the *RUNX1* subunit from proteolysis. The breakpoints in $t(8;21)$ affect *RUNX1* exon 5 and *RUNX1T1* exon 2. The breakpoint in *MYH11* involved in *inv(16)* and $t(16;16)$ is variable and gives rise to at least 10 different fusion variants. In contrast, the breakpoints in *CBFβ* at 16q22 are at intron 5. Both translocations are associated with a favorable prognosis, but they exhibit different leukemic cell morphology.

Approximately 4% of patients with *CBFβ-MYH11* rearrangement do not have a cytogenetically detectable *inv(16)* or $t(16;16)$.

Fig. 56.29 Partial G-banded karyotype from a patient with M4 acute myeloid leukemia showing $t(16;16)$ (top), after FISH study using a breakapart *CBFβ* probe (at 16q22), demonstrating that the 5' end (red) of the gene remains on 16q of one chromosome 16, whereas the 3' end (green) translocated to the short arms of the other chromosome 16. Separation of 5' and 3' ends as single signals is indicated in the bone marrow nucleus (bottom).

Cytogenetic detection of *inv(16)* may be difficult, and interphase FISH with a dual-color *CBFβ* probe at diagnosis is a crucial genetic test. Detection of *CBFβ-MYH11* fusion by either RT-PCR or FISH is found in patients without eosinophilia; therefore *CBFβ* testing should be included in the standard AML testing panel. The presence of additional abnormalities, such as trisomy 8, do not adversely affect clinical outcomes. The *CBFβ-MYH11* chimeric fusion is detected in utero approximately 10 years before development of childhood leukemia. This observation suggests that formation of *CBFβ-MYH11* is not sufficient to cause leukemia and that subsequent genetic events must occur before clinically recognizable leukemia occurs.

Most clinical studies have found that the CBF AML group is associated with a better CR rate, OS, and lower relapse risk than patients with cytogenetically normal AML. However, a recent retrospective analysis of 113 patients with CBF AML demonstrated that at diagnosis, patients with *inv(16)* were less likely to have any normal metaphases when compared with patients showing $t(8;21)$ karyotype. Moreover, the identification of an increasing number of cells with normal metaphases increased the risk for relapse and negatively affected the survival of patients with *inv(16)*; identifying at least one normal metaphase at diagnosis and 19 with *inv(16)* had a significant impact on 5-year survival (60% versus 14%, $p = .00005$). These factors, along with age, were the only independent variables associated with refractory disease and higher relapse. Nevertheless, CBF AML has been defined as a favorable genetic group by National Comprehensive Cancer Network (NCCN) guidelines and ELN recommendations.

NCCN guidelines have classified $t(8;21)$ and *inv(16)* AMLs with *c-KIT* mutations as having intermediate risk disease, whereas the ELN has provided no further recommendations for those with *c-KIT* mutations. Mutations in the *KIT* gene are the most recurrent molecular abnormalities, occurring in 15% to 46% of the cases, and are associated with a higher risk for relapse. The mutation frequency was similar for pediatric and adult patients with $t(8;21)$ whereas pediatric

Fig. 56.30 MOLECULAR CYTOGENETIC DEFECTS IN ACUTE PROMYELOCYTIC LEUKEMIA ARE RESPONSIBLE FOR DIFFERENT RESPONSE TO ALL-*TRANS* RETINOIC ACID DIFFERENTIATION THERAPY. Patients with t(11;17)(q23;q22) and PLZF(ZBTB16)-RARA fusion do not respond to all-*trans* retinoic acid (ATRA) differentiation therapy, whereas patients with classic t(15;17) and other four cytogenetic variants have exquisite sensitivity to differentiate in response to all-*trans* retinoic acid.

patients with inv(16) AML tend to have higher frequency of *KIT* mutations than adult patients. The mutations are clustered within exon 17, which encodes the *KIT* activation loop (A-loop) in the kinase domain, and in exon 8, which encodes an evolutionarily highly conserved region in the extracellular portion of the *KIT* receptor. *KIT* mutations occur almost exclusively at codon D816 in patients with inv(16), and at codons D816 or N8822 in patients with t(8;21). *KIT* mutations represent not only a prognostic indicator but also a potential therapeutic target for TKI therapy. In adults the mutation frequency in exon 17 is significantly higher in t(8;21) than in inv(16) patients with AML (35.6% vs. 6.9%, respectively, $p < .0001$), whereas the mutation frequency in exon 8 is significantly lower in t(8;21) than inv(16) patients with AML (4.4% versus 18.8%, respectively, $p = .0003$). The prognostic value of *KIT* mutations in CBF AML remains debatable. The incidence, characteristics and prognostic effects of *KIT* mutations are different for different subgroups. It appears that mutations in exon 17 have a strong adverse impact on the relapse and survival of adult patients with t(8;21) AML.

Other activated mutations associated with CBF AML include *FLT3*, *CBL*, *NRAS* or *KRAS*, and *ASXL2*. *FLT3* point mutations (most common D835), are frequently associated with inv(16) (6%–24%) and 6% of patients have *CBL* mutations associated with improved OS. *NRAS*- and *KRAS*-activating mutations are preferentially observed in inv(16) and do not impact on prognosis. *ASXL2* mutations (11.5%) are exclusively associated with t(8;21) and were not observed in inv(16) patients. The *ASXL2* protein is involved in epigenetic regulation of gene transcription and seemingly confers a worse prognosis but these results need broader validation. *RUNX1* mutations present in about 5% to 15% of patients with M0 AML, are mutually exclusive when t(8;21) and inv(16) are present. Approximately 5% to 10% of CBF AML patients, mostly those with t(8;21), have concurrent systemic mastocytosis with *KIT* mutations and a good prognosis.

As mentioned earlier, there are 39 recurrent abnormalities involving the 21q22 chromosomal site where *RUNX1* is localized. Some of the more frequent rearrangements are discussed here.

The t(16;21)(q24;q22) is a rare but recurrent chromosomal abnormality associated with therapy-related AML. Studies using FISH and RT-PCR methods have demonstrated fusion of *RUNX1* on 21q22 and *CBFA2T3* on chromosome 16, which produces an *RUNX1/CBFA2T3* fusion gene on chromosome 16. The breakpoints of both t(8;21) and t(16;21) occur within the same intron of the *RUNX1* gene. *RUNX1/CBFA2T3* fusion results in the production of a protein that is very similar to the RUNX1/RUNX1T1 protein in t(8;21).

The (16;21)(p11;q22) is a rare chromosomal rearrangement associated with M1-M2 AML. A proportion of these patients may have additional abnormalities. This translocation fuses the *FUS/ERG* *TLS/FUS* gene on chromosome 16, band p11, to the *ERG* gene on chromosome 22, band q22. The *ERG* gene is a member of the E twenty-six (ETS) family of transcription factors and is a sequence-specific transcriptional activator. The presence of a fusion transcript is detected by RT-PCR, at the time of diagnosis, at relapse, and during remission. These observations are consistent with the impression that patients with t(16;21) have a poor prognosis and may benefit from early detection of this chimeric gene to determine the need for more aggressive therapy.

The t(15;17)(q22;q21) involves the promyelocytic leukemia (*PML*) gene on chromosome 15, band q22, and *RARA* on chromosome 17, band q21. This abnormality constitutes the genetic basis for approximately 95% of all cases of APL (see Fig. 56.26, middle panels).¹⁵ The remaining 5% of cases include nine rare variant translocations: t(11;17)(q23;q21)/*ZBTB16-RARA* and *MLL-RARA*, t(11;17)(q23;q21)/*NUMA1-RARA*, t(5;17)(q35;q21)/*NPM1-RARA*, t(2;17)(q32.3;q21)/*NABP1-RARA*, t(17;17)(q21.2;q21.2)/*STATB-RARA* or del(17)(q21.2q21t), t(4;17)(q12;q21) *FIP1L1/RARA*, t(X;17)(p11.2;q21)/*BCOR-RARA*, and cryptic *PRKAR1A-RARA* detected in a patient with a normal karyotype (Fig. 56.30). Therefore APL, which accounts for 10% to 15% of AML cases, is associated with several different genetic rearrangements fusing the *RARA* gene with a different partner gene in each case. Based on these genomic rearrangements, a FISH assay, using a breakapart probe strategy with dual-color *RARA*, can identify two different clinical syndromes: those responsive to all-*trans* retinoic acid (ATRA) (more than 99%) therapy and those carrying a *ZBTB16-RARA* or *STAT5B-RARA* fusion genes, which are not responsive to ATRA and are naturally resistant to arsenic trioxide (As_2O_3) therapy. Patients with promyelocytes that have exquisite sensitivity to differentiate in response to ATRA treatment have one of the other six *RARA* fusion rearrangements (see Fig. 56.30). ATRA resistance is heterogeneous and commonly involves mutations in the *RARA* ligand-binding domain of the fusion protein. FISH studies have also identified patients with cryptic translocations and unusual chromosomal variants (Fig. 56.31). It is important to recognize patients who will or will not respond to ATRA so that appropriate therapy can be administered.

The t(15;17) is often the only chromosomal abnormality present in 70% to 100% of bone marrow metaphase cells. The most frequent additional abnormality is trisomy 8, but this abnormality does not influence the rate of CR. The *RARA* gene is a nuclear hormone receptor, spanning 7.5 kb, and contains nine exons. The breakpoint

Fig. 56.31 ISOCHROMOSOME 17 IN ACUTE PROMYELOCYTIC LEUKEMIA WITH A GAIN OF PML-RARA FUSION. (A) Partial karyotype from a patient with acute promyelocytic leukemia, showing *ider(17) t(15;17)(q22;q21)*. The karyotype shows isochromosome for the long arms of chromosome 17 and deletion of the short arms. (B) FISH studies revealed three copies of PML-RARA fusion in bone marrow nucleus, confirming that the first event in the pathogenesis was PML-RARA fusion and the subsequent event was a structural rearrangement of isochromosome. (From Cheng L, Zhang DY, editors: *Molecular genetic pathology*, Totowa, NJ, 2008, Humana Press, a part of Springer Science.)

occurs almost exclusively in intron 2 of the *RARA* gene. The *PML* gene locus spans 35 kb and contains nine exons coding for mRNA of 4.6, 3.0 and 2.1 kb. The breakpoints in *PML* occur in three distinct clusters leading to mRNA of different length. The existence of different breakpoint regions in the *PML* gene and the presence of alternative splicing of PML transcripts are responsible for the heterogeneity of *PML RARA* junctions and variants.

APL is a disease characterized by accumulation of blasts blocked at the promyelocytic stage of granulocytic differentiation. APL accounts for only 5% to 8% of pediatric AML, and 95% of children with APL show a classic *t(15;17)*. However, almost 35% of pediatric APL have *FLT3-ITD* mutations. The clinical signs of these mutations on relapse rate and OS is not yet apparent.

Our current understanding of the molecular pathogenesis of APL is that *PML-RARA* behaves as a potent transcriptional repressor and that supraphysiologic doses of retinoic acid can overcome this repression. In the presence of retinoic acid, *PML-RARA* behaves as a transcriptional activator. In patients with variant *ZBTB16-RARA*, an additional co-repressor complex binding site is present, and histone deacetylase inhibitors are used to restore sensitivity to retinoic acid. It appears that *PML-RARA* fusion-induced differentiation arrest of leukemic blasts and increased self-renewal of progenitors are two distinct features of APL and are probably driven by two different gene programs. The *RARA* fusion protein has a dual action, activating transcription of a number of genes and repressing transcription of others. *PML-RARA* and *ZBTB16-RARA* repress several DNA repair genes and activate the Wnt signaling and the NOTCH pathway leading to increased stem cell renewal. Many of the genes targeted by retinoid acid are known to play a key role in regulating myeloid cell proliferation and differentiation. Therefore it is possible that inhibition of their expression by *RARA* fusion proteins may lead to differentiation blockage.

Accurate identification of the APL-associated genomic lesion at diagnosis is important because APL is a medical emergency that frequently presents with abrupt onset, high risk for early death

(10%–20%), and potential for high cure rate (>80%) if appropriate treatment, based on its genetic profile, is initiated. Initial workup may include conventional karyotyping, FISH studies, RT-PCR, and anti-PML antibodies. Longitudinal monitoring of disease with Q-PCR is currently recommended to provide early intervention if relapse should occur.

Less than 1% of patients with AML have the Ph chromosome (see Fig. 56.26, bottom left) and it remains a controversial entity as it is not listed in the WHO 2016 classification as a separate entity. Ph + AML may be cytogenetically distinguished from the myeloid blast crisis of CML by monosomy 7 (also frequently found in Ph + ALL) and *inv(16)*. Moreover, *NPM1* mutations found in 40% to 60% of AML as well as in Ph + AML have not been described in Ph-positive CML. All Ph + AML examined to date showed a unique loss of Ig genes with a specific genomic signature, suggesting a distinct biologic entity. Both *P210^{BCR-ABL1}* and *P190^{BCR-ABL1}* were observed, but *P190* appears to be prevalent. Before TKI therapy, the median survival of the Ph chromosome +AML was 9 months and has been improved to a median survival of 18 months (range 6–71) with the use of imatinib therapy. In rare patients with AML, late appearance of a Ph chromosome either as a sole abnormality or in a clone showing *t(8;21)* is taken as evidence that the Ph chromosome in these patients is a secondary event. The late-appearing Ph chromosome in AML is characterized by *P190^{BCR-ABL1}* protein. The coexistence of the Ph chromosome and *inv(16)* is a rare but recurrent finding in both CML and AML. In CML the fusion transcript is *P210^{BCR-ABL1}*, whereas in AML the fusion transcript is *P190^{BCR-ABL1}*. The presence of both the Ph chromosome and *inv(16)* in AML seems to have a favorable prognosis, whereas in CML, the coexistence of *BCR-ABL1* and *CBFB-MYH11* is predictive of rapid transformation to blast crisis.

Using extrasensitive BCR-ABL1 FISH probe Ph-positive AML expressing *P190^{BCR-ABL1}* protein may be recognized, and distinguished from the Ph-positive CML because it will show a second co-localized “fusion” signal, because the breakpoint on chromosome 22 in AML is more centromeric with two signals closer to each other giving an impression of two fusion signals.

The *KMT2A* [lysine (K)-specific methyltransferase 2A], (*MLL*) gene at 11q23.3 is responsible for 95% of all 11q23 translocations, including those in patients with AML and ALL (Figs. 56.32 and 56.33 and Table 56.9). *MLL* abnormalities are found in approximately 15% of patients with AML and ALL. As of 2013 there were a total of 121 different *MLL* rearrangements of which 79 were characterized at the molecular level.¹⁶ In nearly all direct and reciprocal *MLL* recombinomes, the 3′ portion of the *MLL* gene is retained causing a direct fusion of the 5′ *MLL* gene portion with a gene portion localized telomeric to *MLL*. Of note, an abnormal FISH signal pattern, using dual-color, breakapart FISH, shows an abnormal signal pattern arising from 3′ *MLL* deletions in up to 28% of cases, and very rarely a gain of 3′ *MLL* portion of the gene, usually as a result of an additional derivative partner chromosome.

The seven most frequent rearrangements of the *MLL* gene occur either with a translocation partner gene such as *AFF1/AF4/t(4;11)(q21;q23)*, *MLLT3/AF9/t(9;11)(q21;q23)* (Fig. 56.34), *MLLT1/ENL/t(11;19)(q23;p13.3)*, *MLLT10/AF10/t(10;11)(p12;q23)*, *ELL/t(11;19)q23;p13.1*, *MLLT4/AF6/t(6;11)(q27;q23)*, or derived from *MLL* gene internal duplication (*MLL-PTDs*) of the amino-terminus region of the gene (see Table 56.9 and Fig. 56.32).

The BCR for about 96% of patients is localized between *MLL* exon 9 and *MLL* intron 11. Patients with a breakpoint in *MLL* intron 11 have a worse prognosis compared with those patients with upstream breakpoints. The breakpoint in *MLL* intron 11 causes a *cis to trans* conversion and switches the *MLL* protein from a transcriptional activator/maintenance factor to a transcriptional repressor.

MLL rearrangements are initiated by DNA damage, which induces DNA repair via the nonhomologous-end-joining DNA repair mechanism. These genetic recombinations produce (1) reciprocal chromosomal translocations which fuse the 5′-*MLL* gene portion with the corresponding gene; (2) partial tandem repeats, frequently in AML; (3) inversions or deletions on 11p and 11q in which inversions lead to reciprocal *MLL* fusions whereas deletions cause fusion of the 5′

Fig. 56.32 EXAMPLES OF CHROMOSOME 11 ABNORMALITIES. (A) Deletion of chromosome 11 at band q23. (B), Gain (trisomy) of chromosome 11. (C) Gain of isodicentric, idic(q11) in myelodysplastic syndrome (MDS). (D) Balanced $t(1;11)(q13;p15)$ in MDS. (E) $t(11;19)(q13;p13)$ in a pediatric patient with acute myeloid leukemia. (F) Duplication of the long arms of chromosome 11 and FISH image of *MLL* duplication. (G) Duplication (11;22) in the form of dicder(11;22)dup(11)(q13q14)t(11;22)(q23;p11) in a patient with MDS. (H) der(11)dic(1;11)(q12;q23) in a patient with myelofibrosis transforming to acute myeloid leukemia. (I) der(14)t(11;14)(q23;q23), resulting in trisomy for part of the long arms of chromosome 11. (J) $t(4;11)(q23;q23)$ in pediatric acute lymphoblastic leukemia. (K) $t(6;11)(q27;q23)$ in pediatric acute lymphoblastic leukemia. (L) $t(11;19)(q23;p13)$ in pediatric acute lymphoblastic leukemia and after FISH study, showing separation of *MLL* breakapart probe where the 5' end of the *MLL* (green) remains on der(11), and the 3' end (red) is translocated to 19p. (M) $t(9;11)(p22;q23)$ in pediatric acute myeloid leukemia and after metaphase FISH study (right), showing that the 3' end of the *MLL* (red) is translocated to 9p but the 5' end (green) remains on der(11).

MLL directly to another gene located further downstream (*ARHGEF12*, *BCL9L*, *CBL* and *CEP164*); and (4) complex *MLL* rearrangements involving three- or four-way translocations resulting in more than two fusion alleles (Fig. 56.35) or ring chromosomes (see Fig. 56.25). About 15% of *MLL* recombinations represent in-frame fusions that can be readily expressed into a fusion protein and 85% are out-of-frame fusions and express a 5' truncated *MLL* protein.

The $t(9;11)$, which has been associated with a more favorable outcome in adult and pediatric AML, is distinguished as a separate entity in the latest WHO classification (see Fig. 56.34). Other frequent *MLL* translocations are $t(6;11)(q27;q23)$ involving *MLLT4*(*AF6*) and $t(11;19)(q23;p13.3)$ involving *MLLT1* (*ENL*). A partial tandem duplication of the amino-terminus region of the *MLL* gene is associated in patients with or without trisomy 11 (see Figs. 56.32B, C and F), and *MLL* is an epigenetic regulator that plays a critical role in hematopoiesis, modulating *HOX* gene expression.

The *MLL* gene is encoded by 37 exons. It is recruited to the promoters of select cell-cycle regulatory genes, suggesting its role in cell-cycle control. *MLL* protein regulates gene expression and cell cycle control via chromatin modification. Translocations of 11q23 cluster within an 8.3-kb region that encompasses exons 8–14 of *MLL*

and fuses the N-terminal portion of *MLL*, which contains the AT hook and methyltransferase domains, to numerous different proteins. In infant and in therapy-related AML, the *MLL* genomic breakpoints cluster at the 3' end, near exon 12. In childhood and adult de novo AML, the breakpoints usually occur in the 5' end, between exons 9 and 10. The most frequent *MLL* rearrangements in pediatric and adult patients as well as in ALL and AML are summarized in Fig. 56.33.

Patients with AML with *MLL* rearrangements have a poor prognosis despite treatment with aggressive multiagent chemotherapy. Identical *MLL* rearrangements have been detected in three pairs of infant monozygotic twins, indicating in utero *MLL* rearrangement that result in clinical manifestations developing some time during the first year of life. The contribution of various *MLL* fusion partners to transformation has been recently clarified. More recently, a retrospective analysis demonstrated that the prognosis of *MLL*-rearranged leukemia may be influenced by the fusion partner. Survival associated with the rare $t(1;11)(q21;q23)$ translocation was favorable, in contrast to very poor outcomes with the more frequent $t(4;11)$, $t(10;11)$, and $t(6;11)$ translocations. Even now novel translocations, such as the one shown in Fig. 56.36, are still being discovered and their prognostic indication is currently unknown.

Fig. 56.34 THE MOST FREQUENT *MLL* TRANSLOCATION IS t(9;11)(p22;q23). (A) The G-banded karyotype and (B) a partial karyotype, from another metaphase, after hybridization with dual color “break-apart” *MLL* probe showing the 5′ *MLL* (green) being retained on 11q23 and the 3′ *MLL* (red) moved as a result of the translocation to 9p22. This translocation results in a fusion of *MLLT3-AF9*.

Fig. 56.35 *MLL* AMPLIFICATION. Metaphase cell from a patient with acute myeloid leukemia after DAPI staining (blue) showing *MLL* amplification (yellow) along the abnormal chromosome 11. At least 15 copies of *MLL* amplicon were inserted into an abnormal chromosome 11. A normal copy of chromosome 11 with one copy of *MLL* is shown on the right side of the metaphase.

The partner genes in the translocations do not appear to have any common characteristics that would clarify their role in leukemogenesis. However, two observations suggest that *MLL* fusion partners are not randomly chosen. First, a precise localization of genomic *MLL* breakpoints in 414 samples with *MLL* rearrangements, using a long-distance inverse PCR method, showed that the most frequent translocation fusion partners (*AF4*, *MLLT3*, *MLLT1*, *AF10*) belong to the same nuclear protein network involved in histone methylation. Second, several chromatin structural elements, such as topoisomerase II cleavage sites, DNase I hypersensitive sites, and other chromatin sites, are associated with *MLL* rearrangements observed in infant and therapy-related AML. These characteristics of *MLL* suggest that specific chromatin sites are functionally selected in *MLL* rearrangements rather than randomly chosen.

Gene expression studies have demonstrated clear differences between *MLL*-rearranged AML and ALL in expression of lineage-associated genes, but there appears to be a core gene expression profile found in all *MLL*-rearranged leukemias, independent of the lineage markers.

t(8;16)(p11;p13)/MYST3-CREBBP rearrangements are a distinct pediatric subtype of AML with 97% of cases showing FAB subgroup M4 or M5 (Fig. 56.37). This specific association has also been observed in adult AML. Gene expression analysis revealed that *t(8;16)* cases clustered strongly together with, but separate from, *MLL* rearranged AML.

t(6;9)(p23;q34.1) is a rare cytogenetic abnormality, found in approximately 1% of AML cases, and subsequently reported to be associated with AML and marrow basophilia (Fig. 56.38). Basophilic leukemia is now recognized by the WHO classification as a separate entity. In addition to *t(6;9)*, other chromosomal abnormalities such as *t(8;21)(q22;q22)*, *del(12)(p11-13)*, *t(X;6)(p11;q23)*, and *t(2;6)(q23;p22)* may be associated with basophilic leukemia. As a result of *t(6;9)*, the 3' end of the *NUP214*, nuclear pore complex protein 214 kDa, gene located on chromosome 9, band q34, is fused to the 5' end of the *DEK* gene located on chromosome 6, band p23. The resulting *DEK-NUP214* fusion gene is a derivative of chromosome

Fig. 56.36 A NOVEL *MLL* PARTNER. A partial karyotype showing an abnormal chromosome 16 from two different metaphase cells from a patient with acute myeloid leukemia showing *t(11;16)(q23;q23)* karyotype as a sole abnormality. On the left is chromosome 16 stained with DAPI (blue) after metaphase FISH with three probes: centromere 16 in aqua, *CBFB* "break-apart" probe in yellow, and 3' *MLL* in red. Middle panel is an "inverted" DAPI image and on the right is the G-banding of an abnormal chromosome 16. As a result of *t(11;16)* a part of 11q23 was translocated to 16 and the 3' *MLL* moved at 16q23.

Fig. 56.37 THE *t(8;16)*. A partial karyotype from a patient with acute myeloid leukemia showing a *t(8;16)(p11;p13)* which results in fusion of *MYST3* (red) and *CREBBP* (green).

6. The translocation breakpoints occur in exon 6 in the *NUP214* gene and in exon 2 in the *DEK* gene. As a result, the presence of the *DEK-NUP214* fusion can be identified by PCR methods. Dual-color commercial FISH probes are not available for this translocation. Approximately 70% of patients with *DEK-NUP214* have an *FLT3* tandem duplication.

The nuclear pore complex is a massive structure that extends across the nuclear envelope, forming a gateway that regulates the flow of macromolecules between the nucleus and the cytoplasm. *NUP214* may serve as a docking site in the receptor-mediated import of substrates across the nuclear pore complex and plays a role in nuclear protein import, mRNA export, and cell cycle progression. The role of the *DEK-NUP214* protein in leukemogenesis awaits elucidation.

inv(3)(q21q26.2) or *t(3;3)(q21;q26.2)* (see Fig. 56.23) is a distinct subtype of AML with recurrent chromosome abnormalities and according to 2008 WHO classification, occurring in about 1% to 2.5% of all AML cases. Each rearrangement is associated with the juxtaposition of the *RPN1* (ribophosphorin 1 located on 3q21) gene with the transcription factor *EV11* (located in the 3q26.2 band). Two alternative forms exist, one generated from *EV11*, the other *MECOM* (*MDS1* and *EV11* complex locus) through intergenic splicing with *MDS1*, a gene located 140 kb upstream of *EV11*. Both rearrangements may present as de novo or secondary AML and are characterized by

Fig. 56.38 MARROW BASOPHILIA WITH CHARACTERISTIC $t(6;9)$. $t(6;9)(p23;q24)$. Shown as partial karyotype from a patient with acute myeloid leukemia and marrow basophilia. This translocation results in a fusion between *NUP214* gene on 9p34 and *DEK* gene on 6p23.

normal or increased platelet counts and abnormal megakaryopoiesis. They are also observed in MDS, blast crisis of CML, as well as in Ph-negative MPN. De novo AML associated with $t(3;3)/inv(3)$ is an aggressive type of leukemia with minimal response to chemotherapy and poor clinical outcome. Rare patients with an inversion on both chromosome 3 have been described and the second $inv(3)$ appears to be a secondary event that carries an even worse prognosis. Breakpoints in band 3q21 are distributed in a 235-kb region centromeric to and including the *RPN1* locus, whereas those in band 3q26.2 are scattered over a 900-kb region located on each side of and including the *EVII* locus. There are a few cluster breakpoints within 3q21 region. The first BCR of about 30 kb is located 15 kb centromeric of the *RPN1* gene and the other breakpoints are centromeric to the first one, located up to 60 kb. In contrast to most of the translocations and inversions associated with de novo AML, that lead to the fusion genes, $inv(3)/t(3;3)$ does not generate a chimeric gene, but rather induces gene overexpression. Approximately 68% of reported patients with $inv(3)/t(3;3)$ showed one additional chromosomal abnormality, including $-7/del(7q)$ present in 75% of cases.

Therapy resistance in patients with $inv(3)/t(3;3)$ is linked to the inappropriate activation of the *EVII* as a consequence of the 3q structural rearrangement. *EVII* is a hematopoietic stemness factor and transcription factor with chromatin-remodeling activity. *EVII* is also expressed in approximately 11% of patients with AML in the absence of 3q aberrations and represents an independent adverse prognostic factor. *EVII* is activated as a consequence of $inv(3)/t(3;3)$ via structural repositioning of a distal *GATA2* enhancer from 3q21 to the *EVII* locus at 3q26. Relocation of the enhancer additionally confers reduced and monoallelic *GATA2* expression. Besides deregulated expression of *EVII*, a molecular hallmark of patients with 3q structural rearrangements, 98% of these patients harbor mutations in genes activating RAS/receptor tyrosine kinase signaling pathways including hemizygous mutations in *GATA2*, heterozygous alterations in *RUNX1*, *SF3B1* and genes encoding epigenetic modifiers.

$t(3;5)(q25;q35)$, *NPM1/MLF1*: translocation $(3;5)(q25;q35)$ is present in approximately 0.5% cases of AML and has an intermediate prognosis, it is observed in all age groups, but more commonly in younger patients. These patients have shown to have a 34% survival rate after 10 years. In younger patients, this translocation is usually the sole karyotypic abnormality, whereas older patients may demonstrate a more complex karyotype. This translocation generates an

NPM1/MLF1 chimeric gene, which includes approximately half of the 24-kb *NPM1* gene, localized on 5q35, extending from exons 1–6, juxtaposed to virtually the entire 35-kb *MLF1* gene, localized on 3q25, starting at exon 2. The chimeric *NPM1/MLF1* fusion protein totals 426 amino acids with 175 amino acids from *NPM1* fused to 251 amino acids from *MLF1*, which excludes only the initial 16 amino acids from *MLF1* in this chimeric protein. In approximately 88% of patients with $t(3;5)$ the translocation results in *NPM1/MLF1* fusion. In some patients with balanced $t(3;5)$ the fusion is not apparent because of the variant 3;5 translocations that may include multiple genes at 3q21–25 and 5q31–35.

The presence of a hyperdiploid karyotype in acute erythroleukemia occurs in 47% to 56% of patients, along with a loss of genetic material in chromosomes 5, 7, and 18. A monosomal karyotype was identified in 43% of cases in one series. Balanced translocations are rare in erythroleukemia, although rare cases of *MLL* rearrangements have been reported. The frequent occurrence of a complex karyotype with abnormalities of chromosomes 5 and 7 may be one reason for the poor prognosis associated with acute erythroleukemia. Mutations frequently seen in other subgroups of AML (such as *FLT3*, *KIT* or *RAS* mutations) have not been reported in acute erythroleukemia. In pediatric patients, acute erythroleukemia is very rare, present in 2.3% of all patients with AML. Congenital erythroleukemia is exceedingly rare with only six cases reported in the literature.

Pure erythroid leukemia (PEL) is a rare subtype of AML that is often secondary leukemia or therapy related. The uncontrolled proliferation of immature erythroid precursors comprises at least 80% of the marrow. A complex karyotype is present in 83% of cases and the median OS of 2.9 months. Compared with AML with more than 50% erythroblasts, cases of PEL demonstrate a higher incidence of poor-risk chromosomal abnormalities. Within the complex karyotype monosomy 7 appears to be the most frequent abnormality.

The M7 or megakaryocytic subtype of AML is a rare clonal disease, with an estimated frequency of 0.7% among AMLs, arising in a multipotent stem cell capable of differentiating along the megakaryocytic and granulocytic pathway. This acute leukemia subtype has a variety of genetic and morphologic characteristics. The M7 subtype is more frequent in children than in adults. In adults, megakaryocytic leukemia is frequently observed as a secondary leukemia after chemotherapy or leukemic transformation of several chronic MPNs, including CML. Approximately 65% of acute megakaryocytic leukemia is associated with myelofibrosis. No specific chromosomal abnormality is associated with the adult form of megakaryocytic leukemia. After multivariate analysis, the AML megakaryocytic subtype is an independent predictor of increased mortality. Approximately 50% of patients with M7 AML have chromosomal abnormalities at diagnosis. Observed abnormalities include 3q21–3q26 rearrangements, partial or total deletion of chromosomes 5 and 7, gain of chromosomes 8 and 19, and $t(9;22)$. Three manifestations of childhood megakaryocytic leukemia have been observed. First is the $t(1;22)(p13;q13)$ with constitutional trisomy 21 associated with *GATA1* mutations. Children with constitutional trisomy 21 have a 10- to 20-fold increased risk of developing leukemia. The incidence of developing M7 leukemia is up to 500 times higher in children with constitutional trisomy 21 than in normal children. However, children with constitutional trisomy 21 and megakaryocytic leukemia have a more favorable prognosis as compared with patients without constitutional trisomy 21. In these patients, somatic mutations of the transcription factor *GATA1* leads to exclusive expression of a truncated form of *GATA1*. The second form of childhood acute megakaryocytic leukemia involves $t(1;22)(p13;q13)$ encoding the OTT-MAL (*RBM15-MKL1*) fusion protein in infants without constitutional trisomy 21 (Fig. 56.39). It is a very rare abnormality, described in about 40 cases worldwide (about 5% of infant AML cases), and associated with infantile M7 and with children younger than 3 years of age. Detection of $t(1;22)$ is diagnostic. Adults with $t(1;22)(p13;q13)$ encoding the OTT-MAL fusion protein have not been reported to date. Third, approximately 19% of infants with constitutional trisomy 21 (or mosaic trisomy 21C) and transient MPD subsequently develop M7 leukemia at a mean age of 20

Fig. 56.39 MEGAKARYOCYTIC LEUKEMIA WITH $t(1;22)$. Partial karyotype from two metaphase cells from a 4-week-old baby with M7 megakaryocytic leukemia showing a diagnostic $t(1;22)(p13;q13)$ abnormality.

months. With development of leukemia, these children acquire diverse chromosomal abnormalities, most notably tetrasomy 21 and trisomy 8. The $t(1;22)$ rearrangement has been observed in a set of monozygotic twins, suggesting an in utero origin in some cases. To date there are 16 cases of *GATA1* mutation-related transient MPDs and M7 AML in phenotypically and cytogenetically normal children. Thirteen of the 16 children were diagnosed during the first few months of life and in six cases, the blasts disappeared spontaneously without chemotherapy and the patients did not develop M7 AML. Gene expression profiling (GEP) has provided the first insight into the molecular pathogenesis of M7 leukemia in children with and without constitutional trisomy 21. These patients have distinct molecular phenotypes, with increased expression of chromosome 21 genes in patients with constitutional trisomy 21 as compared with M7 leukemia patients without constitutional trisomy 21. The *RUNX1* gene, localized on chromosome 21 which is essential for normal megakaryopoiesis, is expressed at lower levels in children with constitutional trisomy 21 and M7 leukemia, indicating a mechanism that may contribute to a block in differentiation

Down Syndrome–Associated Acute Myeloid Leukemia

The myeloid leukemia of Down syndrome (DS) was given a special WHO subclassification (ML-DS) because of its unique clinical and biologic features. These erythromegakaryoblastic leukemias are diagnosed before the age of 5 years and often present with thrombocytopenia and/or myelodysplasia. ML-DS is always preceded by the neonatal preleukemic syndrome, transient abnormal myelopoiesis (TAM; also known as transient MPD) that may, or may not, be clinically apparent. Unlike acute megakaryoblastic leukemias in patients without DS, these patients usually respond well to therapy with most patients being cured. Genetically, ML-DS is characterized by an acquired mutation in the *GATA1* gene. The mutation in *GATA1* is necessary but insufficient for development of ML-DS. Virtually all cases of TAM and ML-DS have N-terminal truncating *GATA1* mutations. *GATA1* mutations are present at birth in both neonates with DS with TAM and, through retrospective analysis of neonatal blood spots, also in children with ML-DS without a previous history of TAM. It is not clear at what stage in fetal development *GATA1* mutations arise; the earliest point in gestation at which mutations have been identified is 21 weeks. *GATA1* mutations disappear when TAM (or ML-DS) enters remission, indicating that these are acquired.

Monosomal Karyotype

MK is defined by the presence of at least two separate autosomal monosomies or one monosomy plus one or more structural

abnormalities. The overall frequency of MK in AML varies between 6% and 20%. Although in a study of 1058 patients with AML and abnormal karyotype, 30% had MK (see Fig. 56.27, bottom row). AML with MK is frequently associated with other adverse risk cytogenetic abnormalities, such as $inv(3)$, -5 or $del(5q)$, -7 or $del(7q)$, abnormal $(12p)$, $-18/del(18q)$, abnormal $(17p)$, and a complex karyotype. The frequency of these recurrent monosomies are: -7 and -17 in 6%, -18 in 5%, -5 and -21 in 4%, -20 in 3%, -3 , -12 , and 22 in 2% and loss of chromosomes 2, 4, 9, 13, and 19 in 1%. MK is a strong prognostic predictor of poor outcome compared with a traditionally defined complex karyotype. Patients with MK had a 4-year OS of 4% as compared with 21% in patients with other unfavorable karyotypes but without MK. Responses to induction therapy and OS of patients who have AML with MK are dismal: CR rates of 32% and a 4-year survival of 9%. MKs in a study of 248 patients with AML was found to be associated in more than 50% of patients with deletion of P53, whereas in another study of newly diagnosed 369 patients with AML, MK predicted an adverse treatment outcome and was associated with multidrug-resistance functional activity of leukemic blasts. A low frequency of mutations such as *FLT3* and *NPM1* was found in patients with MK AML.

Gain or Loss of Chromosomes in Acute Myeloid Leukemia

Approximately 15% to 20% of patients with AML have a numerical gain or loss of a single chromosome as the sole primary karyotypic abnormality. Each of the autosomes and sex chromosomes can contribute to the numerical changes. The most common trisomies in decreasing order of frequency are gain of chromosome 8, 22, 13, 21, and 11. The gain of chromosome 8, the most frequent abnormality seen in AML, is found as a sole abnormality in 6.3% of cases and overall occurs in 16% of cases. The incidence of $+8$ detected by FISH varies between 19% and 25% of AML cases. The prognosis of AML with $+8$ depends on whether $+8$ occurs as an isolated abnormality or accompanies other cytogenetic aberrations. In the latter situations, $+8$ does not appear to adversely affect the favorable outcome of patients with $t(15;17)$, $inv(16)t(16;16)$, and $t(8;21)$. By contrast, patients with $+8$ and a complex karyotype and/or an unfavorable aberration such as $del(5q)$ or -7 usually have a very poor outcome. Isolated $+8$ has been considered to be associated with either intermediate or unfavorable prognosis.

Deletion of 17p often results in the loss of tumor suppressor *TP53* gene on band p13.1, which has been reported in 5% to 9% of adult AML patients. The abnormalities of 17p are often associated with other chromosomal aberrations such as $del(5q)$, -5 , -7 , but is also an independent poor-risk prognostic factor. *TP53* mutations are more common in older patients and those who have received previously alkylating agents. These patients were found to have an increase in the number of $CD34^+$ cells, suggesting that the loss of *TP53* function could cause cell cycle arrest at an immature stage.¹⁷

Detection of Genomic Abnormalities

Whether PCR-based molecular screening, conventional cytogenetics, or both, should be used at diagnosis of AML is an important question with major consequences for developing a treatment strategy, monitoring therapy, and overall genetic risk assessment. A prospective study demonstrated an approximately 20% discrepancy between results using broad molecular screening with using a multiplex RT-PCR system and cytogenetic testing. This discrepancy has the potential to influence treatment strategies. Cryptic translocations detected as submicroscopic genetic lesions detected by RT-PCR may have no influence on prognosis or treatment strategy. In contrast, cytogenetic results influence treatment decisions by conferring unfavorable risk assignment on patients with negative broad molecular screening. These methodologies provide complementary genetic information for diagnosis, treatment, and follow-up.

Cytogenetic studies are valuable in assessing the effectiveness of therapy (see box on Genetic Testing for Acute Myeloid Leukemia and Fig. 56.26). In most patients with AML, a clonal cell population cannot be detected during remission. However, some mutations, as mentioned earlier, such as *DNMT3A*, have been found during clinical remissions—hence the fourth aspect of AML heterogeneity. When disease relapses, cells with the original chromosome anomalies are observed. If an appropriate FISH or RT-PCR test is available, these are the genetic tests of choice for predicting relapse because these methods are less expensive and more sensitive than chromosomal studies.

Acute Myeloid Leukemia with Complex Karyotype

Any karyotype with at least three chromosomal aberrations, regardless of their type and the individual chromosomes involved, is designated as “complex.” Several studies have shown that patients with t(8;21), t(16;16)/inv(16) and t(15;17) constitute a separate biologic and clinical entity even if they contain additional abnormalities, because these additional cytogenetic abnormalities do not adversely affect the clinical outcome. Therefore the category of AML patients with a complex karyotype exclude patients with t(8;21), inv(16)/t(16;16) and t(15;17). Approximately, 10% to 12% of AML patients have three or more chromosome abnormalities whereas 8% to 9% have five or more abnormalities. The incidence of a complex karyotype increases with age. In patients with AML, age 18–60, 6% to 8% have three or more chromosomal abnormalities whereas 17% to 19% of patients older than 60 have a complex karyotype. In three large series of AML patients with a complex karyotype analyzed using multicolor FISH, more than 90% of patients had at least five abnormalities, with a median number of chromosomal aberrations being between 6 and 10. Approximately 80% of all patients with a complex karyotype have deletion 5q, followed by deletions 17p and 7q, occurring in approximately 50% of cases. At least 85% of all patients with AML with a complex karyotype showed one of the three deletions. The prognosis of patients with a complex karyotype is generally very poor. Among patients with AML above the age of 60, which constitute the majority of patients with complex karyotype, only 10% to 44% of those who harbor three or more chromosomal abnormalities achieve a CR, usually after a very short duration (median 6–8 months). CR rates of karyotypically complex patients are slightly higher in younger patients.

