Genetic factors play a role in the pathogenesis of WM. Approximately 20% of patients with WM are of Ashkenazi Jewish ethnic background.⁶ Familial disease has been reported commonly, including multigenerational clustering of WM and other B-cell lymphoproliferative diseases.^{7–10} Approximately 20% of 257 sequential patients with WM presenting to a tertiary referral center had a first-degree relative with either WM or another B-cell disorder.⁹ Familial clustering of WM with other immunologic disorders, including hypogammaglobulinemia and hypergammaglobulinemia (particularly polyclonal IgM), autoantibody production (particularly to the thyroid), and manifestation of hyperactive B cells, has also been reported in relatives without WM.^{9,10} Increased expression of the *BCL2* gene with enhanced survival has been observed in B cells from familial patients and their family members.¹⁰

The role of environmental factors is uncertain; however, but chronic antigenic stimulation from infections and certain drug or chemical exposures have been considered but have not reached a level of scientific certainty. Hepatitis C virus (HCV) infection was implicated in WM causality in some series, but no association was found in a study of 100 consecutive patients with WM in whom serologic and molecular diagnostic studies for HCV infection were performed.^{11–13}

PATHOGENESIS

Nature of the WM Clone

Examination of the B-cell clone(s) found in the bone marrow (BM) of patients with WM reveals a range of differentiation, from small lymphocytes with large focal deposits of surface immunoglobulins, to lymphoplasmacytic cells, to mature plasma cells that contain intracytoplasmic IgM (Fig. 87.1).¹⁴ Circulating clonal B cells are often detectable in patients with WM, though lymphocytosis is uncommon.^{15,16} WM cells express the monoclonal IgM, and some clonal cells also express surface IgD.¹⁷ The characteristic immunophenotypic profile of WM lymphoplasmacytic cells includes the expression of the pan-B-cell markers CD19, CD20 (including FMC7), CD22, and CD79.^{17,18} Expression of CD5, CD10, and CD23 can be present in 10% to 20% of cases, and their presence does not exclude the diagnosis of WM.¹⁹ In addition, multiparameter flow cytometric analysis has also identified CD25 and CD27 as being characteristic of the WM clone, and that a CD22^{dim}/CD25⁺/CD27⁺/IgM⁺ population can be observed among clonal B lymphocytes in patients with IgM monoclonal gammopathy of undetermined significance (MGUS) who ultimately progress to WM.²⁰

Somatic mutations in immunoglobulin genes are present with increased frequency of nonsynonymous versus silent mutations in complementarity-determining regions, along with somatic hypermutation, thereby supporting a postgerminal center derivation for the WM B-cell clone in most patients.^{21,22} A strong preferential use of VH3/JH4 gene families without intraclonal variation, and without evidence for any isotype-switched transcripts, has also been shown.^{23,24} Taken together, these data support an IgM⁺ and/or IgM⁺IgD⁺ memory B-cell origin for most cases of WM.

In contrast to myeloma plasma cells, no recurrent translocations have been described in WM, which can help to distinguish IgM myeloma cases that often exhibit t(11;14) translocations from WM.^{25,26} Despite the absence of IgH translocations, recurrent chromosomal abnormalities are present in WM cells. These include deletions in chromosome 6q21–23 in 40% to 60% of patients with WM, with concordant gains in 6p in 41% of patients with 6q deletion.^{27–30} In a series of 174 untreated patients with WM, 6q deletions, followed by trisomy 18, 13q deletions, 17p deletions, trisomy 4, and 11q deletions, were observed.³⁰ Deletion of 6q and trisomy 4 were associated with an adverse prognosis in this series. Because 6q deletions represent the most recurrent cytogenetic finding in WM cases, there has been great interest in identifying the region of minimal deletion and possible target genes within this region. Two putative gene candidates within this region include *TNFAIP3*, a negative regulator of nuclear factor-κB signaling (NFκB), and *PRDM1*, a master regulator of B-cell differentiation.^{29,31} The removal of an NFκB-negative regulator is of particular interest because the phosphorylation and translocation of NFκB into the nucleus is a crucial event for WM cell survival.³² The success of proteasome inhibitor therapy in WM has been postulated to occur because the degradation of negative regulators of NFκB, such as inhibitor of κB (IκB), is blocked.^{33,34}

Fig. 87.1 MARROW FILM FROM A PATIENT WITH WALDENSTRÖM MACROGLOBULINEMIA. Note infiltrate of mature lymphocytes, lymphoplasmacytic cells, and plasma cells. (Used with permission from Marvin J. Stone, MD.)

MUTATION IN MYD88

A highly recurrent somatic mutation (*MYD88*^{L265P}) was first identified in patients with WM by whole genome sequencing (WGS) and confirmed by multiple studies through Sanger sequencing and/or allele-specific polymerase chain reaction (PCR) assays.^{35–40} *MYD88*^{L265P} is expressed in 90% to 95% of WM cases when more sensitive allele-specific PCR is employed using both CD19-sorted and unsorted BM cells.^{36–40} By comparison, *MYD88*^{L265P} was absent in myeloma samples, including IgM myeloma, and was expressed in a small subset (6% to 10%) of patients with marginal zone lymphoma, who surprisingly have WM-related features.^{36–38,41} By PCR assays, 50% to 80% of patients with IgM MGUS also express *MYD88*^{L265P}, and expression of this mutation was associated with increased risk for malignant progression.^{36–38,42} The presence of *MYD88*^{L265P} in patients with IgM MGUS suggests a role for this mutation as an early oncogenic driver, and other mutations and/or copy number alterations leading to abnormal gene expression are likely to promote disease progression.²⁹

The impact of *MYD88*^{L265P} to growth and survival signaling in WM cells has been addressed in several studies (Fig. 87.2). Knockdown of *MYD88* decreased survival of *MYD88*^{L265P}-expressing WM cells, whereas survival was enhanced by knock-in of *MYD88*^{L265P} versus wild-type (WT) *MYD88*.⁴³ The discovery of a mutation in *MYD88*

Fig. 87.2 *MYD88*^{L265P} AND *CXCR4*^{WHIM} MUTATIONS ARE HIGHLY PREVALENT IN PATIENTS WITH WALDENSTRÖM MACROGLOBULINEMIA AND TRIGGER TRANSCRIPTIONAL FACTORS THAT INCLUDE NFκB, AKT, AND ERK THAT SUPPORT THE GROWTH AND SURVIVAL OF LYMPHOPLASMACYTIC CELLS. BTK, Bruton's tyrosine kinase; CXCR4, C-X-C chemokine receptor type 4; ERK, Extracellular signal-regulated kinase; HIVEP2, human immunodeficiency virus type I enhancer binding protein 2; IκBα, nuclear factor of κ light polypeptide gene enhancer in B cells inhibitor α; IKK, inhibitor of nuclear factor-κB kinase; IL1R, interleukin-1 receptor; IRAK, interleukin receptor-associated kinase; MEK, mitogen-activated protein kinase kinase; NEMO, nuclear factor-κB essential modulator; NFκB, nuclear factor-κB; PI3Kδ, phosphoinositide 3-kinase δ; TAK1, transforming growth factor β-activated kinase 1; TIRAP, Toll-interleukin 1 receptor domain-containing adaptor protein; TLR4, Toll-like receptor 4; TNFAIP3, tumor necrosis factor α-induced protein 3; TRAF6, tumor necrosis factor α receptor-associated factor 6; WHIM, warts, hypogammaglobulinemia, infections, and myelokathexis syndrome.

is of significance, given its role as an adaptor molecule in Toll-like receptor (TLR) and interleukin-1 receptor (IL-1R) signaling.⁴⁴ All TLRs except for TLR3 use MYD88 to facilitate their signaling. Following TLR or IL-1R stimulation, MYD88 is recruited to the activated receptor complex as a homodimer, which then complexes with interleukin receptor-associated kinase 4 (IRAK4) and activates IRAK1 and IRAK2.^{45–47} Tumor necrosis factor receptor-associated factor 6 is then activated by IRAK1, leading to NFκB activation via IκBα phosphorylation.⁴⁸ Use of inhibitors of the MYD88 pathway led to decreased IRAK1 and IκBα phosphorylation, as well as to survival of MYD88^{L265P}-expressing WM cells. These observations are of particular relevance to WM because NFκB signaling is important for WM growth and survival.⁴⁹ Bruton's tyrosine kinase (BTK) is also activated by MYD88^{L265P}.⁴³ Activated BTK coimmunoprecipitates with MYD88, which could be abrogated by use of a BTK inhibitor, and overexpression of MYD88^{L265P} but not WT MYD88 triggers BTK activation. Knockdown of MYD88 by lentiviral transfection or use of a MYD88 homodimerization inhibitor also abrogated BTK activation in MYD88^{L265P}-mutated WM cells.

CXCR4 WHIM MUTATIONS

The second most common somatic mutation after MYD88^{L265P} revealed by WGS was found in the C-terminus of the C-X-C chemokine receptor type 4 (CXCR4) receptor. These mutations are present in 30% to 35% of patients with WM, and they impact serine phosphorylation sites that regulate CXCR4 signaling by its only known ligand, SDF-1α (CXCL12).^{29,50–52} The location of somatic mutations found in the C-terminus of CXCR4 in WM are similar to those observed in the germline of patients with WHIM (warts, hypogammaglobulinemia, infections, and myelokathexis) syndrome, a congenital immunodeficiency disorder characterized by chronic noncyclic neutropenia.⁵³ Patients with WHIM syndrome exhibit impaired CXCR4 receptor internalization following SDF-1α stimulation, which results in persistent CXCR4 activation and myelokathexis.⁵⁴

In patients with WM, two classes of CXCR4 mutations occur in the C-terminus. These include nonsense (CXCR4^{WHIM/NS}) mutations that truncate the distal 15- to 20-amino acid region and frameshift (CXCR4^{WHIM/FS}) mutations that comprise a region of up to 40 amino acids in the C-terminal domain.^{29,50} Nonsense and frameshift mutations are almost equally divided among patients with WM with CXCR4 somatic mutations, and over 30 different types of CXCR4^{WHIM} mutations have been identified in patients with WM.^{29,50} Preclinical studies with WM cells engineered to express nonsense and frameshift CXCR4^{WHIM}-mutated receptors have shown enhanced and sustained AKT and extracellular signal-regulated kinase signaling following SDF-1α relative to CXCR4^{WT} (Fig. 87.2), as well as increased cell migration, adhesion, growth, and survival, and also drug resistance of WM cells.^{51,55,56}

Other Somatic Events

Many copy number alterations have been revealed in patients with WM that impact growth and survival pathways. Frequent loss of *HIVEP2* (80%) and *TNAIP3* (50%) genes that are negative regulators of NFκB expression (Fig. 87.2), as well as *LYN* (70%) and *IBTK* (40%) that modulate B-cell receptor signaling have been revealed by WGS.²⁹ WGS has also revealed common defects in chromatin remodeling, with somatic mutations in *ARID1A* present in 17% and loss of *ARID1B* in 70% of patients with WM. Both *ARID1A* and *ARID1B* are members of the SWI/SNF family of proteins, and they are thought to exert their effects via p53 and cyclin-dependent kinase inhibitor 1A regulation. TP53 is mutated in 7% of sequenced WM genomes, whereas *PRDM2* and *TOP1* that participate in TP53-related signaling are deleted in 80% and 60% of patients with WM, respectively.²⁹ Taken together, somatic events that contribute to impaired DNA damage response are also common in WM.

IMPACT OF WM GENOMICS ON CLINICAL PRESENTATION

The importance of MYD88 and CXCR4 mutations in the clinical presentation of patients with WM was recently reported. Significantly higher BM involvement, serum IgM levels, and symptomatic disease requiring therapy, including hyperviscosity syndrome, were observed in those patients with MYD88^{L265P} CXCR4^{WHIM/NS} mutations.⁵⁰ Patients with MYD88^{L265P} CXCR4^{WHIM/FS} or MYD88^{L265P} CXCR4^{WT} had intermediate BM and serum IgM levels; those with MYD88^{WT} CXCR4^{WT} showed the lowest BM disease burden. Fewer patients with MYD88^{L265P} and CXCR4^{WHIM/FS} or NS than with MYD88^{L265P} CXCR4^{WT} presented with adenopathy, further delineating differences in disease tropism based on CXCR4 status. Despite the more aggressive presentation associated with CXCR4^{WHIM/NS} genotype, risk of death was not impacted by CXCR4 mutation status. Risk of death was found to be 10-fold higher in patients with the MYD88^{WT} versus the MYD88^{L265P} genotype.⁵⁰

MARROW MICROENVIRONMENT

In patients with WM, increased numbers of mast cells are found in the BM, where they are usually admixed with tumor cell aggregates (Fig. 87.3).^{14,18,57} The role of mast cells in WM has been investigated in one study in which coculture of primary autologous or mast cell lines with WM lymphoplasmacytic cells resulted in dose-dependent WM cell proliferation and/or tumor colony formation through CD40 ligand (CD40L) signaling.⁵⁷ WM cells release soluble CD27 (sCD27), which may be triggered by cleavage of membrane bound CD27 by matrix metalloproteinase 8.⁵⁸ sCD27 levels are elevated in the serum of patients with WM and follow disease burden in mice engrafted with WM cells, as well as in patients with WM.⁵⁹ sCD27 triggers the upregulation of CD40L as well as a proliferation-inducing ligand on mast cells derived from patients with WM, as well as mast cell lines through its receptor CD70. Modeling in mice treated with a CD70-blocking antibody shows inhibition of tumor cell growth,

(Used with permission from Marvin J. Stone, MD.)

suggesting that WM cells require a microenvironmental support system for their growth and survival.⁶⁰ High levels of CXCR4 and very late antigen-4 (VLA-4) are expressed by WM cells.⁵⁹ In blocking experiment studies, CXCR4 was shown to support migration of WM cells, whereas VLA-4 contributed to adhesion of WM cells to BM stromal cells.⁵⁹

CLINICAL FEATURES

Table 87.1 provides the clinical and laboratory features at the time of diagnosis of patients with WM in one large institutional study.¹⁶

TABLE 87.1

Clinical and Laboratory Findings for 356 Consecutive Newly Diagnosed Patients With Waldenström Macroglobulinemia

	Median	Range	Normal Reference Range
Age (years)	58	32–91	NA
Sex (male/female)	215/141		NA
Marrow involvement (% of area on slide)	30	5–95	NA
Adenopathy (% of patients)	15		NA
Splenomegaly (% of patients)	10		NA
IgM (mg/dL)	2620	270–12,400	40–230
IgG (mg/dL)	674	80–2770	700–1600
IgA (mg/dL)	58	6–438	70–400
Serum viscosity (cp)	2.0	1.1–7.2	1.4–1.9
Hematocrit (%)	35	17–45	35–44
Platelet count ($\times 10^9/L$)	275	42–675	155–410
White cell count ($\times 10^9/L$)	6.4	1.7–22	3.8–9.2

Data from patients seen at the Dana-Farber Cancer Institute, Boston, MA.