The impact of cytogenetics on outcome in a pediatric group of patients with AML (excluding APL) demonstrated about 80% OS for 10 years in patients with CBF AML. In contrast, patients with *MLL* abnormalities had an intermediate prognosis (61% OS at 10 years) with no evidence of heterogeneity according to the translocation partner of *MLL*. Additional abnormalities among the 11q23 leukemia have diverse prognoses; trisomy 8 is an independent favorable, whereas trisomy 19 is considered an adverse prognostic factor in *MLL* rearranged group of pediatric patients.

The striking clinical, cytogenetic, and biologic heterogeneity of AML is only partly explained by the known chromosomal or molecular rearrangements. DNA microarray technology provides a higher resolution and has been demonstrated to detect cryptic copy number alterations (CNA) and UPD. The current clinical implications of aCGH + SNP microarray analyses in AML remains limited. However, in cases with UPD, gene mutations precede mitotic recombination, resulting in loss of the remaining wild-type allele, which can act as a “second hit” mutation. UPD has been shown to be predictive of poor event-free and OS. For example, SNP microarray analysis of patients with AML with a normal karyotype demonstrated UPD of chromosome 13q, leading to duplication of a mutant *FLT3* allele at band 13q12, which was associated with significantly inferior OS. Approximately 20% of patients with AML and a normal karyotype have UPD. The most common chromosomal regions of UPD are 1p, 2p, 2q, 4q (*TET2*), 6p, 7q (*EZH2*), 11p (*WT1*), 11q, 13q (*FLT3*), 14q, 16p, 17p (*TP53*), 19q (*CEBPA*), 21q (*RUNX1*), and Xq. The analysis of genes located within a UPD chromosomal region has shown a

copy-neutral loss of heterozygosity with duplication of gene mutations that have been already implicated in AML pathogenesis and a loss of the corresponding normal allele.

Numerous studies using cytogenomics have uncovered a broad range of cryptic CNAs in patients with AML and a normal karyotype, as well as in patients exhibiting balanced translocations or chromosomal imbalances. Not only do these studies reveal a tremendous degree of genetic diversity of AML; they also have shown that the estimated average number of CNAs per genome is 2–2.5. This finding implies either that most AML genomes are relatively stable or that more sensitive methods are required (e.g., complete genome sequences) to capture the whole spectrum of genetic alterations. Genomic imbalances (and their associated target genes) include gains of regions 4q25–26 (*PRDM5*), 8p11.21 (*ZMAT4*), 8q24.21 (*CCDC26*), 13q32 (*ABCC4*), 14q23.1 (*PRKCH*), 16q24.1 (*USP10*, *CRISPLD2*), and 21q22.3 (*PRMT2*), as well as losses of regions 6q27 (*RPS6KA2*), 7p22.3 (*FAM20C*), 8q24.12 (*TRPS1*), 9p21.2 (*TISCI*), 10q11.21 (*HNRNPF*), 15q21.3 (*RFX7*), Xp11.4 (*BCOR*), and Xp25 (*STAG2*) (Fig. 56.40). The biologic consequences of these small genomic imbalances are not fully understood. In some cases, submegabase-sized CNAs may uncover cryptic rearrangements, as has been shown for *NSD1-NUP98* and *MALT4-MLL* fusion genes. The systemic analysis of CNAs and regions of UPD in AML in the future may fully uncover genomic changes that contribute to AML pathogenesis.

Acute Myeloid Leukemia in the Elderly

The biology of AML changes with age. The spectrum of cytogenetic abnormalities in older adults includes a higher percentage of patients with abnormalities involving –5/del(5q), –7/del(7q), and 17p and a lower incidence of translocations associated with a favorable prognosis and treatment outcome. Older patients with a complex karyotype have an extremely poor prognosis, with only 26% achieving CR owing to high rates of resistant disease. Multidrug resistance is present in 57% of patients over 75 years of age and in 33% of patients with AML younger than 56 years of age. The OS rate in older adult patients with AML is only 2% at 5 years. The biology of AML in the elderly patients may be a consequence of the age of hematopoietic stem cells, shortened telomere length (associated with older cells), presence of fewer normal stem cells to compete with the malignant clones and repopulate marrow following chemotherapy and as mentioned earlier, the increased frequency of age-related somatic mutations present in over 10% of healthy individuals over 70 years of age.

Therapy-Related Acute Myeloid Leukemia and Therapy-Related Myelodysplastic Syndrome

Therapy-related AML and MDS are distinct clinical syndromes occurring as late complications following high-dose chemotherapy, radiation therapy, or autologous stem cell transplantation. A normal karyotype is observed in 8%, and an abnormal karyotype is detected in 92% of the patient population.¹⁸ From the cytogenetic point of view, two different categories of therapy-related AML and MDS can be identified. The first group includes patients who develop AML/MDS following exposure to alkylating agents approximately 5 years after therapy. These leukemias are associated with the presence of monosomy 5/del(5q) or monosomy 7/del(7q) (see Fig. 56.26, third row). Many of these patients initially develop myelodysplastic features before transforming into frank AML. Recurrent abnormalities of chromosomes 5, 7, or both account for 70% of all abnormalities observed in therapy-related leukemia. These patients respond poorly to therapy and have a poor OS. A second group of patients develop therapy-related AML without prior MDS. Leukemia cells in these patients often exhibit 11q23 (3%) and 21q22 (3%) balanced rearrangements, attributed to the late effects of topoisomerase II inhibitors combined with alkylating agents and radiation (see Figs. 56.32 and 56.33). AML may develop within a few months to 3 years after

Fig. 56.40 COMMON MUTATIONS IN DE NOVO AND SECONDARY AML. A number of clonal blood disorders with a myeloid phenotype are represented. Each of these disorders is characterized by recurrent mutations in specific genes, some of which are shared between several different phenotypes (e.g., *TET2*). All of these disorders can transform to secondary AML upon acquisition of additional somatic mutations. When AML arises in the absence of an antecedent clonal blood disorder, it is known as primary AML. *aCML*, Atypical CML; *AML*, acute myeloid leukemia; *CML*, chronic myeloid leukemia; *ET*, essential thrombocytopenia; *IMF*, idiopathic myelofibrosis; *PV*, polycythemia vera; *SM*, systemic mastocytosis. (Reprinted with permission from Grove CS, Vassiliou GS: *Acute myeloid leukaemia: a paradigm for the clonal evolution of cancer?* Dis Model Mech 7:941, 2014.)

therapy. Polysomy (tetrasomy, pentasomy, hexasomy) of chromosome 8 defines a clinicocytogenetic entity associated with therapy-related myeloid malignancies and poor OS (see [box on Genetic Testing for Therapy-Related Neoplasms](#)). When the genome of 22 patients with therapy-related AML was sequenced and compared to whole genome sequence data from patients with de novo AML and secondary AML arising from MDS, the mutational burden of therapy-related AML genomes was found to be similar to that of de novo AML indicating that prior chemotherapy does not induce genome-wide DNA damage. However, a distinct subset of mutated genes is present in therapy-related AML/MDS. The whole genome sequence data revealed that *TP53* mutations and mutations in ABC transporter genes (a subset of which have been implicated in chemotherapy resistance) are significantly increased in therapy-related AML/MDS compared with de novo AML/MDS. *TP53* mutations are present in approximately 33% of patients with therapy-related AML/MDS and are associated with poor risk cytogenetics and a worse prognosis. More recent genomic data suggest that cytotoxic therapy does not directly induce *TP53* mutations. Rather, these studies support a model in which rare stem cells carrying age-related *TP53* mutations that are resistant to chemotherapy expand preferentially following treatment.¹⁹

A novel hierarchical prognostic model of AML solely based on molecular mutations was proposed by a German group in 2012. This model was based on 1000 patients with AML at diagnosis after a median follow-up of 23.7 months. According to Grossman and her colleagues molecular screening for the recurrent balanced rearrangements (*PML-RARA*, *RUNX1-RUNX1T1*, *CBFB-MYH11*) and mutations in *CEBPA*, *NPM1*, *RUNX1*, *ASXL1*, and *TP53* as well as for *FLT3-IDT* and *MLL-PTD* can be used to create a prognostic classification system in AML that improves any prognostic model based on cytogenetics alone.²⁰ Five distinct prognostic subgroups have been identified: (1) very favorable: *PML-RARA* rearrangement or *CEBPA* double mutations with OS at 3 years of 82.9%; (2) favorable: *RUNX1-RUNX1T1*, *CBFB-MYH11* or *NPM1* mutations without *FLT3-IDT*, OS at 3 years of 62.6%; (3) intermediate: none of the mutations leading to assignment into groups 1, 2, 4 or 5; OS at 3 years 44.2%; (4) unfavorable: *MLL-PTD* and/or *RUNX1* mutation and/or *ASXL1* mutation: OS at 3 years 21.9% and (5) unfavorable *TP53* mutation: OS at 3 years 0%. However, using whole-genome or exome sequencing from 71 patients with AML treated with

Genetic Testing for Acute Myeloid Leukemia

At diagnosis, the recommended general practice includes FISH studies using the panel of chromosomal probes for acute myeloid leukemia (AML), including *RUNX1-RUNX1T1*, *PML-RARA*, *CBFB*, *BCR-ABL1*, *MLL*, and *TP53*. Conventional cytogenetic studies must be also performed at diagnosis. Patients with core-binding factor (CBF) AML subtype should be tested for *KIT* exon 17 mutations because these mutations adversely impact the prognosis. These tests are performed at diagnosis to establish a benchmark for the percentage of neoplastic cells and are used in follow-up studies to assess the effectiveness of therapy. In patients with a normal karyotype, mutation studies for the most common genes (*DNMT3*, *NPM1*, *FLT3*, *CEBPA*, and *TET2*) are recommended.

Genetic Testing for Therapy-Related Neoplasms

The best genetic test for therapy-related myelodysplastic syndrome or acute myeloid leukemia is a conventional cytogenetic study. FISH studies with probes for loci on chromosomes 5 and 7, *MLL*, and *RUNX1* should be performed if therapy-related leukemia is suspected. This approach is useful for t(8;21), t(9;22), t(11;var), t(15;17), inv(16), -5/del(5q), -7/del(7q), rearrangements of *ETV6*, and some others.

standard induction therapy demonstrated that for risk stratification the clearance of somatic mutations after chemotherapy is more important than the identification of specific mutations at the time of diagnosis. In this study, the detection of persistent AML-associated mutations in at least 5% of bone marrow cells in day-30 remission samples was associated with significantly increased risk of relapse and reduced OS.

ACUTE LYMPHOBLASTIC LEUKEMIA

ALL accounts for at least 85% of acute leukemias in children and 20% of acute leukemias in adults.²¹ The susceptibility to ALL varies with age; the first peak is between 2 and 5 years of age after birth,

Fig. 56.41 ESTIMATED FREQUENCY OF SPECIFIC GENOTYPES IN CHILDHOOD ACUTE LYMPHOBLASTIC LEUKEMIA (ALL). The genetic lesions that are exclusively seen in cases of T-cell ALL are indicated in *gold* and those commonly associated with precursor B-cell ALL in *blue*. The darker gold or blue color indicates those subtypes generally associated with poor prognosis. *BCR-ABL1*-like cases can be separated into one group with CRLF2 dysregulation and the other with activating cytokine receptor and kinase signaling. (Reproduced with permission from Pui et al: *Pediatric acute lymphoblastic leukemia: where are we going and how do we get there?* Blood 120:1165, 2012).

followed by a gradual decrease during adulthood but an increase in incidence again in individuals older than age 70 years, suggesting that different combinations of environmental and genetic factors contribute to leukemogenesis at different ages. Most published series of patients with acute ALL indicate that 70% to 75% have an abnormal clone by conventional cytogenetic studies (Figs. 56.41 and 56.42). Genomic rearrangements detected with intensive interphase FISH screening have been found in up to 91% of cases. The application of contemporary genome-wide molecular analysis continues to reveal many additional genetic rearrangements that are not detectable with chromosome studies.²² At least one clonal aberration has been detected in 60% to 79% of adults and 57% to 82% of children with ALL.¹⁵ Today, cytogenetic analyses combined with FISH and/or RT-PCR are mandatory in most ALL clinical trials, and genetic findings play a pivotal role in proper risk stratification and identifying treatment options.²³ Several of the ALL-specific chromosome aberrations and their molecular counterparts have been included in the 2008 WHO classification.

Pretreatment cytogenetics is an independent prognostic factor in children and adults presenting with ALL and is important in determining risk categories.¹⁶

As shown in Fig. 56.42 and Table 56.10, the risk categories in children include (a) low risk: high hyperdiploidy (trisomies for chromosomes 4, 10, and 17) and t(12;21)/TEL-RUNX1; (b) high risk: t(1;19)/TCF3-PBX1; and (c) very high risk: t(9;22)/BCR-ABL1, BCR-ABL1-like, 11q23/MLL rearrangements, and iAMP21. In adults the low-risk category includes high hyperdiploidy and del(9p), whereas the high-risk category includes hypodiploidy/near triploidy, t(9;22)(q34;q11), t(4;11)(q21;q23), t(8;14)(q24;q32), and a complex karyotype (five or more chromosomal abnormalities).

Approximately 20% of children and 26% of adults with B-cell ALL are *hyperdiploid*. Two groups are distinguished based on

cytogenetics: (a) those with 51–55 chromosomes whose prognosis is poorer, and (b) those with 56–67 chromosomes whose prognosis is excellent. Both groups have a more favorable prognosis than do children with hypodiploidy or near-haploid ALL. In a study of 1880 children with ALL, patients with 45 chromosomes have an outcome similar to that of pseudodiploid or low hyperdiploid patients with ALL (47–50 chromosomes). Children and adolescents with ALL and hypodiploidy with fewer than 44 chromosomes have a poor outcome. The distribution of specific chromosome gains is not random, with the most often gained chromosomes being 21, X, 14, 6, 18, 4, 17, and 10, each of which is gained in more than 50% of hyperdiploid patients with ALL, followed by gains in chromosomes 8, 5, 11, and 12, that occur more often in patients with 57 or more chromosomes. The prognosis of children with high hyperdiploidy is excellent with a 5-year event-free survival (EFS) rates of between 71% and 83% and a 5-year OS rate of approximately 90%. Pretreatment cytogenetic analyses of more than 5400 children with ALL unequivocally shows that simultaneous trisomies for chromosomes 4, 10, and 17 are associated with a higher long-term EFS (see Fig. 56.42D). By contrast with children who have a favorable prognosis when a hyperdiploid karyotype is present, such a favorable constellation has not been found in patients with adult ALL. The reason for this discrepancy may be that adults often have poor-risk chromosomal translocations, such as the Ph chromosome. Approximately 50% of the high hyperdiploid patients harbor other structural abnormalities, such as gains of 1q, del(6q), which do not appear to influence prognosis, with a possible exception of prognostically adverse isochromosome 17q. Frequently, hyperdiploid leukemic cells fail to proliferate in culture; therefore the use of an ALL panel for FISH is strongly recommended.

Modal chromosome numbers of 45 or less occur in 2% to 3% of cases (specifically, the near-haploid numbers of 24–36)

Fig. 56.42 PROGNOSTIC CYTOGENETIC CATEGORIES IN ACUTE LYMPHOBLASTIC LEUKEMIA. (A) Localization of TEL/ETV6 and AML1 fluorescence probes to chromosomes from a normal bone marrow metaphase cell. TEL/ETV6 is on 12p13 (green) and AML1 is on 21q (red). (B) Partial karyotype showing t(12;21)(p13;q22) (arrows). The short arrow at 12p indicates a possible TEL deletion from normal chromosome 12. (C) FISH study showing loss of TEL (green) from normal 12 homologue in interphase nucleus, a frequent subclonal evolution in patients with t(12;21). (D) Hyperdiploidy, specifically trisomies for chromosomes 4 (green), 10 (red), and 17 (aqua), is associated with low-risk cytogenetic category (see text for details) and is present in disomy in interphase cells (top left). (E) Partial G-banded karyotype showing t(1;19)(q23;p13.3), which occurs in approximately 6% of patients with B-cell precursor childhood acute lymphoblastic leukemia. (F) FISH hybridization to bone marrow nucleus showing BCR-ABL fusion (yellow). (G) As a consequence of t(9;22), occurring in 5% of children and 20% to 25% of adults with acute lymphoblastic leukemia. (H) Interphase nucleus after FISH study with tricolor probe. Dual-color/breakapart MLL shows separation of the 3' end and the 5' end as a result of 11q23 rearrangement. CEP11 (aqua) indicates disomy for chromosome 11, used as internal control. MLL rearrangements in acute lymphoblastic leukemia are associated with unfavorable prognosis.

that confer a poor prognosis. Similarly, ALL in adults presenting with low hyperdiploid/near-triploidy have poor outcomes. Loss of chromosome 7 is frequent in adult patients with ALL and the majority of these patients also have t(9;22). Hypodiploid ALL can be further divided into multiple subgroups according to chromosome number. Genomic profiling have shown that near haploid (24–31 chromosomes) and low-hypodiploid (32–39 chromosomes) childhood ALL are distinct subtypes: near-haploid-ALL is associated with a high frequency of *RAS*-activating mutations including focal deletions of *NF-1* whereas low-hypodiploid ALL has biallelic alterations of the *TP53* locus, deletions of *CDKN2A/B* and/or *Rb1*. *TP53* mutations are also present in nonhematopoietic cells in half of childhood patients with a low-hyperdiploid karyotype, indicating that this disease is a manifestation of Li-Fraumeni syndrome. Diagnosis of low hyperdiploid ALL requires *TP53* testing and genetic counseling.

In childhood ALL, t(12;21) was first reported in 1994 as a fortuitous FISH finding. This translocation is difficult to detect by conventional cytogenetics because the translocated portions of 12p13 and 21q22 have virtually identical G-banding patterns. In contrast, the *ETV6-RUNX1* fusion product of t(12;21) is detected using PCR or FISH in 17% to 30% of pediatric patients with ALL (see Fig. 56.42A–C). The *ETV6-RUNX1* fusion, found almost exclusively in children 1–15 years old with B-precursor ALL, represents the most frequent molecular rearrangement in childhood cancer. Children

with the *ETV6-RUNX1* fusion gene have significantly lower rates of relapse than do *ETV6-RUNX1*-negative patients. *ETV6-RUNX1* positive B-precursor ALL is characterized by a prolonged duration of first remission and excellent cure rates. Prospective analyses have demonstrated that the survival rate in t(12;21)-positive patients is significantly better when compared with cases lacking this abnormality; however, this abnormality in multivariate analysis was not found to be an independent predictor of outcome. The *ETV6-RUNX1* fusion is rare in adult ALL. t(12;21)(p13;q22) fuses the helix-loop-helix domain of the *ETV6* gene, located on chromosome 12, band p13, to the DNA-binding and transactivation domain of the *RUNX1* gene, located on 21q22. FISH studies allow visualization of the fusion gene on 21q22. Fusion with *ETV6* converts *RUNX1* from an activator to a repressor of transcription. The *ETV6-RUNX1* fusion is accompanied in 55% to 70% patients by the loss of the other normal nonrearranged *ETV6* allele.¹⁷ This deletion probably represents subclonal evolution. *ETV6-RUNX1* has been detected in utero, probably in a committed B-cell progenitor, and is present in normal cord blood and peripheral blood samples at frequencies 100-fold greater than the risk for corresponding leukemia. The current view of development of *ETV6-RUNX1*-positive leukemia is that these early events are followed by a long “preleukemic” phase followed by loss of the normal *ETV6* homologue, which appears to be an important event in the multistep pathogenesis of this form of leukemia. Currently, of the 397 children with *ETV6-RUNX1*-positive leukemia reported,

TABLE
56.10

Frequency of Cytogenetic Aberrations in Adult and Childhood Acute Lymphoblastic Leukemia and Their Prognostic Relevance

Cytogenetic Abnormality	Genes Involved	Adults		Children	
		Frequency (%)	Prognosis	Frequency (%)	Prognosis
Normal karyotype	NA	15–34	Good	31–42	Favorable
High hyperdiploidy (>55)	NA	7–8	Good-intermediate	23–30	Good
Low hyperdiploidy (>50)	NA	10–15	Poor	10–11	Intermediate
Near haploidy (<35)	NA	Rare	NA	1–4	Poor
Pseudodiploidy	NA	31–50	Poor	18–26	Intermediate
Hypodiploidy (35–44)	NA	4–9	Poor	6	Poor to intermediate
t(9;22)(q34;q11.2)	<i>BCR-ABL1</i>	11–29	Poor	1–3	Intermediate
t(4;11)(q21;q23)	<i>MLL-AFF1</i> ^a	4–9	Poor	2	Poor
t(1;19)(q23;p13.3)	<i>TCF3-PBX1</i>	1–3	Poor, intermediate favorable	1–6	Intermediate, favorable
t(12;21)(p12;q22)	<i>ETV6 (TEL)-RUNX1</i>	0–3	Not known	22–26	Good
t(8;14)(q24;q32)	<i>MYC-IGH</i>	5–15	Poor	5	Poor
Abnormal 9p	<i>CDKN2A</i>	7–13	Intermediate	7–11	Adverse
Abnormal 9p13	<i>PAX5</i>	2	?Intermediate	2–5	Poor
Abnormal 12p	<i>ETV6</i>	0–3	Favorable/unfavorable	3–9	Not prognostic
del(6q)	Not known	3–6	Not prognostic	6–9	Adverse
del(7p)/del(7q)/–7	Not known	6–11	Not prognostic	1	Adverse
del(5q)	Not known	<2	Not prognostic	2	Not known
Trisomy 8	NA	10–12	Poor	3–4 (17%–22% in T-ALL)	Not prognostic
14q11	<i>TCRα</i>	5–7 (26% in T-ALL)	Excellent	Rare	Poor
t(10;14)(q24;q11)	<i>TRD-TLX1</i>	1–3	Excellent, intermediate		
BCR-ABL1-like	<i>ABL, JAK, EPOR, CRLF2, IKZF del</i>	17	High risk	15	High risk
iAMP21	<i>RUNX1</i>	0.5	Poor	2	Poor, unless treated on intense protocol
Monosomal karyotype	NA	9.2	Treated on high risk protocol	12.8	Treated on high risk protocol

^aSee Table 56.8 for all other mixed lineage leukemia rearrangements.
NA, Not applicable; T-ALL, T-cell acute lymphoblastic leukemia.

approximately 60% harbor additional karyotypic abnormalities that contribute to their pseudodiploid or near-diploid karyotypes. The most common secondary change, which occurs in approximately 50% of cases with additional abnormalities, is trisomy 21.

A rare group of patients with B-precursor ALL lack fusion of *TEL* and *RUNX1* but have 3 to 15 copies of the q22 band of chromosome 21, including the *RUNX1* locus. Intrachromosomal amplification of the 21q22 band of chromosome 21 is a clonal marker of the leukemic cells that defines a distinct ALL subgroup (Fig. 56.43A). The British Childhood Leukemia Working Party prospectively screened 1630 patients with childhood ALL and identified 28 children with intrachromosomal amplification of chromosome 21 (iAMP21) (see Fig. 56.43D).²⁴ Approximately 2% of children and less than 0.5% of adults display iAMP21. Children with iAMP21 have a common or pre-B-cell immunophenotype, a median age of 9 years at presentation, and a significantly inferior event-free and OS at 5 years compared with children exhibiting other cytogenetic subgroups. Even children with Ph-positive ALL have a better 5-year EFS as compared with children with iAMP21. These children have a threefold increased risk for relapse and are twice as likely to die than are their counterparts without iAMP21. The complexity and variability of the iAMP21 includes multiple regions of gains, amplification, inversion, and deletions. In spite of their differences in genomic profiles, the consistent features of patients with ALL and iAMP21 include a common region of highest level amplification spanning 5.1 Mb from 32.8 to 37 Mb,

within which the *RUNX1* gene is located. These observations confirmed that FISH, using probes directed to *RUNX1* locus, to determine the number of copies of the most amplified region, provides a reliable detection method. Thus the finding of three or more extra copies of *RUNX1* on a single abnormal chromosome 21 (a total of five or more *RUNX1* signals per interphase cell) is currently used as the international definition of iAMP21.

Recent genomic, cytogenetic and transcriptional analysis coupled with novel bioinformatic approaches revealed that individuals born with a rare constitutional Robertsonian translocation, t(15;21)(q10;q10)c have an approximately 2700-fold increased risk of developing iAMP21ALL compared with the general population. In these patients, amplification is initiated by a chromothripsis event (a process whereby localized genomic regions are shattered and rearranged in one catastrophic event) that affects both sister chromatids of the Robertsonian chromosome. In sporadic iAMP21, breakage-fusion-bridge (BFB) cycles are typically the initiating event, often followed by chromothripsis. In both sporadic and rob(15;21)c-associated iAMP21, the final stages frequently involve duplications of the entire abnormal chromosome. The end-product is a derivative of chromosome 21 or the rob(15;21)c chromosome with gene dosage optimized for leukemic potential, showing constrained copy number levels over multiple linked genes.

Patients with iAMP21 display a unique spectrum of secondary chromosomal abnormalities and they include gain of X chromosome,

Fig. 56.43 DETECTION OF AML1 AND 21q22 AMPLIFICATION. (A) Intrachromosomal amplification of AML1 (red) (TEL [green], present in disomy) in a pediatric patient with pre-B-cell acute lymphoblastic leukemia. This finding is associated with poor prognosis. (B) G-banding of der(18) chromosome and after FISH study (C) with WCP 18 (green) and LSI 21q22.13 (red), documenting der(18)t(18;21) and amplification of 21q22 region in a patient with myelodysplastic syndrome/acute myeloid leukemia. (D) Amplification of 21q22 region in myelodysplastic syndrome may be present in another formation: der(21) (G-banding, left). FISH study shows amplification of 21q22.13 locus (red) and identified der(21) as t(5;21) with 5p15.2 probe (green). (E) Localization of 21q22.13 LSI probe on normal chromosome 21. (F) Homogeneous staining region (hsr)(21), G-banding (left), and after FISH study (right) with locus-specific probe for 21q22.13 (red) consistent with 21q22.13 band amplification in a patient with myelodysplastic syndrome.

10 or 14, or monosomy 7/deletion 7q deletions of 11q, including *ATM* and *MLL* genes, deletions of *ETV6* and *RBI*.

Both the UK and US Children Oncology groups demonstrated that patients with ALL and iAMP21 when stratified as a high-risk group and treated on the most intensive treatment arm have a 5-year EFS (from 29% to 78%), a risk of relapse (reduced from 70% vs. 16%) and OS from 67% versus 89%.

The *ETV6* transcription factor gene, was first identified as a part of a *TEL*-platelet-derived growth factor receptor β fusion [*TEL* (*ETV6*)-*PDGFRB*] created by t(5;12)(q33;p13) in chronic myelomonocytic leukemia. It was detected using FISH owing to difficulties in detecting cytogenetic rearrangements at the 12p13 site. As a result of this translocation, the helix-loop-helix domain of *ETV6* is fused in frame to the *PDGFRB* transmembrane and tyrosine kinase domain. Fusion of *ETV6* to a tyrosine kinase also occurs as a result of t(9;12)(q34;p13), leading to the *ABL1-ETV6* fusion that has been observed in patients with ALL, AML, and atypical CML. More than 39 partner genes are known to participate in fusions with *ETV6*, primarily in ALL and less frequently in myeloid malignancies.

Other rearrangements involving 12p include deletions, duplications, and translocations and are observed most often as part of a complex karyotype, frequently associated with chromosome 5 and/or 7 abnormalities. Deletion of 12p13 is much more frequent in

Fig. 56.44 The Ph CHROMOSOME IN ACUTE LYMPHOBLASTIC LEUKEMIA. t(9;22)(q34;q11) (arrows) in a patient with acute lymphoblastic leukemia. Note that the first chromosome 9 has deletion of the short arms, a frequent finding in both adult and pediatric patients with acute lymphoblastic leukemia.

children than in adults with ALL and is observed in patients with myeloid disorders, specifically in adults with MDS. Two other genes residing on 12p are also rearranged: *CCND2* is frequently amplified, and *CDKN1B* is often deleted.

Approximately 5% of children and 20% to 25% of adults with ALL have a Ph chromosome, making it the most common structural rearrangement in adult ALL (Fig. 56.44). The breakpoint on the Ph chromosome is more centromeric than in CML (see [Chronic Myelogenous Leukemia section, earlier](#)). It includes the 5' breakpoint on chromosome 22, distal to the first exon (falling between exon e1 and e2) of the *BCR* gene, resulting in the P190^{BCR-ABL1} variant, providing a diagnostic distinction between the lymphoid blast crisis of CML and de novo ALL. Ph-positive ALL is characterized by a smaller BCR-ABL1 (P190) protein, containing less BCR than the P210 and P230 fusion proteins. Among Ph-positive patients with ALL, approximately 58% to 70% of adults and 80% of children have this breakpoint variant. Up to 19% of Ph-positive patients with ALL may express both the P190 and the P210^{BCR-ABL1} proteins. A number of earlier studies indicated that the P190 type of the *BCR-ABL1* breakpoint is associated with a more aggressive form of disease, with greater transforming ability than the P210 protein. Ph-positive ALL has been classified as a stem cell disorder because of the presence of the *BCR-ABL1* transcript in both the myeloid and lymphoid cells.

The *BCR-ABL1* fusion variants are easily detectable by FISH using the extrasensitive probe strategy, and *BCR-ABL1* leukemia can be identified in up to 10% of Ph-negative cases using conventional cytogenetics. Moreover, FISH will identify *ABL* rearrangements in *BCR-ABL1* patients with fusion-negative ALL.

Reactivation of BCR-ABL1 kinase activity is most commonly associated with the emergence of point mutation in the ABL1 kinase domain implicated in imatinib resistance (see [Chronic Myelogenous Leukemia section, earlier](#)). Recent studies have indicated that kinase domain mutations are present in 70% of imatinib resistant patients with T315I (37%), E255K (18%) and Y253H (18%) mutations accounting for 75% of these cases. Moreover, 78% of patients resistant to second-generation TKIs were positive for such mutations, and 58% of them had multiple mutations.

More than 60% of adult patients with Ph-positive ALL show additional chromosomal abnormalities in the Ph-positive clone. Most frequent are gain of Ph chromosome, monosomy 7, +8, +X, del(9p), and high triploidy. The additional chromosomal abnormalities have no effect on survival of these patients. High hyperdiploidy is detected in approximately 15% of Ph-positive ALL. According to the WHO classification, 1% of all leukemias are mixed phenotype acute leukemias with t(9;22)(q34;q11.2) and leukemic blast cells expressing B-cell and myeloid phenotypic markers. Occasional T-cell phenotype and trilineage *BCR-ABL1* mixed phenotype leukemia have been rarely reported.

"BCR-ABL1-like" Acute Lymphoblastic Leukemia

Retrospective studies have demonstrated that GEP can be used effectively to classify ALL into prognostically important subtypes.

BCR-ABL1-like ALL is a newly described ALL subtype lacking *BCR-ABL1*, but with a similar expression profile to *BCR-ABL1+* leukemia. This new “*BCR-ABL1*-like” (“Ph-chromosome-like”) ALL includes approximately 15% of all precursor B-cell ALL in children and 17% of adults with ALL and is associated with higher relapse rate and lower EFS (see Fig. 56.41). According to the currently used risk stratification system, 43% of the “*BCR-ABL*-like” patients are classified as having high-risk disease. Large-scale genomic profiling and sequencing studies of over 1700 childhood and young adult patients with ALL has revealed rearrangements of *ABL*-class genes, rearrangements of *JAK2*, *EPOR*, and *CRLF2*. *ABL*-class rearrangements result in the expression of fusion genes that activate *ABL1*, *ABL2*, *CSFR1*, and *PDGFRB*. In this group of patients *IKZF1* deletions occur in 40% of pediatric and in 46% of adult patients.¹⁹ *CRLF2* (Xp22.33/p11.3) rearrangements are observed in approximately 50% of patients with *BCR-ABL1*-like ALL. The gene encodes for cytokine receptor-like factor 2, also known as thymic-stromal-derived lymphopoietin receptor which in combination with the interleukin-7 receptor forms the receptor for the thymic stromal lymphopoietin. *CRLF2*-rearranged leukemic cells have activated JAK-STAT and PI3K signaling pathways.

t(1;19)(q23;p13.3)/*TCF3/PBX1* occurs in 5% to 6% of patients with B-cell precursor childhood and adult ALL. However, among patients with a pre-B (cytoplasmic Ig-positive) *t*(1;19) is found in approximately 25% of cases (see Fig. 56.32E). Cytogenetically, two forms of *t*(1;19) have been identified: 25% of cases have a balanced reciprocal *t*(1;19), whereas 75% have a rearrangement of unbalanced *der*(19)*t*(1;19)(q23;p13.3). The unbalanced *der*(19)*t*(1;19) arises from the initial trisomy of chromosome 1 followed by the *t*(1;19) translocation, with subsequent loss of the derivative chromosome 1. More than 95% of *t*(1;19) are associated with the *TCF3-PBX1* chimeric gene protein product which arrests cell differentiation. The *TCF3* gene (originally identified by the binding of E2A proteins to the kE2DNA sequence motif contained in the Ig κ light-chain enhancer) on chromosome 19, band p13.3, is fused to the *PBX1* (homeobox) gene on chromosome 1, band q23. Approximately 1% of pediatric patients with B-ALL have a variant *t*(17;19)(q21-q22;p13) translocation resulting in two different genomic rearrangements. The first is the fusion between the *HLF* gene (breakpoint in intron 3) on chromosome 17 and the *TCF3* gene (within intron 13) on chromosome 19, associated with disseminated intravascular coagulopathy. The second is the breakpoint in intron 12 of *TCF3* and intron 3 of *HLF* which is associated with hypercalcemia. In contrast to *ETV6-RUNX1* rearrangements, which have a prenatal origin, current evidence suggests a postnatal etiology for *t*(1;19) translocations.

Currently, it is thought that an unbalanced *der*(19) in pediatric patients with ALL is associated with significantly improved outcome as compared with patients with balanced *t*(1;19). In adults as the sole abnormality, *t*(1;19)/*der*(19)*t*(1;19) is associated with an intermediate prognosis; however, within the context of a hyperdiploid karyotype, it is associated with a poor prognosis. Patients with *TCF3-PBX1* fusion also display *PAX5* (19p13.2) haploinsufficiency, detectable both by conventional and molecular cytogenetics. A variant *t*(17;19) rearrangement is associated with a poor prognosis. A recent study of adult patients with ALL has suggested that prognosis of patients with *t*(1;19) can be substantially improved by the treatment with hyper-CVAD regimen. Both *t*(1;19) and *t*(17;19) are easily identifiable by conventional cytogenetics, FISH, and RT-PCR, the latter two methodologies are particularly useful in posttreatment specimens that are cytogenetically normal.

In ALL, the most frequent *MLL* (*KMT2A*) translocations include *t*(4;11) (1%–2% incidence in children and two-thirds of *MLL*-positive adults) (see Fig. 56.33) leading to a *MLL-AFF1* (AF4) fusion and *t*(11;19)(q23;p13.3) (see Fig. 56.32L) resulting in *MLL-MLLT1* (*ENL*) fusion. These abnormalities are present in more than 80% of patients with infant leukemia and 10% of childhood and adult *MLL*-positive leukemia. *MLL* rearrangements are associated with a poor outcome in both children and adults (see Acute Myeloid Leukemia, earlier, and T-Cell Lymphoproliferative Diseases, later). One-third of

patients with *t*(4;11) have secondary abnormalities; the most frequent are +X, i(7q), abnormalities of 9p, including i(9q), and +8. The outcomes of patients with *t*(11;19) is generally poor, especially in children younger than 1 year of age. The most frequent additional abnormalities in patients with *t*(11;19) are +X, +8, and *del*(6q). Other less common *MLL* translocations include *t*(9;11)(p22;q23)/*MLL-MLLT3*, *t*(10;11)(p13–15;q23)/*MLL-MLLT10* and others. A large multiinstitutional study has determined that secondary aberrations do not affect prognosis of children with ALL and *t*(4;11), *t*(11;19) or other *MLL* translocations.

Secondary forms of ALLs are rarely reported but the majority of them are associated with *MLL* rearrangements, the most frequent being *t*(4;11). Most of these patients have received topoisomerase II inhibitors which are known to cause double-strand DNA breaks.

t(8;14)(q24;q32) is seen in fewer than 5% of all patients with ALL (children and adults) (Fig. 56.45). Variant translocations *t*(8;22)(q24;q11) and *t*(2;8)(p12;q24) are seen in less than 1% of children and adults. These cells express CD10, CD19, CD20, and surface IgM immunophenotype. This form of ALL has extremely poor prognosis. The same translocation is found in Burkitt lymphoma (BL), and both entities likely represent the same disease with different manifestations. The majority of adult patients with *t*(8;14) die within 1 year of diagnosis. Approximately 4% of children and 11% of adult pre-B-cell precursor ALL have recurrent *IGH* translocations usually identified by cytogenetics or FISH. The *CRLF2* gene, which maps to the pseudoautosomal region 1 of the sex chromosomes, is the gene that is most frequently targeted in 20% to 26% of *IGH* translocations in pre-B-cell precursor ALL. *IGH-CRLF2* rearrangements result from the cryptic *t*(Y;14)(p11;q32) or *t*(X;14)(p22;q32). The second most frequent *IGH* translocation resulting in *t*(14;19)(q32;q13), resulting in *IGH-CEBP* chimeric fusion. The third most frequent translocation partner involves *CEBPD* gene (8q11) resulting in *t*(8;14)(q11;q32) and *IGH-CEBPD* fusion, which is primarily found in children and young adults and is strongly associated with Down syndrome (about 30% of cases). This subgroup frequently have a gain of X chromosome, trisomy 21 as an acquired abnormality, and the Ph chromosome/*t*(9;22)(q34;q11). The *t*(14;19)(q32;q13)/*IGH-EPOR* appears to be causally related to pre-B-cell precursor ALL because it always appears always as the single abnormality. The *inv*(14)(q11q32)/*ins*(14;14)(q11;q32) leads to *IGH-TRA/D*, which represent a rearrangement mediated by an interlocus site-specific recombination event between *IGH* and the *TRA* and *TRB* genes. The *t*(14;20)(q32;q13) results in *IGH-CEBPB*. Collectively, patients with *IGH* translocations may be included in a subgroup of pre-B-cell precursor ALL.

Abnormalities of the short arms of chromosome 9 (p21–22) occur at a frequency of 7% to 13%. In adults the presence of *del*(9p) appears to be associated with a favorable outcome, whereas in children with ALL, *del*(9p) is associated with poor outcome. The most frequent abnormalities are co-deletions of two genes, *CDKN2A* and *CDKN2B*, as well as the interferon α and β genes found in many cases. Among the structural rearrangements involving the short arms of chromosome 9, *t*(dic(9;12)(p11–12;p11–13)) is a rare recurrent abnormality associated with L1 morphology (FAB classification), a pre-B-cell phenotype, and an excellent prognosis.

The *IKZF1* gene at 7p12.2 codes for IKAROS, an essential transcription factor in hematopoiesis primarily involved in lymphoid differentiation and is an essential player in the regulation of both T- and B-cell lineage specification.⁵ The gene is composed of eight exons, spanning a total of 6.2 kb and coding for a 519-amino acid protein. Deletions of *IKZF1* have been reported in 15% of pediatric and 30% to 50% of adult patients with ALL, and in 75% of Ph-positive B-cell ALL. Both focal and nonfocal *IKZF1* deletions have been shown to be associated with an increased risk of relapse and decreased EFS in both pediatric and adult ALL. Most laboratories use SNP array technique to detect *IKZF1* deletion. Recent genomic studies of patients with ALL have confirmed a higher hazard of relapse in adult ALL with focal *IKZF1* deletions.

Other chromosomal abnormalities detected in nonrandom fashion in adult patients with ALL include deletions, both terminal and interstitial, of the long arm of chromosome 6, and isochromosomes

Fig. 56.45 $t(8;14)(q24;q32)$ IN ACUTE LYMPHOBLASTIC LEUKEMIA. *Top panel* shows a partial G-banded karyotype of chromosomes 8 and 14 with arrows indicating the breakpoints on each chromosome. The *bottom panel* is a partial metaphase (chromosomes are stained blue with DAPI) after FISH testing using three probes: *IGH* signal (green) is seen on normal chromosome 14, *aqua* signals for centromere 8 are observed on both chromosome 8, *MYC* (red) is seen on both chromosomes 8 but note a more bold signal on one chromosome 8 when compared to the other. Because *MYC* is broken as a result of $t(8;14)$, the third copy of *MYC* is on chromosome 14 where it is fused to *IGH* and seen as a yellow signal.

of 7q, 9q, 17q, and 21q. Adult patients with ALL with $t(9;22)$, $t(4;11)$, $t(8;14)$, -7 , $+8$ chromosomal aberrations have a poorer prognosis and significantly lower probability of long-term CR and survival than do patients with a normal karyotype or patients with other chromosomal rearrangements.