Unlike most indolent lymphomas, splenomegaly and lymphadenopathy are uncommon ($\leq 15\%$). Purpura is frequently associated with cryoglobulinemia and in rare circumstances with light-chain (AL) amyloidosis. Hemorrhagic and neuropathic manifestations are multifactorial (see “IgM-Related Neuropathy” section below). The morbidity associated with WM is caused by the co-occurrence of two main components: tissue infiltration by neoplastic cells and, importantly, the physicochemical and immunologic properties of the monoclonal IgM. As shown in Table 87.2, the monoclonal IgM can produce clinical manifestations through several different mechanisms related to its physicochemical properties, nonspecific interactions with other proteins, antibody activity, and tendency to deposit in tissues.^{61–63}

MORBIDITY MEDIATED BY THE EFFECTS OF IGM

Hyperviscosity Syndrome

The increased plasma IgM levels lead to increased blood hyperviscosity and its complications.⁶⁴ The mechanisms behind the marked increase in the resistance to blood flow and the resulting impaired transit through the microcirculatory system are complex.^{64–67} The main determinants are (1) a high concentration of monoclonal IgMs, which may form aggregates and may bind water through their carbohydrate component; and (2) the interaction of IgMs with blood cells. Monoclonal IgM increases red cell aggregation (rouleau formation) and red cell internal viscosity while reducing red cell deformability. The presence of cryoglobulins contributes to increasing blood viscosity, as well as to the tendency to induce erythrocyte aggregation. Serum viscosity is proportional to the IgM concentration up to 30 g/L, then increases sharply at higher levels. Increased plasma viscosity may also contribute to inappropriately low erythropoietin production, which is the major reason for anemia in these patients.⁶⁷ Renal synthesis of erythropoietin is inversely correlated with plasma viscosity. Clinical manifestations are related to circulatory disturbances that can best be appreciated by ophthalmoscopy, which shows distended and tortuous retinal veins, hemorrhages, and papilledema (Fig. 87.4).⁶⁸ Symptoms usually occur when the monoclonal IgM concentration exceeds 50 g/L or when serum viscosity is greater than 4.0 centipoises (cp), but there is individual variability, with some patients showing no evidence of hyperviscosity even at 10 cp.⁶⁴ The most common symptoms are oronasal mucosal bleeding, visual disturbances because of retinal bleeding, and dizziness that

TABLE 87.2

Physicochemical and Immunologic Properties of the Monoclonal Immunoglobulin M Protein in Waldenström Macroglobulinemia

Properties of IgM Monoclonal Protein	Diagnostic Condition	Clinical Manifestations
Pentameric structure	Hyperviscosity	Headaches, blurred vision, epistaxis, retinal hemorrhages, leg cramps, impaired mentation, intracranial hemorrhage
Precipitation on cooling	Cryoglobulinemia (type I)	Raynaud phenomenon, acrocyanosis, ulcers, purpura, cold urticaria
Autoantibody activity to myelin-associated glycoprotein, ganglioside M ₁ , sulfatide moieties on peripheral nerve sheaths	Peripheral neuropathies	Sensorimotor neuropathies, painful neuropathies, ataxic gait, bilateral foot drop
Autoantibody activity to IgG	Cryoglobulinemia (type II)	Purpura, arthralgia, renal failure, sensorimotor neuropathies
Autoantibody activity to red blood cell antigens	Cold agglutinins	Hemolytic anemia, Raynaud phenomenon, acrocyanosis, livedo reticularis
Tissue deposition as amorphous aggregates	Organ dysfunction	Skin: bullous skin disease, papules, Schnitzler syndrome Gastrointestinal: diarrhea, malabsorption, bleeding Kidney: proteinuria, renal failure (light-chain component)
Tissue deposition as amyloid fibrils (light-chain component most commonly)	Organ dysfunction	Fatigue, weight loss, edema, hepatomegaly, macroglossia, organ dysfunction of involved organs (heart, kidney, liver, peripheral sensory and autonomic nerves)

IgM, Immunoglobulin M.

Fig. 87.4 CRYOGLOBULINEMIA MANIFESTING WITH SEVERE ACROCYANOSIS IN A PATIENT WITH WALDENSTRÖM MACROGLOBULINEMIA (A) BEFORE AND (B) FOLLOWING WARMING AND PLASMAPHERESIS.

rarely may lead to stupor or coma. Heart failure can be aggravated, particularly in the elderly, owing to increased blood viscosity, expanded plasma volume, and anemia. Inappropriate red cell transfusions can exacerbate hyperviscosity and may precipitate cardiac failure.

Cryoglobulinemia

The monoclonal IgM can behave as a type I cryoglobulin in up to 20% of patients, and it leads to no symptoms in most cases.^{16,64,69,70} Cryoprecipitation is dependent mainly on the concentration of monoclonal IgM; for this reason, plasmapheresis or plasma exchange is commonly effective in this condition. Symptoms result from impaired blood flow in small vessels and include Raynaud phenomenon; acrocyanosis; necrosis of the regions most exposed to cold, such as the tips of the nose, ears, fingers, and toes (Fig. 87.5); malleolar ulcers; purpura; and cold urticaria. Renal manifestations are infrequent. Mixed cryoglobulins (type II) consisting of IgM-IgG complexes may be associated with HCV infection.⁷⁰

Autoantibody Activity. Monoclonal IgM may exert its pathogenic effects through specific recognition of autologous antigens, the most notable being nerve constituents, immunoglobulin determinants, and red blood cell antigens.