Complex and Monosomal Karyotype

Patients with ALL and a complex karyotype have a poorer outcome in terms of OS and EFS, with most relapses occurring during the first 2 years after diagnosis. More recently a study found that 9.2% of adult patients with ALL had a complex karyotype and 12.8% had a monosomal karyotype. In this study, neither was associated with a

worse prognosis when treated with risk-adapted or subtype oriented protocols. Monosomal karyotype did not have an impact on prognosis in Ph-positive ALL irrespective of imatinib treatment.

The lymphoid leukemias associated with Down syndrome (DS-ALL) are almost exclusively B-precursor ALLs. In a recent large series of DS-ALLs, there were only five cases of T-ALL among 700 patients. Also, in a sharp contrast to the myeloid neoplasms, they almost never occur in infants. Clinically the outcome of DS-ALL is significantly worse than sporadic childhood B-cell precursor ALLs because of intrinsic resistance to therapy and increased treatment-related mortality. Although all known cytogenetic subgroups of childhood B-cell ALLs have been observed, the common abnormalities such as *ETV6/RUNX1* fusion and hyperdiploidy, are less frequent.

Up to 60% of DS-ALLs have aberrant expression of the cytokine receptor *CRLF2* that is often associated with additional mutations activating JAK-STAT signaling. The aberrant expression of this receptor is caused by genomic rearrangements consisting either of a translocation into the *IgH* locus control region or a microdeletion upstream to the *CRLF2* gene, located on the pseudoautosomal component of the sex chromosomes. This deletion fuses *CRLF2* with the promoter of an upstream constitutively expressed *P2RY8* gene. Analysis of the breakpoint sequences suggest that this rearrangement is mediated by *RAG1* or *RAG2* in early B-cell precursors.

Somatic Mutations

The most commonly altered pathways in ALL, involving the transcriptional regulation of lymphoid development, such as *PAX5* (9p13.2), *IKZF1* (7p12.2) and *EBF1* (5q33.3), are frequently mutated. *PAX5* is required for B-lymphoid lineage commitment and maturation. *PAX5* genetic alterations include deletions, sequence mutations, and chimeric genes with at least 16 different chromosomal partners (<http://atlasgeneticsoncology.org/Genes/PAX5ID62.html>). *IKAROS* is required for the development of all lymphoid lineages and its genetic lesions are implicated in resistance to chemotherapy and TKIs.

Other commonly mutated pathways in ALL include genes involved in tumor suppression and cell cycle regulation (*TP53*, *Rb1*, and *CDKN2A*), cytokine receptor, RAS-signaling, lymphoid signaling and epigenetic modification such as *EZH2*.

Multistep Pathogenesis of Acute Lymphoblastic Leukemia

Epidemiologic and twin studies indicate a multistep pathogenesis of B-cell ALL in infants and children, with an initial leukemogenic event(s) occurring in utero and subsequent genomic changes occurring postnatally. Most of the current thinking of the natural history of childhood ALL was based on the exquisite work of Mel Greaves who studied the clonal origin of leukemia in monozygotic twins. Greaves found that most common chromosomal translocations and their resultant gene fusions can be documented by molecular analysis of neonatal blood spots or Guthrie cards. If a unique gene fusion sequence is present in at least one cell per 30,000 in the peripheral blood, it can be detected by a sensitive PCR assay. The first observations of an in utero origin of an acute leukemia were demonstrated with *MLL* rearrangements in three children with ALL, in monozygotic twins who shared the identical *ETV6-RUNX1* fusion, and in a pair of twins diagnosed at age 3 with B-precursor ALL. Subsequently in utero occurrence of *BCR-ABL1*, and loss of *IKZF1*, *PAX5*, and biallelic loss of *CDKN2A* have been documented prenatally on Guthrie cards. The concordance rate of twins who share a monochorionic placenta and develop leukemia is nearly 100%, whereas older twins have a discordance rate of 90%, indicating that additional postnatal leukemic events are needed. The frequency of an in utero origin of a B-cell precursor ALL in nontwins as measured by clonal *IGH* rearrangements is reported to be 71%, supporting the notion that in the majority of infants older

Genetic Testing for Acute Lymphoblastic Leukemia (ALL)

At diagnosis, conventional cytogenetic studies should be performed, especially for pediatric patients in whom solely numerical anomalies occur in 25%. FISH and molecular genetic methods are helpful in detecting certain cryptic chromosome anomalies, such as *ETV6-RUNX1* fusion associated with t(12;21)(p12;q22). The panel of FISH probes useful at the diagnosis of pediatric ALL include *ETV6-RUNX1*, *MLL*, *BCR-ABL1*, *TCF3/PBX1* and *CDKN2A* (9p21.3), and *CDKN2B* (9p21.3) on the short arms of chromosome 9, and centromeric probes for chromosomes 4, 10, and 17. In adults, the role of hyperdiploidy as it relates to prognosis is uncertain; thus FISH testing with centromeric probes is not useful. Establishing benchmarks with FISH and/or molecular testing is crucial for follow-up of patients during and after therapy.

than 1 year, the development of ALL occurs during fetal development because they share a single placenta resulting in blood cell chimerism. The prenatal mutation occurs commonly, exceeding the actual rate of developing leukemia by some 100-fold, indicating a low rate of reentrance or evolution. The acquisition of the additional genetic lesions, such as copy number alterations of *ETV6*, *PAX5* and *CDKN2* (25%–75% of cases) are recurrent and contribute to leukemogenesis. After testing five pairs of monozygotic twins with concordant *ETV6-RUNX1*-positive ALL, Greaves and his colleagues demonstrated that all recurrent driver mutations detected (32 in total) were different within twin pairs, indicating that they are postnatal in origin in both twins and most likely represent secondary mutations. Further single cell analyses revealed considerable complexity within a tree-like or branching structure of genetically distinct subclones, and as Greaves and colleagues suggested, very reminiscent of Darwin's original 1837 evolutionary divergence diagram (see box on Genetic Testing for Acute Lymphoblastic Leukemia, and earlier section on clonal origin).

B-CELL CHRONIC LYMPHOCYTIC LEUKEMIA

Historically, classic metaphase cytogenetic analyses of CLL were difficult because of the low mitotic yield of neoplastic B cells despite the use of polyclonal B-cell mitogens. FISH analysis of nondividing interphase cells was applied for the first time to hematologic malignancy, for the risk stratification of CLL. Introduced in 2000 by Dohner, the FISH hierarchical prognostic model stratifies patients into good [normal cytogenetics, del(13q)], intermediate with trisomy 12, and poor prognostic groups [del(11q) and del(17p)] and remains the most accepted and validated genomic prognostic model.²⁶ Moreover, current guidelines still recommend FISH analysis before treatment initiation and also following relapse or lack of response to therapy.

Cytogenetically CLL is characterized by relatively stable genome with a gain or loss of chromosomal regions; balanced translocations, a hallmark of AML, are rare in CLL. With improved detection rate of aberrant karyotypes in CLL using cultivation with CD40 ligand (DSP30) and interleukin 4 and the application of molecular cytogenetics, such as FISH, aCGH, as well as NGS, the detection rate of genomic changes has been raised to 80% to 90%. Analysis of clinically relevant chromosomal loci, combined with immunophenotyping, mutational analyses of the Ig heavy-chain variable region (IgV_H), and ZAP-70 overexpression, are of prognostic importance, even though the oncogenic events that lead to the origin of B-CLL remain unknown (Tables 56.11 and 56.12 and Fig. 56.46; see also box on Genetic Testing for B-Cell Chronic Lymphocytic Leukemia). Although microarray and high-density SNP array studies have not identified genes involved in the pathogenesis of CLL, they are helpful in clarifying the heterogeneous nature of CLL, which is a single disease entity with a common genetic phenotype resembling memory B lymphocytes. Genetic testing is strongly recommended for all patients with CLL, particularly in the context of novel therapeutic

trials for CLL. Moreover, a complex conventional karyotype remains an independent prognostic indicator associated with a poor outcome.

Chromosomal abnormalities in CLL detected by FISH are of prognostic significance (Fig. 56.47). Four genomic aberrations, as well as normal findings, are independent predictors of disease progression and survival. Genomic aberrations of prognostic significance include 17p deletion, 11q deletion, trisomy 12, and 13q deletion. Survival in these groups was 32, 79, 114, and 133 months, respectively, and the treatment-free interval was 8, 12, 33, and 92 months, respectively (see Fig. 56.46). Survival of patients with a normal karyotype was 111 months, and the treatment-free interval was 49 months. The deletion of 17p13 affects the tumor suppressor gene *TP53*. In 80% to 90% of the cases, a deletion of 17p is associated with mutated *TP53* on the remaining copy. This is one possible reason why p53 pathway-based therapies are not effective in patients with 17p deletion. *TP53* mutations have been found in 4% to 15% of patients with early-stage CLL and are associated with poorer outcome. Deletion of 11q and deletion of the *ATM* gene on 11q23.1 are found in 18% of patients with CLL. In about one-third of patients with deleted 11q, a simultaneous mutation of *ATM* has been found. The OS of these patients is shorter.

FISH-detected anomalies are frequent in B-CLL cases with Rai stages 0 to 1 disease, but are more frequent among patients with progressive disease (88%) than in those with stable disease (66%). Two risk groups have been recognized: (a) low risk disease includes patients with a normal karyotype or isolated del(13q); (b) high risk includes patients with del(11q) and del(17p). Patients with +12 are high risk, but in contrast to del(11q) and del(17p), they respond to fludarabine-based therapies (see Fig. 56.46). A comparison of quantitative PCR method with FISH for assessment of the four most frequent aneuploidies revealed a tight correlation in 103 of 110 patients examined, with FISH being more sensitive in detecting subclonal genetic evolution.

The frequency of chromosome 13 abnormalities in CLL detected by conventional cytogenetics is 10% to 15%. However, with the use of FISH, smaller or larger deletions of band q14.3 are detected in up to 60% of patients over time. When multiple DNA probes are used, D13S319 and D13S25 DNA markers are deleted more frequently than is *RBI*. Molecular analyses have detected deletions of 13q in cells that are cytogenetically normal as well as abnormal. These deletions can either be heterozygous (76%) or homozygous (24%). Heterozygous deletions most frequently occur in the early stage of the disease and homozygous deletions occur in the more advanced stages. In a study examining loss of heterozygosity and subchromosomal copy losses of chromosome 13, two types of deletions were defined: type 1 aberrations occurred in 60% of cases and were associated with loss of Rb1 and breaks close to the *miR16/15a* locus; and type 2 aberrations that included Rb1 occurred in 40% of cases. The 13q14.3-deleted segment contains micro-RNA (miRNA) genes. miRNAs are normally made by cells, including B lymphocytes, and they regulate the function of many genes. All patients with homozygous 13q deletion have a dramatic downregulation of miRNA15a, whereas patients with hemizygous 13q deletions are indistinguishable from controls, providing the first molecular clues for pathogenesis of CLL. The percentage of CLL cells with del(13q) is predictive of survival: a high percentage (>80%) of del(13q) cells results in a shorter survival as compared with patients with a lower percentage (<80%) of del(13q) cells. The clinical correlation with del(13q) cells include a higher lymphocyte count, a tendency to exhibit a diffuse pattern of bone marrow infiltration, and splenomegaly. Trisomy 12 or 13q rearrangements are found separately in a substantial proportion of patients with CLL. They co-exist in only 2% to 5% of patients, suggesting that each change may have a distinct pathogenetic route. The presence of del(13q) as the sole abnormality in CLL is associated with the most favorable prognosis, with a median survival of 11 years.

Among the first-degree relatives of patients, population studies have demonstrated a sevenfold increased risk for developing CLL and a twofold increased risk for developing other lymphoproliferative disorders. More than 80 families with CLL affecting multiple family

^a223 naive patients with chronic lymphocytic leukemia.^bGain of 3q and 8q and loss of 17p are independent unfavorable prognostic biomarkers.

members have been reported. Linkage studies suggest a region of interest in band q22.1 of chromosome 13 (marker D13S156). Fine FISH mapping of six CLL-prone families (63 individuals) reveals deletion of 13q14 in 85% of patients with familial CLL, and four CLL families shared a 3.6-Mb minimal region in 13q21.33–q22.2. This region included 12 candidate genes, but thus far informative candidates have not been identified.

Trisomy 12 was the first recurrent abnormality reported in CLL. It is detected by classic cytogenetics in 7% to 15% of all cases. FISH detects +12 in 15% to 20% of patients with CLL. Trisomy 12 may be present as the sole abnormality or in combination with other chromosomal rearrangements. Because only a proportion of cells are trisomic, normal cells or disomic neoplastic cells may also be present. Follow-up analysis over a 4-year period demonstrates clonal expansion of cells with trisomy 12 as the disease progresses. These observations suggest that trisomy 12 might be relevant in the cell proliferation

**Fig. 56.46** SURVIVAL OF PATIENTS WITH SPECIFIC GENOMIC DEFECTS IN CHRONIC LYMPHOCYTIC LEUKEMIA.

process in CLL cells. The observation that trisomy 12 is documented in B cells and is absent from T lymphocytes and CD34 cells in the majority of patients is consistent with the original hypothesis that CLL has a clonal origin and that trisomy 12 arises in a progenitor cell already committed to the B-cell pathway. The exact mechanism by which trisomy 12 contributes to the pathogenesis of CLL remains unknown.

Increased expression of the *CCLU1* gene on 12q22 has been observed in CLL samples from patients with or without trisomy 12. Overexpression of *CCLU1* in patients with CLL without IgV_H hypermutation combined with restricted and CLL-unique expression pattern suggests that *CCLU1* is among the first disease-specific genes identified in CLL. Small duplications have also been reported encompassing the 12q15 region that harbors the *MDM2* gene locus.

Recent studies utilizing whole genome sequencing detected *NOTCH1* mutations in 42% of patients with trisomy 12. Almost all

Fig. 56.47 SURVIVAL IN CHRONIC LYMPHOCYTIC LEUKEMIA ACCORDING TO GENETIC DEFECTS. Expected survival of patients with chronic lymphocytic leukemia stratified according to the integrated mutational and cytogenetic model and compared to the matched general population. Expected survival is calculated at 10 years. (Reprinted with permission from Foa et al: *Clinical implications of the molecular genetics of chronic lymphocytic leukemia*. *Haematologica* 98:675, 2013.)

Fig. 56.48 PANEL OF CHROMOSOMAL PROBES USED FOR DETECTION OF GENOMIC DEFECTS IN CHRONIC LYMPHOCYTIC LEUKEMIA. They include 13q14.3 (red), 13q34 (aqua), and CEP12 (all present in disomy; left) and 11q22.3 (ATM, green) and 17p13.1 (P53; red, right). Note there is only one copy of the *ATM* gene (green, right) consistent with deletion of sequences from the 11q22.3 band region, which is associated with unfavorable prognosis.

NOTCH1 mutations resulted in a truncated protein, lacking the C-terminal PEST degradation domain, rendering it constitutively active.

Deletions of the long arm of chromosome 11 in CLL as detected by conventional cytogenetics have been reported in 5% to 8% of cases. An interphase FISH study identified deletion of 11q22.3–23.1 in 10% to 20% of cases. FISH characterization of aberrations involved in 11q21–q23 demonstrate a minimal consensus deletion segment of 2–3 Mb, containing a number of genes including *ATM*

at 11q22.3 (Fig. 56.48). Up to 12% of patients have simultaneous deletions of *ATM* and *MLL* at 11q23. Mutations in *ATM* gene are responsible for the ataxia-telangiectasia syndrome. *ATM* functions as a cell-cycle checkpoint regulator. Somatic disruptions of both *ATM* alleles by deletion or point mutation are detected in 25% to 34% of cases. This finding strongly suggests the pathologic role of *ATM* in some patients with B-CLL. A study revealed discontinuous deletions at 11q23.1–q23.3, indicating that genes in this region may have pathogenic significance because they constitute independent

targets for amplification or deletion in cases of B-CLL. Most of the patients with del(11q) are relatively young. The appearance of this deletion is clinically associated with lymphadenopathy, rapid disease progression, poor response to treatment and a shorter OS.

Structural aberrations of chromosome 17 are observed in 4% of cytogenetically evaluable B-cell CLL cases. This abnormality frequently affects the short arm of chromosome 17, the site of the *TP53* tumor suppressor gene. Monoallelic deletions of *TP53*, detected by FISH, are present in 7% to 20% of patients and represent the strongest predictor of inferior survival. The median survival of these patients is only 32 months. *P53* mutations are associated with aggressive disease and a lack of response to conventional therapy. A novel recurrent dic(8;17)(p11;p11) abnormality also results in loss of *TP53*, and low copy repeats in 17p12 and 8p11 may represent the origin of the translocation by nonallelic homologous recombination on a single chromosome 17. B-CLL in patients with deletion of the *TP53* gene is associated with progressive disease, resistance to treatment, and shortened survival. Patients with 17p deletions or *TP53* mutations are resistant to purine analogs.

Deletion 6q is a relatively rare chromosomal change occurring in approximately 6% of CLL cases and is associated with marked lymphocytosis, abnormal morphology, splenomegaly, overexpression of CD38, and unmutated *IGH* heavy chain variable region.

Because the leukemic phase of certain lymphomas can clinically mimic B-CLL, FISH for translocations using an *IGH* probe is important. Fewer than 7% of patients with CLL/prolymphocytic leukemia patients have t(11;14)(q13;q32), and these conditions usually transform into prolymphocytic leukemia. Moreover, *IGH* testing in CLL is important for detecting patients with recurrent del(14)(q24.1) associated with unmutated IgV_H status (66%) and trisomy 12 (47%). Other rare chromosomal aberrations in CLL include trisomy 3q27 (3%), trisomy 8q24 (5%), gains of 15q15-qter, trisomy 18 and trisomy 19. Other recurrent rearrangements involving loss of 8p21-pter and del(9)(q11) have been reported. A complex karyotype remains a poor prognostic indicator associated with a significantly shorter OS.

Based on the recent CGH results, CLL may be classified into three groups: those with poor outcome (20.6%) exhibit at least one aberration: gain of 2p, 3q, 8q, 17q, and loss of 7q, 8p, 11q, 17p, and 18p; good outcome (32.5%) includes 13q14 loss without any of the other 10 aberrations (gain: 1p, 7p, 12, 18p, 18q 19, loss: 4p, 5p, 6q,7p) and the third, intermediate outcome are all other abnormalities. The three groups are significantly separated with respect to time to first treatment and OS ($p < .001$). Gain of 3q and 8q and 17p loss are independent unfavorable prognostic biomarkers.

Cumulative evidence over the last 20 years of over 20,000 patients with CLL suggests that FISH and Ig heavy chain variable region (*IGHV*) mutation status are standard clinical tests for all patients with newly diagnosed CLL for initial risk stratification.

Gene Mutations as Diagnostic and Prognostic Biomarkers

Approximately 60% to 65% of patients with CLL have somatic mutations in the *IGHV*. The remaining 35% to 40% lack *IGHV* mutations. *IGHV* gene mutations (M-CLL) are markers for a favorable prognosis, whereas an unmutated *IGHV* gene (U-CLL) in CLL is associated with clinically more aggressive disease. The OS rate for U-CLL is 8–9 years whereas that for M-CLL is more than 24 years. The frequency of other somatic mutations is shown in Table 56.13. Mutations in *ATM* may occur in patients with and without a del(11q) in 10% and 25% of patients, respectively. Because del(11q) includes loss of hundreds of other genes, or miRNAs, obviously other genes such as *BIRC3* may play a role in CLL pathogenesis. Thus far the *ATM* mutation remains the most important marker of poor outcome in del(11q) CLL patients. As mentioned earlier, in addition to del(17p) resulting in deletion of *TP53*, 17p may be targeted by acquired copy neutral loss of heterozygosity (cnLOH) which results from somatic recombination event that duplicates a single mutated

TABLE 56.13 Most Frequent Somatic Mutations in Chronic Lymphocytic Leukemia

Chromosomal Location	Gene	Pathway	Co-Segregation	Frequency
Alterations Associated With M-IGHV				
15q26	<i>CDH2</i>	Chromatin modification		5

M-IGHV, Mutated immunoglobulin heavy chain variable; U-IGHV, unmutated *IGHV* gene.

TP53 allele. Sanger sequencing has identified *TP53* mutations without loss or cnLOH of the other *TP53* allele, and these patients exhibit poor survival. Most CLL patients with *TP53* mutations are refractory to chemotherapy. Most *TP53* somatic mutations are missense and located within the DNA binding domain of *TP53* encoded by exons 5–8, and six “hot spots” are mutated in approximately 20% of patients. A subset of patients with CLL exhibit 17p genomic changes, mutated *IGHV* genes and have a stable disease course.

Recently, mutations of *NOTCH1*, *BRAF*, *SF3B1*, *NFKB1E* and *EGR2* have detected in CD34⁺ cells and CD14⁺ (myeloid) progenitors in patients with CLL suggests involvement of early immature

hematopoietic cells before B-cell differentiation.²¹ These observations may indicate that CLL develops from preleukemic multipotent hematopoietic progenitors as a result of deregulation of B-cell receptor intracellular signaling and that CLL develops from a preleukemic phase.

Genome Complexity in Chronic Lymphocytic Leukemia

Most patients with CLL have two chromosomal abnormalities suggesting genomic stability at the microscope level. Solid evidence exists that chromosomal translocations detected by conventional cytogenetics independently predict treatment failure, treatment-free survival, and OS in untreated and treated patients with B-cell CLL. When CLL-derived metaphase cells were obtained following systematic stimulation using B-cell mitogens and activators, balanced and unbalanced translocations were observed in 34% to 42% of patients, respectively. Following multivariate analysis, unbalanced translocations have independently been associated with risk for treatment failure. Because del(13q) usually is cryptic by conventional cytogenetics but easily detected with FISH, both conventional cytogenetics and interphase FISH should be performed at baseline in patients with advanced CLL.

Array CGH and NGS studies have effectively clarified the level of genomic complexity in CLL and revealed that the average number of mutations in CLL cells at diagnosis of CLL lies between 10 and 20, which is one of the lowest among the adult cancers, confirming previous cytogenetic observations. The recent studies also revealed that no single unifying mutation is responsible for CLL. Array-based genomic profiling has extended previous cytogenetic data demonstrating that a subset of patients with CLL have complex genomic profiles pointing to the interplay between chromosomal abnormalities and somatic mutations that are associated with reduced OS. Moreover, telomere dysfunction in CLL and acute telomere attrition results in fusion events that contribute to genomic complexity such as *chromothripsis*, which is a high level of DNA damage that may occur during a single mitotic division. In 2011, using NGS technique, a new phenomenon called chromothripsis (from the Greek *chromos*, meaning “chromosomes,” and *thripsis*, meaning “shattering into pieces”) was identified in CLL (Fig. 56.49). Chromothripsis describes a process whereby hundreds of genomic rearrangements have been acquired as a result of a single catastrophic event. A chromosomal region or a chromosome or telomere of other chromosomes is shattered into hundreds of pieces, some but not all are stitched together by the DNA repair machinery in a mosaic patchwork of genomic fragments. Cells not only survive this crisis but emerge with a genomic landscape that confers a selective advantage, thereby promoting further malignant evolution. Chromothripsis has been observed in cancer patients with *TP53* mutations. In addition to the clustering of structural variants, multiple base-pair mutations can also be acquired in a single mitotic explosion, called *kataegis*. This process drives cytosine-specific mutagenesis in regions flanking sites of genomic rearrangement, and can result in the rapid occurrence of up to 20 base-pair substitutions. Chromothripsis have been shown to occur in approximately 5% of patients, primarily in patients with unmutated *IGHV* status (74%) and high-risk genomic aberrations (79%). The presence of chromothripsis and kataegis in CLL implies that multiple cancer genes can be disrupted in a single step, providing a “quantum leap” for the malignant potential of the initial CLL clone.

Whole exome sequencing methodologies combined with follow-up studies have revealed that early genomic events include *MYD88*, trisomy 12, and del(13q) and subclonal evolution are followed by late events such as acquisition of mutations of *SF3B1* and *TP53*. Other studies have demonstrated the prognostic value of four driver mutations in *SF3B1*, *NOTCH1*, *BIRC3*, and *TP53*. Patients who have received therapy exhibited a greater degree of clonal evolution and increased heterogeneity, which has been linked to a poor clinical outcome. How treatment affects clonal evolution in CLL remains the subject of investigation. In 18 patients monitored at two time points, two general patterns were observed: clonal equilibrium, in which the

C

Fig. 56.49 CHROMOTHRIPSIS. (A) Conventional G-banded cytogenetic analysis showed a derivative chromosome 18 composed of additional chromosomal segments. (B) Various FISH probes confirmed that the derivative chromosome 18 is composed of segments of chromosome 5, 7, 18, and 22, whereby the fragments of multiple chromosomes are stitched together by paired end joining. (C) Array comparative genomic hybridization (aCGH) of chromosome 5 shows segments within both the p arm and q arm with gains (blue bars) and loss (red bars) of genomic DNA illustrating that there are frequent copy number changes in a localized region of a chromosome as a result of chromothripsis.

relative size of each subclone has maintained, and clonal evolution, in which some subclones emerge as dominant. More recent studies not only confirmed that molecular lesions in CLL are temporally ordered with del(13q) and +12 occurring initially followed by co-segregation of 11q22–3 deletions and mutations of *SF3B1* observed within the intermediate time point. Therefore two distinct and mutually exclusive evolutionary paths in CLL have been delineated. The first path involves acquisition of trisomy 12 and *NOTCH1*

mutations followed by clonal evolution proceeding with *TP53* and *BIRC3* genomic lesions. The second evolutionary pathway involves del(13q) and proceeds towards acquisition of SF3B1 mutations and *BIRC3* abnormalities. These molecular events confirmed earlier cytogenetic observations, that trisomy 12 coexists with 13q rearrangements in rare patients. Recent integration of cytogenetic and mutation studies in 637 patients with newly diagnosed CLL consistently showed that patients with *TP53* or *BIRC3* lesions had a worse prognosis, followed by patients with mutations in *SFRB1* and *NOTCH1* and del(11q). The presence of a minor subclone composed of as little as 2% of the tumor cells within a population in early CLL predated its emergence as a dominant subclone at relapse and the development of a chemoresistant phenotype.

Richter Syndrome

Approximately 15% of patients with CLL transform eventually to Richter syndrome (RS), a highly aggressive phase of CLL, which morphologically mimics diffuse large B-cell lymphoma (DLBCL) and frequently has a dismal outcome. RS is characterized by a complex karyotype, *TP53* disruption (50%–60%), *NOTCH1* activation (30%), and *MYC* abnormalities (30%). The majority of RS cases are derived from the original CLL clone with an average of 20 acquired molecular lesions during the evolution to RS. There appears to be considerable heterogeneity regarding the number and type of genomic abnormalities.

Several clinical and biologic risk factors may predict future RS development. Patients with CLL with an unmutated *IGHV* are four times more likely to develop RS as compared to those with mutated *IGHV*. High ZAP70 expression and CD49d have also been associated with an increased risk of RS in some studies.

Recently, two genetic pathways that lead to transformation of RS from CLL have been delineated. Approximately 50% of patients with RS have cell-cycle deregulation via inactivation of *TP53*, loss of *CDKN2A* (9p21.3), gains or translocations of *MYC*, and loss of 13q14.3 region. These patients had a high cell proliferation rate (Ki-67 >70%) and a worse OS than patients with wild-type *TP53* and *CDKN2A*. The loss of *CDKN2A* function appears to be acquired at the time of transformation, as evidenced by its presence in the RS but not CLL cells. The second group of patients with RS (30%) is characterized almost exclusively by trisomy 12 and *NOTCH1* mutations. The remaining 20% represent a heterogeneous group, and do not exhibit either *TP53/CDKN2A* inactivation or trisomy 12 and individual cases are characterized by del(11q), del(14q), *MYC* activation, *IGH* translocations, and *NOTCH1* mutations. Using paired-sample analysis CLL-specific lesions are almost always present in the RS cells along with RS-specific abnormalities. These observations imply that RS develops through a linear model of clonal evolution from the underlying CLL. Genome-wide DNA analysis confirmed that RS DNA profile remains clearly separate when compared to DLBCL DNA profile.

Newly diagnosed RS is an oncologic emergency requiring assessment of a karyotype and at least FISH detection of *TP53* and *MYC*.

Genetic Testing for B-Cell Chronic Lymphocytic Leukemia (CLL)

Interphase FISH is used in lieu of karyotype studies because FISH detection of abnormalities in CLL correlates with clinical risk groups and prognosis. FISH studies should be performed on blood for detection of trisomy 12, deletions of 11q22.3, 13q14.3, and the *P53* loci, as well as rearrangement of 14q32.3, *IGH* locus. The FISH test can distinguish between patients with B-cell chronic lymphocytic leukemia and those with the leukemic phase of certain lymphomas, such as mantle cell lymphoma and follicular lymphoma. If FISH for these loci is negative then somatic mutations for *ATM*, *BIRC3*, *NOTCH 1* and *TP53* should be performed.

MULTIPLE MYELOMA

MM is a malignancy of terminally differentiated B cells (see Chapter 86). MM plasma cells have a very low proliferation rate, a characteristic that has limited the field of cytogenetic studies. Conventional karyotyping reveals chromosomal abnormalities in 25% to 30% of newly diagnosed patients, especially in cases with an exceptionally high plasma cell proliferative rate. Karyotypes obtained from these cells usually are complex and exhibit more than 20 aberrations in approximately 10% of cases.

When reassessed by FISH, CGH, and multicolor karyotyping using a large panel of centromere-specific and translocation-specific probes, interphase plasma cell nuclei have been shown to be characterized by chromosomal aneuploidy in almost all patients with MM or monoclonal gammopathy of unknown significance (MGUS). Array CGH indicates that 100% of patients with newly diagnosed MM have copy number alterations and frequent homozygous deletions of genes including *TRAF3*, *BIRC1/BIRC2*, *RB1* and *CDKN2C*. Even during CR, after therapy, 12% to 71% of plasma cells still have numerical gain or loss of chromosomes 3, 7, 8, 9, 11, 13, 15, 21, and X.

Table 56.14 lists the most frequent chromosomal rearrangements that occur in patients with MM. Analysis of numerical abnormalities reveals two groups of MM patients: those who are hyperdiploid and those who are not hyperdiploid.

TABLE 56.14 Most Frequent Chromosomal Abnormalities in Multiple Myeloma and Their Frequencies

Genetic Lesion	Frequency (%)	Oncogenes/Fusion Genes
Hyperdiploid	~50	Gain of odd-number chromosomes
Nonhyperdiploid		IGH translocations
Translocations

Fig. 56.50 RECURRENT CHROMOSOMAL ABNORMALITIES ASSOCIATED WITH MULTIPLE MYELOMA.

Hyperdiploid Multiple Myeloma

Approximately 55% to 60% of patients with newly diagnosed MM are characterized by a hyperdiploid karyotype with the number of chromosomes ranging from 48 to 74 and trisomies of odd-numbered chromosomes including 3, 5, 7, 9, 11, 15, 19, and 21 and few *IGH* translocations (Fig. 56.50 bottom row, and Fig. 56.51). The prognostic relevance of numerical abnormalities using classic cytogenetics is unknown, although the presence of cells with abnormal metaphases cells is an indicator of poor prognosis. However, hyperdiploid MM detected by FISH tend to have a better prognosis than do those with nonhyperdiploid disease. This prognostic benevolence is lost in cases where hyperdiploidy is also associated with other genetic markers of progression or aggressiveness such as gain of 1q21 and deletion of 17p13. A study of 847 patients with MM has demonstrated a median OS of 60.8 months for hyperdiploid patients with MM with no adverse cytogenetic lesions as compared to 33.7 months for those hyperdiploid patients with MM who had one or more of the adverse cytogenetic abnormalities such as t(4;14), t(14;16), t(14;20), del(17p), and +1q (see Figs. 56.50 and 56.51). The exact origins of hyperdiploidy remain unknown, although four processes are proposed: (1) a near-haploid cell doubles all chromosomes; (2) a tetraploid cell experiences subsequent loss of chromosomes; (3) a diploid cell undergoes sequential gains of chromosomes during clonal evolution; and (4) a diploid cell suffers a single mitotic catastrophe resulting in simultaneous gain of additional chromosomes. The data suggest that a single mitotic catastrophe may be the most likely mechanism of acquisition of hyperdiploidy, which may be followed by the secondary gain of extra chromosomes during subclonal evolution.

Nonhyperdiploid Multiple Myeloma

Approximately 45% to 50% patients with MM have nonhyperdiploid MMs that include patients with hypodiploid, near diploid, pseudo-diploid, or near-tetraploid chromosome numbers (fewer than 48 or more than 74 chromosomes), which are characterized by a high frequency of *IGH* translocations (>85%) (see Fig. 56.50 fifth row). With the exception of t(11;14)(q13;q32), most of the nonhyperdiploid patients have an aggressive disease course characterized by a short time to relapse and limited survival.

Table 56.15 outlines a lists risk stratification system of patients with MM based upon chromosomal abnormalities.

These patients are at risk of acquiring genetic events such as deletion of chromosomes 13 and 14, chromosome 17 abnormalities, as well as 1q amplification and 1p deletion.

Both hyperdiploidy and nonhyperdiploidy are also present in patients with MGUS, suggesting that such abnormalities occur early in the evolution of disease. More detailed analyses using genome-wide CNAs have revealed numerical aberrations in 98% of MM cases and identified amplification of 1q and deletions of 1p, 12p, 14q, 16q, and 20p to be associated with a poor prognosis, whereas amplification of chromosomes 5, 9, 11, 15, and 19 conferred a superior outcome in patients with MM.

Hypodiploid karyotype (<44 chromosomes) in MM accounts for one-fifth of all patients with MM and represents an aggressive subtype. In these patients, abnormalities such as monosomy of chromosomes 13, 14, and 22 as well as deletions for 1p, 12p, 16q, and 17p are common. These genotypes are associated with a poor outcome and disease progression. Hypodiploid chromosomal status is an independent risk factor for a poor survival.

Fig. 56.51 A complex hyperdiploid karyotype from a patient with multiple myeloma (A) and after multicolor FISH (B), which was used to resolve a number of complex derivative chromosomes: 54, X,-X, der(1)t(1;8)(q34;q21q24)×2, der(2)del(2)(p13p25)t(X;2)(p21p22.3;p13), t(3;8)(q27;q22q24), +(5)(p13p15), +7, der(8;17)(p23;q11.2q25), +der(11)t(1;9;11)(p36;q21q31;p15), t(11;20)(q13;q11.2, der(11)t(9;11)(q13q34;q25), t(12;13)9(p13;q14q34), +15, +19, +20.

Translocations

Primary translocations appear to occur early during the course of MM, whereas secondary translocations occur later on and are involved in tumor progression. Most primary translocations are simple balanced translocations that juxtapose an oncogene and one of the Ig

enhancers. An *IGH* rearrangement on 14q32.3 is found in most patients with MM. This rearrangement consists of complex and heterogeneous translocations with the breakpoint involving either the switch region of *IGH* or the *V_H*, *D_H*, or *J_H* gene (see Fig. 56.50 fifth row and Table 56.10). The primary translocations are caused by somatic hypermutation or errors in the VDJ portion of the switch

recombination region. The translocations include a promiscuous array of at least 20 nonrandom chromosomal partners. The characterization of these translocations has led to the identification of critical dysregulated oncogenes (e.g., *BCL2*, *cyclin D*). In each translocation, a potent enhancer is juxtaposed to dysregulated oncogenes. The five most frequent *IGH* translocations are t(4;14)(p16.3;q32.3), t(6;14)(p21;q32.3), t(11;14)(q13;q32.3), t(14;16)(q32.3;q23), and t(14;20)(q32.3;q12) (see Table 56.12 and Fig. 56.50).

A recurrent *CCND1-IGH* rearrangement is characterized by overexpression of cyclin D1. In contrast to MCL, breakpoints on 11q13 with MM are not clustered but are scattered over a relatively large genomic region. Virtually all MM and MGUS cells have cyclin D dysregulation, suggesting that this abnormality is an early and unifying pathogenetic event (see Fig. 56.50, first row). In contrast to other abnormalities involving the *IGH* locus, t(11;14) MM cells tend to be diploid. There appears to be an association of t(11;14) with an oligosecretory or light chain form of MM with CD20 expression, and a lymphoplasmacytic morphology. This chromosomal rearrangement is the most common genetic lesion in MM (15%–20% of patients with MM) but it has been also observed in MGUS, primary plasma cell leukemia, and light chain amyloidosis. Two groups of patients with t(11;14) are recognized: one with a rather indolent course and the other associated with a more aggressive course.

Approximately 15% of patients have a recurrent t(4;14)(p16.3;q32.3) abnormality associated with aggressive disease (see Fig. 56.50 third row). This cytogenetic abnormality is associated with IgA λ form of MM with immature plasma cell morphology, and a poor response to therapy. This abnormality is cytogenetically cryptic and is detected

by FISH. Two genes on chromosome 4p16.3 and the *IGH* switch region on 14q32.3 are involved. The fibroblast growth factor receptor 3 gene (*FGFR3*) is detected on der(14), where it is overexpressed along with a fusion of the MM set domain (*MMSET*) gene, which is located on 4p16.3. This is the first example of a translocation that simultaneously deregulates two genes with oncogenic potential: the *FGFR3* gene detected on der(14) and the *MMSET* gene detected on der(4). *FGFR3* is 50–100 kb telomeric to *MMSET*. Loss of *FGFR3* on der(14) is detected in approximately 20% of cases. A significant number of these patients have del(13q) within the same clone and are hypodiploid.

Translocation (14;16)(q32.3;q23) can only be detected with (see Fig. 56.50 second row) FISH studies. The incidence of t(14;16) has been estimated to be approximately 5% of cases. This translocation results in the relocation of the *MAF* proto-oncogene from its position on 16q23 to chromosome 14, band q32.3, and it is overexpressed. Rare variants t(14;20)(q32;q11)/*IGH-MAFB* and t(8;20) are included within this group because they share a similar gene expression signature and clinical outcome. Survival of patients with t(14;16) is significantly shorter as compared with patients without t(14;16).

A large number of secondary chromosomal aberrations are found during disease progression. Disease progression is accompanied by four main abnormalities including translocations of *MYC*, the loss or deletion of chromosome 13, deletions of short arms and amplification of long arms of chromosome 1, and the deletion of short arms of chromosome 17. Translocations and/or amplification of *MYC* (8q24) may involve up to 45% of patients with an advanced MM, and then cytogenetic study frequently involves very complex nonreciprocal rearrangements, duplications, and amplifications. More recent data based on the CGH- or SNP-array technologies has revealed homozygous deletions such as *BIRC2/3* on chromosome 11, deletions of *TRAF3* on chromosome 14, and deletions of *CYLD* on chromosome 16. Another recurrent double deletion that has been observed in a limited number of the patients occurs on chromosome 1, targeting the tumor suppressor *CDKN2C* gene at 1q21 chromosomal site.

Deletion of either band q14 or q14.3 (*RBI*, DNA marker D13S319) on chromosome 13 is detected in 10% to 20% of patients using conventional cytogenetics and in 50% using interphase FISH. Microarray CGH data of the critical region on chromosome 13 is consistent with previous findings (Fig. 56.52). Loss of the entire chromosome 13 (82%) is more frequent than is deletion of the long arms of chromosome 13. The most commonly deleted region has not been delineated. The median percentage of plasma cells carrying del(13q), as identified by FISH, ranges from 75% to 90%. Deletion of 13q is associated with specific clinicopathologic features, including

Fig. 56.52 CYTOGENOMIC PROFILES IN MULTIPLE MYELOMA. Summary of genomic profiles and recurrence of chromosomal alterations in primary tumors demonstrated by array comparative genomic hybridization. The recurrence plot mirrors the frequencies of previously reported chromosomal gains and losses, including the deletions of 1p and amplifications of 1q. Integer-value recurrence of copy number aberrations across the samples in segmented data is plotted on the y-axis. The x-axis is in chromosomal order. Dark red or green bands denote the number of samples with gain or loss of chromosome material, and bright red or green bars represent the number of samples showing amplification or deletion. Black dots show focal deletions of the kappa (2p12), IgH (14q32), and lambda (22q11) loci physiologic in B-cell postgerminal center neoplasms. (Reprinted with permission from Carasco DR, Tonon G, Huang Y, et al: High resolution genomic profiles define distinct clinic pathogenic subgroups of multiple myeloma patients. *Cancer Cell* 4:313, 2006.)

a higher frequency of λ -type MM, high plasma cell-labeling index, female predominance, and inferior survival after standard chemotherapy. Numerous earlier studies have demonstrated that del(13q) represents an adverse prognostic marker in patients with MM treated with conventional chemotherapy. However, more recent studies have demonstrated that del(13q) no longer has adverse prognostic significance in patients treated with bortezomib. Molecular cytogenetics analyses have revealed that del(13q) is present in 90% of patients with t(4;14) or t(14;16); therefore the apparent adverse impact of del(13q) may be related to translocation events.