IgM-Related Neuropathy. IgM-related peripheral neuropathy is common in patients with WM, with estimated prevalence rates of 5% to 40%.^{71–73} Approximately 8% of idiopathic neuropathies are associated with a monoclonal gammopathy, with a preponderance of IgM (60%), followed by IgG (30%) and IgA (10%).^{74,75} The nerve damage is mediated by diverse pathogenetic mechanisms: (1) IgM antibody activity toward nerve constituents causing demyelinating

polyneuropathies; (2) endoneurial granulofibrillar deposits of IgM without antibody activity, associated with axonal polyneuropathy; (3) occasionally by tubular deposits in the endoneurium associated with IgM cryoglobulin; and, rarely, (4) amyloid deposits or neoplastic cell infiltration of nerve structures.^{73,76}

Half of the patients with IgM neuropathy have a distinctive clinical syndrome that is associated with antibodies against a minor 100 kDa glycoprotein component of nerve known as the *myelin-associated glycoprotein* (MAG). Anti-MAG antibodies are generally monoclonal IgMκ and usually also exhibit reactivity with other glycoproteins or glycolipids that share antigenic determinants with MAG.^{77–79} The anti-MAG-related neuropathy is typically distal and symmetrical, affecting both motor and sensory functions; it is slowly progressive with a long period of stability.^{72,80} Most patients present with sensory complaints (paresthesias, aching discomfort, dysesthesias, or lancinating pains); imbalance and gait ataxia, owing to lack of proprioception; and leg muscle atrophy in advanced stage. Patients with predominantly demyelinating sensory neuropathy in association with monoclonal IgM to gangliosides with disialosyl moieties, such as GD1b, GD3, GD2, GT1b, and GQ1b, have also been reported.^{81,82} Anti-GD1b and anti-GQ1b antibodies were associated with sensory ataxic neuropathy. These antiganglioside monoclonal IgMs present core clinical features of chronic ataxic neuropathy sometimes associated with ophthalmoplegia and/or red blood cell cold agglutinating activity. The disialosyl epitope is also present on red blood cell glycoporphins, thereby accounting for the red cell cold agglutinin activity of anti-Pr2 specificity.^{83,84} Monoclonal IgM proteins that bind to gangliosides with a terminal trisaccharide moiety, including ganglioside M₂ and GalNac-GD1A, are associated with chronic demyelinating neuropathy and severe sensory ataxia, unresponsive to glucocorticoids.⁸⁵ Antiganglioside IgM proteins may also cross-react with lipopolysaccharides of *Campylobacter jejuni*, an infection known to precipitate the Miller Fisher syndrome, a variant of Guillain-Barré

Fig. 87.5 MARROW CLOT SECTION. (A) Tryptase-staining mast cells surrounding a nodule of lymphoplasmacytic cells in a patient with Waldenström macroglobulinemia. (B) Mast cells in the same section exhibit strong CD40 ligand signaling, which has been shown to support (at least in part) the growth and survival of lymphoplasmacytic cells.

syndrome.⁸⁶ Thus molecular mimicry may play a role in this condition. Antisulfatide monoclonal IgM proteins, associated with sensory-sensorimotor neuropathy, have been detected in 5% of patients with IgM monoclonal gammopathy and neuropathy.⁸⁷ Motor neuron disease has been reported in patients with WM and monoclonal IgM with anti-GM₁ and sulfoglucuronyl paralogloboside activity.⁸⁸ Polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes (the POEMS syndrome) are rare in patients with WM.⁸⁹

Cold Agglutinin Hemolytic Anemia. Monoclonal IgMs may have cold agglutinin activity; they recognize specific red cell antigens at temperatures below 37°C, producing a chronic hemolytic anemia. This disorder occurs in less than 10% of patients with WM and is associated with cold agglutinin titers greater than 1:1000 in most cases.⁹⁰ The monoclonal component is usually an IgMκ and reacts most commonly with red cell I/i antigens, resulting in complement fixation and activation.^{91,92} Mild to moderate chronic hemolytic anemia can be exacerbated after cold exposure. Hemoglobin levels usually remain above 70 g/L. The hemolysis is usually extravascular, mediated by removal of C3b opsonized red cells by the mononuclear phagocytes, primarily in the liver. Intravascular hemolysis from complement destruction of red blood cell membrane is infrequent. The agglutination of red cells in the skin circulation also causes Raynaud syndrome, acrocyanosis, and livedo reticularis. Macroglobulins with the properties of both cryoglobulins and cold agglutinins with anti-Pr specificity can occur. These properties may have as a common basis the binding of the sialic acid-containing carbohydrate present on red blood cell glycoproteins and on Ig molecules. Several other macroglobulins with antibody activity toward autologous antigens (e.g., phospholipids, tissue and plasma proteins), and foreign ligands have also been described.

IgM Tissue Deposition. The monoclonal IgM can deposit in several tissues as amorphous aggregates. Linear deposition of monoclonal IgM along the skin basement membrane is associated with bullous skin disease.⁹³ Amorphous IgM deposits in the dermis result in IgM storage papules on the extensor surface of the extremities, referred to as *macroglobulinemia cutis*.⁹⁴ Deposition of monoclonal IgM in the lamina propria and/or submucosa of the intestine may be associated with diarrhea, malabsorption, and gastrointestinal bleeding.^{95,96} Kidney involvement is less common and less severe in WM than in myeloma, probably because the amount of light chain that is excreted in the urine is generally less in WM than in myeloma and because of the absence of contributing factors, such as hypercalcemia.

Urinary cast nephropathy, however, has occurred in WM.⁹⁷ On the other hand, the IgM macromolecule is more susceptible to being trapped in the glomerular loops, where ultrafiltration presumably contributes to its precipitation, forming subendothelial deposits of aggregated IgM proteins that occlude the glomerular capillaries.⁹⁸ Mild and reversible proteinuria may result, and most patients are asymptomatic. The deposition of monoclonal light chain as fibrillar amyloid deposits (AL amyloidosis) is uncommon in patients with WM.⁹⁹ The clinical manifestations and prognosis are similar to those of other patients with AL amyloidosis, with involvement occurring in the heart (44%), kidneys (32%), liver (14%), lungs (10%), peripheral or autonomic nerves (38%), and soft tissues (18%). The incidence of cardiac and pulmonary involvement is higher in patients with monoclonal IgM than in those with other immunoglobulin isotypes. The association of WM with reactive amyloidosis has been documented rarely.^{100,101} Simultaneous occurrence of fibrillary glomerulopathy, characterized by glomerular deposits of wide nonconglomerular fibrils and amyloid deposits, has been described.¹⁰²

Manifestations Related to Tissue Infiltration by Neoplastic Cells

Tissue infiltration by neoplastic cells is uncommon but can involve various organs and tissues, including the liver, spleen, lymph nodes, lungs, gastrointestinal tract, kidneys, skin, eyes, and central nervous system.

Lung. Pulmonary involvement in the form of masses, nodules, diffuse infiltrate, or pleural effusions is uncommon; the overall incidence of pulmonary and pleural findings is approximately 4%.^{103–105} Cough is the most common presenting symptom, followed by dyspnea and chest pain. Chest radiographic findings include parenchymal infiltrates, confluent masses, and effusions.

Gastrointestinal Tract. Malabsorption, diarrhea, bleeding, or obstruction may indicate involvement of the gastrointestinal tract at the level of the stomach, duodenum, or small intestine.^{106–109}

Renal System. In contrast to myeloma, infiltration of the kidney interstitium with lymphoplasmacytoid cell can occur in WM, and renal or perirenal masses are not uncommon.^{110,111}

Skin. The skin can be the site of dense lymphoplasmacytic infiltrates, similar to those seen in the liver, spleen, and lymph nodes, forming cutaneous plaques and, rarely, nodules.¹¹² Chronic urticaria and IgM

gammopathy are the two cardinal features of the Schnitzler syndrome, which is not usually associated initially with clinical features of WM, although evolution to WM is not uncommon.¹¹³ Thus close follow-up of such patients is important.