Deletion of *TP53* at 17p13.1, which occurs in 10% of patients with MM, is a powerful independent predictor of shortened survival

and is associated with clonal evolution, drug resistance, and genetic instability (see Fig. 56.50 fourth row). This deletion is not found in patients with other high-risk abnormalities such as t(4;14) or t(14;16), and it appears to be mutually exclusive. Patients with P53 deletion have a significantly shorter OS regardless of therapy. The 17p deletion, identified by FISH, is considered the most important molecular cytogenetic factor when determining prognosis.

The gain of 1q21 locus has been identified in 45% of cases of MGUS, 43% of newly diagnosed MM, and 72% of relapsed MM, and represents one of the most frequent recurrent chromosomal abnormalities in MM (see Fig. 56.50 sixth row and Fig. 56.53). Gain of 1q is observed cytogenetically as an isochromosome, duplications,

Fig. 56.53 REPRESENTATIVE PARTIAL KARYOTYPES OF METAPHASE CHROMOSOMES DEMONSTRATING THE DIFFERENT TYPES AND DEGREE OF AMPLIFICATION OF CHROMOSOME 1. FISH probes for 1q12 (red), 1q21 (green), and 16q11 (aqua) are shown on inverted DAPI images of chromosomes. (A) Interstitial deletion of 1p (arrow) in the homolog on the left and a direct dup1q12-q23 on chromosome on the right. (B) Normal homolog 1 on the left and the abnormal homolog on the right, demonstrating both an interstitial deletion of 1p and the amplification of 1q in the same chromosome. Note four copies of 1q21 (arrows) in an inverted duplication pattern. (C) Examples of an unbalanced whole-arm translocation of 1q to chromosome 16q. Chromosomes 1 are on the left, and chromosomes 16 are on the right. Aqua probe denotes 16q11 heterochromatin. Note the loss of 16q distal to the aqua probe on the der(1;16)(q10;p10). The entire long arm 1q is translocated to the pericentromeric region of 16q, and a total of three copies of 1q21 (arrows) are present. (D) Examples of an unbalanced whole-arm translocation of 1q to 19q. Note that the result of this translocation is the der(1;19)(q10;p10) chromosome, which shows an extra copy of 1q21 (arrows) and loss of the entire 19q. (E) Examples of jumping 1q, in which all or a part of 1q is translocated to three copies of 1q (arrows) on the three different nonhomologous chromosomes. The whole-arm der(19)(q10;p10) in this case is the same type seen in patient in (D). The der(21) results from the segmental translocation of the inverted dup of 1q to the short arm of 21. The der(22) results from the whole-arm 1q translocated to the short arm of 22. (F) Homologous of chromosome 1 demonstrating amplification of 1q12-q23 by breakage-fusion-bridge cycles. Note multiple copies of 1q21 (arrows) on the abnormal homologue on the right. The copies of the 1q12-q23 amplicon occur in an inverted repeated pattern, with a deletion of the 1q distal to the amplified region. Dotted lines between normal homologue 1 (left) and abnormal homologue denote the size of expansion of the 1q12-q23 region by break-fusion-bridge cycles. (Reprinted from Sawyer JR: *The prognostic significance of cytogenetics and molecular profiling in multiple myeloma*. Cancer Genetics 204:3, 2011; with permission.)

or jumping translocations and is detected with a 1q21-specific FISH probe. Among 479 patients with newly diagnosed MM, 43% with amp 1q21 with either a hypodiploid and hyperdiploid karyotype and del(13q) was associated with poor prognosis as compared with patients lacking amp1q21 (see Fig. 56.53). In a study of 92 patients treated with lenalidomide and dexamethasone, del(17p) and gain of 1q21 was associated with a dismal OS. In the most comprehensive expression profiling survey of patients with MM, reported by the Arkansas Multiple Myeloma Group using GEP70 (gene expression profiling of 70 genes), 30% of these genes were located on chromosome 1, with most of the downregulated genes located on the short arms of chromosome 1 and most of the upregulated genes on 1q. The mechanism for the amplification of 1q is believed to involve 1q12 pericentromeric instability, which most commonly increases the copy number of 1q by a direct and/or inverted duplication. Further instability can result in adding a whole-arm segment of 1q to non-homologous chromosomes by jumping translocations of 1q. The 1q12–q23 amplicon has been reported to be formed by BFB cycles of the 1q12 pericentromeric heterochromatin and the adjacent bands of 1q, resulting in an inverted repeat pattern of amplification of the 1q12–q23 region. Copies of the 1q12–q23 amplicon can become integrated into complex multichromosome translocations during tumor progression. In vitro studies have shown that treatment with hypomethylating agents apparently amplify any 1q region juxtaposed to 1q12 chromosome band producing copy number aberrations in the bone marrow of these patients. Frequent additional deletions detected by conventional cytogenetics include regions within 6q, 8p, 12p, 14q, 16q, or 20p.

The Arkansas Multiple Myeloma Group pioneered the use of GEP as a highly sensitive method to stratify patients with MM in terms of outcome and to more fully characterize an individual's tumor at the molecular level. This group identified a distinctive 70-gene molecular signature (GEP70) for high-risk myeloma that was correlated with a strong probability of early recurrence and shorter OS. These 70 genes have overlapping functions and are involved in cell-cycle regulation, angiogenesis, cell adhesion, cell migration, and proliferation. When compared with standard metaphase and interphase FISH, the GEP70 gene signature significantly reduces the number of patients traditionally classified with a poor prognosis, while at the same time identifies those patients who may be at increased risk for relapse. The marked increase of GEP70 high-risk patients from 13% at diagnosis to 76% at relapse provides strong molecular evidence for disease evolution. This MM signature was validated using many patient cohorts, both in European and US institutions and have repeatedly shown that 15% to 30% of patients identified as high risk using GEP70 is superior to conventional risk stratification in identifying these patients. The GEP 70 gene assay is now commercialized under the name “MyPRS” (Myeloma Prognostic Risk Score) and is currently generated with as little as 15 ng of total RNA from approximately 30,000 CD138⁺ plasma cells.

Although GEP is being widely used for MM classification and survival risk prediction it remains unclear whether GEP-based signatures can predict response to specific therapies. Therefore GEP-based signature in MM has a limited ability to predict the probability of attaining a CR. Gene expression by itself may not delineate eventual cellular behavior and responses to various therapeutic interventions.

Even with the application of GEP, CGH + SNP arrays and other DNA-based approaches such as NGS, MM-specific oncogenes or mutations have not been identified to date. The median number of mutations per MM genome is about 55–60, with a very large range (21–488). Moreover, in contrast to leukemia, “good-risk” cytogenomic abnormalities have not been described. The current data indicate that genetic abnormalities have a major role in determining prognostic value.²⁷ The current thinking is that development of subclones is a very early event in MM, probably soon after the cell undergoes transformation.

Frequent mutations in MM include *KRAS* (particularly in previously treated patients), *NRAS*, *BRAF*, *FAM46C* (hyperdiploid subgroup), *TP53*, and *DIS3* (in nonhyperdiploid MM with *IGH* rearrangement). Subclonal *KRAS*, *NRAS*, and *BRAF* mutations are

Fig. 56.54 Bone marrow nuclei from a patient with multiple myeloma after hybridization using three probes: 1q21 (aqua), PBX1 (red) localized on 1q25, and TCF3 (green) localized on 19q13. Note amplification (up to 17 copies) of 1q21 and 1q25 (white arrows), as well as multiple copies of 19q loci. Amplification of 1q21–q25 is associated with disease progression and very poor prognosis in multiple myeloma despite novel therapies.

Genetic Testing for Multiple Myeloma

Chromosome studies of isolated plasma cells from the marrow are very useful at diagnosis. Perform interphase FISH and molecular genetic studies for detection of *CCND1-IGH* [t(11;14)], del(13)(q14.3)/D13S319, del(17)(p13.1)/P53, *IGH*/14q32.3, and 1q21 locus. If *IGH* rearrangements are detected using a breakpoint *IGH* locus and *CCND1-IGH* fusion is not identified, refine the translocation partner and use the following set of probes: *MAF-IGH* for detection of t(14;16) and *FGFR3-IGH* for detection of t(4;14).

observed in about one-third of patients with MM.²² Other recurrent mutations include *SP140* that are linked to germline susceptibility to CLL and associated with an increased risk of relapse in MM. Most of the mutated genes in MM detected by exome sequencing have limited, low, or no known biologic significance, suggesting a silent biologic role.

Testing for genetic lesions in MM is an integral part of proper disease management. A simple approach is to identify high-risk genetic subtypes using FISH or genetic expression profiling. If FISH is to be used, preferably after isolation of purified plasma cells, the probes should include, at minimum, t(4;14)(p16;q32), t(14;16)(q32;q23), t(14;20)(q32;q11), gain of 1q and loss of 17p (Fig. 56.54). In our laboratory we also include testing for the t(11;14) and an *IGH* breakpoint probe because if the t(11;14) as well as other *IGH* lesions mentioned earlier are not detected, *IGH* translocations without known partners are associated with adverse prognosis. GEP studies require the isolation of purified plasma cells and highly specific dedicated platforms (including very sophisticated bioinformatics), which are not widely available to the majority of physicians. However, the GEP70 analysis and numerous other reports have indicated that gains of 1q12–q44 are an independent marker associated with disease progression and that deletion of TP53 defines a group of patients with ultra high-risk MM (see Figs. 56.50, 56.53 and 56.54). Hence testing with FISH for alterations of 1q21 and/or 1q25 loci, as well as for deletion of the 17p13.1 chromosomal region, will identify patients with unfavorable prognoses (see Fig. 56.54).

LYMPHOMA

Non-Hodgkin lymphoma (NHL) is a heterogeneous group of disorders characterized by a localized proliferation of lymphocytes (see

Chapters 76 through 84). Analogous to other hematopoietic neoplasms, the pathogenesis of NHL is attributable to a multistep process involving progressive and clonal accumulation of genetic lesions. The majority of NHLs are of B-cell origin and involve translocations of Ig loci (see Table 56.10 and Fig. 56.55). *IGH* translocations usually are detected by cytogenetics, often in conjunction with FISH probes that span the *IGH* loci and/or PCR-based technologies. These molecular abnormalities exhibit enormous complexity with multiple and complex translocations, deletions, and amplifications within one clone (Table 56.16). Genetic anomalies represent one of the most reliable criteria for classification of malignant lymphomas. The most common associations between chromosome anomalies and specific lymphomas include t(14;18)(q32;q21) and FL; t(8;14)(q24;q32) and BL; t(11;14)(q13;q32) and MCL; and t(11;18)(q21;q21) and mucosa-associated lymphoid tissue (MALT) lymphoma (see box on Genetic Testing for Non-Hodgkin Lymphoma and Fig. 56.55). However, identification of a specific translocation is not diagnostic of a specific lymphoma subtype (see later). Chromosome studies are difficult and expensive for the study of lymphomas. Thus many investigators use FISH and/or molecular genetic methods to study touch-cell preparations or paraffin-embedded biopsy material to detect genetic anomalies.

Approximately 85% to 90% of patients with FL and some patients with DLBCL exhibit t(14;18)(q32.3;q21.3), resulting in fusion of *BCL2* on 18q21 and *IGH* on 14q32. This translocation is one of the most common chromosomal abnormalities in NHL (see Fig. 56.55D). This somatic rearrangement places *BCL2* gene under the influence of transcriptional enhancers associated with *IGH*, resulting in overexpression of the antiapoptotic *BCL2* protein. Translocation 14;18 appears to originate from erroneous *IGH* rearrangement, during B lymphopoiesis in the bone marrow (pre-B cells) and therefore represents a very early genomic event. About 75% of the *BCL2* breakpoints occur within a remarkably narrow region of 15–20 bp at the 3' end of the *BCL2* gene, whereas the breakpoints in *IGH* fall within the D_H and J_H regions. With regular and fiber FISH methods using *BCL2* breakpoint flanking probes, individual 5' and 3' breakpoints can be detected. With disease progression, 100% of patients have *BCL2* protein overexpression. Variant translocations, such as t(2;18)(p12;q21) and t(18;22)(q21;q11) involving the *IGK* or *IGL* gene, respectively, rather than *IGH*, are also associated with overexpression of *BCL2*.

Although t(14;18) is most likely an early genetic event in the pathogenesis of FL, it is not sufficient for malignant transformation. It has been known for many years that approximately 50% of healthy individuals harbor low levels of circulating t(14;18) cells but do not develop FL, indicating that ectopic *BCL2* expression is necessary but not sufficient for lymphoma progression. Recent studies of 520,000 healthy participants enrolled in the European Prospective Investigation into Cancer and Nutrition study determined that approximately 20% of healthy individuals with t(14;18) will subsequently develop FL up to 20 years later.²³ Progression to FL was significantly associated with elevated t(14;18) burdens in peripheral blood as measured by Q-PCR. They determined that individuals with t(14;18) frequency reaching one in every 10,000 blood cells had a 23-fold greater incidence of progression to FL.

Numerous secondary chromosomal abnormalities have been identified by conventional cytogenetics, and at least five recurrent anomalies, each occurring in at least 20% of FL, may distinguish two subgroups of patients with FL. Patients with t(14;18) and additional trisomy for chromosome 2, 7, or 8 are associated with a more favorable course of disease as compared with patients with del(1p), del(1q), del(6q), der(18), del(22q), or gain of chromosome 12 and X. Interstitial del(6)(q25–q27) is the strongest predictors of a poor prognosis and a shorter survival time. Rearrangements of chromosome 1, such as del(1)(p32–36), +1(p11–q44), and unbalanced translocations of der(1)(1;1)(p36;q11–23) are among the most frequent secondary chromosomal abnormalities in FL. Progression of FL to DLBCL occurs in 60% to 80% of patients and is accompanied by the accumulation of secondary abnormalities, including homozygous del(9p).

TABLE 56.16 Recurrent Chromosomal Translocations in B-Cell Lymphoproliferative Disorders

Translocations	Genes Involved	Associated Diseases
Immunoglobulin (Ig)-Related Translocations		
t(1;14)(p22;q32)	<i>CNN3-IGH</i>	B-cell ALL, NHL

t(9;14)(p13;q32.3)	<i>PAX5-IGH</i>	LPL

ALL, Acute lymphoblastic leukemia; B-ALL, B-cell ALL; B-CLL, B-cell CLL; CLL, chronic lymphocytic leukemia; LPL, lymphoplasmacytoid lymphoma; MALT, mucosa-associated lymphoid tissue; NHL, non-Hodgkin lymphoma; PLL, polyclonal lymphocytic leukemia; SLL, small lymphocytic leukemia; T-PLL, T-cell PLL.

Mutations in the *BCL2* gene are found in 12% of patients with FL at diagnosis and in 53% at the time of progression/transformation. The presence of *BCL2* mutations at the time of diagnosis correlates with increased risk of transformation and an increased risk of death owing to lymphoma (the median survival of patient with *BCL2* mutations is 9.5 years vs. 20.4 years without). Currently it is unknown whether acquired mutations in *BCL2* gene cause FL.

As mentioned earlier, the *IGH-BCL2* fusion is believed to represent a very early event in the pathogenesis of FL. FL-like cells (FLIC)

Fig. 56.55 MOST FREQUENT CHROMOSOMAL ABNORMALITIES IN NON-HODGKIN LYMPHOMA. (A) Partial G-banded karyotype of $t(11;14)(q13;q32.3)$ (*left*), resulting in $CCND1$ - IGH fusion (*yellow*) on metaphase (*middle*) and in interphase cell (*right*) present in the majority of patients with mantle cell lymphoma. (B) Partial G-banded karyotype of $t(8;14)(q24;q32.3)$ (*left*), resulting in MYC - IGH fusion [*yellow* on $der(8)$ on isolated chromosomes]. Application of MYC breakapart probe shows separation of red and green signals consistent with MYC rearrangement. Approximately 80% of Burkitt lymphomas are characterized by $t(8;14)$. (C) Partial G-banded karyotype of $t(8;22)(q24;q11)$, a variant of Burkitt lymphoma (*left*). Two interphase lymph node cells after hybridization with MYC breakapart probe and $CEP8$ (*aqua*). Separation of green and red signals is consistent with MYC relocation from $8q24$ to $22q11$. (D) Partial G-banded karyotype of $t(14;18)(q32.3;q21.3)$ (*left*), resulting in IGH - BCL fusion (two *yellow* signals, *middle*). A composite image on the *right* shows both a partial karyotype and FISH study of triplicated $der(18)t(14;18)$ and three copies of IGH - $BCL2$ fusion (*yellow*), as well as normal chromosome 14 and 18. Multiple copies of abnormal $der(18)$ chromosome are associated with progressive disease similar to a duplication of the Philadelphia chromosome in the blast crisis of chronic myelogenous leukemia. (E) Lymph node cell from a patient with diffuse large B-cell lymphoma, showing four copies of $BCL6$ (breakapart probe). $BCL6$ is localized at $3q27$ and is numerically or structurally rearranged in 35% of diffuse large B-cell lymphoma. (F) Bone marrow metaphase and interphase cell hybridized with breakapart $MALT1$ gene at $18q21$ (*left*) indicating two fusion (*yellow*) signals when $MALT1$ gene is intact. In contrast, rearrangement of the $MALT1$ gene in MALT lymphoma usually is the consequence of $t(11;18)(q21;q21.1)$, as shown in the cell (*right*) with clear separation of the 3' end (*green*) and the 5' end (*red*).

reside in the germinal center of normal lymph nodes. In a study of 85 reactive lymph nodes of healthy individuals 14% were found to contain high levels of t(14;18) by Q-PCR. These studies provide evidence that FLLCs consistently accumulate within the germinal center, as nonproliferating, early precursor cells that have not acquired other genetic events leading to FL transformation.²⁸

GEP has revealed a distinct pattern associated with an indolent form of FL (median survival 11.1 years) and a more aggressive form (median survival 3.9 years), indicating that these different conditions may represent distinct stages in the evolution of FL. Detailed genetic analyses have confirmed that a single mechanism driving the transformation of FL to DLBCL does not exist, rather several discrete mechanisms are operational, including alterations of cell-cycle control (mutations and deletions of cyclin-dependent kinase, *CDKN2A/B*), *MYC* rearrangements and impairment of the DNA damage response (loss of *TP53* and/or *CDKN2A/B*). NGS has shown that each is associated typically with between 20 and 200 small somatic mutations. At least 21 different tumor suppressor genes are altered in FL at frequencies between 2% and 86%, suggesting that FL requires multiple collaborative genomic events acquired over many years.

Three translocations, all affecting the *MYC* gene at 8q24, have been recognized in BL. In 80% of patients a reciprocal translocation t(8;14)(q24;q32) is observed between the *MYC* gene and the *IGH* locus (Figs. 56.56 and 56.57). In the remainder of patients, the reciprocal translocation t(8;22)(q24;q11) or t(2;8)(p12;q24) occurs juxtaposing *MYC* to one of the light-chain loci (κ on 2p12 and λ on 22q11). The t(8;14) translocation was originally described in Epstein-Barr virus (EBV) tumor cells obtained from patients in Africa (see Fig. 56.56B–C). Variant translocations involving *MYC* with a variety of other non-*IG* loci subsequently have been reported. In most patients with sporadic BL, the breakpoints on 8q24.1 are located on 5' end of the coding region of *MYC* gene. By contrast, in most cases of endemic BL and in non-*IG* translocations, the *MYC* breakpoints are at the 3' end. As a result of the translocation, control of *MYC* is lost, and the intact protein is constitutively expressed throughout the cell cycle.

Although *MYC-IGH* translocations are sine qua non for the diagnosis of BL, they are not restricted to BL because they also occur in other forms of lymphoma, such as DLBCL (see later), plasma cell myeloma, ALL, MCL, and CLL.

MYC regulates almost 15% of human genes. The *MYC* gene can function as both a transcriptional activator and a transcriptional repressor. *MYC* forms a heterodimer with *MYC* associated factor X (MAX). *MYC-MAX* heterodimer binds to the E-box consensus sequence (CACATG) and serves as a platform for other proteins involved in chromatin remodeling and transcriptional regulation. *MYC* represses genes when it is not bound directly to DNA, but instead is recruited by the *MIZ1* transcription factor, which in turn recruits DNA methyltransferase (*DNMT3*) and histone deacetylase 3 (*HDAC3*) which alter chromatin configuration making it less accessible.

An increased level of constitutive *MYC* syntheses in leukemic disorders is found not only as a result of a translocation but also as a result of mutations and amplification of *MYC* (see Fig. 56.57). Approximately 65% of BL are associated with *MYC* point mutations. As mentioned previously, overexpression of *MYC* protein is linked to amplification of *MYC* genes reported in plasma cell leukemia, AML, CML, and T-cell lymphoma. *MYC* both directly and indirectly activates *CCND2* and cyclin dependent kinases and downregulates cell cycle inhibitors, promoting the transition from G0 to S phase. *MYC* has a role in the formation and maintenance of germinal centers.

The most common secondary change associated with t(8;14) in BL is duplication of the long arms of chromosome 1, and these were associated with disease progression. A common duplicated region of 93 kb at 1q21.2 has been defined by FISH studies. A rare complex BL karyotype is shown in Fig. 56.56. Rearrangements of *MYC* can now be detected in nondividing cells as well as in paraffin-embedded lymph node biopsies using a very sensitive interphase FISH assay for t(8;14).

According to the WHO classification, three BL variants are recognized: endemic, sporadic, and immunodeficiency-associated BL. In contrast, many cases of Burkitt-like lymphoma (a separate WHO entity), lack BL translocations but do exhibit increased *MYC* expression.

High-throughput RNA sequencing has revealed acquired somatic mutations in the *CCND3* gene in 38% of sporadic BL cases. This is an important gene in cell cycle progression and 70% of these patients acquire mutations affecting the transcription factor *TCF3* or its negative regulator *ID3*. In an extended study mutations in the *ID3* gene were detected in 50% of all *IGH-MYC* translocation-positive sporadic BL and these mutations were found to be rare in other *IG-MYC*-positive lymphomas. These findings suggest that disruption of *ID3* function may be a key mechanism in the pathogenesis of BL. Moreover, recurrent mutations in *TP53*, *SMARCC4* (chromatin modulating complex gene), and *DDX3X* (chromatin modulating complex gene) may contribute to BL evolution.

Approximately 35% of patients with DLBCL and approximately 5% to 10% of patients with FL have rearrangements in the *BCL6* gene which resides at 3q27. Translocation and dysregulation of *BCL6* gene represents a key mechanism of transformation of DLBCL. Chromosomal rearrangements of the *BCL6* locus occur in about 35% to patients with DLBCL, and at least 33 different partners have been described as participating in these rearrangements (<http://atlasgeneticsoncology.org/>) (see Fig. 56.55E). The most frequent chromosomal band partners are 2p13, 4p13, 6p22, 7p12, 8q24, 13q14, 14q32, 18p11.2, and 22q11. These translocations juxtapose the coding domain of *BCL6* downstream to heterologous promoters derived from different chromosomal partners, leading to dysregulated expression of an intact protein by preventing its downregulation during postgerminal center differentiation. The *BCL6* 5' sequences are targeted by multiple point mutations in over 70% of cases. Most of the breakpoints in 3q27 occur within a 10-kb region. The fact that the 3q27 region is affected in different lymphomas, irrespective of the translocation partner chromosomes, strongly suggests that alterations of *BCL6*, and not the reciprocal loci, are important in the pathogenesis. The alterations in 3q27 are small so most can be detected with PCR-based assays, or FISH. *BCL6* functions as a transcriptional repressor of genes containing its binding sites; therefore the mechanism responsible for the malignant phenotype is transcriptional deregulation.

Over the past decade NGS has enhanced our understanding of the complex multiple pathways by which DLBCL develops. Approximately 30% of patients with DLBCL harbor mutations and/or deletions inactivating *CREBBP* and more rarely *EP300*, two acetyltransferases that modify lysine residues on both histone and nonhistone nuclear proteins, and therefore modulate the activity of a large number of DNA-binding transcription factors. About one-third of patients with DLBCL harbor mutations in the *MLL2* gene, which broadly affects chromatin structure. Inactivating mutations of both *CREBBP* and *MLL2* have also been observed in FL (49% and about 89%, respectively). Gain-of-function somatic mutations in *MEF2B* transcription factor gene are observed in 10% to 15% of patients with DLBCL. Other genetic lesions include loss-of function/deletions of *FBX011* (4%), which causes *BCL6* dysregulation by impairing proteasomal-mediated degradation of the *BCL6* protein. Mutations and deletions of *TP53* remain an important genetic lesion in about 20% of patients with DLBCL, including those resulting from transformation from FL.

t(14;15)(q32;q11–13) occur in 3% to 4% of DLBCL, which results in fusion of the *BCL8* gene on chromosome 15 to the V_H segment of the *IGH* locus. The most common secondary abnormalities are trisomies of chromosomes 3, 5, 7q, 11, 12p, 18q, and Xq, which are observed in greater than 10% of cases. Amplification of *REL*, *MYC*, *BCL2*, *GLI*, *CDK4*, and *MDM2* genes are most frequently associated with advanced-stage disease. The most frequent monosomies include chromosomes 13, 14, and 15. A complex karyotype may have an adverse impact on prognosis.

The use of modern molecular studies identified two major subgroups in DCLBC: activated B cell-like DLBCL (ABC-DCLBC)

Fig. 56.56 COMPLEX KARYOTYPE OF BURKITT LYMPHOMA. Bone marrow karyotype of a patient diagnosed in an advanced stage of Burkitt lymphoma (A) and after application of the multicolor FISH (B) to resolve complex derivative chromosomes, showing 46, XY, del(2)(p21p23), t(8;14)(q24;q32), dup(12)(q13q24.3), der(16)(t(11;16)(p11.2;q24) karyotype. Arrows indicate abnormal chromosomes. In addition to the classic t(8;14), both duplications of 11q and 12q were identified with multicolor FISH technology.

and germinal center B (GCB)–like DLBCL. According to the WHO 2016 classification, these two subgroups of DLBCL the GCB and ABC subgroups differ in their chromosomal alterations activation of signaling pathways and clinical outcome. Patients with ABC-DLBCL frequently exhibit trisomy of 3, gains of 3q and 18q21–23, and loss

of the 6q21–23 region. Patients with GCB DLBCL have frequent gains of the 12q12 chromosomal region. Patients with primary mediastinal lymphoma have gains of 2p14–p16 and 9p21–pter. Apparently, gains in several regions of chromosome 3 are significantly associated with inferior survival. Moreover, genomic gains involving

MYC Amplification

Fig. 56.57 MYC AMPLIFICATION. (A) A conventional G-banded bone marrow metaphase from a patient with non-Hodgkin lymphoma. Note very pale doublets of chromatin material all over metaphase cells. They are termed double minutes. (B) All double minutes after hybridization with *MYC* breakpoint probe were hybridized to *MYC* consistent with *MYC* amplification. (C) Interphase, nondividing bone marrow cell showing a very high number of *MYC* amplicon. Note that *MYC* gene is not rearranged, only amplified.

the 3p11–p12 region have an independent prognostic power for survival based on previously defined optimal gene expression-based models. Somatic point mutations of the polycomb-group oncogene *EZH2* have been reported in 22% of patients with GCB-DLBCL. The differentiation of GCB B cells into plasma cells requires *PRDM1*,

a sequence-specific transcriptional repressor that is upregulated; 25% of ABC-DLBCL have deletions of *PRDM1* as a result of truncated mutations, or genomic deletions, while an additional fraction of patients lacks the *PRDM1* protein as a result of transcriptional repression by a constitutively active translocated *BCL6* gene.

Patients with non-BL may have *MYC* translocations without additional mutation in *BCL2* or *BCL6* and they are described as having single hit lymphomas. Although the most recent studies suggested that patients with *MYC*+, but *BCL2*– and *BCL6*– DLBCL do not have an inferior outcome when compared to those who are *MYC* negative, the clinical relevance of *MYC* rearrangement as sole abnormality in DLBCL is still controversial with some studies indicating an adverse prognosis.

Double hit lymphoma (DHL) refers to B-cell lymphoma with multiple activating oncogenes, one of them being *MYC*. Among DHL, those with alterations in *MYC* and *BCL2* are the most common by far, occurring in 87% of patients, followed by *MYC* and *BCL6* rearrangements, found in 5% of patients. Triple hit lymphoma (THL) involves rearrangements of *MYC*, *BCL6*, and *BCL2* in a single cell and are observed in about 8% of patients with DLBCL (Fig. 56.58).

DHL can be detected cytogenetically but cryptic gene rearrangements may be missed. FISH therefore should be used for the detection of DHL and THL. FISH studies can be successfully performed using formalin-fixed paraffin embedded tissue sections as well as fresh smears, touch-cell imprints.

Because one of the translocations may be cryptic, a combination of three FISH probes, labeled with three colors, is especially useful in identifying these very complex translocations (see Fig. 56.43). Non-*IGH* genes also act as *MYC* translocation partners in 35% to 53% of *MYC* rearranged DLBCL. The t(8;9)(q24;p13), which results in the juxtaposition of *MYC* to *PAX5*, has been frequently reported, accounting for 20% of non-*IGH*/*MYC* rearrangement. Both the DHL and THL have complex karyotypes. Complex karyotypes are not seen in BL, which by definition always have single abnormality.

The detection of increased number of cells expressing *MYC*s correlates well with the presence of gene rearrangements, but the relationship varies. Tumors with more than 70% of *MYC*-positive cells usually are associated with gene rearrangements, but *MYC* translocations can be present in up to 17% of cases with less than 30% *MYC*-positive cells. The variability between the protein expression and gene alterations makes it difficult to recommend the use of *MYC* immunohistochemistry as a screening method to detect gene rearrangements. The current recommendation is that all patients with DLBCL have FISH for *MYC* rearrangements because combined alterations in *MYC*, *BCL2*, and *BCL6* confers a more aggressive disease phenotype.

All patients with MCL exhibit t(11;14)(q13;q32) abnormality as detected by FISH (see Fig. 56.55 top panel). t(11;14)(q13;q32) is also found in a variety of other B-cell malignancies, including MM, splenic lymphoma with villous lymphocytes, and B-cell prolymphocytic leukemia. Most breakpoints on chromosome 11, band q13, are dispersed over a region of approximately 130 kb centromeric to the *cyclin D1* (*CCND1*) gene. At the molecular level, the *BCL1* locus (*CCND1*) on chromosome 11q13 is juxtaposed to an enhancer sequence within the *IGH* gene on 14q32, leading to overexpression of the *cyclin D* gene (involved in cell cycle control), which is not expressed in normal B and T cells or in other malignant lymphomas.

Because the breakpoints within 11q13 are scattered along a 130-kb distance, dual-color FISH has proved to be the most sensitive assay for detection of *IGH*-*CCND1* fusion in MCL. Furthermore, the *CCND1* fusion rearrangement can also be detected in formalin-fixed, paraffin-embedded samples, making this a rapid and reliable method (see Fig. 56.42A).

Gene expression studies have identified a subset of D1-negative MCL patients, so called because of the lack of cyclin D1 expression and t(11;14). However, both cyclin D1-positive and cyclin D1-negative patients have the same secondary genomic alterations. These secondary chromosomal alterations include gains of 3q, 8q, and 15q

Fig. 56.58. TRIPLE HIT LYMPHOMA (A) A karyotype of patient with triple hit lymphoma with arrows pointing the abnormal chromosomes. Note a gain of der(7;8) resulting in three copies of 7q and three copies of rearranged 8q, and the three-way translocation between chromosomes 8, 14, and 18 as well as a translocation (3;22). (B) A bone marrow nucleus showing normal MYC (aqua), IGH (green) and BCL2 (red) as well as two copies of MYC-IGH-BCL2 fusion, MYC-IGH, and IGH-BCL2 fusion. (C) A partial karyotype after multicolor metaphase FISH study, using chromosome pairing probes, showing a t(3;22) resulting in BCL6 rearrangement. (D) A partial karyotype of chromosomes 7, 8, 14, and 18. G-banded chromosomes are on the left, DAPI-stained chromosomes with MYC (aqua), IGH (green) and BCL2 are in the middle and multicolor stained chromosomes are on the right. Note der(7) is composed of 7q (brown), gain of 8q (dark green), and the third copy of MYC-IGH-BCL2 fusion is on the tip of the 8q. The patients had three copies of IGH2-BCL2 although cytogenetically this was manifested as a gain of 8q. (Reprinted with permission from McFarland et al: Two cases of triple hit lymphoma: A call for imperative MYC, BCL2 and BCL6 testing by FISH in aggressive lymphomas. *Personalized Medicine in Oncology*, April 2015 Vol 4, 16-22. Copyright 2015. Green Hill Healthcare, LLC.)

and losses of 1p, 8p23-pter, 9p21-pter, 11q21-23, and 13q. Some of the genes residing in these chromosomal regions are dysregulated and are involved in cell proliferation, DNA repair, cellular homeostasis, and apoptosis. In MCL, DNA amplification of several chromosomal regions appears to be associated with a blastoid variant. Loss of 9p21-pter, inactivation of *TP53*, gain of 3q, and high cyclin D expression are biomarkers of a shorter survival and a more aggressive clinical phenotype. The prognostic value of 3q27-qer gains and loss of 9q21-32 region have been determined to be independent of the gene expression-based signature. Extra copies of 3q are prognostic in patients with low proliferation, whereas loss of 9q has improved clinical value in a subgroup of patients with high proliferation. Exome sequencing of patients with MCL has identified genetic heterogeneity underlying MCL with relatively few genes mutated in more than 10% of the cases. Genes most frequently and recurrently showing acquired mutations include *ATM*, *CCND1*, *TP53*, *RBI*, *WHSC1*, *POT1*, *SMARCA4*, *NOTCH1*, and *UBR5*.

Extranodal marginal zone lymphoma and MALT lymphoma are considered the third most frequent subtypes of NHL. An etiologic link between low-grade gastric MALT lymphoma and a lymphoid reaction associated with *Helicobacter pylori* infection has been well

established. Growing evidence suggests that chronic antigenic stimulation caused by autoimmune diseases, such as Hashimoto thyroiditis, also contributes to an increased risk for developing MALT lymphomas.

The most frequent and specific aberration occurring in MALT lymphomas is t(11;18)(q21;q21.1) (Fig. 56.55F). Although it has been described in other B-cell lymphomas, t(11;18) in MALT lymphoma is usually the sole lesion. It is the only recurrent translocation that does not involve *IG* genes, even though it presents as a B-cell lymphomas. As a consequence of t(11;18), *API2* gene on chromosome 11, band q21, which encodes an inhibitor of apoptosis (also known as IAP2, HIAP1, and MIHC), and a novel gene *MALT1* on chromosome 18, band q21, characterized by several Ig-like C2-type domains, are often rearranged. The resultant chimeric transcript consists of 5'-*API2* and 3'-*MALT1* located on der(18). More than 90% of breakpoints in the *API2* locus occur in intron 7, whereas the breakpoints within *MALT1* are variable and occur in four different introns. The *API2-MALT1* fusion is easily identified using a dual-color *API2-MALT1* FISH probe or the breakapart dual-color *MALT1* probe on lymph node biopsy specimens (see Fig. 56.55F). However, detection of deletions and duplications occurring at high frequencies

in both the *API2* and *MALT1* genomic sequences require more precise molecular cytogenetic methods.

t(1;14)(p22;q32) and its variant t(1;2)(p22;q12) occur in less than 5% of MALT lymphomas, and are associated with an advanced stage of the disease. This translocation relocates the entire *BCL10* gene from 1p22 to chromosome 14, bringing it under the control of an *IGH* enhancer. Currently, a specific probe for detecting *BCL10-IGH* fusion is not commercially available, but an *IGH* dual-color break-apart FISH probe may determine *IGH* rearrangements without identifying the partner chromosome. The recurrent t(3;14)(p13;q32) abnormality, which results in fusion of the *FOXP1F* gene on chromosome 3 to *IGH*, is a rare rearrangement that causes *FOXP1F* overexpression. Its significance in lymphoma remains unknown. The t(14;18)(q32;q21), which occurs in 2% to 18% of all MALT lymphomas, results in fusion of *IGH-MALT*. The 18q21 breakpoint involving the *MALT1* gene is 5 Mb centromeric from the *BCL2* breakpoint on chromosome 18, which is associated with FL. In contrast to *API2-MALT1* cases, patients with *IGH-MALT1* fusion have disease outside the gastrointestinal tract, usually presenting with ocular, skin, liver, or salivary gland tumors. FISH studies are useful for detecting the *IGH-MALT* fusion in paraffin-embedded lymph node biopsies. Compelling evidence links these translocations to constitutive activation of the NF- κ B pathway.

Splenic marginal zone lymphoma (SMZL) lacks recurrent chromosome translocations although approximately 30% of patients have heterozygous 7q deletions. Studies utilizing whole-exome sequencing have identified a novel and recurrent inactivating mutations in Krupel-like factor 2 (*KLF2*) in 42% of patients. These mutations are rarely observed in other B-cell lymphomas. Different *KLF2* mutations compromise the ability of *KLF2* gene to suppress NF- κ B activation, leading to an altered gene expression pattern favoring B-cell homing to the marginal zone. *KLF2* inactivation alone is insufficient for malignant transformation and requires cooperating genetic events. Other common mutations found in SMZL include *NOTCH2*, *TRAF3*, *TNFAIP3*, and *CARD11*. These mutations with and without *KLF2* mutations indicate that *KLF2* mutation identifies a subset of patients with SMZL with distinct genotype. NGS has demonstrated that 40% of patients with SMZL have mutations in four genes: *TP53*, *KLF2*, *NOTCH2*, and *TRAF3*, of which *TP53* mutations were associated with a shorter survival whereas mutations in *MYB* gene were predictors of a longer OS.

Lymphoplasmacytoid lymphoma (LPL) is a small lymphocytic lymphoma with plasmacytoid differentiation (CD5⁺CD10⁻) characterized by t(9;14)(p13;q32) in approximately 50% of cases. As a result of this translocation, the paired homeobox 5 (*PAX5*) gene on 9p13 moves to the *IGH* locus on der(14), causing dysregulation of *PAX5*. Molecular characterization of t(9;14) has revealed that the coding region of the *PAX5* gene remains intact in some patients. t(9;14) should be considered a regulatory mutation in which the *PAX5* gene is brought under the control of the *IGH* locus. In other cases, molecular studies of t(9;14) reveal that the breakpoint occurs upstream of the *PAX5* promoter, leading to insertion of the *IGH* enhancer upstream of the *PAX5* gene. Recurrent mutations in *MYD88*, specifically L265P mutation, have been identified in over 96% of patients with LPL whereas mutations in chemokine receptor, *CXCR4*, has been observed in about 36% of cases. These mutations identify a subgroup of LPL with aggressive disease.

Waldenström macroglobulinemia (WM) (see Chapter 87) is characterized by a lymphoplasmacytic clonal expansion in the marrow. Historically recurrent chromosomal abnormalities include deletion of the long arms of chromosome 6 in 21% to 55% of cases and trisomy 4 present in approximately 20% of cases. In contrast to other B-cell disorders, abnormalities of *IGH* at 14q32 as detected by FISH are rarely observed. Whole-genome sequencing of WM lymphoplasmacytic cells has led to the identification of a recurring sequence variant at position 38182641 in chromosome 3p22.2. A single-nucleotide change from T to C in the *MYD88* gene resulted in a leucine-to-proline change at amino acid position 265. *MYD88* (3p22 locus) mutations are detected by PCR in the peripheral blood of untreated patients. The *MYB88* L265P mutation is highly specific and is the

Genetic Testing for Non-Hodgkin Lymphoma

FISH testing can be performed on touch preparations, paraffin-embedded tissue, or bone marrow cells if involved in disease. Peripheral blood cells are not appropriate for genetic testing of non-Hodgkin lymphoma. Bone marrow cytogenetics at diagnosis is not mandatory but is important for staging in some cases. Fig. 56.42 lists the most useful FISH probes for detection of genomic defects in non-Hodgkin lymphoma. They include CCND1-*IGH*, *IGH*-*BCL2*, *MYC*-*IGH*, *BCL6*, *MYC* for detection of Burkitt variant not associated with t(8;14), and *MALT1* for detection of t(11;18). For patients with suspected anaplastic large cell lymphoma, *ALK* probe should be informative.

most frequent mutation in WM. It is found in over 91% of cases, including those with a gain of chromosome 3 (approximately 12%). This mutation may be considered as the first detectable genetic hit in WM that promotes NF- κ B and JAK-STAT signaling pathways. *MYD88* L265P mutation is also seen in SMZL and MALT lymphoma. *MYD88* L265P cannot be used to differentiate between WM and IgM MGUS. Patients with mutated *MYD88* have a shorter survival as compared with patients with unmutated *MYD88*. The *CXCR4* (2q22.1 locus), one of the main regulators of B-cell homing is mutated in almost 30% of patients with WM and 20% of patients with IgM MGUS. Collectively these results indicate that *CXCR4* is an activating mutation in WM and has a critical role in WM pathogenesis.