Joints. Invasion of articular and periarticular structures by WM malignant cells is rarely reported.¹¹⁴

Eye. The neoplastic cells can infiltrate the periorbital structures, lacrimal gland, and retroorbital lymphoid tissues, resulting in ocular nerve palsies.^{115,116}

Central Nervous System. Direct infiltration of the central nervous system by monoclonal lymphoplasmacytic cells as infiltrates or as tumors constitutes the rarely observed Bing-Neel syndrome, characterized clinically by confusion, memory loss, disorientation, and motor dysfunction (reviewed by Civit et al.¹¹⁷).

LABORATORY FINDINGS

Blood Abnormalities

Anemia is the most common finding in patients with symptomatic WM and is caused by a combination of factors: decrease in red cell survival, impaired erythropoiesis, moderate plasma volume expansion, hepcidin production leading to an iron reuse defect, and blood loss from the gastrointestinal tract.^{16,118,119} Blood films are usually normocytic and normochromic, and rouleau formation is often pronounced. Mean red cell volume may be elevated spuriously owing to erythrocyte aggregation. In addition, the hemoglobin estimate can be inaccurate (i.e., falsely high) because of interaction between the monoclonal protein and the diluent used in some automated analyzers.¹²⁰ Leukocyte and platelet counts are usually within their reference ranges at presentation, although patients may occasionally present with severe thrombocytopenia. Monoclonal B lymphocytes expressing surface IgM and late-differentiation B-cell markers are uncommonly detected in blood by flow cytometry. A raised erythrocyte sedimentation rate is almost always present and may be the first clue to the presence of macroglobulinemia. The clotting abnormality detected most frequently is prolongation of thrombin time. AL amyloidosis should be suspected in all patients with nephrotic syndrome, cardiomyopathy, hepatomegaly, or peripheral neuropathy. Diagnosis requires the demonstration of green birefringence under polarized light of amyloid deposits stained with Congo red.

MARROW FINDINGS

Central to the diagnosis of WM is the demonstration, by trephine biopsy, of marrow infiltration by a lymphoplasmacytic cell population characterized by small lymphocytes with evidence of plasmacytoid and plasma cell maturation (Fig. 87.1).^{1,14} The pattern of marrow infiltration may be diffuse, interstitial, or nodular, usually with an intertrabecular pattern of infiltration. A solely paratrabecular pattern of infiltration is unusual and should raise the possibility of follicular lymphoma.¹ The marrow cell immunophenotype should be confirmed by flow cytometry and/or immunohistochemistry. The cell immunoprofile sIgM⁺CD19⁺CD20⁺CD22⁺CD79⁺ is characteristic of WM.^{14,120,121} Up to 20% of cases may express either CD5, CD10, or CD23.¹⁹ In these cases, chronic lymphocytic leukemia and mantle cell lymphoma should be excluded. “Intranuclear” periodic acid-Schiff–positive inclusions (Dutcher-Fahey bodies)¹²² consisting of IgM deposits in the perinuclear space, and sometimes in intranuclear vacuoles, may be seen occasionally in lymphoid cells. An increased number of mast cells, usually in association with the lymphoid aggregates, is commonly found, and their presence may help in differentiating WM from other B-cell lymphomas (see Fig. 87.3).¹⁴ *MYD88*^{L265P} testing of BM samples has been incorporated

into many clinical laboratories and may help in clarifying the diagnosis of WM from other IgM-secreting entities.^{35–39} The use of peripheral blood B cells may also permit determination of *MYD88*^{L265P} status by allele-specific PCR assays, particularly in untreated patients with WM.

IMMUNOLOGIC ABNORMALITIES

High-resolution electrophoresis combined with immunofixation of serum and urine is recommended for identification and characterization of the IgM monoclonal protein. The light chain of the monoclonal IgM is κ in 75% to 80% of patients. More than one M component may be present. The concentration of the serum monoclonal protein is very variable, but in most cases it lies within the range of 15–45 g/L. Densitometry should be adopted to determine IgM levels for serial evaluations because nephelometry is unreliable and shows large laboratory variation. The presence of cold agglutinins or cryoglobulins may affect determination of IgM levels, and therefore testing for cold agglutinins and cryoglobulins should be performed at diagnosis. If present, subsequent serum samples should be analyzed at 37°C for determination of serum monoclonal IgM level. Although Bence Jones proteinuria is frequently present, it exceeds 1 g/24 h in only 3% of cases. Whereas IgM levels are elevated in patients with WM, IgA and IgG levels are most often depressed and do not recover after successful treatment.¹²³

SERUM VISCOSITY

Because of their large size (molecular weight almost 1 million), most IgM molecules are retained within the intravascular compartment and can exert an undue effect on serum viscosity.⁶⁴ Serum viscosity can be measured if the patient has signs or symptoms of hyperviscosity syndrome, though levels are often slow to be reported and erratic owing to a lack of standardization in most clinical laboratories.¹⁶ As such, serum IgM levels may be more expedient and relied upon. Patients typically become symptomatic at serum viscosity levels of 4.0 cp and above, which relate to serum IgM levels above 6000 mg/dL.^{124,125} Patients may be symptomatic at lower serum viscosity and IgM levels, and in these patients cryoglobulins may be present. Recurring nosebleeds, headaches, and visual disturbances are common symptoms in patients with symptomatic hyperviscosity.¹⁶ Funduscopy is an important indicator of clinically relevant hyperviscosity. Among the first clinical signs of hyperviscosity are the appearance of peripheral and midperipheral dot- and blotlike hemorrhages in the retina, which are best appreciated with indirect ophthalmoscopy and scleral depression.⁶⁸ In more severe cases of hyperviscosity, dot, blot, and flame-shaped hemorrhages can appear in the macular area along with markedly dilated and tortuous veins with focal constrictions resulting in “venous sausaging,” as well as papilledema (Fig. 87.4).

IMAGING

Magnetic resonance imaging (MRI) of the spine in conjunction with computed tomography (CT) of the abdomen and pelvis are useful in evaluating disease status.¹²⁶ Marrow involvement can be documented by MRI studies of the spine in more than 90% of patients; CT of the abdomen and pelvis demonstrates enlarged nodes in approximately 20% of patients with WM at diagnosis, but this proportion may be higher at relapse.¹²⁶

LYMPH NODE BIOPSY

Lymph node biopsy may show preserved architecture or replacement by infiltration of neoplastic cells with lymphoplasmacytoid, lymphoplasmacytic, or polymorphous cytologic patterns.

TREATMENT

Initiating Treatment

As part of the Second International Workshop on Waldenström's Macroglobulinemia, a consensus panel was organized to recommend criteria for the initiation of therapy in patients with WM.¹²⁷ The panel recommended that initiation of therapy should not be based on the IgM level per se, because this may not correlate with the clinical manifestations of WM. The consensus panel did, however, agree that initiation of therapy is appropriate for patients with constitutional symptoms, such as recurrent fever, night sweats, fatigue as a consequence of anemia, or weight loss. Progressive symptomatic lymphadenopathy and/or splenomegaly provide additional reasons to begin therapy. Anemia with a hemoglobin value ≤ 10 g/dL or a platelet count $\leq 100 \times 10^9$ /L owing to marrow infiltration also justifies treatment. Certain complications, such as hyperviscosity syndrome, symptomatic sensorimotor peripheral neuropathy, systemic amyloidosis, renal insufficiency, or symptomatic cryoglobulinemia, may also be indications for therapy.^{16,127}

Initial Therapy

The International Workshops on Waldenström's Macroglobulinemia have also formulated consensus recommendations for both initial therapy and therapy for refractory disease based on the best available evidence. The most recent recommendations emerged from the Seventh International Workshop on Waldenström's Macroglobulinemia.¹²⁸ Individual patient considerations, including the presence of cytopenias, need for more rapid disease control, age, and candidacy for autologous transplant therapy, should be taken into account in making the choice of the drugs to use. For patients who are candidates for autologous stem cell transplant (SCT), which typically is reserved for those patients younger than 70 years of age, the panel recommended that exposure to alkylating agents or nucleoside analogues should be limited. The use of nucleoside analogues should be approached cautiously in patients with WM because there appears to be an increased risk for the development of disease transformation as well as myelodysplasia and acute myelogenous leukemia.

Oral Alkylating Agents. Oral alkylating drugs, alone and in combination therapy with glucocorticoids, have been evaluated extensively in the treatment of WM. Chlorambucil has been administered on both a continuous (i.e., daily dose schedule) and an intermittent schedule. Patients receiving chlorambucil on a continuous schedule typically receive 0.1 mg/kg per day, whereas on the intermittent schedule patients typically receive 0.3 mg/kg for 7 days, every 6 weeks. In a prospective, randomized study, no significant difference in the overall response rate (ORR) between these schedules was observed,¹²⁹ although the median response duration was greater for patients receiving intermittent- versus continuous-dose chlorambucil (46 vs. 26 months). Despite the favorable median response duration in this study for use of the intermittent schedule, no difference in the median overall survival was observed. Moreover, an increased incidence for development of myelodysplasia and acute myelogenous leukemia with the intermittent (3 of 22 patients) versus the continuous (0 of 24 patients) chlorambucil schedule prompted the preference for use of continuous chlorambucil dosing. The use of glucocorticoids in combination with alkylating agent therapy has also been explored. Chlorambucil (8 mg/m²) plus prednisone (40 mg/m²) given orally for 10 days, every 6 weeks, resulted in a major response (i.e., reduction of IgM by more than 50%) in 72% of patients.¹³⁰ Alkylating agent regimens employing melphalan and cyclophosphamide in combination with glucocorticoids have also been examined.^{131,132} This approach produced slightly higher ORRs and response durations, although the benefit of these more complex regimens over chlorambucil remains to be demonstrated. Pretreatment factors associated with shorter survival in the entire population of patients receiving single-agent chlorambucil were older than 60 years of age,

male sex, hemoglobin less than 10 g/dL, leukocytes less than 4×10^9 /L, and platelets less than 150×10^9 /L. Organomegaly, signs of hyperviscosity, renal failure, monoclonal IgM level, blood lymphocytosis, and percentage of marrow lymphoid cells were not significantly correlated with survival.¹³³ Additional factors to be taken into account in considering alkylating agent therapy for patients with WM include necessity for more rapid disease control, given the slow response, as well as consideration for preserving stem cells in patients who are candidates for autologous SCT. A large randomized study showed an inferior response rate and time to progression in patients with WM receiving chlorambucil versus fludarabine, as well as a higher incidence of secondary malignancies in the former. Neutropenia was more pronounced, however, in those patients on fludarabine.¹³⁴

Nucleoside Analogue Therapy. Cladribine administered as a single agent by continuous intravenous infusion, by 2-hour daily infusion, or by subcutaneous bolus injections for 5–7 days has resulted in major responses in 40% to 90% of patients who received primary therapy, whereas in the previously treated patients, responses have ranged from 38% to 54%.^{135–141} Median time to achievement of response in responding patients following cladribine ranged from 1.2 to 5 months. The ORR with daily infusion of fludarabine, administered mainly on 5-day schedules, in previously untreated and treated patients ranged from 38% to 100% and from 30% to 40%, respectively,^{142–147} similar to the responses to cladribine. Median time to achievement of response for fludarabine (3–6 months) was also similar to cladribine. In general, response rates and durations of responses have been greater for patients receiving nucleoside analogues as initial therapy, although no difference in the ORR was reported in several studies in which both untreated and previously treated patients were enrolled.

Myelosuppression commonly occurs following prolonged exposure to either of the nucleoside analogues. A sustained decrease in both CD4⁺ and CD8⁺ T lymphocytes, measured 1 year following initiation of therapy, is notable.^{135–137} Treatment-related mortality as a consequence of myelosuppression and/or opportunistic infections attributable to immunosuppression occurred in up to 5% of all treated patients in some series with nucleoside analogues.

Factors predicting a better response to nucleoside analogues include younger age at start of treatment (<70 years), higher pretreatment hemoglobin (>95 g/L), higher platelet count ($>75 \times 10^9$ /L), disease relapsing off-therapy, and a long interval between firstline therapy and initiation of a nucleoside analogue in relapsing patients.^{135,140,146} There are limited data on the use of an alternate nucleoside analogue in previously treated patients in whom disease relapsed or who had resistance when not on cladribine or fludarabine therapy.^{148,149} Three (75%) of 4 patients responded to cladribine after progression following an unmaintained remission with fludarabine, whereas only 1 (10%) of 10 with disease resistant to fludarabine responded to cladribine.¹⁴⁸ A response to fludarabine has been reported in two (33%) of six patients and disease stabilization in the remaining patients, in spite of an inadequate response or progressive disease, following cladribine therapy.¹⁴⁹

Harvesting autologous blood stem cells succeeded on the first attempt in 14 of 15 patients who did not receive nucleoside analogue therapy, as compared with 2 of 6 patients who received a nucleoside analogue.¹⁵⁰ A sevenfold increase in patients transforming to an aggressive lymphoma and a threefold increase in the development of myelodysplasia or acute myelogenous leukemia were observed among patients who received a nucleoside analogue versus other therapies for their WM.¹⁵¹ A meta-analysis of several trials in which patients with WM were treated with nucleoside analogues included patients who had previously received an alkylating agent, and the results showed a crude incidence of approximately 8% of developing a disease transformation event and approximately 5% for developing myelodysplasia or acute myelogenous leukemia.¹⁵² None of the risk factors—that is, sex, age, family history of WM, or B-cell malignancies, typical markers of tumor burden and prognosis, type of nucleoside analogue therapy (cladribine vs. fludarabine), time from diagnosis to nucleoside analogue use, nucleoside analogue treatment as primary

or salvage therapy, or treatment with an oral alkylator (i.e., chlorambucil)—predicted the occurrence of transformation or development of myelodysplasia or acute myelogenous leukemia in patients treated with a nucleoside analogue.¹⁵²

CD20-Directed Antibody Therapy. Rituximab is a chimeric monoclonal antibody that targets CD20, a widely expressed antigen on lymphoplasmacytic cells in WM.¹⁵³ Several retrospective and prospective studies have indicated that rituximab, when used at standard doses (i.e., 4 weekly infusions of 375 mg/m²/week) induced major responses in approximately 30% of previously treated and untreated patients.^{154,155} Even patients who achieved minor responses benefited from rituximab by improved hemoglobin and platelet counts, as well as reduction of lymphadenopathy and/or splenomegaly.¹⁵⁴ The median time to treatment failure in these studies was found to range from 8 to 27+ months. Patients on an extended rituximab schedule consisting of 4 weekly courses at 375 mg/m² per week, repeated 3 months later by another 4-week course have demonstrated major response rates of approximately 45%, with time to progression estimates of 16+ to 29+ months.^{156,157}