Little progress has been made in delineating recurrent chromosomal abnormalities in Hodgkin lymphoma (HL) (see Chapter 75). Less than 1% of the cells in HL are Reed-Sternberg cells, of B-cell origin. The most specific chromosomal abnormalities in HL are hyperdiploidy/tetraploidy with tremendous variations in chromosome number, indicating heterogeneity from patient to patient. Even with use of nine different centromeric probes, no specific numerical chromosomal abnormality has been identified. Deletions of 1p, 4q, 6q, and 7q are recurrent, and *JAK2*, located on 9p21, frequently is amplified in patients with HL. Another gene, *REL*, on chromosome 2, band region p14–p15, is amplified in 50% of patients. Of note, *REL* is under the influence of NF- κ B transcription factor, and constitutive NF- κ B activation is a critical prerequisite for Reed-Sternberg cell survival and proliferation.

The genome of Reed-Sternberg cells was largely unexplored because of the technical difficulties in isolating these cells. This difficulty was recently overcome and preliminary results of full-exome deep sequencing of 10 patients revealed inactivating mutations in β 2-microglobulin gene (*B2M*, localized at 15q21.1) in 7 of 10 patients. These mutations lead to the loss of major histocompatibility complex class I (MHC1) expression. A lack of *MHC1* expression in Reed-Sternberg cells was previously reported as an independent adverse prognostic factor. Therefore molecular mechanisms leading to MHC1 downregulation in Hodgkin lymphoma is through inactivating mutations in *B2M* gene.

HAIRY CELL LEUKEMIA

No recurrent chromosomal aberrations have been identified in hairy cell leukemia (HCL) although as shown in Fig. 56.59 some patients may have a complex bone marrow karyotype at diagnosis. HCL is a mature B-cell malignancy with the bone marrow, spleen and liver infiltrated by leukemic B cells that have abundant cytoplasm with hairy-looking projections and unique immunophenotyping features. High-density genome-wide SNP genotyping have shown a remarkable balanced genomic profile. In 2011, a *BRAF*-V600E mutation was described for the first time in every one of 47 patients. The *BRAF*-V600E mutation defines HCL, is present in virtually all patients with HCL, and is absent in other B-cell malignancies except a small number of patients with MM.²⁹ *BRAF* is a kinase within the RAS-RAF-MEK-ERK pathway that plays a pivotal role in regulating hematopoietic stem cells from patients with HCL. Quantitative

Fig. 56.59 A COMPLEX KARYOTYPE FROM A PATIENT WITH HAIRY CELL LEUKEMIA. In this karyotype there are nine complex structural abnormalities as indicated by arrows and the karyotype is 47, XY, del(5)(q15;q31), der(8)t(3;8)(p21p26;q24), der(17)t(1;17)(p36.1;p13)t(17;21)(q25;q22.2), -21, +r(21)x2.

sequence analysis revealed a mean *BRAF*-V600E-mutant allele frequency of 4.9% in human hematopoietic stem cells from patients with HCL and functional studies showed that these cells have self-renewal capacity, indicating that this mature B-cell malignancy originates within the hematopoietic stem cell compartment. Detection of the *BRAF*-V600E mutation by PCR is the gold standard for the genetic diagnosis of HCL.

T-CELL LYMPHOPROLIFERATIVE NEOPLASMS

This is a diverse group of hematologic disorders that includes T-cell ALL and T-cell CLL/PML, as well as several indolent T-cell disorders, large granular lymphocyte leukemia, natural killer leukemia/lymphoma, and anaplastic large cell lymphoma (ALCL).

T-cell ALL represents 15% of childhood ALL cases and 25% of adult ALL cases. At diagnosis, approximately 50% of patients have a normal karyotype. Table 56.11 lists recurrent cytogenetic and molecular genomic changes associated with T-cell ALL and Table 56.18 lists the frequency of recurrent chromosomal abnormalities in T-ALL. Immunophenotypic and gene expression analyses are consistent with genetic heterogeneity in T-cell ALL, reflecting, to some degree, distinct stages of T-cell maturation arrest.

One of the common themes in T-lymphoid malignancies is the juxtaposition of the *TCR* gene enhancer element adjacent to a variety of transcription factors located at or near breakpoints on the partner chromosome. The chromosomal bands most frequently involved are 14q11, where *TCRA* and *TCRD* are located (see Fig. 56.60); 7q35, the site of *TCRB*; and 7p15, the site of the *TCRG*. *TCR* translocations are found in approximately 35% of T-cell ALL cases (Table 56.17). The rearrangements of *TCRB* and *TCRG* are relatively rare, whereas 14q11 rearrangements involving both *TCRA* and *TCRD* are frequent in T-lymphoid neoplasms (see Table 56.13).

In children, the overall frequency of T-cell ALL translocations is 40% to 50%, and several molecular/cytogenetic abnormalities have prognostic relevance (see Table 56.14). *TAL1* rearrangements include t(1;14)(p32;q11), t(1;7)(p32;q35), rare t(1;3)(p32;p21), t(1;5)(p32;q31) and t(14;19)(q11.2;q13.1) (Fig. 56.61). In general, *TAL1* rearrangements are submicroscopic and best identified with FISH. Disruption of *TAL1* is frequently associated with a submicroscopic interstitial deletion (90 kb) between the 5' untranslated region of the *TAL1* (1p32) and the *SIL* (*STIL*) genes (1p32) in 9% to 26% of cases depending on the different studies. The *SIL-TAL1* fusion product gives rise to inappropriate expression of TAL1 protein. Among 382 children, 16% showed the presence of *SIL-TAL1*, which was more

frequently observed in older children. These 1p32 rearrangements are less frequent in adult ALL. *TAL1*-positive ALL is characterized by an arrest in differentiation at the CD4⁺CD8⁺ stage of thymocyte development, when *TAL1* gene is normally silent. *TAL1* gene encodes a transcription factor and several of the core components of the transcription complex include *GATA3*, LIM domain only, and *RUNX1*.

TAL2, residing at 9q32, is detected in rare t(7;9)(q34;q32) rearrangement as a result of juxtaposition of *TAL2* to *TCRB*. *LYL1*, originally described as a fusion partner of *TCRB* in rare (7;19)(q34;p13), and is associated with poor prognosis. Rearrangements of *HOX11L2*, which include cryptic t(5;14)(q35;q32), t(5;7)(q35;q21), and other variants, occur at a frequency of 24% in children and represent a predictor of poor outcome, regardless of treatment strategies. Similarly, the presence of t(10;11)(p13;q14), which results in the *CALM-MLL10* fusion gene and occurs at a frequency of 2% to 5% in children, may be associated with poor outcome. Abnormalities of *HOX11* are more common in adults than in children (31% versus 7%) and are associated with t(10;14)(q34;q24) and t(7;10)(q34;q24). t(10;14) is the most frequent chromosomal translocation in patients with T-cell ALL. It is associated with excellent outcome in both children and adults with t(10;14) and in these patients the homeobox gene *HOX11* is fused with *TCRD*. The coding regions of *HOX11* are not disturbed by the translocation. In the variant translocation t(7;10)(q35;q24), *HOX11* is juxtaposed to *TCRB*, which results in overexpression of normal *HOX11* mRNA by bringing *HOX11* under the influence of *TCR* promoter sequences.

MLL rearrangements are present in 8% of T-cell ALL cases (see Fig. 56.33). The most frequent *MLL* translocation partners in T-cell ALL include *ENL*, which results from t(11;19)(q23;p13.3) and is associated with a better prognosis than T-cell ALL with other fusion partners. GEP has characterized T-cell ALL with *MLL* rearrangements as a distinct molecular subtype. Homeobox genes, regulators of embryonic development, are known targets of *MLL* and are overexpressed in patients with T-cell ALL and *MLL* rearrangements.

Dysregulation of *NOTCH*, tyrosine kinase genes (*ABL1*, *JAK2*), and LIM domain genes (*LMO1*, *LMO2*) is also common in T-cell ALL. *NOTCH1* is a fusion partner of *TCRB* in t(7;9)(q34;q34.3). These mutations are present in 56% of T-cell ALL cases. The *NOTCH1* gene is important in lymphoid lineage specification, and resequencing of functional domains of *NOTCH1* have revealed that activating *NOTCH1* mutations are present in most primary pediatric and adolescent molecular cases of T-ALL as well as in adult ALL. Mutations in the heterodimer domain as well as ITD result in constitutive ligand-independent activation of *NOTCH1*.

The LIM family of genes is found at the breakpoint of rare but consistent chromosomal translocations in T-cell ALL. *LMO1*, located at 11p15, is involved in t(11;14)(p15;q11). *LMO2*, located at 11p13, is involved in t(11;14)(p13;q11) and t(7;11)(q35;p13). As an oncogenic transcription regulator, *LMO2* overexpression in erythroid and T cells leads to a differentiation arrest, which is a prerequisite for development of T-cell malignancies.

The *MYB* gene, which is localized on chromosome 6, band q23.3, is rearranged in a rare T-cell ALL subtype observed in young patients (median 2.2 years). Two types of recurrent *MYB* genomic alterations are found in T-cell ALL: (a) a reciprocal t(6;7)(q23;q34) that results in juxtaposition of *MYB* near *TCRB* regulatory sequences on chromosome 7 and (b) a short genomic tandem duplication, identified using genome-wide copy-number analysis. Both rearrangements are cytogenetically cryptic. The breakpoints in t(6;7) are subtelomeric and usually missed. The translocation was discovered using a locus-specific FISH probe for *MYC*.³⁰ The tandem *MYB* duplication is cryptic using both conventional cytogenetics and locus-specific FISH. It is mapped using high-density oligonucleotide aCGH. Discovery of *MYB* highlights the strength of high-density aCGH in identifying cryptic copy-number abnormalities associated with leukemia.

Although only 1% of Ph-positive ALL have a T-cell phenotype, the *ABL1* gene, is also involved in fusion with *NUP214* (9q34.11), creating the *NUP214-ABL1* chimeric gene/t(9;22)(q34.11-q22.1), which is identified in up to 6% of T-cell ALL. This fusion gene is

Fig. 56.60 REARRANGEMENTS OF T-CELL RECEPTOR (TCR) GENES IN T-CELL MALIGNANCIES. A partial karyotype of chromosomes 7 and 14 from a patient with T-cell prolymphocytic leukemia. (A) Ring chromosome 7 and inversion of chromosome 14. Black arrows indicate two breakpoints on chromosome 14, q11.2 and q32, where inv(14) have occurred. (B) Different partial karyotype from the same patient showing a dicentric ring 7. (C) An isolated bone marrow nuclei after hybridization with TCRα/δ FISH probe. Yellow arrows indicate separation of the 3' and 5' of TCR, consistent with inv(14). Because of the ring (7) this patient also had rearrangements of TCR β/γ.

TABLE 56.17 Frequency of T-Cell Receptor (TCR) Rearrangements Using Conventional Cytogenetics Versus FISH

Locus	Conventional Cytogenetics (%)	FISH (%)	
		Total Karyotype	Abnormal Karyotype
TCRαδ	9.5	17.4	24.7
TCRβ	3.1	19	26.9
TCRγ	0	0	0

found amplified only in T-cell ALL. When identified with FISH using the *ABL1* probe, it appears as an amplified episome between the chromosomes in metaphase cells, usually showing 5–50 copies/cell and very rarely identified by conventional cytogenetics (Fig. 56.62). RT-PCR can also be used for its detection. The most common fusion gene involves the breakpoint in exon 2 of *ABL1* and the

breakpoint in exon 31 of *NUP214*, although variant breakpoints in both genes have been reported. *NUP214-ABL1* is a constitutively activated tyrosine kinase activating similar pathways as *BCR-ABL1* and is sensitive to inhibition with TKIs, especially nilotinib and dasatinib. These patients usually have homozygous or heterozygous deletions of *CDKN2A* at 9p21 chromosomal site as well as trisomy 8, t(7;10)(q35;q24), or t(10;14)(q24;q11), indicating that *NUP214-ABL1* is not a primary genetic event. Patients with *NUP214-ABL1* usually present with high-risk T-cell ALL and their outcome is poor. del(9)(q34.11–q34.13) or rare t(9;9)(q34;q34) results in the formation of a *SET-NUP214* fusion gene frequently observed in T-cell ALL (Fig. 56.63). In rare cases of T-cell ALL, *JAK2* has been identified as a partner chromosome with *ETV6* in t(9;12)(p24;q13), with *PCMI* in t(8;9) and in multiple amplified copies (Figs. 56.64–56.66), two of the three *JAK2* fusion transcripts seen in hematologic malignancies (see Ph-Negative Myeloproliferative Neoplasms, earlier, and Table 56.13).

Adult T-cell ALL is characterized by an aberrant karyotype in almost 70% of cases and by recurrent acquisition of somatic

Fig. 56.61 *BLI* AMPLIFICATION IN T-CELL NEOPLASMS. *ABL1* amplification as a result of *NUP214-ABL1* chimeric gene resulting from $t(9;22)(q34.11;q22.1)$ chromosomal translocation in a patient with Ph-positive T-cell acute lymphoblastic leukemia. (A) Three interphase cells showing 2 *BCR* loci (green) and numerous copies of *ABL1* (red). (B) More than 40 copies of *ABL1* (red) were identified in this bone marrow nucleus. (C) Approximately 30 copies of *ABL1* (red) were shown as an amplified episome between the chromosomes in this bone marrow metaphase cell.

Fig. 56.64 *JAK-TEL* FUSION. Partial karyotype of $t(9;12)(p24;q23)$ (top) and after FISH study (bottom) with *JAK2* (red) and *TEL/ETV6* (green), showing *JAK2-TEL* fusion (yellow) at 9p24.

Fig. 56.63 A PARTIAL BONE MARROW CHROMOSOME 9 KARYOTYPE FROM TWO METAPHASE CELLS FROM A PATIENT WITH T-CELL ACUTE LYMPHOBLASTIC LEUKEMIA. The rare variant $t(9;9)(q22;q34)$ also results in *SET-NUP214* fusion gene.

mutations in 93% (Table 56.18). The most frequent recurrent molecular lesions observed in adult T-cell ALL include mutations in the following genes: *NOTCH1* (71%), *PHF6* (39.5%), *FBXW7* (18.9%), *DNMT3A* (17.8%), *RUNX1* (15.5%), *PTEN* (10%), *FLT3-IDT* (2.2%), *FLT3-TKD* (1.1%), and *CDKN2A* (3.3%). Combining these data with frequent *CDKN2A/B* deletions and aberrant *CDKN2B* methylation status, 98.9% of adult T-cell ALL have a minimum of one genetic defect. *DNMT3A* and *RUNX1* mutations are preferentially found in early immature T-cell leukemias and are associated with poor OS.

Early T-cell precursor ALL (ETP) is an aggressive subtype of T-cell ALL that comprises up to 15% of T ALL cases. Whole-genome sequencing of 94 T-ALL cases revealed a mutational spectrum similar to AML and global transcriptional profile is similar to that of normal and myeloid hematopoietic stem cells. ETP ALL is characterized by activating mutations in genes regulating cytokine receptor and RAS signaling (67% of cases: *NRAS*, *KRAS*, *FLT3*, *IL7R*, *JAK3*, *JAK1*, *SH2B3*, and *BRAF*), inactivating lesions disrupting hematopoietic development (58% of cases: *GATA3*, *ETV6*, *RUNX1*, *IKZF1*, and *EP300*) and histone modulating genes (48% of cases: *EZH2*, *EED*, *SUZ12*, *SETD2*, and *EP300*).

Fig. 56.65 GAIN OF *JAK2* IN ADULT T-CELL LEUKEMIA/LYMPHOMA. (A) A partial karyotype of der(9) chromosome from a patient with adult T-cell leukemia/lymphoma showing *JAK2* (red) amplification. (B) A partial dup(9)(p24) karyotype showing duplication of *JAK2* (red is 5' *JAK2*, green is 3' *JAK2*).

Fig. 56.66 *t(8;9)(PCMI-JAK2)* IN T-CELL ACUTE LYMPHOBLASTIC LEUKEMIA. (T-ALL) A partial karyotype from a patient with T-ALL showing *t(8;9)(p22;p24)* resulting in *PCMI-JAK2* fusion also observed in patients with Ph-negative myeloproliferative neoplasms. In this translocation 5' *JAK2* (green) is translocated from 9p24 to 8p22 using *JAK2* two-color breakapart FISH probe.

MYC translocations identify a genetic subtype of T-cell ALL, which occurs in about 6% of cases within a cohort of 196 patients with T-cell ALL, including both children and adults. Two types of translocations were observed: those involving the *TCR* loci and those with other partners. Specifically, *MYC* translocations were significantly associated with TAL/LMO subtype of T-cell ALL and trisomies for chromosomes 6 and 7. GEP has revealed that *MYC* translocations occur as secondary abnormalities present either in subclones at diagnosis or following disease progression.

In contrast to childhood B-cell ALL, the majority of childhood T-cell ALL cases develop after birth. In utero origin of this form of leukemia is rare.

T-cell CLL and prolymphocytic leukemia are characterized by T-cell leukemia 1 (*TCL1*) gene rearrangements. These include *inv(14)*

(q11;q32.1), *t(14;14)(q11;q32.1)*, and *t(7;14)(q35;q32.1)* (see Fig. 56.60). In patients showing these karyotypic changes, *TCL1* is found to be dysregulated.

Adult T-cell leukemia/lymphoma is associated with human T-cell lymphotropic virus type 1. The most frequent genetic lesions include altered expression of *CDKN2* (cyclin-dependent kinase inhibitor) gene on 9p21 (15%–20%) and loss of heterozygosity at 6q15 to q21. The most frequent chromosomal abnormalities are gain of 3p, 7q, and 14q and loss of 6q and 13q. Translocations involving 14q32 or 14q11 are frequently observed.

Natural killer lymphoma/leukemia is a group of highly aggressive lymphoid malignancies of natural killer cell origin. They exhibit chromosomal rearrangements in greater than 80% of cases by conventional karyotyping. The most frequent abnormalities include *del(6)(q21–23)* and gain of the X chromosome. FISH, CGH, and spectral karyotyping have confirmed the presence of *del(6)* in CD3⁺CD56⁺ tumor cells. Other less common but recurrent karyotypic changes include isochromosome 1q, 6p, and 17q, as well as *del(11q)*, 13q, and 17p, and trisomy 8.

Angioimmunoblastic T-cell lymphoma and unspecified peripheral T-cell lymphoma are the most frequent nodal T-cell lymphomas. Losses of 5q/10q/12q, identified by CGH, characterize a subtype of peripheral T-cell lymphoma associated with a better prognosis. Gain of 11q13 may represent a primary change in angioimmunoblastic T-cell lymphoma. In general, chromosomal imbalances are more common in unspecified peripheral T-cell lymphoma than in angioimmunoblastic T-cell lymphoma. Both disorders may share similar genomic imbalances.

The molecular basis of ALCL is the result of *t(2;5)(p23;q35)*, which fuses part of the *NPM* gene on 5q35 with part of the *ALK* receptor tyrosine kinase gene on 2p23 to produce a chimeric *NPM-ALK* gene. This encodes a chimeric protein that has activated kinase function. *ALK* is thought to play a direct role in the malignant transformation of lymphoid cells, probably by aberrant phosphorylation of intracytoplasmic substrates. ALCL is a distinct clinical entity, with *t(2;5)* detected by cytogenetics in 60% to 85% of patients. The *NPM-ALK* fusion is identified by FISH (Fig. 56.67) and by RT-PCR assay in 88% of pediatric patients and 60% of adult patients. The other cases of ALCL have variant translocations with at least 21 different fusion genes and include rearrangements with *TPM3* (1q24), *EML4* (2p24), *RANBP2* (2q13), *ARIC* (2q35), *TCG* (3q21), *SEC31A* (4q21), *CARS* (11p15), *CLTC* (17q23), *ALO17* (17q25), *TPM4* (19p13), *CLTC1* (22q11), *MYH* (22q11.2), and *MSN* (Xq11). Detection of *ALK* rearrangements by FISH corresponds to a cytoplasmic staining pattern associated with translocations other than *t(2;5)* in 100% of cases. Recently two copies of *NPM-ALK* and *TPM3-ALK* fusions were reported in children with an aggressive form of ALCL.

The prognosis of patients with *t(2;5)* or variant translocations is excellent, with 5-year survival rates of 70% to 90%. By contrast, *ALK*-negative ALCL is associated with a 5-year survival rates of 40% to 60%. The true nature of *ALK*-negative ALCL remains obscure. Most cases have clonally rearranged *TCR* genes. Recurrent rearrangements of the *DUSP22-IRF4* locus on 6p25.3 has been identified in about 30% of *ALK*-negative ALCLs resulting in *t(6;7)(p25.3;q32.3)*. Other recurrent rearrangement in *ALK* negative cases involves *inv(3)(q26q26)* resulting in *TBL1XR-TP63* fusion. CGH showed that *ALK*⁺ ALCL have more complex copy number abnormalities than *ALK*⁺ ALCL, specifically gains of 1q41-ter, 5q, 6p, 8q, 12q, and 17q and losses of 6q21 and 13q21–22. The interferon regulatory factor 4 (*IRF4*), localized at 6p25.3, is highly expressed in both *ALK*⁺ and *ALK*[−] ALCLs. GEP has revealed that *MYC* is the primary target of *IRF4* and that *MYC* itself is essential for ALCL cell survival. Collectively these observations indicate that ALCL is dependent on *IRF4* and *MYC* signaling. Immunochemical analysis has revealed that both proteins are co-expressed in 82% of patients with ALCL.

A variety of genomic rearrangements are seen in the T lymphocytes of patients with mycosis fungoides and Sézary syndrome. However, specific cytogenetic abnormalities are not associated with these disorders. Most frequent abnormalities involve loss of chromosome 10,

Fig. 56.67 FISH STUDY WITH BREAKAPART *ALK* GENE AT 2p23 IN A PATIENT WITH ANAPLASTIC LARGE CELL LYMPHOMA. Partial karyotype shows a normal chromosome 2 (*left*) with yellow signal, as the 3' end and the 5' end of *ALK* gene are in close proximity on chromosome 2. The other chromosome 2 homologue (*middle*) has only a single green signal (5' end) as a result of t(2;5)(p23;q35), the most frequent translocation in anaplastic large-cell lymphoma. The 3' end (*red*) of the *ALK* gene is translocated to 5q35. Abnormal *ALK* gene is also shown in interphase cell (*right*).

deletion of 1p, isochromosome 17q, additions of 17p and 19p, and translocations involving 1p, 10q, and 14q. Both CGH and M-FISH identify chromosome 10, region 10q22–26, as the most frequent abnormality in these disorders.

Posttransplant lymphoproliferative disorder (PTLD) is a morphologically diverse group of lymphoid disorders that occurs in immunosuppressed organ transplant recipients. Chromosomal abnormalities are detected in 51% to 72% of B-cell variant and in almost all T-cell variants, as measured by CGH, FISH, and conventional karyotyping. In general, three groups of nonrandom abnormalities are of importance. The pathogenetic roles of abnormalities known to be involved in lymphomas, such as *MYC*, *TP53*, and 18q21 associated with *BCL2* and *MALT1*, and those associated with large genomic imbalances, such as 2p24–25, 9q22–34, 12q22–24, and 14q32, await elucidation. Trisomy of chromosomes 9 and 11 appears to be associated with EBV PTLD and prolonged survival. In contrast, patients with PTLD showing *MYC* rearrangements (about 50%) are associated with BL, an aggressive clinical course. T-cell PTLD develops late after transplantation. These disorders are EBV⁺ and are associated with a poor outcome and short survival.

ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION

Molecular and cytogenetic analyses can be used to characterize the origin of engrafted cells and the development and evolution of recurrent malignancies after allogeneic hematopoietic cell transplantation (HCT). Hematopoietic cells that emerge after allogeneic HCT may

be of host origin, donor origin, or both. Genetic studies of post-transplant hematopoiesis are termed *chimerism analysis*. Chimerism should be distinguished from mosaicism, which is characterized by two or more different cell populations originating from one zygote. Monitoring chimerism in recipients of allogeneic HCT is essential to identify early engraftment, monitor residual disease, predict relapse, and optimize posttransplantation therapy in case of graft failure.

Historically, karyotype analysis was used to evaluate engraftment after sex-mismatched allogeneic HCT. Polymorphism of chromosomes 1, 9, and 16, as well as satellite polymorphism of chromosomes 13, 14, 15, 21, and 22, were used to differentiate donor from recipient cells in sex-matched allogeneic HCT. Karyotype analysis could identify not only chimerism but also recurrence of the hematologic malignancies. However, this is a time-consuming process and has low sensitivity (5%). In the past two decades, many methods for detection of chimerism have been developed. All follow the basic principle of using the differences in polymorphic genetic markers to distinguish donor from recipient hematopoiesis. These methods include restriction fragment length polymorphism, red cell phenotyping, and interphase FISH, but do not offer the possibility to study all patients. The most widely used technique is PCR for a variable number of tandem repeats/short tandem repeats (VNTR/STR-PCR). This technique has a sensitivity of 3% to 5%, but the quantitation of donor and recipient cells may be cumbersome. The method that allows study of chimerism in all patients involves fluorescence labeling of the primers and resolution of PCR products with capillary electrophoresis. It provides high quantitative accuracy with 1% to 5% sensitivity. Real-time PCR or RQ-PCR for analysis of the *SRY* gene

on the Y chromosome allows identification of male cells in the background of 100,000 female cells, providing a high sensitivity for mixed chimerism. However, this approach is limited to the 50% of patients who receive sex-mismatched transplants. Nevertheless, it remains the most sensitive and the fastest method of chimerism analysis, providing reliable quantitative results within 2 hours.

Detection of SNPs by chimerism analysis (SNP-PCR) is highly sensitive. In one study using 11 different SNP loci, SNP-PCR analysis identified independent predictors of relapse after HCT. The two most commonly used methods for detection of chimerism after HCT are fluorescence-based PCR amplification of short tandem repeats (STR-PCR) and interphase FISH. Both methods are accurate and reproducible. The sensitivity of both methods approaches 1%; however, STR-PCR is sex independent and can be applied to all patients. FISH analysis, on the other hand, permits simultaneous evaluation of chimerism and residual disease in the same cell when high sensitivity is not a requirement. FISH analysis for diagnostic genomic abnormalities in conjunction with conventional cytogenetics remains useful and reliable in determining the presence of residual disease (Fig. 56.68).

Leukemia relapse in donor cells after allogeneic HCT is a rare complication occurring in 0.12% to 5% of cases. It was first described in 1971, and more than 90 cases have been reported. Careful genetic analysis of relapse cells is essential. VNTR, restriction fragment

length polymorphism, STR analysis, or FISH XY analysis alone may not definitively assign the origin of the leukemic clone because genomic deletions or amplifications of chromosomal segments may occur during transplantation or disease process. The increased use of unrelated cord blood as a source of stem cells for allogeneic HCT raises the concern that hematopoietic progenitors containing preleukemic clonal molecular rearrangements may be inadvertently transplanted. Systematic screening of unselected cord blood samples revealed putative preleukemic rearrangements such as *ETV6-RUNX1* and *RUNX1-RUNX1T1*. In a study of 1417 umbilical cord blood samples evidence for the *ETV6* or *RUNX1/RUNX1T1* fusions were not found. However, recent reports comparing clinical characteristics of donor-cell derived leukemia (DCL) from the standpoint of the transplant source, with umbilical cord blood and bone marrow, showed in some studies, that AML and MDS were recognized more frequently in DCL after cord blood transplant, but not in other studies, whereas the incidence of AML and ALL was similar after bone marrow transplant. The median duration between the occurrence of DCL following cord blood and bone marrow transplant was 14.5 and 36 months, respectively ($p < .0001$). DCL occurred in a significantly shorter period after cord blood transplant than after marrow transplant. Abnormal karyotypes involving chromosome 7 were observed in 52.4% of cord blood recipients and 17.3% of marrow recipients ($p < .003$). The types of abnormal karyotypes in DCL following marrow transplant were similar to those characteristically observed in adult de novo AML and MDS. Patients with DCL generally have a poor prognosis in both groups. Stem cell transplantation is the best treatment for curing DCL. Therefore DCL appears to have different clinical features according to the transplant source. The reason for an increased risk for leukemia or myelodysplasia in donor cells is not understood and may be a function of the conditioning regimen used or the less stringent HLA matching required for unrelated cord blood stem cell transplantation. Specific mechanisms that result in development of DCL leukemia are unknown. Proposed mechanisms include the following: (a) sustained host-origin antigenic stimulation, (b) impaired hematopoietic microenvironment and defective stromal support system, (c) immune surveillance escape secondary to posttransplant immunosuppressive therapy, (d) similar genetic susceptibility in cases of related donors, (e) viral driven pathogenesis (cytomegalovirus, EBV), (f) delayed effects of conditioning regimen, and (g) transfection of host cell oncogene into donor cells. Most likely, the underlying cause is a combination of these mechanisms operating in individual cases. A very compelling hypothesis for the mechanisms leading to the development of DCL is the “2-hit” hypothesis. A donor HSC that has an inherent susceptibility to malignant transformation (hit 1) is placed within a defective stromal structure creating a microenvironment that elaborates repeated stress signals (hit 2), inducing additional genetic or even epigenetic mutations promoting malignant transformation.

Nevertheless, these patients must be carefully evaluated using an array of molecular methods for determination of leukemia in donor cells (see [box on Genetic Testing for Hematopoietic Cell Transplantation](#)). Ideally an examination of every sample before transplantation to determine whether the cord blood cells contain abnormal clones is suggested. In addition, long-term surveillance of stem cell transplant recipients and donors is also required (Fig. 56.69).

Fig. 56.68 DETECTION OF ENGRAFTMENT AND RESIDUAL DISEASE WITH FISH IN SEX-MISMATCHED HEMATOPOIETIC CELL TRANSPLANTATION. Metaphase and nondividing cell (blue) after DAPI counterstaining, hybridized with X (large red) and Y (large green) for detection of engraftment and with ABL (small red) and BCR (small green) for detection of residual chronic myelogenous leukemia (top panel). Left nucleus (bottom panel) shows a donor male (XY) cell origin and lack of BCR-ABL fusion. In contrast, a host female (XX), BCR-ABL fusion (yellow)—positive cell is shown on the right. Combination of XY FISH probes with diagnostic genomic markers is a powerful and fast FISH method for simultaneous detection of chimerism and minimal residual disease.

Genetic Testing for Hematopoietic Cell Transplantation

Testing consists of either variable number of tandem repeats/short tandem repeats PCR for detection of engraftment in patients with sex-mismatched hematopoietic cell transplantation (HCT) or single-nucleotide polymorphism PCR, which has a high sensitivity. In sex-mismatched HCT, both interphase FISH with XY probes and real-time quantitative PCR for analysis of *SRY* gene on the Y chromosome can be used for detection of engraftment. Detection of both engraftment and minimal residual disease is best accomplished by FISH, simultaneously using probes for XY and the explicit probe for diagnostic genetic defect, such as XY and *BCR-ABL1*.

Fig. 56.69 DONOR-DERIVED MYELODYSPLASTIC SYNDROME (MDS) FOLLOWING CORD BLOOD TRANSPLANTATION IN ACUTE LYMPHOBLASTIC LEUKEMIA. (A) At diagnosis of acute lymphoblastic leukemia, in January 2006, cytogenetic analysis of bone marrow revealed a 56, XY, +X, inv(2)(p11.2q13), +4, +6, +9, +14, +14, +17, +18, +21, +21 hyperdiploid karyotype (arrows indicate abnormal chromosomes). (B) A bone marrow nucleus from a specimen obtained in January 2007 after FISH showed 5% of cells with tetrasomy 21 (red signals), two copies of X chromosome (green signals), and one copy of Y chromosome (aqua). (C) A partial karyotype of chromosome 2 from the peripheral blood specimen, PHA-stimulated for 72 h, obtained in May 2006, showing a constitutional inversion (2)(p11.2q13). (D) At the time of the diagnosis of MDS in May 2011, bone marrow cytogenetic analysis revealed 65% of cells with a 44, XY, -3, del(4)(q23q33), der(5;17)(p10;q10), -7, t(8;22)(p21;q13), +mar karyotype (arrows indicate abnormal chromosomes). (E) Five bone marrow nuclei after FISH studies from the June 2011 specimen showing 75% cells with deletion of *EGR1* at 5q31 chromosomal location (red) and deletion of *P53* at 17p13.1 chromosomal localization (red) as a result of der(5;17); 71% showing a loss of 7q31 locus as a result of monosomy 7, as well as disomy 21 (red), one X (green), and one Y (aqua) chromosome. (F) A partial bone marrow karyotype of chromosome 2 from May 2011 specimen showing a normal chromosome 2 from the donor cells and absence of inv(2) observed in the bone marrow and PHA-stimulated PB at the time of diagnosis peripheral blood specimen, PHA stimulated for 72 h, obtained in May 2006, showing a constitutional inversion (2)(p11.2q13). (D) At the time of the diagnosis of MDS in May 2011, bone marrow cytogenetic analysis revealed 65% of cells with a 44, XY, -3, del(4)(q23q33), der(5;17)(p10;q10), -7, t(8;22)(p21;q13), 1mar karyotype (arrows indicate abnormal chromosomes). (E) Five bone marrow nuclei after FISH studies from the June 2011 specimen showing 75% cells with deletion of *EGR1* at 5q31 chromosomal location (red) and deletion of *P53* at 17p13.1 chromosomal localization (red) as a result of der(5;17); 71% showing a loss of 7q31 locus as a result of monosomy 7, as well as disomy 21 (red), one X (green), and one Y (aqua) chromosome. (F) A partial bone marrow karyotype of chromosome 2 from May 2011 specimen showing a normal chromosome 2 from the donor cells and absence of inv(2) observed in the bone marrow and PHA-stimulated PB at the time of diagnosis. FUTURE DIRECTIONS

The question of how initial genetic damage in hematopoietic stem cell disorders causes a cascade of genetic events that leads to the development of malignancy is unresolved for many diseases. However, major advances have been made, and molecular unraveling of the consequence of the Philadelphia chromosome has led to the rationally designed imatinib treatment that has transformed CML from a fatal disease into a chronic disorder compatible with normal life. Precise molecular characterization of leukemic cells not only provides more insight into the pathogenesis of disease but also allows patients to be stratified as having high or low risk for recurrence and adverse outcome. The ultimate goal is to translate this basic knowledge into increasingly better treatment options. Molecular diversity is currently the genetic hallmark of many leukemias, even within a single disease entity such as AML or T-cell ALL. We are at the threshold of understanding other genetic events, common genetic pathways and intra-tumor heterogeneity. Such an understanding is crucial to designing molecular interventions for specific abnormalities of genetic pathways underlying hematologic malignancies. It is clear that the genetic revolution has already changed the practice of clinical hematology. In the future, molecular cytogenetics and cytogenomics, such as interphase-directed locus-specific FISH technologies and aCGH + SNP, will be the key diagnostic, prognostic and follow-up tools during the routine management of patients with hematologic malignancies. NGS technology has enhanced the understanding of leukemic pathogenesis and the origin and evolution of mutations and their temporal sequence, increasing the power for subclassifying leukemic entities and allowing earlier diagnosis and more appropriate treatment for patients. Perhaps most dramatically, the complementary application of these genetic methods has demonstrated intratumor heterogeneity. Nonetheless, modern genomic studies provide a snapshot portrait of the total DNA within the tumor along with a mixture of normal and abnormal cells. Systematic interrogation of subclonal genetic complexity and clonal architecture or phylogeny currently poses a technical challenge because three categories of mutational change; fusion genes, CNVs, and SNPs, need to be identified in a single cell. In the future, to construct a clonal evolutionary phylogeny, single cell analysis using genetic profiling at diagnosis and relapse will provide detailed subclonal genetic architecture. The challenge remains to translate the large leukemogenomics data into easily interpretable results accessible to the hematologist for the purpose of more accurate and effective therapies.

PHARMACOLOGY AND MOLECULAR MECHANISMS OF ANTINEOPLASTIC AGENTS FOR HEMATOLOGIC MALIGNANCIES

Stanton L. Gerson, Paolo F. Caimi, Basem M. William, and Richard J. Creger

The treatment of patients with hematologic malignancies has been revolutionized over the past decades as new therapeutic targets continue to be identified through cellular and molecular studies of these conditions. These investigations have spawned the discovery, clinical evaluation, and US Food and Drug Administration (FDA) approval of new mechanistic-based therapeutic agents. A surprising number of these agents have progressed from the discovery phases to validation, animal modeling, and successful clinical testing. The results have led to a virtual explosion in the therapeutic armamentarium and an increase in the spectrum of drugs including small molecules, monoclonal antibodies, radiolabeled antibodies, drug immunoconjugates, immunotoxins, and complex delivery systems. This chapter provides information on new and existing therapeutic agents available for the treatment of patients with hematologic malignancies. The chapter reviews the “classic” agents as well as the newly developed, target-based agents. Both cytotoxic and growth-inhibitory agents are covered; however, the use of therapeutic antibodies and antibody conjugates is reviewed within the chapters dealing with specific diseases.

TUMOR CELL HETEROGENEITY OF HEMATOLOGIC MALIGNANCIES

Whereas hematologic malignancies are of clonal origin (i.e., they are derived from a single transformed cell), individual neoplastic cells from a patient's malignancy exhibit a great deal of phenotypic diversity and acquire secondary mutations that affect proliferation, drug sensitivity, and resistance. This diversity likely arises from the progeny of clonal populations and subsets of stem cells. In animal models, it has been shown that the clones themselves can give rise to progeny that can transmit the clonal malignancy after transplantation into secondary recipients, suggesting that stem cells are not required to transmit the malignant phenotype.

New evidence indicates that leukemia stem cells are more quiescent, have higher levels of protective proteins such as efflux pumps for drugs, and have higher levels of DNA repair proteins or antiapoptotic proteins than the more abundant cell making up the circulating population of cells. Tumor cell heterogeneity arises as a consequence of spontaneous mutational events, changes in gene promoter methylation, abnormal expression of transcription factors, lymphoid reactivity, and cytokine responsiveness. For example, a mutation or change in expression that renders a hematopoietic cell clone autonomous or growth factor-independent would be expected to render such cells less susceptible to adverse environmental conditions (e.g., growth factor withdrawal). Similarly, one would also predict that a genetic change facilitating cell cycle entry or disruption of cellular maturation would ultimately lead to overgrowth of affected clones. For obvious reasons, mutations that interfere with drug metabolism or the cell death pathway itself would provide a net survival advantage, particularly under the selection pressure of cytotoxic drug treatment.

Malignant myeloid and lymphoid cells have many reasons to have increased mutational rates. Genomic instability can arise from dysregulation of the cell cycle machinery because of a number of events, including perturbations of cyclins leading to MYC overexpression;

AKT activation; disruption of replication sequences; loss of DNA repair enzymes such as mismatch repair (MMR) enzymes; loss of proper homologous recombination from a defect in the BRCA–Fanconi pathways; and loss of ATM/ATR kinases, which can give rise to chromosomal recombination, loss, and microsatellite instability, and loss of checkpoint regulation. These events can give rise to intracлонаl emergent point mutations, translocations, and intragenic losses that might not only result in malignant transformation, but also lead to disruption of genomic stability and selection in favor of proliferative and apoptosis-resistant subclones. Leukemic clonal evolution favors drug resistance.

Common mechanisms may be involved in events associated with malignant transformation and the development of mutations that result in tumor heterogeneity. For example, the cell cycle checkpoint and tumor suppressor gene, *TP53*, is induced during DNA damage, leading to G₁ arrest and, if the damage is too severe to repair, cell death by apoptosis occurs. The presumed goal of this process is to eliminate cells that develop deleterious mutations as a result of damage to the genome. Loss of *TP53* may not only increase cellular survival by inhibiting the cell death process, but may also promote the transmission of mutations that would otherwise be deleted. In this manner, a defect of the cell death pathway can have multiple consequences, including (1) selection of cells exhibiting a growth advantage over their normal counterparts, (2) development of drug resistance, and (3) promotion of mutations that result in either (1) or (2), as well as neoplastic cell heterogeneity. Age-dependent changes in these processes may explain the more favorable behavior of leukemias and lymphomas in response to chemotherapy in young patients than older patients.

A model of the relationship between tumor growth rate, the occurrence of spontaneous mutations, and the development of drug resistance was first described by Goldie and Coldman and is referred to as the Goldie and Coldman hypothesis. In this model, the size of a tumor depends on a complex interaction between tumor growth rate and cell loss, the latter stemming from the status of the cell death process, exhaustion of available nutrients, and outstripping of the blood supply. As tumors increase in size, the cell death rate tends to increase. The heterogeneous nature of additional mutations makes it likely that multiple mechanisms of resistance will develop as well. From an operational standpoint, this model has clear implications for the rational design of therapeutic strategies and provides a basis for early and intensive combination drug therapy. The successful implementation of this strategy is exemplified by the administration of dose-intensive multidrug regimens (i.e., the BEACOPP [bleomycin, etoposide, Adriamycin, cyclophosphamide, vincristine (Oncovin) procarbazine, and prednisone] regimen in Hodgkin lymphoma, CODOX-M-IVAC [cyclophosphamide, vincristine, doxorubicin, high-dose methotrexate alternating with ifosfamide, etoposide and high-dose cytarabine] in Burkitt lymphoma [non-Hodgkin lymphoma (NHL)] and combinations of cytotoxic agents with monoclonal antibodies, such as CHOP (cyclophosphamide, hydroxydaunorubicin, vincristine [Oncovin], and prednisone)–rituximab, which are potentially curative when given early in the course of the disease. Other examples include combined use of multitargeted agents such as lenalidomide and bortezomib for myeloma, fludarabine, cyclophosphamide and rituximab for chronic

lymphocytic leukemia (CLL), or maneuvers to overcome resistance of pretreated disease outside of cell-based therapies. However, as predicted by the model, administration of these or other intensive regimens in patients with relapsed or late-stage disease generally fails because of a generalized resistance of tumor cells to all classes of chemotherapeutic agents.

DEVELOPMENT OF CHEMOTHERAPEUTIC AGENTS

The quest for anticancer agents for hematologic malignancies began with the nitrogen mustard class of compounds developed from the chemical warfare agent sulfur mustard gas used in World War I. Since that time, the National Cancer Institute (NCI) and the pharmaceutical industry have developed complex approaches to drug development, screening, and evaluation. Initial screening consisted of toxicity assessment against murine tumor cell lines. Currently, screening is directed toward numerous cell targets, including receptor and downstream signaling kinases; inducers of cell death pathways, including those at the cell surface; mitochondrial enzymes; nuclear DNA and DNA replication, processing and repair proteins, including base excision repair, PARP, CHK1, topoisomerases, and telomerase; and inhibitors of histone deacetylase (HDAC) and histone methylation, cell cycle proteins, proteasomes, and the mitosis and spindle machinery. Therapeutic agents targeting microenvironment, angiogenesis, and immune checkpoints round out the spectrum of therapeutic approaches. Whereas killing cells had been the backbone of chemotherapeutic approaches to human malignancies, the field of antineoplastic agent development, which in the first decade of the 21st century was at a tipping point, has now embraced novel targeted and highly effective compounds that block the function of specific kinases with surprising efficacy, even at late stages of disease. Ultimately a balanced approach is likely, with much more precision in drug selection, use of mechanism-based combinations, and attention towards and anticipation of tumor heterogeneity, complex subclonality, and emergence of predictable resistance patterns that dictate proactive drug selection and utilization.

Examples include Bruton tyrosine kinase (Btk) and phosphatidylinositol 3-kinase (PI3K) inhibitors in lymphoid malignancies as well as Janus kinase (JAK) inhibitors for treatment of myelofibrosis and polycythemia vera. A number of differentiating agents, kinase inhibitors, and immunomodulatory and cytostatic agents complete the antineoplastic armamentarium. The field of drug development also has to contend with much more complex assessments of toxicities due to both on- and off-target effects, as well as normal tissue effects. In the sections that follow these toxicities will be noted because they restrict the utility of many drugs and toxicities need to be monitored when using new drug combinations.

Screening for Antitumor Activity Among Chemotherapeutic Agents

Identification of critical targets for therapy in cancer cells and the microenvironment starts with the recognition of a known or novel target that appears critical for cancer development, dormancy, growth, or metastasis. The NCI Division of Cancer Treatment has a well molecularly characterized cell bank of malignancies that are available for new drug screening. A more contemporary cell line resource is the Cancer Cell Line Encyclopedia (CCLE), developed to assist in drug analysis. It is a compilation of gene expression, chromosomal copy number, DNA sequence, and RNA data from 947 human cancer cell lines collected across databases and repositories. Many cell lines have drug sensitivity profiles from more than 20 anticancer drugs. Both academia and pharma utilize high-throughput gene knockdown (shRNA and siRNA) library approaches, drug screening using large compound libraries, and in silico screening based on protein and drug structures for docking analysis. Repurposed drugs that are FDA approved or for which there are extensive data provide a rich resource for lead compound identification. Medicinal chemistry can then be

applied to improve potency and specificity, solubility, kinetic profile, and tissue penetration and residence. For instance, to screen for a kinase inhibitor, cells overexpressing an activated kinase may be used. After an initial in vitro screen, human tumor cell activity is evaluated using a series of athymic mouse xenograft studies targeting tumors from tissues that show promise in in vitro assays. More informative data is generated from banks of patient-derived tumor cell lines, often using Rho-associated kinase (ROCK) inhibition, and using patient-specific tumor xenografts for drug screening. These in vivo models consist of primary malignancies grown in immunodeficient mice, typically NSG mice. Some genetically engineer mice to express needed human cytokines that promote leukemic cell growth, or reconstitute mice with a human immune system to evaluate immunomodulatory drugs and cell-based immune responses. Another model system mimics the human disease by establishing mice with specific chromosomal translocations and oncogene mutations found in human cancers. Drug efficacy endpoints are complex, since target effects may produce cell death, senescence, apoptosis, differentiation, polyploidy, inhibition of metastasis, and loss of cancer stem cell populations. Drugs with promising efficacy and novel mechanisms of action then go on to formulation and toxicology testing, and are ultimately developed for phase I clinical testing through academic centers, industry, or the NCI Cancer Therapy Evaluation Program. Effective drug screening includes evidence of target effect specificity and potency, consideration of effects across tumor types, recognition of predictors of sensitivity and resistance that depend on the mechanism of action and known pathways of resistance, characterization of genetic changes associated with resistance and acquired resistance, and pharmacokinetic preclinical analysis. In all instances, animal studies often fail to provide accurate prediction of therapeutic efficacy, pharmacokinetics, emergence of resistance, or even toxicities.

Variants of patient-specific tumor xenograft (PDX) models, which allow for direct passage of human tumors in mice, include orthotopic models that assess the tissue microenvironment for tumor growth and drug efficacy, metastatic models that allow for removal of primary tumor and metastasis to the brain, lungs and bone, and direct implantation and metastasis, for instance into colon, spleen or marrow sites.

Phase I Clinical Trial Design

New anticancer agents are assessed through a series of clinical trials termed *phase I*, *phase II*, and *phase III* (Table 57.1). The purpose of phase I clinical trials is to establish the safe and optimal biochemically active dose of the compound in question with acceptable toxicity that can be used in disease-targeted phase II testing. During phase I development, pharmacokinetics and pharmacodynamic measures are studied in detail so that appreciable information can be forthcoming from the very first set of patients targeted for treatment and to allow confirmation of these observations in larger phase II disease-focused trials. Dose schedule and route of administration are key

TABLE 57.1 Clinical Trial Design

Phase I
Evaluate safety by dose escalation and multiple dose schedules
Establish maximum tolerated dose and dose-limiting toxicity
Consider use of hematopoietic support if myelosuppression is dose limiting
Phase II
Establish response (complete, partial, objective) in specific diseases
Phase III
Compare new treatment with established regimen for the disease in randomized trials

considerations in early phase I development. Numerous considerations have guided dose-escalation strategies that accompany phase I trial development. The starting dose is typically 10% of the lethal dose in animals adjusted for species dose equivalency. In classic phase I development, a modified Fibonacci dose schedule is used. Groups of three patients are treated at each of the following doses until the maximum tolerated dose is observed: 1N (the starting dose), 2N, 5N, 7N, 9N, 12N, and 16N. Typically, the maximum tolerated dose is defined as the maximum dose not causing irreversible toxicity of any type and causing less than grade 4 toxicity in any organ. Newer agents often have off-target toxicities, and these complicate drug evaluation because the dose-dependent toxicities are replaced by rashes, cardiac effects from prolonged QT intervals, activation or inhibition of other pathways, and unusual side effect profiles such as pleural and pericardial polyserositis. Typically, if one dose-limiting toxicity is observed, the patient cohort is expanded to six patients, and if two patients develop dose-limiting toxicity, typically defined as grade 4 toxicity except as previously noted, then further entry at this dose is not pursued, and the next lower dose level is used to establish the maximum tolerated dose with a total of six patients accrued at that dose level.¹

Alternative strategies of drug escalation have included the use of toxicity grades to enhance dose escalation in early drug development, allowing that if no toxicity is observed, fewer patients might be accrued to each dose. Using the modified Fibonacci scheme, one patient is entered at each dose level until grade 2 toxicity is observed, at which point cohorts of three patients are entered at each level. Early in drug development, level skipping may take place if no toxicity is observed. The overall impact of this is to reduce the number of patients treated at suboptimal doses of therapy and to increase the number of patients evaluated at biologically active doses.

More importantly, biomarker-driven studies can be used to optimize inhibition of the target rather than treating to toxicity. This can then be extended in phase II to determine whether the drug effects on its biochemical target correspond to efficacy and tolerance.

Phase II Drug Development

Phase II drug development uses the established phase I dose to define therapeutic efficacy, typically in a two-stage design. If an expectant response rate in excess of 20% is deemed clinically significant, 15 patients are accrued, and if two or more responses are seen, accrual is continued to a total of 26 patients to establish the definite response rate. Modifications include phase Ib/II designs in specific diseases with dose escalations and efficacy assessments in a disease-specific manner. Phase II combination therapies optimize therapeutic efficacy, often with dose escalation of one or both agents. For instance, topotecan was found in phase I testing to have efficacy against refractory leukemias, leading to combinations of topotecan with ara-C. When a new agent is combined with an established agent, the new agent undergoes dose escalation. In the past, strategies for combination chemotherapeutic agents have included the use of non-cross-resistant agents with nonoverlapping toxicities. Mechanism-based therapeutic combinations have been more successful. In rare diseases, and now with genomic-driven studies, randomized phase II trials in a specific disease comparing standard to novel therapy can be used as evidence for drug approval, a “registration” trial.

Most phase III trials randomize patients between an established standard therapy and a new therapy that has appeared promising in the phase II setting. These studies are usually multi-institutional and many involve large national (e.g., National Clinical Trials Network) and international cooperative groups. The endpoint of these studies is disease response, time to progression (TTP), survival, and patient tolerance. Phase III trials are important for positive and negative results.² All trials must have rigorous objective data collection, safety and quality review, and reporting. All clinical trials should be

registered at clinicaltrials.gov and all should have public reporting of results.

TRADITIONAL CYTOTOXIC ANTINEOPLASTIC AGENTS TARGETING THE CELL CYCLE AND DNA

Targeting Tumor Cell Growth Kinetics

Malignant hematopoietic cells proliferate more and differentiate less than their normal counterparts. The cell cycle consists of a series of stages through which normal and neoplastic cells proceed during the course of cellular replication (shown schematically in Fig. 57.1). The cell cycle is divided into G₁ (pre-DNA synthetic phase), S phase (in which DNA replication takes place), G₂ (post-DNA synthetic phase), and mitosis (M), during which chromosomal division and segregation occur. In addition, nonproliferating, resting cells reside in G₀, a phase that may theoretically last for an indefinite period. Such cells remain in G₀ until they are induced to cycle (at G₁) by specific triggers (e.g., hematopoietic growth factors). The growth fraction of a tumor

Fig. 57.1 PROGRESSION THROUGH THE CELL CYCLE IS CONTROLLED THROUGH COMPLEX INTERACTIONS AMONG CYCLINS, CYCLIN-DEPENDENT KINASES, AND CYCLIN-DEPENDENT KINASE INHIBITORS. Progression across the G₁/S interface and through S phase involves the E2F transcription factor, which activates numerous enzymes (e.g., thymidylate synthase, dihydrofolate reductase) required for DNA replication. The pRb in its dephosphorylated state binds to and inactivates E2F in conjunction with DP proteins, thereby inhibiting S-phase progression. Conversely, phosphorylation of pRb antagonizes binding to E2F, allowing S-phase events to proceed. Phosphorylation of pRb results from activation of (1) CDK2:cyclin A/E and (2) CDK4/6:cyclin D complexes. The former complexes are inhibited by the CDK1s p21, p27 (and p57), and the latter are inhibited by the low-molecular-weight CDK inhibitors (p14–18) but also by p21 and p27. The complex formed by CDK1 (p34^{cdc2}) and cyclins A and B regulates G₂/M progression and is inhibited by the “universal” CDK inhibitor, p21. Moreover, its phosphorylation status, which plays a major role in determining activity, is regulated by the phosphatase cdc25. Proteins such as pRb, E2F, p21, and p27 can influence the response of cells to chemotherapeutic agents by controlling cell cycle progression and possibly via cell cycle-unrelated actions. *CDK*, Cyclin-dependent kinase; *CDK2*, cyclin-dependent kinase-2; *DHFR*, dihydrofolate reductase; *pRb*, retinoblastoma protein.

represents the percentage of cycling cells relative to the total cell population. The generation time represents the time required for a cell to proceed through a single cell cycle (generally 24–36 hours for hematopoietic tissues). Surprisingly, in the case of acute myeloid leukemia (AML), the generation time of leukemic blasts is not shorter than that of normal hematopoietic progenitors and may be longer. The proliferative advantage of malignant hematopoietic cells (and of many nonhematopoietic tumors) stems, at least in part, from the fact that a higher percentage of cells are in cycle at any one point in time (i.e., the growth fraction is higher). The doubling time represents the period required for a tumor to double in mass and is, in general, inversely related to the tumor's growth fraction. Tumor-doubling times range from longer than 120 days in the case of some solid tumors (e.g., lung and colon) to less than 2 weeks (in some leukemias and lymphomas). Tumors with high growth fractions and short doubling times tend to be more sensitive to chemotherapy than slowly growing neoplasms with low growth fractions and long doubling times.

Cell cycle progression is governed by a complex network of proteins consisting of cyclins, cyclin-dependent kinases (CDKs), and CDK inhibitors. Progression through S phase is regulated primarily by CDK2 in association with cyclins A and E; progression through G₂M is regulated by CDK1 (p34^{cdc2}) and cyclins A and B; and progression through G₁ involves CDKs 4–6 in conjunction with cyclin D. CDK inhibitors fall into two major categories: the low-molecular-weight inhibitors (p16^{INK4A}, -15, -16, -17, and -18), which primarily inhibit cyclin D (and to some extent, CDK2) complexes, and the higher molecular-weight inhibitors, p21, p27, and p57, which are more universal in their actions and inhibit most or all CDKs. Signals for the progression of cells through G₁S are essential for maintenance of the neoplastic phenotype. In the commonly accepted model of G₁S progression, inactivation of the retinoblastoma protein (pRb) is required. In quiescent cells, pRb is in an active dephosphorylated state and bound to the transcription factor E2F. Phosphorylation of pRb by CDK4, CDK6 and CDK2 leads to release of E2F, which is then free to activate diverse genes essential for S-phase progression, such as *MYC* (also known as c-Myc), *TYMS* (thymidylate synthetase), and *DHFR* (dihydrofolate reductase). Conversely, induction of CDK inhibitors (e.g., by transforming growth factor- β [TGF- β] or differentiation-inducing agents) results in inactivation of CDK4, CDK6 and CDK2, dephosphorylation of pRb, inactivation of E2F, and inhibition of the progression through S phase. Aberrant expression of cyclins and CDK inhibitors is commonly encountered in hematopoietic malignancies.

In addition to growth control, cell cycle proteins are intimately involved in the regulation of programmed cell death (apoptosis) and checkpoint control mechanisms. Consequently, cell cycle regulatory proteins can exert a major influence on the response of neoplastic cells to cytotoxic agents. For example, when cells undergo DNA damage, they may arrest in G₂M or G₁, during which repair occurs, or if the damage is too severe, the cells undergo apoptosis. In particular, the tumor suppressor gene *TP53* and its downstream inducible target p21 have been implicated in the G₁ arrest process after genotoxic insult. Dysregulation of various cell cycle regulatory proteins can have a major impact on the sensitivity of neoplastic cells to chemotherapeutic agents. Loss of the *TP53* gene renders cells resistant to diverse chemotherapeutic agents, presumably by preventing cells from undergoing repair in G₁ and thereby inhibiting the cell death processes and allowing DNA damage to accumulate, culminating in cellular transformation. Conversely, transfection of P53-negative cells with wild-type P53 restores responsiveness to most drugs. Dysregulation of the CDK inhibitors p21 (a downstream target of P53) and p27 increases the sensitivity of neoplastic cells to various cytotoxic agents, possibly by uncoupling S-phase progression and mitosis. After DNA damage, checkpoints block the cell cycle, but loss of the CDK inhibitors p21 or p27 prevents cells from arresting in G₁ and cells die during G₂M. Mutations in the E2F protein have been shown to lengthen S phase and increase the sensitivity of malignant cells to S-phase-specific agents. Furthermore, cells lacking functional pRb have been shown to be

significantly less sensitive to the actions of antimetabolites, including methotrexate.

In vivo the growth of tumors is limited by various factors such as vascular supply, nutritional requirements, and possibly physical restraints. Consequently the rate of tumor growth declines as the number of cells increases. To the extent that tumor-doubling times are inversely correlated with drug responsiveness, large, late-stage tumors are less susceptible to cytotoxic drugs than early-stage tumors, with higher growth fractions. Most chemotherapeutic drugs kill by first-order kinetics. The implication of this phenomenon is that it requires the same drug dose to reduce the number of tumor cells from 10⁴ to 10¹ cells as it does to reduce the tumor burden from 10¹⁰ to 10⁷ cells.

Hematopoietic malignancy-initiating or stem cells, such as leukemia stem cells, appear to explain resistance and treatment failure. These cells express high levels of hematopoietic stem cell proteins and markers, and are resistant to cell cycle-specific agents because of an increase in quiescent cell populations. They overlap with normal hematopoiesis stem cells and there appears to be a set of HSCs that contain preleukemic-promoting mutations that both predispose and may be sufficient for conversion to leukemic stem cells. The proteins expressed by these cells have become targets of therapy, including alterations in DNA damage, quiescent cell cycle factors such as the thrombopoietin receptor MPL, stem cell proliferation signals such as NOTCH and WNT protein families, and niche occupancy proteins such as KIT.

Cytotoxic agents may be divided into several categories with respect to their effects on the cell cycle or the cell cycle specificity of their actions, or both.

1. *Noncycle-active drugs* kill both cycling and noncycling cells in all phases of the cell cycle. Examples include steroids and antitumor antibiotics (except bleomycin).
2. *Cycle-active, nonphase-specific drugs* are more active against cycling cells and can kill cells in each phase of the cell cycle. However, such drugs may preferentially kill cells in a particular phase of the cell cycle. Examples include alkylating agents, cisplatin, and 5-fluorouracil (5-FU).
3. *Cycle-active, phase-specific drugs* primarily kill cells in a specific phase of the cell cycle. Examples include most antimetabolites, which are active against cells engaged in DNA synthesis (S-phase cells), and microtubule-active drugs (e.g., vinca alkaloids, taxanes), which kill cells in G₂M.

An example of a cytogenetically rational approach to chemotherapy involves the combination of a noncycle-active agent (e.g., daunorubicin) with a cycle- and a phase-specific agent (e.g., ara-C, fludarabine, decitabine, gemcitabine, clofarabine and nelarabine). From a theoretical standpoint, administration of a noncycle-active agent may reduce tumor mass, leading in turn to an increase in the growth fraction caused by recruitment of cells into cycle. Such cells would then be more susceptible to a cycle- and phase-specific agent, particularly one administered over a prolonged interval. In the case of hematopoietic malignancies, attempts have been made to recruit neoplastic cells into the more susceptible S phase of the cell cycle through the use of hematopoietic growth factors. The success of such a strategy has been limited because of several factors, including the inability of growth factors to increase the S-phase fraction significantly, the lack of selectivity of this strategy, and the theoretical possibility that growth factors may protect neoplastic cells from apoptosis.

Unfortunately, cytokinetic differences between normal and neoplastic tissues have been difficult to exploit. Both normal hematopoietic stem cells and hematologic malignant stem cells have a low proportion of cells in G₁. However, prolonged dosage schedules can provoke these malignant cells into cell cycle and may explain their efficacy. Consequently, rapidly dividing normal tissues such as gastrointestinal epithelium and normal hematopoietic progenitors tend to be very sensitive to most chemotherapeutic agents. As a result, mucositis and myelosuppression represent frequent dose-limiting toxicities for many cytotoxic drugs.

Fig. 57.2 OVERVIEW OF SITES AND MECHANISMS OF ACTION OF THE MOST USEFUL CHEMOTHERAPEUTIC AGENTS. 5-FU, 5-Fluorouracil; 6-MP, 6-mercaptopurine; ara-C, cytarabine; ara-G, 9'- β -D-arabinofuranosylguanine; DTIC, dacarbazine; *Topo*, topoisomerase.

Newer agents that target cell cycle proteins are often first utilized in patients with hematologic malignancies. As noted in the section on CDK and CHK1 inhibitors, these agents can have potent cytotoxic effects on dividing cells.

PHARMACOLOGY OF TRADITIONAL CHEMOTHERAPEUTIC AGENTS

Traditional agents are classified by their site of action, and as such all have a targeted mechanism, albeit not that of newer kinase targeted agents. They are divided into alkylating agents, antimicrotubule agents, antimetabolites, topoisomerase I or II inhibitors, platinum analogs, and miscellaneous agents. The pharmacology and cellular mechanisms of action of these agents are schematically presented in Fig. 57.2.

Alkylating Agents

Drug treatment for cancer began with the use of the mustard class of alkylating agents, initially mechlorethamine (nitrogen mustard), which entered into clinical use in the mid-1940s. Alkylating agents are used in many regimens but are rapidly being supplanted by newer classes of agents.

All alkylating agents undergo molecular rearrangements to form covalent bonds to DNA bases. Some form monoadducts, while others form cross-links either with intrastrand or interstrand bases, or with adjacent proteins. All alkylating agents are cytotoxic to tumor cells through interruption of DNA replication, induction of DNA damage repair and stress response, or through checkpoints in the cell cycle that result in apoptosis, senescence, or necrosis. All alkylating agents induce DNA strand breaks directly or through the damage response. Alkylating agents can also cause DNA mutations that can induce a

cytotoxic response or can alter proteins, leading to immune responses to novel protein sequences.

Mechanisms of Resistance

Efficient removal of the DNA adducts reduces the lesion burden, while loss of DNA damage recognition can invoke damage tolerance, as in the case of loss of MMR and temozolomide tolerance. Detoxifying enzymes can serve as acceptor molecules for alkylation, alter the agent prior to DNA attack, or metabolize the parent compound. Loss of TP53 results in loss of cell cycle checkpoint induction of DNA repair signals. Increased AKT signaling promotes cell proliferation to compensate for the DNA damage response-associated toxicity.

Nitrogen Mustard

The nitrogen mustard class includes mechlorethamine, cyclophosphamide, 4-hydroperoxy cyclophosphamide, ifosfamide, chlorambucil, and melphalan. These drugs all share a common bischloroethyl group attached to nitrogen and a substituted “R” group that provides drug specificity (Fig. 57.3). All nitrogen mustards react with DNA in an SN_2 reaction, a bimolecular nucleophilic displacement reaction also called a *second-order reaction*. Although numerous sites are targeted for alkylation, nucleophiles in DNA, including nitrogen (N), oxygen (O), and phosphate (P), attract the chloroethyl moiety attached to the R–N backbone, and the chlorine is displaced by the nucleophilic atom to form an aziridinium moiety. The remaining chloroethyl group is then attracted to a second nucleophilic atom, forming a second aziridinium intermediate, leading to a second alkylation, forming a cross-link. Both intrastrand and interstrand cross-links are formed. The N⁷ guanine position is the most critical for cytotoxic cross-link formation. Clinical use of mechlorethamine is limited because the MOPP regimen (mechlorethamine, vincristine [Oncovin], procarbazine, prednisone) has been replaced by ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, dacarbazine [DTIC]) in Hodgkin lymphoma (see Chapter 75). Local use of mechlorethamine occurs in a dermatologic suspension for the treatment of cutaneous T-cell lymphomas (CTCLs; see Chapter 85).

Cyclophosphamide is a nitrogen mustard with a ringed structure off the end-chloroethyl backbone that decreases spontaneous decomposition (see Fig. 57.3). Enzymatic activation is required through multifunction P450 enzymes in the liver. Phenobarbital and corticosteroids may alter activation. The bioavailability of cyclophosphamide orally and intravenously is quite similar, although most use of the drug is by bolus IV injection. Cyclophosphamide is detoxified through oxidation to 4-keto-cyclophosphamide and carboxyphosphamide by aldehyde dehydrogenase. Cyclophosphamide is used in doses as small as 50–100 mg/day orally (PO) and in bolus doses of 400–700 mg/m² for solid tumors and 750 mg/m² in combination with doxorubicin and vincristine and prednisone as part of the CHOP regimen for NHLs, or alone or with bortezomib for patients with myeloma. It is also used at doses of up to 60 mg/kg/day for 4 days in autologous and allogeneic bone marrow (BM) transplantation protocols. Cyclophosphamide is used in numerous treatment protocols for NHLs and high-dose therapy regimens designed to eradicate tumor and BM in patients with lymphomas and leukemias and those undergoing BM transplantation. It is commonly used with granulocyte colony-stimulating factor (G-CSF) for mobilizing hematopoietic stem cells to be collected before autologous transplantation.

Cyclophosphamide is metabolically activated by cytochrome P450 mixed function oxidases in the liver to 4-hydroxycyclophosphamide. 4-Hydroxycyclophosphamide is further converted to aldophosphamide and then to phosphoramidate mustard, the alkylated species, and acrolein. High levels of aldehyde dehydrogenase detoxify cyclophosphamide in hematopoietic stem cells and, thus, high doses are not marrow ablative. Acrolein is a highly reactive aldehyde and the cause of hemorrhagic cystitis. Mercaptoethane sulfonate (Mesna) is used to provide prophylaxis against hemorrhagic cystitis caused by cyclophosphamide and ifosfamide, and is now standard for doses of cyclophosphamide and ifosfamide above 1000 mg/m². Mesna is given in divided doses every 4 hours or as a continuous infusion for 18–24 hours in a dose equivalent to either cyclophosphamide or ifosfamide. Other than hemorrhagic cystitis, BM suppression is dose limiting and can be rescued by reinfusion of autologous or allogeneic hematopoietic progenitor cells. Other toxicities include alopecia and cardiac toxicity, which is unusual and most often seen after high-dose therapy.

Fig. 57.3 STRUCTURE OF COMMON ALKYLATING AGENTS.

4-Hydroperoxycyclophosphamide, a chemically stable form of the reactive intermediate of cyclophosphamide, 4-hydroxycyclophosphamide, is more toxic to committed hematopoietic progenitors such as colony-forming unit–granulocyte/macrophages (CFU-GM), burst-forming unit–erythroids (BFU-E), and colony-forming unit–erythroids (CFU-E).

Melphalan, or phenylalanine mustard, has an amino acid side chain that alters its cellular uptake and stabilizes its structure, allowing PO administration (see Fig. 57.3). It is available in both PO and IV forms, and has a similar effect on DNA cross-linking as cyclophosphamide and the other nitrogen mustards. Melphalan uptake by cells is by means of a neutral amino acid transporter. Its rate of cross-link formation is much slower than that of mechlorethamine, presumably because of delayed metabolism. Oral melphalan is used predominantly for the standard treatment of multiple myeloma (MM) and IV in high-dose regimens in preparation for stem cell transplantation (see Chapter 86) for MM patients.

Chlorambucil has been used for more than 40 years for the treatment of CLL. Chlorambucil is the phenylbutyric acid derivative of nitrogen mustard and is very stable, entering the cell by diffusion rather than by a specific uptake mechanism. It is typically administered orally on a daily basis or intermittently. It appears to have greater bioavailability than melphalan and a more consistent half-life of approximately 2 hours.

Busulfan is an alkylsulfonate unique among alkylating agents because of two sulfur groups and lack of a chloroethyl moiety (see Fig. 57.3). Busulfan, similar to the nitrogen mustards, reacts predominantly at the N⁷ position of guanine and produces an N⁷–N⁷ biguanyl DNA cross-link, although the precise nature of this cross-link appears different than that of the nitrogen mustards. The pharmacokinetics of busulfan is important for its use in high-dose therapy for ablation of the BM in patients undergoing autologous transplantation for acute leukemia or allogeneic stem cell transplantation (see Chapter 104). Because the incidence of venoocclusive disease is lower in patients receiving high-dose busulfan with predosing pharmacokinetics performed, this is now recommended in high-dose regimens, the target being an area under the curve (AUC) of 1125 $\mu\text{mol/L} \times \text{min}$ (range 900–1350) with every 6 hour dosing. Busulfan is a potent stem cell toxin, killing both early and late hematopoietic progenitor cells and damaging the BM stroma. Other toxicities of busulfan include nausea and vomiting, and pulmonary interstitial and intraalveolar edema leading to fibrosis. The pulmonary fibrosis is distinct from the interstitial pneumonitis, which accompanies allogeneic stem cell transplantation and is not related to cytomegalovirus or other viral infections.

Nitrosoureas

Four chloroethyl nitrosoureas and one methyl nitrosourea are in clinical use. These agents are different from the nitrogen mustards in that they alkylate through an SN¹ reaction, forming a highly reactive intermediate in the presence of N, O, and P nucleophiles in DNA. The commonly used clinical agent is (2-chloroethyl)-*N*-nitrosourea (BCNU). *N*-[(4-amino-2-methyl-5-pyrimidinyl) methyl]-*N*-(2-chloroethyl)-*N*-nitrosourea (ACNU) is commonly used in Japan. A third agent, *N*-(2-chloroethyl)-*N*-cyclohexyl-*N*-nitrosourea (CCNU), is used predominantly as an PO nitrosourea in children with brain tumors. All of these compounds have high hydrophobicity, actively penetrating the blood–brain barrier.

The DNA alkylation sites include N⁷ and O⁶ of guanine. Chloroethylation at the O⁶ position of guanine appears critical to cytotoxicity. DNA cross-linking by chloroethyl nitrosoureas include at 1-(3-cytosinyl), 2-(1-guanyl) ethane, and 1-2-bis(7-guanyl) ethane. The former is responsible for much of the cytotoxicity observed with the chloroethyl nitrosoureas. It is formed after alkylation at the O⁶ position of guanine. This adduct undergoes intramolecular rearrangement to a circular intermediate, N¹. O⁶ ethanoguanine is formed, which can then rearrange by attack at the opposite hydrogen-bonded base N³ of cystine, forming the interstrand cross-link. This is a unique

DNA cross-link and is poorly recognized by DNA repair processes, leading to marked cytotoxic potency of this cross-link.

The pharmacokinetics of the chloroethyl nitrosoureas reveal a very short half-life. BCNU is predominantly used for high-dose treatment of recurrent lymphomas. Regimens including BCNU induce sustained complete remission (CR) rates of approximately 40%–60%. Doses of between 300 and 600 mg/m² have been safely administered. The chloroethyl nitrosoureas cause profound and cumulative BM suppression at conventional doses of 120–150 mg/m², limiting treatment to three to five cycles at 6-week intervals.

Complications of high-dose BCNU therapy include pulmonary toxicity and renal toxicity at doses higher than 600 mg/m². Pulmonary toxicity, as evidenced by a decrease in the DL_{CO} (diffusing capacity of the lung for carbon monoxide), occurs in up to 40% of patients. It can be managed with high-dose oral steroids during the inflammatory phase. Interstitial nephritis with glomerulosclerosis, interstitial fibrosis, and dropout of tubules has been reported with BCNU or CCNU.

Methylating Agents

Four methylating alkylating agents are in clinical use. These include procarbazine, DTIC, streptozotocin, and temozolomide. Procarbazine and DTIC are triazines. Streptozotocin is a monofunctional methyl nitrosourea derivative with an attached sugar moiety, and temozolomide is an imidazotetrazine. All react with DNA by undergoing SN¹ reactions forming a methyldiazonium ion, resulting in methylation of N⁷ guanine (67%), O⁶ guanine (9%), O⁴ and O² thymine (2%), and N³ adenine (3%). None form DNA cross-links. However, all induce high levels of DNA methylation, and their recognition and repair results in both single- and double-strand breaks. N⁷ methylguanine is removed through the BER system. Recognition by the *N*-methylpurine glycosylase results in removal of the adducted base with formation of an abasic site that is recognized by the apurinic (AP) endonuclease, which then cleaves the backbone at the AP site. Subsequently, the free 5' sugar is released by DNA lyase, with repair initiated by β -polymerase and DNA ligase. BER effectively removes N⁷ methylguanine and N³ methyladenine, and restores DNA to normal. Inhibition of BER by the investigational agent methoxyamine (TRC102) blocks this pathway and increases toxicity.

O⁶ methylguanine mispairs with thymine during DNA synthesis, resulting in a lesion recognized by the MMR system. Mismatch recognition proteins are MSH6, MSH3, and MSH2. Recognition of the mismatch recruits additional proteins to the complex, including MLH1 and PMS1/PMS2. These proteins initiate exonuclease cleavage of a long patch in the newly synthesized strand of DNA. This is then repaired by polymerases δ and ϵ . If unrepaired, a thymine is repeatedly inserted opposite the O⁶ methylguanine, resulting in multiple single-strand breaks. Cells expressing high levels of the DNA repair protein for O⁶ methylguanine, O⁶ methylguanine-DNA methyltransferase (MGMT), are approximately 10-fold more resistant to methylating agents than MGMT-negative cells. Cells lacking MMR are very resistant to methylating agents. Acquisition of MMR defects is associated with acquired resistance to methylating agents and cisplatin, which is also recognized by this protein complex.

Procarbazine was synthesized as a monoamine oxidase inhibitor and has been used since the 1950s for the treatment of Hodgkin lymphoma and NHL, as well as a component of combination therapies for gliomas. DTIC is metabolically activated by cytochrome P450 microsomal oxidoreductases, ultimately leading to formation of the methyldiazonium ion and DNA methylation. DTIC is used in combination with ABVD for treating Hodgkin lymphoma (see Chapter 75) and is also used for patients with metastatic malignant melanoma in combination with BCNU, cisplatin, and tamoxifen. Activation of DTIC requires hydroxylation of one terminal methyl group caused by demethylation forming 5-[3-methyl-triazene-1-yl]-imidazole-4-carboxamide (MTIC), with spontaneous decomposition to the methyldiazonium ion, which alkylates the DNA, as noted earlier. Maximum tolerated doses of DTIC are approximately

1000 mg/m², with myelosuppression and gastrointestinal toxicity (including severe watery diarrhea) being the most common side effects.

Temozolomide represents an imidazotetrazinone. It differs from DTIC in that it is chemically degraded to the monomethyl triazine, MTIC, at neutral pH and does not require P450 enzymatic demethylation. Compared with DTIC, temozolomide has much more consistent pharmacokinetic parameters, including peak serum concentrations, volume of distribution and clearance, and conversion to MTIC. Clinical studies documented considerable activity in acute leukemias. The dose-limiting toxicity was thrombocytopenia and, less frequently, neutropenia, with maximum tolerated doses of 1000 mg/m² given over 5 days on a daily or twice-daily regimen. Nausea and vomiting were the other common side effects, easily controlled with antiemetics.

Bendamustine

Bendamustine is comprised of a 2-chloroethylamine nitrogen mustard alkylating group, a benzimidazole ring, and a butyric acid side chain. Its mechanism of action is unknown but appears to be different to other alkylating agents, causing DNA damage that is repaired predominantly by the base-excision repair system and has activity against lymphoid cell lines resistant to alkylating agents.³ Myelosuppression with leukopenia and thrombocytopenia is the most frequent side effect, with mild nonhematologic side effects including nausea, fatigue, constipation and diarrhea. Phase III studies comparing standard treatment with bendamustine and rituximab in front-line treatment of CLL⁴ and indolent lymphomas (see Chapter 77) have established this combination as first-line treatment. Bendamustine is also active against MM, and combinations with steroids and bortezomib or the immunomodulatory agents thalidomide and lenalidomide have been reported to result in high response rates in patients with relapsed or refractory disease.

Alkylating Agent–Induced Leukemias

Alkylating agents induce dose-limiting myelosuppression and cause sublethal DNA damage to hematopoietic progenitors, causing mutational events that lead to malignant transformation to preleukemic and leukemic states. A concern exists about the use of hematopoietic growth factors after exposure to alkylating agents (see Chapter 59). There is evidence of increased cytotoxicity to hematopoietic progenitors during simultaneous exposure to these agents and growth factors. Treatment-related AML (T-AML) accounts for approximately 15% of all adult AML. Approximately 50% of T-AML patients have a preleukemic phase compared with only 10% of patients with de novo AML. CRs are achieved in 15%–30% of patients with T-AML and a mean remission duration of 2 months. Chromosomal abnormalities and gene mutations characteristic of T-AML establish this as a distinct disease requiring novel therapeutic approaches. Loss or deletion of all or part of the long arm [q] of chromosomes 5 or 7 is common, as are trisomy 8 and deletions of the short arm of chromosomes 12, 17, and 21.

Historically, patients with Hodgkin lymphoma treated with mechlorethamine and procarbazine in the MOPP regimen or with CCNU were at the highest risk if exposed to radiation as well as an alkylating agent combination. Patients with polycythemia vera treated with chlorambucil were at much higher risk than patients treated with phlebotomy alone, which can contribute to a shift in treatment strategy. Patients with myeloma and ovarian cancer have developed T-AML, especially after prolonged exposure to alkylating agents. Patients treated with alkylating agents for benign diseases such as nephritis, lupus, psoriasis, rheumatoid arthritis, and Wegener granulomatosis also have an increased risk of T-AML. The mean latency between exposure and T-AML from alkylating agents is 4–5 years, in contrast to T-AML from etoposide, which has a latency period as short as 1 year. The cumulative risk of developing T-AML is between

10% and 17% at 4–6 years for myeloma patients treated with melphalan and between 2% and 10% at 7–10 years in patients with Hodgkin lymphoma. Alkylating agent-associated T-AML has also been recognized in patients with breast and colon cancer.

Antimicrotubule Agents

The antimicrotubule drugs include the vinca alkaloids (e.g., vincristine, vinblastine, vinorelbine and vindesine), taxanes (e.g., paclitaxel and docetaxel), and epothilones (ixabepilone).

Molecular Targets

The vinca alkaloids are naturally occurring (vincristine and vinblastine) or semisynthetic (vinorelbine) nitrogenous bases derived from the pink periwinkle plant, *Catharanthus roseus*. Paclitaxel was originally isolated from the bark of the Pacific yew, *Taxus brevifolia*. Paclitaxel can also be isolated from other members of the *Taxus* genus and from a fungal endophyte that grows on the Pacific yew. Docetaxel is derived semisynthetically from 10-deacetyl-baccatin III, which is obtained from the needles of the European yew, *Taxus baccata*.

The vinca alkaloids bind to the protein tubulin at a site distinct from that of the taxanes and, at low concentrations, inhibit microtubule dynamics. At higher concentrations, these vinca alkaloids disrupt microtubules and mitotic spindle, resulting in cell cycle mitotic arrest and apoptosis of cells (see Fig. 57.3). In contrast, after binding to α -tubulin, taxanes kinetically stabilize microtubule dynamics at their plus ends and shift the equilibrium toward tubulin polymerization into microtubule bundles. This also causes mitotic arrest and apoptosis of cells. The mitotic arrest caused by antimicrotubule drugs is associated with phosphorylation of the B-cell lymphoma (BCL2) protein and increased intracellular levels of the BCL2-associated X protein (Bax), which promote apoptosis.

As natural products, overexpression of the efflux pump multidrug resistance gene-1 (MDR-1) and the ABCB-1 transporter mediate resistance. Intracellular resistance to mitotic spindle and microtubule formation is mediated by numerous pathways and proliferative signals including MYC, nuclear factor kappa-B (NF κ B) and AKT.

Antimicrotubule agents, particularly the vinca alkaloids, are used in the management of lymphomas and leukemias, and continue to be used in the mainstay of clinical chemotherapeutic regimens. Because of their mechanism of action, they are best used in multi-agent combinations, in which potentiation of efficacy with other classes of agents, such as antimetabolites and DNA-damaging agents, provide better therapeutic responses and well-tolerated treatments.

Inhibitors of Nucleotide Synthesis

Within this class are two important agents used for hematologic malignancies, hydroxyurea and methotrexate. They both serve to disrupt nucleotide synthesis, and slow or stop DNA and RNA synthesis.