In many patients with WM, a transient increase or flare of the serum IgM may occur immediately following initiation of rituximab treatment.^{156,158,159} Such an increase does not herald treatment failure, and most patients will return to their baseline serum IgM level by 12 weeks. Some patients continue to show a prolonged increase in IgM despite an apparent reduction in their marrow tumor cells. However, patients with baseline serum IgM levels >50 g/dL or serum viscosity >3.5 cp may be particularly at risk for a hyperviscosity-related event, and plasmapheresis should be considered in these patients in advance of rituximab therapy.¹⁵⁸ Because of the decreased likelihood of response in patients with higher IgM levels, as well as the possibility that serum IgM and blood viscosity levels may abruptly rise, rituximab monotherapy should not be used as sole therapy for the treatment of patients at risk for hyperviscosity symptoms.^{128,156,157}

Time to response after rituximab is slow and exceeds 3 months on average. The time to best response in one study was 18 months.¹⁵⁷ Patients with baseline serum IgM levels <60 g/dL are more likely to respond, regardless of the underlying degree of marrow involvement by tumor cells.^{156,157} An analysis of 52 patients who were treated with single-agent rituximab found the objective response rate was significantly lower in patients who had either low serum albumin (<35 g/L) or a serum monoclonal protein greater than 40 g/L.¹⁶⁰ The presence of both adverse prognostic factors was associated with a short time to progression (3.6 months). Patients who had normal serum albumin and relatively low serum monoclonal protein levels derived a substantial benefit from rituximab, with a time to progression exceeding 40 months.

A correlation between polymorphisms at position 158 in the FcγRIIIa receptor (CD16), an activating Fc receptor on important effector cells that mediate antibody-dependent, cell-mediated cytotoxicity, and rituximab response was observed in patients with WM.¹⁶¹ Individuals may encode either the amino acid valine or phenylalanine at position 158 in the FcγRIIIa receptor. Patients with WM who carried the valine amino acid (either in a homozygous or heterozygous pattern) had a fourfold higher major response rate (i.e., 50% decline in serum IgM levels) to rituximab versus those patients who expressed phenylalanine in a homozygous pattern.

Proteasome Inhibitors. Both bortezomib and carfilzomib have been evaluated in prospective studies in patients with WM, though the latter only in combination therapy (discussed below). In a retrospective study, 10 patients with refractory or relapsed WM were treated with bortezomib administered intravenously at a dose of 1.3 mg/m² on days 1, 4, 8, and 11 in a 21-day cycle for a total of four cycles. Most patients had been exposed to all other active agents for WM, and eight patients had received three or more regimens. Six of these patients achieved a partial response that occurred after a median of 1 month. The median time to progression in the responding patients is expected to exceed 11 months. Peripheral neuropathy occurred in three patients, and one patient developed severe paralytic ileus.¹⁶² In

a prospective study including 27 relapsed or refractory patients who received up to 8 cycles of bortezomib at 1.3 mg/m² on days 1, 4, 8, and 11, median serum IgM levels declined significantly, from 4.7 g/dL to 2.1 g/dL.³³ The ORR was 85%, with 10 and 13 patients achieving a minor (<25%) and major (<50%) decrease in IgM level, respectively. Responses occurred after a median of 1.4 months. The median time to progression for all responding patients in this study was 7.9 (range, 3–21.4+) months, and the most common grade III/IV toxicities were sensory neuropathies (22.2%), leukopenia (18.5%), neutropenia (14.8%), dizziness (11.1%), and thrombocytopenia (7.4%). Sensory neuropathies resolved or improved in nearly all patients following cessation of therapy. Twenty-seven patients with both untreated (44%) and previously treated (56%) disease received bortezomib, using the standard schedule until they either demonstrated progressive disease or two cycles beyond a complete response or stable disease.¹⁶³ The ORR was 78%, with major responses observed in 44% of patients. Sensory neuropathy occurred in 20 patients following two to four cycles of therapy. Among the 20 patients who developed a neuropathy, 14 showed resolution or improvement 2–13 months after therapy.

Combination Therapies. Because rituximab is not myelosuppressive, its use in combination with chemotherapy has been explored. A regimen of rituximab, cladribine, and cyclophosphamide in 17 previously untreated patients resulted in a partial response in 94% of patients with WM, including a complete response in 18%.¹⁶⁴ No patient had relapsed with a median follow-up of 21 months. The combination of rituximab and fludarabine was used in 43 patients, of whom 32 (75%) were previously untreated, which led to an ORR of 95.3%, with 83% of patients achieving a major response (i.e., 50% reduction in disease burden).¹⁶⁵ The median time to progression was 51.2 months in this series, and it was longer for those patients who were previously untreated and for those achieving a very good partial remission (i.e., 90% reduction in disease) or better. Hematologic toxicity was common: Grade 3 neutropenia and thrombocytopenia were observed in 27 and 4 patients, respectively. Two deaths occurred in this study as a result of pneumonia. Secondary malignancies, including transformation to aggressive lymphoma and development of myelodysplasia or acute myelogenous leukemia, were observed in six patients. The addition of rituximab to fludarabine and cyclophosphamide has also been explored in previously treated patients, and four of five patients had a response.¹⁶⁶ In another combination study, rituximab along with pentostatin and cyclophosphamide given to 13 patients with untreated and previously treated WM or LPL resulted in a major response in 77% of patients.¹⁶⁷ The combination of rituximab, dexamethasone, and cyclophosphamide was used as primary therapy to treat 72 patients with WM, among whom a major response was observed in 74% of patients, and the 2-year progression-free survival was 67%.¹⁶⁸ Therapy was well tolerated, although one patient died as a result of interstitial pneumonia.

Two studies have examined cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) therapy in combination with rituximab (R-CHOP). In a randomized trial involving 69 patients, most of whom had WM, the addition of rituximab to CHOP resulted in a higher ORR (94% vs. 67%) and median time to progression (63 vs. 22 months) in comparison to patients treated with CHOP alone.¹⁶⁹ R-CHOP was also used in 13 patients with WM, 10 of whom had relapsed or refractory disease.¹⁷⁰ Among 13 evaluable patients, 10 patients achieved a major response (77%), including 3 complete and 7 partial remissions. Two other patients achieved a minor response. Patients in a retrospective study of symptomatic WM received either R-CHOP; rituximab, cyclophosphamide, vincristine, and prednisone (R-CVP); or cyclophosphamide, prednisone, and rituximab (R-CP). The patients were similar in most pretreatment variables, and the ORRs to therapy were comparable among all three treatment groups—R-CHOP (96%), R-CVP (88%), and R-CP (95%)—although there was a trend for more complete remissions among patients treated with R-CVP and R-CHOP.¹⁷¹ Adverse events attributed to therapy showed a higher incidence for neutropenic fever and treatment-related neuropathy for R-CHOP and R-CVP versus

R-CP. The results of this study suggest that in patients with WM, the use of R-CP may provide treatment responses analogous to those of more intense cyclophosphamide-based regimens while minimizing treatment-related complications. The extended alkylator bendamustine has also been evaluated in combination with rituximab in both untreated and previously treated patients with WM. A randomized study by the German STiL Group examined bendamustine plus rituximab (Benda-R) versus R-CHOP in patients with untreated, indolent B-cell lymphomas including WM.¹⁷² Patients with WM in this study showed similar overall responses (96% vs. 94%), though progression-free survival was significantly longer (69 vs. 29 months) in patients who received Benda-R versus R-CHOP. Treatment was also better tolerated in patients receiving Benda-R. In the relapsed or refractory setting, an ORR of 83% was observed with bendamustine in combination with a CD20 monoclonal antibody.¹⁷³ The median time to progression was 13 months in this study. Prolonged myelosuppression was more common in patients who had received prior nucleoside analogue therapy.