Hydroxyurea

Hydroxyurea inhibits ribonucleotide diphosphate reductase, blocking de novo synthesis of purines and pyrimidines. S-phase arrest is commonly observed. Given this exquisite cell cycle specificity, resting and quiescent cells are rarely affected and there is virtually no hematopoietic stem cell toxicity. As a consequence of disruption of nucleotide synthesis and direct binding to telomere binding factors, telomere synthesis and function are compromised in leukemic cells. In cells arrested in S phase, apoptosis and senescence are observed.

Hydroxyurea is used in the treatment of myeloproliferative neoplasms including essential thrombocythemia, polycythemia vera and myelofibrosis (Chapters 68–70). It may also be used for acute cyto-reduction prior to induction therapy of AML and for management of chronic myelomonocytic leukemia. It is commonly used for

extended periods of time to induce fetal hemoglobin and reduce sickle crisis in patients with sickle cell anemia (Chapter 42).

Folic Acid Analogs (e.g., Methotrexate)

Folic acid analogues block the formation of thymidine, resulting in accumulation of UMP, leading to high levels of UTP, which is incorporated into DNA and causes purine nucleotide pool imbalance, slowing DNA synthesis. These agents bind thymidylate synthase and dihydrofolate reductase, and disrupt cell cycle progression and cell division. Methotrexate polyglutamation results in higher affinity binding to DHFR and improved inhibition. Aminopterin, the first antifolate, was used by Sidney Farber (reported in 1948) and became one of the first chemotherapeutic agents to be administered with success to children with acute lymphocytic leukemia (ALL). Methotrexate is the agent currently used in hematologic diseases, while the family of agents includes pemetrexed and trimetrexate. Inhibition of folate-dependent methyl transfer enzymes disrupts purine synthesis pathways. Toxicity of methotrexate is reversed by N^5 -formyl FH_4 , or leucovorin, which serves as a direct folate coenzyme. Since it has no tumor selectivity, normal tissues in active cell cycle are affected, including mucosa, bone marrow and hair follicles, resulting in mucositis, pancytopenia and alopecia. Prolonged use is associated with pulmonary and liver fibrosis. High-dose therapy and excessive periods of high blood levels result in interstitial nephritis, sometimes requiring dialysis.

The most common resistance is due to amplification of DHFR expression by upregulation of translation and gene amplification, including the establishment of minichromosomes with the DHFR gene. A second mechanism is decreased affinity of DHFR to methotrexate. A third mechanism is decreased thymidylate synthase, and the fourth mechanism of resistance is impaired methotrexate polyglutamate formation.

While use has diminished in recent years, methotrexate remains part of the regimen for maintenance in children and adults with ALL (Chapter 66). It is also used to depress T-lymphocyte proliferation after allogeneic stem cell transplantation to prevent acute graft-versus-host disease (GVHD). High-dose methotrexate, with careful blood level monitoring to prevent acute renal toxicity and mucositis, and leucovorin rescue, is effective in the management of CNS leukemias, primary CNS lymphoma, and high proliferative fraction (myc positive, bcl6 positive and high KI67) intermediate- and high-grade lymphomas, including Burkitt.

Nucleoside Analogues

The nucleoside analogs exhibit structural similarities to naturally occurring nucleosides and are incorporated into either DNA or RNA with lethal consequences. Alternatively, they block key enzymes *de novo* purine or pyrimidine biosynthesis. There are two broad categories:

1. Pyrimidine analogs (e.g., ara-C, 5-azacytidine, gemcitabine)
2. Purine analogs (e.g., 6-thioguanine [6-TG], 6-mercaptopurine, fludarabine, chlorodeoxyadenosine, deoxycoformycin, clofarabine, nelarabine)

These categories are not mutually exclusive; for example, some nucleoside analogs (e.g., ara-C and 6-TG) also inhibit enzymes involved in DNA or deoxyribonucleotide biosynthesis. These agents are predominantly cycle-active agents and in most cases are phase specific, being primarily active against cells in S phase. Because the growth fraction of hematologic malignancies tends to be higher than that of nonhematologic malignancies, nucleoside analogs are particularly useful in the former disorders. In contrast to alkylating agents, nucleoside analogs have limited carcinogenic and leukemogenic potential. The fluorinated pyrimidines (e.g., 5-FU) are generally not used in treating hematologic disorders and are not discussed further.

ara-C has been used in the treatment of acute leukemias—particularly acute nonlymphocytic leukemias, aggressive lymphomas

including Burkitt, and CNS lymphomas for over 30 years. It is incorporated into DNA during replication and inhibits polymerase- α , is cell cycle specific, and penetrates the blood–brain barrier. In rapidly replicating cells, it stalls polymerase function, leading to replication fork collapse and strand breaks at the replication fork, signaling apoptosis and differentiation.

Mechanisms of Resistance

Although ara-C remains the backbone of therapy for aggressive hematologic malignancies, resistance has been observed that is both specific to the drug and nonspecific. Specific resistance could be due to nucleotide transport down regulation, uncommon in dividing cells. Inside the cell, ara-C is phosphorylated by deoxycytidine kinase to the active 5'-triphosphate derivative ara-CTP, whereas catabolism of ara-C by cytidine deaminase (CDD) to the nontoxic metabolite arabinoside uridine is a major pathway of detoxification that can be overcome by high-dose therapy. Low penetration into the cerebrospinal fluid is overcome by bolus administration of very high doses: 1–2 g/m² over 1 hour. Other resistance mechanisms appear nonspecific and result in leukemia tolerance to cell cycle arrest and induction of apoptosis, tolerance to DNA strand breaks, and rapid cell division after therapy.

Clinical Use

Standard induction therapy for AML includes a 5–7-day continuous infusion of 100–200 mg/m² or high-dose ara-C at doses of 1–3 g/m² over 1 hour every 12 hours. Many modifications to these schedules have improved tolerance without sacrificing efficacy. For CNS leukemia, a depo form of ara-C has been developed with improved tolerance and sustained cerebrospinal fluid levels (Chapter 60).

Subcutaneous administration has provided responses in older individuals with AML or MDS who do not respond well to more intensive induction therapy.

5-Azacytidine and Decitabine

These agents were initially developed as antimetabolites but are more effective at low doses that inhibit the function of histone demethylation, and are described below.

Gemcitabine

Developed as an agent for the treatment of pancreatic cancer, gemcitabine has gained therapeutic attention for use in patients with Hodgkin lymphoma and NHL, particularly in the relapsed state.

Like other nucleotide analogues, gemcitabine is a prodrug that is phosphorylated by deoxycytidine kinase to gemcitabine diphosphate (FdCDP) and gemcitabine triphosphate (dFdCTP), which, when incorporated into DNA, stalls the polymerase- α , which adds one more deoxynucleotide to the elongating strand. The polymerase replication complex then falls off the DNA, causing replication fork collapse and chain termination. In addition, FdCDP is a potent inhibitor of ribonucleoside reductase, causing depletion of deoxyribonucleotide pools and further encouraging dFdCTP incorporation while disrupting DNA synthesis.

Specific resistance is caused by upregulation of deoxycytidine deaminase, which metabolizes gemcitabine to 2,2'-difluorodeoxyuridine. Nonspecific resistance emerges due to upregulation of membrane transporters, although their role in clinical resistance is less clear.

Numerous studies have identified the utility of adding gemcitabine to cisplatin and other agents for the treatment of both relapsed Hodgkin lymphoma and NHL, and CTCLs. The combination of oxaliplatin or cisplatin and gemcitabine is effective and well tolerated, and the majority of patients remain eligible for autologous stem cell collection and transplantation.

Fludarabine

Fludarabine was introduced 25 years ago as an agent with potent activity against lymphoid malignancies and remains an active agent in CLL and other low-grade lymphomas. It has since emerged as an agent in combination that is effective in leukemias, and in induction therapy for nonmyeloablative conditioning prior to allogeneic stem

cell transplantation. It is recognized for its immunosuppressive function and inducing tolerance to allografts transplantation. Fludarabine phosphate is the 2-fluoro, 5'-monophosphate derivative of vidarabine (9'- β -D-arabinofuranosyladenine [ara-A]) and is converted to the di- and triphosphate by intracellular kinases, as are gemcitabine and ara-C. It has greater potency because it confers resistance to deamination by adenosine deaminase (ADA) and improved solubility. It is incorporated into DNA as a nucleotide and causes chain termination. It is a potent inhibitor of cytosolic 5'-nucleotidase II. It is also a substrate for uracil glycosylase, causing abasic sites as the first stem in BER and has recently been used in combination with TRC102, which binds to these sites and prevents their repair. Like other nucleoside analogues, it causes replication fork collapse, double-strand breaks, and induction of P53, leading to apoptotic signaling. Its efficacy against normal lymphoid T and B cells appears linked to both cytotoxicity against proliferating cells and resting cells; the latter effect is mediated by interference with the normal activity of the nucleotide excision repair pathway.

Fludarabine is a complex agent. Resistance is multifactorial including active transport, decreased cytosolic 5'-nucleotidase II and deoxycytidine kinase, and Ku80 binding to telomerase. Other non-specific mechanisms include mutations in *p53* or loss due to chromosome deletion, which is important in many cases of CLL, and other proliferation-associated genes such as *NOTCH1*, *SF3B1*, and *BIRC3*. Low-level miR-34a is also associated with fludarabine resistance.

Fludarabine, at a standard dose of 25 mg/m² for 5 days and rituximab with or without cyclophosphamide were the mainstay of primary treatment for CLL (Chapter 77). Fludarabine has also been used in refractory leukemias, marginal cell and other low-grade lymphomas. Recognition of the appearance of lymphopenia after treatment led to studies establishing fludarabine as part of the non-myelosuppressive preparative regimens for allogeneic transplantation, used particularly for older individual recipients. This is most often at a dose of 30–35 mg/m² for 5 days and used in combination with radiation, melphalan, or cyclophosphamide. In addition to lymphopenia, multiple cycles are associated with prolonged myelosuppression and a chronic peripheral neuropathy.

Clofarabine

Clofarabine (2-chloro-2'-arabino-fluoro-2'-deoxyadenosine) is a purine analog with activity in patients with relapsed acute leukemia. Its activation requires cellular uptake and conversion to the triphosphate nucleotide. It then decreases ribonucleotide reductase; alters nucleotide precursors; inhibits and reduces the function of antiapop-

totic proteins such as Bcl-X(L), Mcl-1, and Bax with dephosphorylation of akt; and inhibits DNA synthesis.

It appears more active against B-cell than T-cell lymphomas, but also has activity in AML and myelodysplastic syndromes (MDS). It is well tolerated. Recent studies show its significant efficacy in ara-C–refractory AML. Reversible liver toxicity and myelosuppression can be dose limiting (see Chapter 59).

Nelarabine

Nelarabine (9- β -D-arabinofuranosylguanine) is another FDA-approved purine analog for the treatment of refractory T-cell leukemias and lymphomas (Chapter 85).

As a nucleotide analogue, it preferentially accumulates in T cells and is incorporated into DNA, causing chain termination and inhibiting DNA synthesis. The FDA approved this drug after analyzing the results of two phase II clinical trials, one in pediatric T-cell acute lymphoblastic leukemia (ALL) and the other in adults with T-cell lymphoblastic lymphoma. In both cases, patients had relapsed after at least two induction regimens. Because CRs were seen in 13% of the 39% of pediatric patients and in 18% of the 28 adult patients, the FDA granted approval. Neurologic toxicity is dose limiting. Good response rates, including CRs, have been seen in patients with refractory T-cell leukemias.

Reduced ara-G incorporation into DNA is likely due to both altered nucleotide transport, increased nucleotidase activity, reduced nucleoside kinase activity, and nonspecific resistance mechanisms as described earlier for this class of agent.

Inhibitors of DNA Topoisomerase I and II

Inhibitors of DNA topoisomerases I and II include such drugs as doxorubicin, daunorubicin, mitoxantrone, etoposide, and topotecan. Before describing the specific inhibitors, a brief review of the drug targets (topoisomerase enzymes) will be presented (Table 57.2).

DNA Topoisomerase I

Topoisomerase I is a ubiquitous enzyme whose function in vivo is to relieve the torsional strain in DNA, specifically to remove positive supercoils generated in front of the replication fork and to relieve negative supercoils occurring downstream of RNA polymerase during transcription. Topoisomerase I is catalytically active as a 100-kDa

TABLE 57.2 Characteristics of Mammalian DNA Topoisomerases

	Topoisomerase I	Topoisomerase II α and Topoisomerase II β	
Size of monomer (kDa)	100	170	180
mRNA (kb)	4.2	6.2	6.5
Chromosome	20q12–13.2	17q21–22	3p24
DNA cleavage	Single-strand breaks	Double-strand breaks	Double strand
Covalent intermediate	3'PO ₄ -Tyr ⁷²³	5'PO ₄ -Tyr ⁸⁰⁴	5'PO ₄ -Tyr ⁸²¹
ATP requirement	No	Yes	Yes
Nuclear location	Nucleoli, diffuse	Nuclear matrix and scaffold, nucleoli	Nucleoli Nuclear matrix
Cell cycle dependence	None	Yes, maximum in G ₂ /M	None
Nuclear localization signal	NH ₂ -end	COOH-end	COOH-end
Phosphorylation	By CK II and PKC (increases activity)	By CK II, PKC, p34 ^{cdc2} , MAPK	Increases mass to 190 kDa
Role	In replication, transcription, and recombination	In replication, transcription, chromosome condensation/segregation, and recombination	rRNA transcription
Inhibitors	Camptothecins	(see Table 57.3)	

MAPK, mitogen-activated protein kinase; PKC, protein kinase C.

monomer and is concentrated in nucleoli, although smaller amounts are found in a diffuse nuclear distribution. The gene for this enzyme is located on human chromosome 20q12–13.2. Topoisomerase I does not require ATP for catalytic activity. It binds double-strand DNA over 15–25 bp (with a preference for supercoiled or bent DNA) followed by cleavage of one DNA strand and forming a transient covalent phosphotyrosyl bond at the 3'-end of DNA. DNA torsional strain is then relieved by a "controlled rotation" mechanism (see Fig. 57.1), subsequent to which the cleaved DNA is religated. The three-dimensional crystal structure of human topoisomerase I, both in covalent and noncovalent complexes with DNA, has defined the structural elements of the enzyme that contacts DNA. The association between topoisomerase I and the 3'-end of cleaved DNA has been termed the *cleavable complex*, which is stabilized by topoisomerase I inhibitors.

DNA Topoisomerase II

Two isoforms of human topoisomerase II (α and β) exist. They act as homodimers to cleave double-stranded DNA and require ATP for full activity. Their role in vivo is to relieve torsional strain in DNA, and their cellular distribution is determined by nuclear localization signals contained in the C-terminal domain. These isoforms are distinct in that they have different-size monomers (see Table 57.2), their genes are located on separate chromosomes, their nuclear distribution is different, and only the α -isoform shows cell cycle variations in amount and activity (with maximal activity being in G₂/M). The mechanism of action of topoisomerase II involves several steps (Fig. 57.4): DNA

Fig. 57.4 DNA TOPOISOMERASE II CATALYTIC CYCLE. (1) Noncovalent binding of DNA by the topoisomerase II homodimer. (2) DNA recognition and preferential binding to crossovers by topoisomerase II. (3) Binding of ATP promotes the formation of a topologic complex. (4) DNA cleavage with covalent linkage of each topoisomerase II monomer to the 5'-DNA terminus of the break. (5) Poststrand passage cleavable complex. (6) Religation of the cleaved DNA is followed by ATP hydrolysis and enzyme turnover. DNA topoisomerase II inhibitors generally increase cleavable complexes by inhibiting the religation activity.

recognition and binding (curved and supercoiled DNA, as well as DNA crossovers, are preferred), the sequential cleavage of the two strands of DNA with covalent attachment of a monomer to each 5'-end of the cleaved DNA, passage of another DNA duplex through the break site (e.g., to relieve DNA torsional strain or decatenate daughter chromosomes at the end of replication), religation of the cleaved DNA, and ATP hydrolysis-dependent enzyme turnover. The binding of ATP by topoisomerase II is required for the strand passage reaction. Again, the association between topoisomerase II monomers and the 5'-end of the cleaved DNA has been termed the *cleavable complex*, the stabilization of which generally correlates with the cytotoxic activity of specific topoisomerase II inhibitors.

Because topoisomerase I and II inhibitors convert their respective enzymes into DNA-damaging agents, it is usually true that the more enzyme target a cell contains (provided it is in the nucleus), the more cytotoxic is the specific inhibitor. An exception to this generalization is CLL cells, which have abundant topoisomerase I but are not very sensitive to topoisomerase I inhibitors because topoisomerase I inhibitors are S-phase specific and CLL cells have very few cells in S phase. Finally, in addition to topoisomerase I and II, a mammalian DNA topoisomerase III has been described and found to be essential for early embryogenesis in the mouse. In addition to the presumed lethality of a homozygous deletion of the topoisomerase II gene, topoisomerases I and III appear to be essential for cell growth and division in mammals. The specific role of topoisomerase III in humans is unknown at present.

DNA Topoisomerase I Inhibitors

Camptothecin is a plant alkaloid first identified in 1966 from the tree *Camptotheca acuminata*. Early clinical studies with camptothecin were stopped primarily because of hemorrhagic cystitis resulting from conversion of the sodium salt form to the active lactone form owing to its acidic pH in the bladder. Renewed interest in camptothecin occurred in 1985 when topoisomerase I was identified as the target of this drug and as new more water-soluble analogs became available. At present, two topoisomerase I inhibitors have been approved by the FDA as second-line agents for the treatment of ovarian carcinoma and colorectal cancer; these are topotecan and irinotecan (CPT-11; Fig. 57.5). Topotecan has been shown to be active in the treatment of MDS and inactive in the treatment of CLL. Responses to topotecan have also been seen in refractory MM, refractory large-cell lymphoma, and refractory acute leukemia.

The lactone forms of topotecan and SN-38 (the active form of CPT-11 generated in vivo by the action of a carboxylesterase) are as

Fig. 57.5 STRUCTURE OF CAMPTOTHECIN ANALOGS.

much as 1000-fold more active inhibitors of DNA topoisomerase I than are their carboxylate forms. The lactone form predominates at an acidic pH. Topoisomerase I inhibitors stabilize the DNA–enzyme cleavable complex and thus inhibit DNA religation, but the production of DNA double-strand breaks results from a collision of the DNA replication fork with the ternary drug–enzyme–DNA complex, which is the lethal event (see Fig. 57.4). Topoisomerase I inhibitors are considered S-phase-specific agents because they require ongoing DNA synthesis to exert their cytotoxic effect.

DNA Topoisomerase II Inhibitors

Inhibitors of DNA topoisomerase II are commonly used for the treatment of hematologic malignancies. Three general types of topoisomerase II inhibitors exist (Table 57.3). The first are the topoisomerase II poisons, typified by etoposide, which results in the stabilization of cleavable complexes. The second group are the catalytic inhibitors, represented by aclarubicin, merbarone, and the bis-2,6-dioxopiperazine derivatives (ICRF-193, ICRF-159, ICRF-187); these are drugs that, except for aclarubicin, do not bind DNA and do not stabilize cleavable complexes, but rather interfere with some aspect of topoisomerase II catalytic activity (e.g., ICRF-187 inhibits topoisomerase II adenosine triphosphatase [ATPase] activity). The final class includes drugs that can inhibit both DNA topoisomerases I and II, and are represented by intoplicin and saintopin.

DNA topoisomerase II poisons (see Fig. 57.5 for structures) are most likely cytotoxic because they trap DNA topoisomerase II complexes on nascent DNA in the nuclear matrix. The topoisomerase II poison-stabilized enzyme–DNA complex likely acts as a replication fork barrier and leads to the generation of irreversible DNA damage and cell death in proliferating cells. Whereas experiments in yeast show that although DNA synthesis is a major determinant for cell killing by topoisomerase I inhibitors, topoisomerase II poisons are also cytotoxic during other phases of the cell cycle.

Drug Resistance to Topoisomerase Inhibitors

Essentially all of the topoisomerase II poisons (see Tables 57.2 and 57.3) are substrates for the drug efflux pump P-glycoprotein (PGP), and many are substrates for multidrug-resistance protein (MRP) and

lung resistance-related protein. In addition, several point mutations and gene deletions have been defined in the gene for topoisomerase II, resulting in the production of an enzyme with altered catalytic or cleavage activity. The third mechanism of resistance is a decrease in expression of the enzyme such that there is less target for the inhibitor to “convert” to a DNA-damaging agent. This can result from a proliferation-dependent or cell cycle-dependent decrease in topoisomerase II, from a specific attenuation of topoisomerase II, or from an intrinsic absence of topoisomerase II (identified in some acute and chronic leukemias). The fourth resistance mechanism involves alterations in the subcellular distribution of the enzyme. Truncation of the COOH-end of topoisomerase II has resulted in the cytoplasmic distribution of enzyme caused by a loss of nuclear localization signals, so that the enzyme cannot interact with DNA in the presence of an inhibitor and the cell is resistant. However, mutations in the gene for topoisomerase II do not appear to be common, because only a single patient with AML has been found to have a point mutation. By contrast, CLL cells are resistant to topoisomerase II inhibitors because they express very low levels of the protein.

Platinum Analogs

Mechanism of Action

During a study of the effects of electric current on growing bacteria, the antibacterial and, later, the antitumor activities of the platinum compounds were fortuitously discovered. The antitumor agent cisplatin, its *cis*-carboxylester analog, carboplatin, and the diaminocyclohexane-containing oxaliplatin, are heavy-metal platinum complexes. They are activated when one of their ligands (cisplatin; chloride and carboplatin; carboxylester) is displaced by water, leading to the formation of positively charged aquated platinum complexes, allowing platinum to stably bind DNA, RNA, proteins, or other critical biomacromolecules (see Fig. 57.2). With DNA, platinum complexes form covalent links to the N⁷ position of guanine and adenine. The N⁷ adducts at d(GpG) or d(ApG) result in intrastrand or interstrand DNA cross-links that bend the DNA helix and inhibit DNA synthesis. The cytotoxicity of platinum analogs correlates with the total platinum binding to DNA, as well as with the intrastrand or interstrand cross-links. This results in DNA damage, which triggers apoptosis of sensitive cells.

Clinical Activity

Cisplatin, carboplatin, and oxaliplatin are used in the treatment of refractory lymphomas in a variety of combinations, and as part of high-dose and intensification therapy for lymphomas as definitive treatment including prior to autologous stem cell transplantation.

Miscellaneous Agents

Among the agents included in this category, only plicamycin, bleomycin, procarbazine, L-asparaginase, gallium nitrate, and glucocorticoids are of current interest to hematologists; these are discussed in [Appendix 57.6](#).

PHARMACOLOGY OF TARGETED ANTINEOPLASTIC AGENTS

Since the year 2000, the therapeutic arsenal available for treatment of hematologic malignancies has expanded to include a group of drugs that have collectively been termed as “targeted agents.” Traditional chemotherapeutic drugs affect specific targets, many times identified after the cytotoxic and clinical activity of these agents have been demonstrated. Dobbstein and Moll describe three “waves” or “epochs” in anticancer drug development.⁴ The first wave includes traditional chemotherapeutic agents, comprised mostly of drugs that affect DNA replication, repair and cell division; these drugs are nonspecific and can affect normal cells, but take advantage of the increased proliferation of cancer cells to exert their cytotoxic activity. Second-wave drugs target cellular signals, including those mediated by surface receptors and protein kinases. Monoclonal antibodies are included in this second wave. The targets of signaling inhibitors are diverse, and include the products of oncogenes, essential for the development and survival of neoplasms (“oncogene addiction”). The prototype of this class of agents is imatinib, targeting the chimeric product of B-cell receptor (BCR)-ABL in CML. Other cellular signaling proteins are not the product of oncogenes, but have an essential role in intracellular processes of malignant cells. This state is known as “nononcogene addiction” and has expanded the number of targets that can be used for cancer treatment with signaling inhibitors. Examples of the latter agent class include inhibitors of mammalian target of rapamycin (mTOR) and BTK. The third wave of anticancer drugs target cellular mechanisms and effector systems distinct from those targeted by drugs of the first two waves, but that are still essential for the survival of cancer cells. The cellular processes targeted by drugs of the third wave are those that contain several types of constitutive stress experienced by cancer cells (separate from replicative stress), including proteotoxic stress leading to abnormal protein folding and increased protein degradation (targeted by heat-shock protein inhibitors and proteasome inhibitors), DNA damage (targeted by PARP inhibitors), DNA modifications (targeted by hypomethylating agents and HDACs), prosurvival balance in organelles governing cell survival (targeted by BCL2 inhibitors), increased need for protein transport (inhibited by nuclear transport inhibitors), as well as transcriptional, ribosomal, metabolic, and oxidative stress, targeted by several other drugs in development. Other agents not easily included in these three waves include immunomodulatory drugs (thalidomide, lenalidomide, and pomalidomide), as well as agents promoting cancer cell differentiation (all-*trans* retinoic acid).

Signaling Inhibitors (Table 57.4)

Imatinib Mesylate and Other BCR-ABL Kinase Inhibitors

Imatinib Mesylate

Imatinib mesylate is a phenylaminopyrimidine developed as an inhibitor of the constitutively active tyrosine kinase (TK) BCR-ABL,

expressed in the leukemic cells of most patients with CML. The recognition that the constitutively active TK BCR-ABL played a central role in the pathogenesis of chronic myeloid leukemia led to the search for potential inhibitors. The introduction of the TK inhibitor imatinib for treatment of CML is a major milestone in the development of targeted therapy for hematologic and neoplastic disorders. The role of the BCR-ABL kinase in the pathogenesis of CML and ALL and the use of BCR/ABL inhibitors in the treatment of these disorders are discussed in further detail in [Chapter 67](#).

Imatinib mesylate is the founding agent in the class of TK inhibitors. It causes direct inhibition of the BCR-ABL kinase, but is not absolutely specific for this molecule, as it also inhibits other kinases, including KIT (formerly designated c-KIT), platelet-derived growth factor (PDGF), stem cell factor (SCF), and TEL-ARG.

Radiographic crystallography studies show that imatinib mesylate competitively binds to the ATP-binding site of the ABL kinase and stabilizes it in an inactive conformation. The 50% inhibitory concentration (IC₅₀) of imatinib mesylate for BCR-ABL is in the submicromolar range, and is substantially lower than the supramicromolar levels achievable in the plasma of patients receiving the drug by the oral route.

Despite the success with imatinib mesylate in the treatment of chronic-phase CML and, to a lesser extent, accelerated or blast-phase CML, the preexistence or development of resistance represents a major therapeutic challenge that can occur at any stage of the disease. Primary or secondary resistance can develop through a variety of mechanisms. BCR-ABL-dependent mechanisms correspond to the emergence of mutations in ABL kinase domain, which can be located in the imatinib binding site, the P loop, the catalytic domain, or the activation loop. Many of these mutations are present at the time of diagnosis and resistant clones emerge after exposure to imatinib. Resistance mechanisms independent of BCR-ABL include development of multidrug resistance mechanisms (e.g., PGP related); decreased levels of human organic cation transporter; acquisition of additional genetic abnormalities (clonal evolution) including acquisition of an additional Philadelphia-positive chromosome (Ph+), trisomy 8 and isochromosome 17q, increased expression of the BCR-ABL protein, and SRC kinase overexpression.

Imatinib also has activity in diseases dependent on other kinases, such as PDGF receptor (PDGFR) α , PDGFR β , or KIT, and is active against myeloproliferative disorders associated with eosinophilia and FIP1L1/PDGFR α or PDGFR β fusion genes, as well as against systemic mastocytosis without *KIT*^{D816V} mutation ([Chapters 71 and 72](#)).

Common adverse events due to imatinib include fluid overload and edema, and development of heart failure, fatigue, rash, and myelosuppression. Gastrointestinal side effects are common, and nausea and vomiting are frequent reasons for poor compliance.

Dasatinib

Dasatinib is a second-generation ABL kinase inhibitor approved for the treatment of CML. Dasatinib is an oral multikinase inhibitor, affecting BCR-ABL, KIT, PDGFR and src kinases. It binds the ATP binding site of ABL in an opposite direction to imatinib, can inhibit active and inactive forms of the kinase, and requires fewer points of contact. This reduced structural stringency in kinase inhibition allows for inhibition of all kinase mutations, with the exception of the *T315I* mutation.

Compared with imatinib, dasatinib is several hundred times more potent as an inhibitor of ABL. Initial studies demonstrated dasatinib-induced responses in patients who had developed resistance to imatinib treated in the chronic, accelerated, and blast phase of CML.

There is a high response rate in patients with wild-type sequences of *bcr-abl* and also in patients with mutations in the ABL protein conferring resistance to imatinib, with the exception of the *T316I* mutation.

As a multikinase inhibitor, dasatinib has a broader and alternative toxicity profile, with pulmonary edema, pleural effusions, and thrombocytopenia being the more frequent adverse effects. Recently, higher rates of pulmonary hypertension have been observed in patients receiving dasatinib.

TABLE 57.4 Targets and Approvals for Signaling Inhibitors

Agent	Identified Target Molecules	Approved Indications
Imatinib	BCR-ABL, KIT, PDGFR α , PDGFR β , SCF, RET	CML, KIT-positive GIST, Ph+ ALL, myeloproliferative syndromes with PDGFR gene rearrangements Systemic mastocytosis without C-Kit mutation D816V Chronic eosinophilic leukemia and adult hypereosinophilic syndrome with FIP1L1-PDGFR α fusion or with unknown status of this fusion
Nilotinib	BCR-ABL, Kit, Lck, Ephrins, PDGFR β , MAPK11, ZAK	CML
Dasatinib	BCR-ABL, Kit, Src, Lck, Yes, Fyn, Ephrins, PDGFR β , STAT5B	CML Ph+ ALL
Bosutinib	BCR-ABL, Kit, Src, HCK, Lyn, MAPK1-2	CML
Ponatinib	BCR-ABL, Kit, PDGFR α , VEGFR, Src, Lyn, Lck, FGFR1-4, FLT3, TEK	CML with <i>T315I</i> mutation ALL with <i>T315I</i> mutation
Ibrutinib	BTK	Relapsed CLL, CLL with del(17p), relapsed mantle cell lymphoma, Waldenström's macroglobulinemia
Idelalisib	PI3K δ	Relapsed CLL, SLL and follicular lymphoma
Ipatasertib	AKT	
Afuresertib	AKT	
Temsirolimus	mTOR	Renal cell carcinoma
Everolimus	mTOR	Renal cell carcinoma Advanced hormone receptor positive, HER2-negative breast cancer
Crizotinib	ALK, HGFR	ALK-positive non-small-cell lung cancer
Sorafenib	BRAF, VEGFR, FLT3, PDGFR β , Kit, FGFR1, Ret	Hepatocellular carcinoma Renal cell carcinoma Recurrent thyroid cancer
Ruxolitinib	JAK1, JAK2,	Intermediate or high risk myelofibrosis Polycythemia vera refractory to hydroxyurea
Pacritinib	JAK2, FLT3	

ALL, Acute lymphoblastic leukemia; CML, chronic myeloid leukemia; CLL, chronic lymphocytic leukemia; FLT3, fms-like tyrosine kinase 3; HGFR, hepatocyte growth factor receptor; mTOR, mammalian target of rapamycin; PDGFR, platelet-derived growth factor receptor; PI3K, phosphatidylinositol 3-kinase; SCF, stem cell factor; SLL, small lymphocytic lymphoma; STAT5B, signal transducer and activator of transcription 5B; VEGFR, vascular endothelial growth factor receptor.

Nilotinib

Nilotinib is the other second-generation ABL kinase inhibitor approved for treatment of CML. Nilotinib is structurally related to imatinib, but has structural modifications that increase affinity for the ABL kinase site, binding with an improved topological fit to the kinase site in its inactive form. Nilotinib is 10–30 times more potent than imatinib.

In contrast with imatinib and dasatinib, nilotinib is a selective inhibitor of BCR-ABL. Nilotinib is active in chronic- and accelerated-phase CML patients who have developed resistance to imatinib. As with dasatinib, nilotinib was compared with imatinib in a phase III randomized trial as initial therapy for chronic-phase CML patients, with nilotinib achieving higher rates of complete cytogenetic and major molecular responses, and with fewer cases of CML phase progression or clonal evolution in the nilotinib-treated cohorts (PMID21856226). Nilotinib is active against all *BCR-ABL* mutations that confer resistance to imatinib, with the exception of *T315I*.

Common adverse events with nilotinib include rash, gastrointestinal disturbances (nausea, vomiting, diarrhea), as well as neutropenia and thrombocytopenia. Pleural effusion and peripheral edema are less common than with dasatinib. In addition, QT prolongation and risk of pancreatitis are serious side effects of nilotinib.

Bosutinib

Bosutinib is a dual kinase inhibitor of Src and ABL kinases. Although originally described as a Src-selective TK inhibitor, cell line screening

assays allowed discovery of its ABL inhibitory activity. ABL kinase assay studies showed the IC₅₀ was 1.4 nM. Cell line and animal studies supported the potential therapeutic activity of bosutinib against CML. Bosutinib has does not inhibit wild-type c-KIT of PDGFR, although recent studies have shown inhibitory activity of other kinases, including CSK, Eph receptors, Trk, Tek, and Axl kinases, as well as some epidermal growth factor receptor and KIT mutants.

Bosutinib docks inside the intermediate conformation of the ATP binding site of ABL (in contrast to imatinib, which binds to the inactive conformation of the site). Binding to the intermediate conformation overcomes the resistance to imatinib conferred by mutations *Y253F*, *E255K*, and *D276G*, but does not confer activity against cells expressing *T315I*. In addition, Bosutinib appears to be a poor substrate of MDR transporters, overcoming this additional mechanism of resistance.

Common adverse events observed with bosutinib include gastrointestinal upset (diarrhea, vomiting, and abdominal pain), whereas the more common serious adverse events include diarrhea, myelosuppression, and elevated serum lipase and transaminases.

Ponatinib

Ponatinib is a third-generation, dual Src-ABL inhibitor. It was developed using computational and structure-based design to have activity against BCR-ABL forms with mutations that convey resistance to other TKIs, in particular *T315I* mutation. Ponatinib binds

ABL in its inactive form as imatinib. Differences in the chemical structure allow ponatinib to maintain interaction with ABL even in the presence of isoleucine in position 315, in cases with a *T315I* mutation. Initial cell- and murine-based studies showed that ponatinib inhibits cells expressing mutant or native *BCR-ABL*. Subsequent human studies demonstrated that ponatinib had activity in CML, including those with *T315I* mutation. Toxicities observed in early clinical trials included pancreatitis and elevation in pancreatic enzymes, fatigue, rash, and elevated aminotransferase levels. Ponatinib received FDA-accelerated approval in 2012 for the treatment of resistant or intolerant CML and Ph+ ALL. However, subsequent trials showed increased arterial thrombosis events in patients randomized to ponatinib arms, leading to limitations in the indications for ponatinib and the requirement for thrombosis prevention strategies in subjects treated with this drug.

Bruton Tyrosine Kinase Inhibitors

Btk is a cytoplasmic TK with a well-defined role in B-cell receptor signaling that is fundamental in B-lymphocyte development, differentiation, and signaling. Btk is a member of the Tec family of kinases (see Chapter 77). Activation of Btk triggers a cascade of signaling events that culminates in the generation of calcium mobilization and fluxes, cytoskeletal rearrangements, and transcriptional regulation of NF κ B and nuclear factor of activated T cells.⁵ Ibrutinib (PCI-32765) is a first-in-class, selective, irreversible, small-molecule inhibitor of Btk. Ibrutinib binds covalently to a cysteine (Cys 481) in the Btk active site, with potent and irreversible enzymatic activity. Clinical trials demonstrated a favorable toxicity profile with remarkable clinical activity in patients with relapsed CLL, mantle cell lymphoma (MCL), and Waldenström macroglobulinemia, with additional activity observed in activated B-cell-like diffuse large B-cell lymphoma and other lymphoid malignancies.

An early transient phase of lymphocytosis has been associated with response in CLL and MCL patients. Bruising can be observed in up to half of patients treated with ibrutinib. Serious adverse events associated with ibrutinib occurred in approximately 10% of patients, including rash, febrile neutropenia, diarrhea, and life threatening bleeding. The diarrhea follows two patterns: an early diarrhea that usually presents in the first weeks of treatment, which can usually be managed with antidiarrheal agents, and a late diarrhea that has an inflammatory bowel component and that may require more aggressive therapies, including corticosteroids and other antiinflammatory therapies. Atrial fibrillation or flutter has been observed in 6%–9% of patients. The mechanism for increased bleeding risk appears to be related to a platelet function defect secondary to interference of collagen receptor glycoprotein VI signaling.

Dosing for CLL and Waldenström's macroglobulinemia patients is 420 mg PO once daily; MCL patients is 560 mg once daily.

PI3K/AKT/mTOR Inhibitors

The PI3K/AKT/mTOR pathway is involved in the regulation of diverse cellular functions, including cell growth, protein synthesis, cell cycle regulation, glucose metabolism, and motility. PI3K represents a family of enzymes with multiple subunits. These subunits cooperate to transduce upstream signals (from RTKs, G-protein-coupled receptors, and other intracellular stimuli) into the enzymatic conversion of phosphatidylinositol diphosphate (PIP₂) to phosphatidylinositol triphosphate (PIP₃). The dual-specific phosphatase and tensin homolog (PTEN) opposes the actions of PI3K. PTEN is one of the most frequently mutated tumor suppressor genes in human malignancies, with inactivating mutations, genetic losses, and epigenetic silencing leading to PTEN loss. Phosphatidylinositol triphosphate, through phosphoinositide-dependent kinase-1 (PDK1), leads to the phosphorylation and activation of the serine/threonine kinase AKT.

AKT signals to multiple downstream targets, in particular mTORC1, to promote cell survival and growth. Additional targets of AKT include molecules involved in cell survival and proliferation (e.g., Bad, Bim, procaspase 9, CREB, forkhead transcription factors [FKHR], IB), cell cycle regulators (p21^{CIP1}, p27^{KIP1}, cyclin D₁), glycogen synthesis (GSK3), and protein synthesis (FRAP1, p70^{S6K}).

The mechanistic target of rapamycin (also known as mTOR) operates through two complexes: mTORC1 (mTOR-Raptor) and mTORC2 (mTOR-Rictor). mTORC1 is activated by AKT and mediates its downstream proliferation, growth, and survival signaling, specifically through phosphorylation and inactivation of the repressor of mRNA translation initiation factor 4E-binding protein 1 (4E-BP) and ribosomal protein S6 kinase 1 (S6K1; see Fig. 57.6), resulting in enhanced translation of transcripts relevant to lymphoma pathogenesis, including CCND1, MYC and MCL1. The mTORC1 complex is activated by AKT whereas mTORC2 is capable of activating AKT. The majority of the downstream canonical functions are conducted by mTORC1.

Because of the frequency of PTEN losses or mutations (less common in hematologic malignancies) in transformed cells and the dependence of numerous cancers on an intact PI3K/AKT/mTOR pathway for survival, this cascade has become an attractive therapeutic target.

Fig. 57.6 RAPAMYCIN OR ITS ANALOGS INHIBIT MAMMALIAN TARGET OF RAPAMYCIN AND THE DOWNSTREAM PHOSPHORYLATION OF S6K1 AND 4EBP1, THEREBY ATTENUATING THE TRANSLATION INITIATION OF MRNAS WITH HIGHLY STRUCTURED 5'-UTR. Activation of the receptor (FLT-3) or cytosolic tyrosine kinase (e.g., BCR-ABL) can lead to increased activity of PI3K/AKT. Although it can directly phosphorylate mTOR, AKT activity inhibits the TSC1–TSC2 complex, thereby derepressing RHEB and activating mTOR. The phosphorylation and activation of S6K1, and phosphorylation and inactivation of 4E-BP through Raptor, results in the phosphorylation of S6, eIF4B, and eIF4E, which are involved in the cap-dependent translation of mRNAs with highly structured 5'-UTR. *eIF*, Eukaryotic translation initiation factor; *mTOR*, mammalian target of rapamycin; *PI3K*, phosphatidylinositol 3-kinase; *PTEN*, phosphate and tensin homolog; *RHEB*, Ras homolog enriched in brain; *TSC*, tuberous sclerosis; *UTR*, untranslated region.

PI3K Inhibitors

Idelalisib (CAL-101, GS 1101) is a highly selective inhibitor of the p110 δ isoform of PI3K (PI3K δ), an isoform of PI3K that is expressed selectively in hematopoietic cells, in particular those of the lymphoid lineage. Idelalisib has *in vitro* activity against lymphoid cell lines and primary CLL and MCL cells, but does not affect normal B-cell viability (see [Chapter 77](#)). Idelalisib inhibits not only the B-cell receptor signaling pathway-induced survival signals but also appears to disrupt the effects of microenvironmental signals on neoplastic cells,⁶ affecting chemotaxis of tumor cells, which could explain the transient lymphocytosis observed after treatment of CLL patients with this agent. Clinical trials have shown that idelalisib is active in treating patients with relapsed CLL and other relapsed indolent lymphoid malignancies. Additional trials are investigating the activity of idelalisib in combination with other chemotherapeutic agents for the treatment of aggressive and indolent lymphoid malignancies, as well as its role in the treatment of AML and ALL.

Idelalisib is currently approved as a single agent for relapsed follicular lymphoma and SLL and in combination with rituximab for CLL patients. The approved dosing is 150 mg PO twice daily. Common dose-limiting toxicities include diarrhea, fever, and rash. Elevation of liver function tests is also commonly observed, requiring interruption of idelalisib. Serious adverse events include hepatotoxicity occurring in the first 3 months of treatment, diarrhea and colitis, intestinal perforation, pneumonitis, and neutropenia.

Other PI3K Inhibitors

Several other PI3K inhibitors are currently in various stages of development. Buparlisib is a pan PI3K inhibitor that appears to have activity against solid tumors as well as lymphoid malignancies. Pictilisib is a PI3K α and δ selective inhibitor that may overcome resistance conferred by constitutive expression of the α isoform of the enzyme. The main additional toxicity observed with PI3K inhibitors that target the α isoform is the development of insulin resistance and hyperglycemia. Additional agents have specificities that include other isoforms such as PI3K β , δ and γ .

Resistance to selective PI3K inhibitors may be mediated by constitutive activation of other isoforms of PI3K, as has been observed in certain MCL lines and primary cells. *O*-linked *N*-acetylglucosamine transferase, dendrin, and PAK1 overexpression have been associated with resistance to idelalisib in cell lines. Mechanisms of resistance may include PTEN loss, MYC and eIF4e upregulation. Mutations of the catalytic domain of the α subunit (PIK3CA), common in solid tumors, are much less frequent in hematologic malignancies, although treatment with these agents may increase the selective pressure for emergence of this abnormality.

AKT Inhibitors

The frequent presence of AKT abnormalities in human neoplasms makes this enzyme an attractive target for potential novel treatment strategies. Several drugs have been developed using dephosphorylation of the active enzyme, allosteric enzyme inhibition, and ATP competition as strategies for targeting AKT. Allosteric inhibitors bind the lipid-binding domain of AKT, resulting in a change in conformation that prevents localization to the plasma membrane and subsequent activation. The allosteric inhibitor perifostine had modest clinical activity as a single agent in patients with Waldenström macroglobulinemia and in patients with myeloma alone or in combination with bortezomib. Phase III studies failed to demonstrate clinical benefit. MK2206 is another oral allosteric inhibitor with minimal single-agent activity against solid tumors and hematologic malignancies.

Early ATP-competitive AKT inhibitors had significant off-target effects. More recently, ipatasertib (GDC-0068), an oral pan AKT inhibitor, has been observed to have significant selectivity for AKT. Clinical development has focused on solid tumors. Afuresertib (GSK 2110183) is a reversible ATP-competitive AKT inhibitor with *in vitro* activity against ALL, CLL, lymphoma, and myeloma. A phase I study of single-agent afuresertib showed activity in MM, with a maximum tolerated dose of 125 mg PO once daily. Subsequent

studies have demonstrated activity of afuresertib when used in combination with bortezomib and dexamethasone for the treatment of myeloma, and with ofatumumab for the treatment of CLL. Frequent adverse events include gastrointestinal complaints (diarrhea, nausea, dyspepsia, gastrointestinal reflux, and anorexia) and fatigue. Severe adverse events include rash, fatigue, elevations in liver function tests, and thrombocytopenia.

Inhibitors of the Mammalian Target of Rapamycin

The first mTOR inhibitor discovered was the naturally occurring macrolide rapamycin (sirolimus), widely used as an immunosuppressant (see [Chapter 108](#)). The importance of the mTOR pathway in cancer suggested this agent would have antineoplastic activity. Improvements in solubility and pharmacokinetic properties led to development of rapamycin analogs (rapalogs), of which everolimus and temsirolimus are available as antineoplastic agents.⁷ The mechanism of rapamycin and its analogs is similar: after complexing with the small protein FKBP12, they bind irreversibly to the FKBP12-rapamycin binding site on the mTOR protein. Acute rapamycin treatment only affects mTORC1 because the FKBP12-rapamycin is occluded in mTORC2. Prolonged rapalog exposure may result in decreased mTOR availability and therefore indirectly decreased mTORC2 activity through limited mTORC2 complex formation. It is well recognized that growth factor signaling initiated through the receptor tyrosine kinases (RTKs) or caused by the activity of cytosolic tyrosine kinases (TKs), such as BCR-ABL, results in activation of PI3K/AKT signaling. AKT has been shown to phosphorylate and inactivate tuberous sclerosis (TSC)2 (also known as tuberlin), thereby disrupting its interaction with TSC1 (or hamartin; see [Fig. 57.6](#)). Inhibition of the TSC1–TSC2 complex derepresses RHEB, which is a small G protein that activates mTOR. When RHEB is in an active GTP-bound state, its localization to the membrane stimulates mTOR-mediated phosphorylation of the downstream eukaryotic initiation 4E-BP and ribosomal protein S6K1 (see [Fig. 57.6](#)). However, the association of mTOR with the 150-kDa Raptor (regulatory-associated protein of mTOR) is necessary for the phosphorylation of 4E-BP and S6K1. mTOR-mediated phosphorylation and activation of S6K1 results in the phosphorylation of the ribosomal S6 protein and eIF4B (see [Fig. 57.6](#)). AKT has also been shown to directly activate S6K1. S6K1 activity is involved in regulating the translation of a group of mRNAs that have a highly structured 5'-UTR (untranslated region), including mRNAs that have a 5'-TOP (terminal oligopyrimidines; a stretch of 4–14 pyrimidines).⁸

The rapalogs temsirolimus and everolimus have been tested in lymphoid malignancies, and as single agents they have demonstrated activity, although modest, against a variety of lymphomas (see [Chapter 82](#)). In the initial phase II study in patients with MCL, temsirolimus was administered at a dose of 250 mg based on a phase II study done in renal cell carcinoma patients. A modest response rate was noted (overall response rate [ORR]: 38%), but the majority of patients required a dose reduction because of myelosuppression, particularly thrombocytopenia. A second trial in relapsed refractory MCL patients was conducted to determine if a lower dose of temsirolimus could be used. In a follow-up phase II study, temsirolimus was given at a dose of 25 mg IV weekly and was found to be as effective as the 250-mg IV dose, with a modest improvement in the toxicity profile and dose reductions. This dose and schedule were also noted to be efficacious in nonmantle cell NHL, with thrombocytopenia being the main dose-limiting toxicity. A recent phase III study in relapsed refractory MCL patients evaluated two different dosing regimens of temsirolimus; 175 mg weekly for 3 weeks followed by 75 mg weekly versus 175 mg weekly for 3 weeks followed by 25 mg weekly versus the investigator's choice.⁹ At the conclusion of this study, it was determined that the temsirolimus regimen with 175/75 mg dosing had a significant improvement in progression-free survival (PFS) and objective response rate compared with the investigator's choice. Everolimus, given orally at a daily dose of 10 mg has single-agent activity against Hodgkin lymphoma (PMI, Waldenström macroglobulinemia, diffuse large B-cell lymphoma [DLBCL], CLL, and other relapsed lymphomas).

The most common side effect of rapalogs is myelosuppression; other common side effects include fatigue, oral ulcers, and dermatologic abnormalities. Metabolic abnormalities are common, including hyperglycemia, hypercholesterolemia, and hypertriglyceridemia. An uncommon pulmonary toxicity manifested as interstitial lung disease has also been observed with rapalogs.

Anaplastic Lymphoma Kinase Inhibitors

Anaplastic lymphoma kinase (ALK) encodes for a 210-kDa RTK, a member of the insulin receptor superfamily closely related to leukocyte TK. While ALK has a normal role in nervous system development, translocations involving ALK have been described in a variety of malignancies, including anaplastic large-cell lymphoma (NPM-ALK, TFG-ALK, ATIC-ALK, and CLTC-ALK translocations), DLBCL (NPM-ALK, CLTC-ALK, SQSTM1-ALK, and SEC31A-ALK translocations), as well as non-small-cell lung cancer (NSCLC; EML4-ALK translocation and others). These translocations result in ALK chimeras, with fusion of the intracytoplasmic domain of ALK with partner proteins that provide a dimerization domain that results in ALK-mediated autophosphorylation and constitutive activation. Subsequent signaling promotes cellular proliferation, survival and growth via phospholipase C γ , RAS/mitogen-activated protein kinase (MAPK), PI3K and c-Src.

Crizotinib

Crizotinib is a dual ALK/c-MET inhibitor with additional inhibitory activity against the kinase ROS1 (c-ros). It inhibits kinase activation through binding to the kinase domain and displacing the kinase activation loop, interfering with ATP and substrate binding. Crizotinib was shown to be 20-fold more selective for ALK and MET than other kinases, and inhibited cell proliferation and induced apoptosis in NPL-ALK-dependent cell lines. The initial clinical studies done in patients with NSCLC showed the maximum tolerated dose was 250 mg PO twice daily. Although initially tested as a c-MET inhibitor in these patients, ALK translocations were reported to be associated with marked responses in patients treated with crizotinib. Subsequent studies in ALK-rearranged NSCLC confirmed the activity of crizotinib in NSCLC with ALK translocations. In 2011, the FDA granted approval for crizotinib in this patient population. Subsequent studies conducted in relapsed and refractory ALK-positive anaplastic large-cell lymphoma showed a high rate of response to single-agent crizotinib. Additional trials testing crizotinib for ALK-positive lymphomas are ongoing.

The most common adverse events include gastrointestinal symptoms (nausea, vomiting, diarrhea), visual impairment, asthenia, cough, and myelosuppression (neutropenia, lymphopenia), as well as elevations of hepatic function tests.

Inhibitors of the RAF1/Mek/ERK Pathway

The MAPK pathways consist of three parallel serine-threonine kinase modules that are intimately involved in the control of cell survival, proliferation, and differentiation. Two of these, c-Jun N-terminal kinase (JNK) and p38 MAPK, are activated in response to environmental stresses, including DNA damage and osmotic stress, but p42/44 MAPK (also known as extracellular signal-regulating kinase [ERK]) is primarily induced by growth factors and other mitogenic stimuli. Although exceptions exist, JNK and p38 MAPK primarily exert proapoptotic functions, but ERK activation is generally associated with cell survival. The only well-defined activator of ERK is the serine-threonine kinase mitogen-activated protein kinase 1/2 (MEK1/2), but numerous ERK targets have been identified, including ELK-1, CREB, BCL2, Bad, FRAP1 (also known as mTOR), and caspase 9, among numerous others. The activating effects of MEK1/2 on ERK are opposed by phosphatases that dephosphorylate and inactivate the enzyme (e.g., MAP kinase phosphatase 1/2).

The major activator of MEK1/2 is the serine-threonine kinase RAF, of which three forms exist: RAF1, B-RAF, and A-RAF. RAF can be activated by Ras (discussed earlier), as well as through various RAS-independent pathways, including PKC, KSR, as well as the SRC and JAK family of kinases, among others. The activation of RAF involves several processes, including recruitment to the plasma membrane, phosphorylation on serine and threonine residues, and dimerization. Interference with any of these processes can lead to inhibition of Raf activation as well as downstream targets.

Dysregulation of the RAF/MEK/ERK pathway has been observed in most hematopoietic malignancies, including acute leukemia, CLL, MM, and lymphomas. Consequently, there has been considerable interest in the development of pharmacologic inhibitors of the RAF/MEK/ERK pathway in these disorders. In addition to their potential intrinsic activity against malignant hematopoietic cells, evidence indicates that such agents might also enhance the activity of conventional cytotoxic drugs.

Sorafenib

Initial approaches to RAF inhibition focused on efforts to destabilize the protein. For example, geldanamycin and the related compound 17-AAG act as inhibitors of HSPCA, a chaperone protein necessary for Raf processing and stabilization. Interference with HSPCA results in destabilization and proteasomal degradation of RAF as well as numerous other proteins, including AKT. More recently, however, a Raf kinase inhibitor, sorafenib, which is approved for use in kidney cancer, has been developed and has entered phase I and II clinical trials in humans with leukemia. In preclinical studies, induction of leukemic cell death by sorafenib has been shown to stem from inhibition of translation and downregulation of the short-lived antiapoptotic protein Mcl-1 and induction of endoplasmic reticulum (ER) stress with bim-mediated apoptosis. In the clinical setting, modest response rates of 10% were observed in two studies, suggesting the need to consider combination therapy.

Janus Kinase 2 Inhibitors

JAK2 is a non-RTK that plays a central role in the transduction of differentiation and proliferation signals in hematopoietic progenitor cells. Ligand binding to surface receptors for hematopoietic growth factors leads to phosphorylation of JAK2 with subsequent activation of transcription factors in the JAK/signal transducer and activator of transcription (STAT) pathway, including STAT3 and STAT5 (see Chapters 68–70). Identification of the JAKV617F mutation in patients with myeloproliferative neoplasms, including polycythemia vera, essential thrombocythemia, and primary myelofibrosis, represented a fundamental step in understanding the pathophysiology of these disorders. The genetic abnormality corresponds to a point mutation in nucleotide 1849 of the molecule, where guanine replaces thiamine, resulting in substitution of a valine for phenylalanine in the JH2 pseudokinase autoinhibitory domain of the molecule. The result is either hypersensitivity to cytokine signals or constitutive activation of the kinase. Development of JAK2 inhibitors followed as a rational, targeted therapeutic strategy for these neoplasms (see Chapters 68–70).

Ruxolitinib

Ruxolitinib (INCB018424, Jakafi) is a small-molecule inhibitor of JAK1 and JAK2, and the first-in-class JAK inhibitor to receive FDA approval for treatment of intermediate- and high-risk myelofibrosis^{10,11} (see Chapter 70). It exerts its inhibitory activity through competitive inhibition of the kinase's ATP-binding catalytic site. In preclinical studies, JAK1/2 inhibition with ruxolitinib decreased STAT3/5 signaling both in wild-type cells and those carrying JAKV617F. In the initial phase I/II study, the maximum tolerated dose was 25 mg when given twice daily and 100 mg on once-daily dosing. After 3 months of therapy, 44% of patients with splenomegaly experienced a reduction of more than 50%. Responses were observed in patients with the JAKV617F mutation as well as those with

wild-type *JAK2*. Importantly, the majority of patients experienced a decrease in constitutional symptoms and improved exercise tolerance and performance status, as well as weight gain. In larger, randomized trials, while clinical improvement was superior with ruxolitinib treatment, this agent was not effective in reversing histologic, cytogenetic, or molecular abnormalities in peripheral blood or BM, suggesting that ruxolitinib is not curative. Recent studies have also shown ruxolitinib to be effective in controlling symptoms, spleen size and hematocrit in patients with polycythemia vera. Dosing of ruxolitinib in myelofibrosis patients is based on platelet count, ranging from 5 mg twice daily for patients with platelet counts lower than 50,000/ μ L to 20 mg twice daily if platelet counts are above 200,000/ μ L; in patients with polycythemia vera the starting dose of ruxolitinib is 10 mg twice daily. Rapid redevelopment of splenomegaly and symptom exacerbation can occur after abrupt interruption or discontinuation of ruxolitinib. Common side effects of ruxolitinib include myelosuppression, primarily anemia, and thrombocytopenia requiring dose modifications; increased risk of infections and herpes zoster; gastrointestinal symptoms (abdominal pain, diarrhea), fatigue and headache.

Other JAK2 Inhibitors

Several other inhibitors with activity against JAK2 are under investigation.

Pacritinib (SB1518) is a JAK2 inhibitor with activity against the wild-type kinase as well as the JAKV617F-mutated kinase; it also inhibits fms-like tyrosine kinase 3 (FLT3). It achieves high rates of reduction in spleen volume. The tested dose is 400 mg daily. Recent studies confirm the activity of pacritinib in the treatment of MF, resulting in improvements in hematologic, radiologic, and clinical symptom endpoints. The main side effects are gastrointestinal, predominantly diarrhea, nausea, vomiting, and abdominal pain, while hematologic adverse events are modest.

Momelotinib (CYT387) is an oral multikinase inhibitor affecting JAK1/2, TYK2, TBK1, PRKD1, ROCK2, PRKCN, MAPK8, and CDK2/cyclin A. Early trials in myelofibrosis patients resulted in decreased splenomegaly and improvement in symptoms in the majority of patients treated. Of note, more than one-third of patients with improved splenomegaly had previously been treated with ruxolitinib. The most common side effects included myelosuppression, primarily thrombocytopenia. Nonhematologic side effects included headache, QTc prolongation, neuropathy, and abnormal liver test results. The maximum tolerated dose has been established at 300 mg/day given continuously in 28-day cycles.

Immunomodulatory Agents

Thalidomide and its related compounds provide effective oral immunomodulatory (see [Chapter 86](#)) therapy for patients with hematologic malignancies, in particular plasma cell dyscrasias and lymphoid malignancies. They have complex mechanisms of action. Further details on their therapeutic impact are found in [Chapters 86 and 81–82](#).

Thalidomide

Experimental studies have identified that thalidomide reduces expression of the cellular inhibitor of apoptosis protein and potentiates proapoptotic processes such as TNF-related apoptosis-inducing ligand (TRAIL)/po2L. Thalidomide also reduces NF κ B and I κ B expression, thereby reducing IL-6 expression. In addition, thalidomide decreases vascular endothelial growth factor (VEGF) and reduces angiogenesis and vessel density in the bone marrow of patients with MM. The lack of a simple mechanism of action has been confusing because it is unclear which, if any, biomarker is an appropriate correlate for clinical success or toxicity. Thalidomide has been in clinical use for more than 50 years and has well-documented and sometimes serious side effects, including severe birth defects, somnolence, axonal length-dependent peripheral neuropathy, orthostatic hypotension, neutropenia, bradycardia and occasional heart block, and increased viral load in HIV-positive patients. The risk of developing thrombotic

events is elevated, giving rise to the recommended use of an anticoagulant regimen such as aspirin, low-molecular-weight heparin or Coumadin. Nonetheless, efficacy is certainly seen clinically and has been validated in SCID models of human myeloma. Data also point to its potential clinical efficacy in patients with solid tumors and MDS. The approved dose of thalidomide for treatment of plasma cell myeloma is 200 mg PO given once daily. Dose reductions should be considered in the presence of hematologic toxicity.

Lenalidomide

Lenalidomide was identified as an analog of thalidomide with more potent immunomodulatory functions but fewer side effects. Lenalidomide also has antiangiogenic properties, blocks IL-6 production, and reduces NF κ B and I κ B levels. In addition, lenalidomide induces caspase 8-mediated apoptosis and mitochondrial-mediated cell death. T-cell activation and increased natural killer (NK) activity are observed, thus increasing the anticancer immune response. Lenalidomide can cause a similar dose-dependent peripheral neuropathy as thalidomide, and causes more significant myelosuppression, which can be dose limiting. The risk of thrombosis is also increased and the administration of lenalidomide should be accompanied by antithrombotic prophylaxis. Hypersensitivity rash occurs in up to 10% of patients. In trials of CLL and lymphoma, initial treatment with lenalidomide can result in tumor flare, characterized by fever, rash and painful lymphadenopathy; lower initial doses should be considered in patients with high tumor burden and CLL. A variety of dosing schedules provides a flexible therapeutic approach and a high response rate in relapsed myeloma patients, with an ORR of 25% and median overall survival (OS) of 28 months. In 5q- MDS patients, response in over 40% of patients was observed, indicating more based on the achievement of transfusion independence (see [Chapter 60](#)). The activity of lenalidomide has been observed in several lymphoid malignancies, with its current approval limited to MCL that has relapsed after two lines of therapy. The approved starting dose of lenalidomide is 25 mg PO once daily (days 1–21 of a 28-day cycle) for plasma cell myeloma and MCL. A dose of 10 mg once daily is used in 5q- MDS patients.

Pomalidomide

Pomalidomide is a third-generation member of the immunomodulatory drugs (IMiDs) class. In addition to its immunomodulatory and antiangiogenic activity, pomalidomide has direct activity against myeloma cells, affecting gene expression, and promoting apoptosis and cell cycle arrest. Pomalidomide upregulates expression of p21^{WAF} and downregulates interferon (IFN) regulatory factor 4. p21^{WAF} inhibits CDK2, which in turn results in phosphorylation of the retinoblastoma (Rb) protein and cell cycle arrest at G1. Apoptosis is also induced via activation of caspase 8. In vitro studies showed that pomalidomide was active in cell lines resistant to thalidomide and lenalidomide.

Phase I studies established that the maximum tolerated dose of pomalidomide was 4 mg given PO on days 1–21 of 28-day cycles, which corresponds to the currently approved starting dose. Results of a phase II study combining pomalidomide with dexamethasone in patients with relapsed myeloma showed an encouraging ORR of 63% (partial response [PR] or better), including 60% of patients who were refractory to bortezomib and 40% of patients who were refractory to lenalidomide. The most common severe adverse events are myelosuppression (anemia, neutropenia, and thrombocytopenia), infections, and fatigue. Venous thromboembolic events were observed in early-phase studies and subsequent trials have required thromboprophylaxis, under which the rate of VTE with pomalidomide is less than 5%.

Proteasome Inhibitors

The 26S proteasome is the central proteolytic machinery of the highly conserved ubiquitin proteasome system. In eukaryotic cells, whereas the lysosomal pathway degrades extracellular proteins imported into the cell through endocytosis or pinocytosis, the proteasome controls

the degradation of intracellular proteins. Numerous studies have demonstrated that the ubiquitin–proteasome system controls basic cellular functions such as cell cycle progression, signal transduction, and programmed cell death, hence the interest in therapeutic interventions that manipulate proteasomal activity and potentially restore cellular homeostasis into transformed cells (see [Chapter 4](#)).

Ubiquitin is a highly conserved 76-amino-acid polypeptide that is expressed in all eukaryotic cells. Under the sequential action of E1 (ubiquitin-activating enzyme), E2 (ubiquitin-conjugating enzyme), and E3 (ubiquitin ligase), ubiquitin is activated and covalently conjugated to potential proteasome substrates via an isopeptide bond between the C-terminal glycine residue of ubiquitin and the ϵ -amino group of internal lysine residues in target proteins. The same set of enzymes also catalyzes the formation of the isopeptide bond between G76 and the lysine residue (K48) of previously conjugated ubiquitin, leading to formation of a polyubiquitin chain. Polyubiquitinated substrates are usually targeted for proteasomal degradation.

The 26S proteasome is a large (2000-kDa) threonine protease present in the nucleus and cytoplasm of all eukaryotic cells. This ATP-dependent, multicatalytic protease eliminates damaged or misfolded proteins and regulates cyclins and CDK inhibitor cell cycle regulatory proteins as well as other proteins that govern the transcription factor activation, apoptosis, and cell trafficking. Its structure consists of two parts: the 20S core and the 19S cap regulatory particle ([Fig. 57.7](#)). The 19S cap is involved in the recognition, binding, and unfolding of ubiquitinated proteins and in the regulation of the opening of the 20S core. The 20S core is a cylinder composed of four stacked heptameric rings, each containing seven different α or β subunits ($\alpha\beta\beta\beta\beta\alpha\beta$; [Figs. 57.7 and 57.8](#)). Three different active sites are located inside the cylindrical core within the β -subunit rings. Proteasome inhibitors target the 20S subunit of the proteasome. At

least three distinct proteolytic activities are associated with the proteasome: chymotryptic, tryptic, and peptidylglutamyl. After release from the substrate, the polyubiquitin chain is hydrolyzed into single ubiquitin moieties, and tagged proteins are degraded to small peptides. Both the assembly of the 26S proteasome and the degradation of protein substrates are ATP dependent. The mechanism leading to cell death after proteasome inhibition are not fully understood, but it is hypothesized that accumulation of incompatible regulatory proteins within the cell, accumulation of misfolded proteins from the ER (“ER stress”) leading to suspension of protein synthesis, and interference with degradation of proteins that inhibit NF κ B, leading to inhibition of NF κ B, are the major contributors to cell death induced by proteasome inhibitors. Synergism between proteasome inhibition and cytotoxic chemotherapy is an area of active research. The activated B-cell subtype of DLBCL (ABC-DLBCL), which has inferior survival after anthracycline-based chemotherapy, is characterized by constitutive activation of the NF κ B pathway, leading to resistance to apoptosis via the mitochondrial pathway through upregulation of NF κ B-regulated genes (including bcl-2, bcl-XL, X-linked inhibitor of apoptosis [XIAP], and survivin). This explains the clinical benefit seen with the addition of bortezomib, the first-in-class proteasome inhibitor to anthracycline-based chemotherapy in ABC-DLBCL.

Transformed cells are much more sensitive to blockade of the proteasome than are normal cells; the exact mechanism of this selective susceptibility is not fully understood. Early studies revealed that proteasomes are abnormally highly expressed in rapidly growing metazoan embryonic and human neoplastic cells, but not in their well-differentiated and normal proliferating cells. The selectivity of proteasome inhibitors is not solely dependent on proliferative status since both transformed and normal fibroblasts have similar growth rates, although proteasome inhibitors are selectively toxic to SV-40–transformed cells.

Mechanisms of Resistance to Proteasome Inhibitors

Initial studies conducted using bortezomib-resistant cell lines identified mutations that affected the shape of the S1 pocket of the B5 subunit of the proteasome that is responsible for chemotrypsin-like activity. However, the clinical relevance of this finding is less certain, as mutations in the B5 subunit have not been identified in myeloma patients who are resistant to proteasome inhibitors. Upregulation of glutathione/oxidative injury defense systems (such as MUC1) was also demonstrated in bortezomib-resistant cell lines. Other mechanisms of proteasome resistance that have been observed in myeloma cell lines and disease models include upregulation of heat-shock proteins (such as heat-shock protein [HSP]90 and HSP27), which function as ubiquitin chaperones facilitating NF κ B signaling and bortezomib efflux from cells through expression of PGP transporter. Gene expression signatures associated with bortezomib sensitivity and resistance have been characterized in cell lines derived from animal models of myeloma, yet the clinical relevance of such signatures awaits confirmation in large clinical trials.

Bortezomib

Bortezomib (pyrazylcarbonyl-Phe-Leu-boronate), the first in this class of agents to enter clinical trials, is a dipeptidyl boronic acid that is a specific and selective inhibitor of the 26S proteasome. The Boron atom interacts reversibly with the catalytic threonine residue of the proteasome, primarily inhibiting its chymotrypsin-like activity. The inhibition of the ubiquitin–proteasome pathway with bortezomib was demonstrated to arrest the growth of malignant cells (breast, colon, prostate tumor cell lines, Burkitt lymphoma, adult T-cell leukemia, Lewis lung carcinoma, CLL, and myeloma cell lines) and sensitize them to chemotherapeutic agents (5-FU, cisplatin, taxol, doxorubicin, CPT-11, and gemcitabine). Bortezomib mediates these effects through multiple mechanisms by regulating the expression of proteins involved

Fig. 57.7 26S PROTEASOME.

Fig. 57.8 CROSS-SECTION OF THE BETA RING OF THE 20S CORE OF THE 26S PROTEASOME.

in cell cycle progression (P21^{cip1}, P27^{Kip1}), oncogenesis (P53, IκB), apoptosis (BCL2, BIRC2, BIRC3, BIRC4, Bax), and, more recently, DNA repair (DNA-PKcs, ATM). Loss of IκB destabilizes NFκB, reducing expression of a critical plasma cell cytokine stimulatory molecule, interleukin (IL)-6 (see [Chapter 86](#)). The process of cell death appears to be p53 independent and to result in mitotic catastrophe, although the classical caspase 8-dependent apoptosis pathway has also been implicated. A recent study found a strong correlation between immunoglobulin production and apoptotic sensitivity to bortezomib, suggesting that the active requirement for protein folding in the ER provides a direct target and explains sensitivity to proteasome inhibition. It also suggests a selective mechanism that could explain the emergence of less differentiated myeloma cells with decreased immunoglobulin production during treatment. These processes also increase oxidative stress and contribute to apoptotic signaling, explaining the sensitivity of myeloma cells to proteasome inhibition.

Preclinical Studies With Bortezomib

Screening of the NCI tumor cell lines revealed that bortezomib is active against a broad range of tumor types. The average growth inhibition of 50% (GI₅₀) across the entire NCI cell panel (60 human-derived cell lines) occurred at 7 nM. Among solid tumor cell lines, those of the prostate, breast, colon, and pancreas were exquisitely sensitive to proteasomal inhibition. PC-3 prostate carcinoma cells, treated with bortezomib, underwent growth arrest in G2-M phase with a parallel increase in P21 levels and decreased activity, but not the levels of CDK-4. Bortezomib treatment also led to caspase activation, PARP cleavage, and apoptotic cell death with an IC₅₀ of 20 nM. Bortezomib exhibited synergistic effects when combined with SN-38 and radiation against colon tumor cells and in mouse xenografts. Similarly, pancreatic tumor xenografts were sensitive to the cytotoxic effect of bortezomib, particularly when combined with gemcitabine or CPT-11. Cytotoxic activity was reported as well against Lewis lung carcinoma cells and nasopharyngeal squamous cell carcinoma cells. In most of these studies, an increase in the cellular levels of P21/WAF1, P27/KIP1, P53, and IκB was observed.

In hematologic malignancies, proteasome inhibitors exhibited cytotoxic activity in a wide range of cell lines, including MM, U937 human monocytic leukemia, HL-60 promyelocytic leukemia, Jurkat T-cell leukemia, K562 CML, Ramos Burkitt lymphoma, and primary B-cell CLL. In MM cells, bortezomib induced p53 and MDM2 protein expression, induced phosphorylation (Ser15) of p53 protein, and activated JUN NH₂-terminal kinase (JNK), which in turn activated caspase 8 and caspase 3. Bortezomib was also shown to activate the intrinsic (mitochondria-cytochrome C [cyt c]-caspase 9) and extrinsic (JNK-death receptor-activated caspase 8) apoptotic pathways of the myeloma cells. Bortezomib blocked tumor necrosis factor (TNF)-induced NFκB activation through inhibition of IκB degradation. TNF-induced intracellular adhesion molecule (ICAM)-1 expression on RPMI8226 and MM.1S cells was also inhibited. The unfolded protein response not only was increased in plasma cells producing large quantities of immunoglobulin, but also induced a stress apoptosis response. Bortezomib also induced osteoblast activity through the Runx2/Cbfa2 pathway. Furthermore, bortezomib inhibited receptor activator of NFκB ligand-induced osteoclastogenesis through inhibition of P38 kinase. Increased osteoblast activity has the potential to restore the osteoporosis associated with MM when used with or without bisphosphonates. Moreover, it prevented the adherence of myeloma cells to BM stromal cells and the NFκB-dependent production of IL-6. Importantly, bortezomib demonstrated synergistic activity with dexamethasone, thalidomide, melphalan, and doxorubicin and did not appear to be a substrate for multidrug-resistance transporters. However, the NFκB blockade could not account for all of the antimyeloma activity of bortezomib, and other mechanisms clearly contribute to its antineoplastic effects. Finally, an IC₅₀ concentration of bortezomib in myeloma cells had no effect on peripheral blood mononuclear cells from healthy volunteers and did not affect cultured BM stromal cells. This did not preclude the observation of myelosuppression during treatment of patients with bortezomib as a single agent.

Pharmacology of Bortezomib

Bortezomib is primarily metabolized through cytochrome P450 (CYP) and not via phase II pathways (e.g., glucuronidation and sulfation). In vitro studies indicated that the primary metabolic pathway was deboronation mediated by CYP3A4. Bortezomib was also metabolized by CYP2D6, but the rate of metabolism was slower than that observed with CYP3A4. The deboronated metabolites have been shown to be inactive in the 20S proteasome assay. Bortezomib rapidly exits the plasma compartment, with more than 90% cleared within 15 minutes of IV administration. In whole-body autoradiography of [¹⁴C] bortezomib-treated rats, the CNS, testes, and eyes appeared to be protected from bortezomib. Bortezomib specifically and selectively inhibits proteasome function by binding tightly (dissociation constant [*K_d*] >0.6 nM) and reversibly to the enzyme's chymotrypsin-like site. In ex vivo 20S proteasome activity bioassays, the proteasome was inhibited within 1 hour of bortezomib administration, and baseline proteasome activity was restored within 48–72 hours. An intermittent but high level of inhibition (>70%) of proteasome activity was better tolerated than sustained inhibition. Thus, a twice-weekly clinical dosing regimen is better tolerated. Nonetheless, this dose schedule is often associated with significant myelosuppression and the onset of peripheral neuropathy. Reducing the dose schedule to a weekly regimen ameliorates these toxicities and appears to increase patient tolerance without jeopardizing clinical efficacy.

Clinical Studies With Bortezomib

Phase II clinical trials (11 years ago) with bortezomib demonstrated the effectiveness of this agent in relapsed/refractory MM were reported. In the SUMMIT study of 202 patients with relapsed MM, 27% of patients achieved a PR or complete response (CR), and median time to progression was 7 months. The FDA approved the drug for use in relapsed/refractory MM in 2003 on the basis of this study. In 2008, the VISTA trial presented evidence demonstrating the superiority of bortezomib plus melphalan and prednisone (VMP) compared to MP alone for patients with newly diagnosed MM, which led to FDA approval for the use of bortezomib combinations as front-line therapy. In the VISTA trial, the median TTP was 24 months for VMP versus 16.6 months with MP. After initial treatment, many patients remain sensitive to bortezomib and can be retreated upon relapse; 63% of patients who responded to initial treatment with bortezomib respond to retreatment, with a median TTP of 9.3 months. Bortezomib is also approved for the treatment of relapsed MCL based on a demonstrated ORR of 33% in the phase II PINNACLE trial. Friedberg et al^{11a} showed that the addition of bendamustine to bortezomib and rituximab (BVR) resulted in an ORR of 83% with a 2-year PFS of 47% in patients with relapsed/refractory MCL. More recently, the results of the phase III LYM-3002 trial were published where 487 adults with MCL ineligible for intensive therapy were randomized to R-CHOP vs VR-CAP (replacing vincristine with bortezomib). The VR-CAP arms had a median PFS of 24 months with a relative improvement of 59% over the R-CHOP arm and 4-year OS was also better (64% vs. 54%).

Second-Generation Proteasome Inhibitors

Carfilzomib: Carfilzomib is a second-generation proteasome inhibitor that selectively inhibits the chymotrypsin-like activity of the proteasome and is active in bortezomib-resistant patients. Carfilzomib induces irreversible inhibition (once carfilzomib binds to its active site within the barrel of the proteasome, the proteasome is permanently inactivated and new proteasomes must be synthesized to restore proteasome activity) compared with the reversible effects of bortezomib (duration of proteasome inhibition lasts about 72 h). Carfilzomib was approved in 2012 for the treatment of patients with myeloma who have received at least two prior therapies. As a monotherapy in phase II studies, carfilzomib induced an ORR of 20% in patients refractory to bortezomib. Carfilzomib appears to be less likely to cause peripheral neuropathy, and is safe in patients with renal impairment. Phase III studies of carfilzomib are ongoing. Higher

response rates are observed when carfilzomib is used in combination with other agents such as lenalidomide and low-dose dexamethasone. The current FDA-approved dose of carfilzomib is 20 mg/m² for cycle 1, and 27 mg/m² for cycle 2. Recent data have shown MTD of carfilzomib is higher; therefore, a phase II study is underway to compare the two different doses of carfilzomib in combination with dexamethasone in a randomized fashion to determine if a higher dose can improve the efficacy while maintaining a safe toxicity profile.

Oprozomib (ONX-0912): Oprozomib is a structural analog of carfilzomib that is orally bioavailable. Oprozomib had demonstrated clinical activity in a phase I trial in patients with hematologic malignancies (myeloma and CLL). A once-daily administered oral dose was introduced in a phase Ib/II trial in order to improve gastrointestinal tolerability, and is demonstrating a good safety profile and promising preliminary response data.

Ixazomib (MLN9708): Ixazomib is a boronic acid-containing peptide with chymotrypsin- and caspase-like proteasome inhibitory activity, formulated for oral administration. Clinical trials, as single agent and in combination with HDAC inhibitors (HDIs), are underway to assess its effects in bortezomib-refractory patients. Early indications suggest that ixazomib may be associated with less neuropathy than bortezomib.

Delanzomib (CEP-18770): Delanzomib is a boronic acid-containing peptide formulated for oral administration. Early indications suggest that delanzomib may be associated with less neuropathy than bortezomib but it was noted to cause rash. A phase II trial of this drug has been terminated due to lack of efficacy in relapsed/refractory myeloma patients.

Marizomib (NPI-0052): Marizomib is a novel nonpeptidic, orally active, irreversibly-binding proteasome inhibitor with broad activity at all three catalytic sites of the proteasome. Since it is not peptide based, marizomib is resistant to degradation by endogenous proteases. It is capable of overcoming bortezomib resistance *in vitro*; clinical trials are underway but are still in early stages. Dose-limiting toxicities in phase I trials have included cognitive changes, transient hallucinations, and loss of balance, which were reversible. The most common drug-related adverse effects included fatigue, gastrointestinal adverse events, dizziness, and headache. There was no evidence of neuropathy or thrombocytopenia. Since marizomib has a different mechanism of action from bortezomib, and a nonoverlapping toxicity profile, combinations of these agents may be evaluated in future studies.

This is a very active area of research; there are over 10 structurally distinct classes of proteasome inhibitors in development, with new agents expected to enter clinical testing in the hopes of finding drugs with optimal potency, reduced toxicity and oral bioavailability. Table 57.2 outlines some of the ongoing clinical trials investigating the combination of second-generation proteasome inhibitors with other agents.

Toxicities of Proteasome Inhibitors

Given their broad application, prolonged exposure, and use in combination with other agents with similar toxicities (especially vinca alkaloids and IMiDs), there has been a considerable effort to characterize and mitigate the side effects of proteasome inhibitors. One of the major motivations for the development of the second-generation agents has been to reduce the occurrence of neuropathy. Unlike IMiDs, proteasome inhibitors, as a class, do not appear to induce chromosomal abnormalities and therefore are not associated with an increased risk for secondary malignancies. Proteasome inhibitors may therefore be safer for long-term use/maintenance therapy than other agents.

(see Table 57.2).

Peripheral Neuropathy

The peripheral neuropathy associated with bortezomib is typically a sensory neuropathy affecting the hands and feet in a “stocking and

glove” distribution, and is frequently painful. Grade ≥ 3 PN occurs in 5%–15% of patients but is reversible in the most cases (in the phase III VISTA trial, 60% of instances of neuropathy showed complete resolution within a median of 5.7 months). The mechanism by which bortezomib produces peripheral neuropathy is unknown, but is hypothesized to be due to aggresome formation and cytoskeletal collapse in dorsal root ganglion sensory neuron axons, alterations in mitochondrial function, or other off-target effects. It is possible that the boron moiety is implicated in the peripheral neuropathy since carfilzomib (which does not contain a boron atom) is much less likely to cause neuropathy than bortezomib. The incidence of peripheral neuropathy with bortezomib is reduced by subcutaneous (SC) administration and weekly dosing. The lower incidence of neuropathy of SC vs. IV administration of bortezomib has been attributed to IV dosing achieving peak serum levels of bortezomib that exceed the threshold that causes peripheral neuropathy, whereas the slower pharmacokinetics of SC administration deliver an effective antimyeloma dose without exceeding the neuropathy threshold.

Hematologic Toxicity

Hematologic adverse events appear to be a class effect associated with proteasome inhibitors; all agents tested so far are associated with thrombocytopenia, neutropenia, anemia, and lymphopenia. Differences in the tendency of the different agents to cause hematologic toxicity remain to be established as newer agents undergo further testing in clinical trials (there is hope that second-generation drugs may have lower rates of hematologic toxicity). Bortezomib, carfilzomib, and ixazomib cause transient, cyclical thrombocytopenia, with platelet counts dropping and then returning to baseline prior to the next cycle of treatment. The exact mechanism of bortezomib-induced thrombocytopenia remains to be fully elucidated. Bortezomib does not appear to adversely affect stem cell function. One hypothesis is that proteasome inhibition with bortezomib prevents the activation of NF κ B, which leads to impairment of platelet budding from megakaryocytes.

Herpes Zoster Reactivation

Bortezomib has been associated with a significantly increased rate of herpes zoster reactivation. In the phase III study of bortezomib plus melphalan and prednisone versus MP alone, zoster reactivation was observed in 13% of patients in the VMP group versus 4% in the MP group. In the subgroup of patients in the VMP group who were receiving antiviral prophylaxis, the rate of zoster reactivation was reduced to 3%. The increased susceptibility to herpes zoster reactivation in patients treated with bortezomib may be due to the effect of bortezomib treatment on the number and function of specific lymphocyte subsets.

Other Toxicities