The use of two cycles of oral cyclophosphamide along with subcutaneous cladribine to 37 patients with previously untreated WM led to a partial response in 84% of patients, and the median duration of response was 36 months.¹⁶⁴ Fludarabine in combination with intravenous cyclophosphamide resulted in partial responses in 6 (55%) of 11 patients with WM with either primary refractory disease or who had relapsed on treatment.¹⁷⁴ The combination of fludarabine plus cyclophosphamide was also evaluated in 49 patients, 35 of whom were previously treated. Seventy-eight percent of the patients achieved a response, and the median time to treatment failure was 27 months.¹⁷⁵ Hematologic toxicity was frequent, and three patients died as a result of treatment-related toxicities. Two important findings in this study were the development of acute leukemia in two patients, histologic transformation to diffuse large B-cell lymphoma in one patient, and two cases of solid malignancies (prostate and melanoma), as well as failure to mobilize stem cells in four of six patients.

The combination of bortezomib, dexamethasone, and rituximab (BDR) as primary therapy in patients with WM resulted in an ORR of 96% and a major response rate of 83%.¹⁷⁶ The incidence of grade 3 neuropathy was approximately 30%, but this was reversible in most patients following discontinuation of therapy. An increased incidence of herpes zoster was also observed, prompting the prophylactic use of antiviral therapy. Alternative schedules for administration of bortezomib (i.e., once weekly at higher doses) in combination with rituximab in patients with WM have achieved ORRs of 80% to 90%.^{177,178} The European Myeloma Network recently showed that transitioning bortezomib from twice-weekly intravenous dosing during the first cycle to weekly administration thereafter reduced grade 3 neuropathy to under 10% in patients treated with BDR.¹⁷⁹ There have been no studies addressing the safety and efficacy of subcutaneous bortezomib use in WM.

Carfilzomib, which is associated with a low risk of treatment-related peripheral neuropathy, has been evaluated in combination with rituximab and dexamethasone in patients with WM.³⁴ Carfilzomib was administered intravenously at 20 mg/m² (cycle 1), then 36 mg/m² (cycles 2–6), together with dexamethasone (20 mg) on days 1, 2, 8, and 9 as part of a 21-day cycle. As part of this regimen, rituximab 375 mg/m² was given on days 2 and 9 every 21 days. Maintenance therapy was given 8 weeks following induction therapy with intravenous carfilzomib (36 mg/m²) and dexamethasone (20 mg) administered on days 1 and 2 and with rituximab 375 mg/m² on day 2 every 8 weeks for up to 8 cycles. The ORR with this regimen was 87.1% (1 complete response, 10 very good partial responses, 10 partial responses, and 6 minimal responses) and was not impacted by *MYD88*^{L265P} or *CXCR4*^{WT/WT} mutation status. With a median follow-up of 15.4 months, 20 patients remained progression-free. Grade ≥2 toxicities included asymptomatic hyperlipasemia (41.9%), reversible neutropenia (12.9%), and cardiomyopathy in 1 patient (3.2%) with multiple risk factors. Grade 2 treatment-related neuropathy occurred in one patient (3.2%). Declines in serum IgA and IgG were common, and some patients required intravenous immunoglobulin therapy for recurring sinus and bronchial infections.

Novel Therapeutics. The use of ibrutinib was recently approved by the U.S. Food and Drug Administration for the treatment of symptomatic patients with WM. Ibrutinib targets BTK, a target of ibrutinib that is activated by *MYD88*^{L265P}.⁴³ In a multicenter study in which researchers examined the role of ibrutinib in previously treated (median 2 prior therapies, 40% refractory) patients with WM, the ORR was 87%.¹⁸⁰ Patients on this study received 420 mg per day of ibrutinib by mouth. Posttherapy median serum IgM levels declined from 3610 to 915 mg/dL; hemoglobin rose from 10.5 to 13.5 g/dL; and BM involvement declined from 60% to 30%. Decreased or resolved adenopathy was observed in 60% of patients with extramedullary disease, and five of nine patients with IgM-related peripheral neuropathy had symptomatic improvement. The 18-month estimates for progression-free and overall survival were 83% and 93%, respectively. Although major response rates were lower in patients with *MYD88*^{wild-type} and *CXCR4*^{WT/WT} mutations, it is not recommended that genotyping be used to select which patients should be placed on ibrutinib until further data are available. Grade ≥2 treatment-related toxicities included neutropenia (25%) and thrombocytopenia (14%) that were more common in heavily pretreated patients, atrial fibrillation associated with a prior history of arrhythmia (5%), and bleeding associated with procedures and marine oil supplements (3%). Serum IgA and IgG levels were unchanged following treatment with ibrutinib, and treatment-related infections were infrequent.

Everolimus is an oral inhibitor of the mammalian target of rapamycin (mTOR) pathway that is active in WM. In a multicenter study, investigators examined everolimus in 60 previously treated patients and showed an ORR of 73%, with 50% of patients attaining a major response.¹⁸¹ The median progression-free survival in this study was 21 months. Grade 3 or higher related toxicities were observed in 67% of patients, with cytopenias constituting the most common toxicity. Pulmonary toxicity occurred in 5% of patients, and dose reductions owing to toxicity occurred in 52% of patients. In a clinical trial in which researchers examined the activity of everolimus in 33 previously untreated patients with WM, serial BM biopsies were included in response assessment.¹⁸² The ORR in this study was 72%, including partial or better responses in 60% of patients. However, discordance between serum IgM levels upon which consensus criteria for response are based and BM disease response was common, which complicated response assessment. In a few patients, discontinuation of everolimus led to rapid increases in serum IgM levels and symptomatic hyperviscosity. Grade ≥2 hematologic and nonhematologic toxicities in this study that were related to everolimus were predominately hematological, including anemia (40%), thrombocytopenia (12%), and neutropenia (18%). Nonhematologic toxicities included oral ulcerations (27%) that improved with oral dexamethasone swish and spit solution, as well as pneumonitis (15%), the latter leading to treatment discontinuation.

Maintenance Therapy. The outcome of rituximab-naïve patients who were either observed or received maintenance rituximab categorical responses was examined in a large retrospective study.¹⁸³ Categorical responses improved after induction therapy in 42% of patients who received maintenance rituximab versus 10% in patients in the observation group. Additionally, both progression-free (56.3 vs. 28.6 months) and overall (>120 vs. 116 months) survival were longer in patients who received maintenance rituximab. Improved progression-free survival was evident despite previous treatment status, induction with rituximab alone, or in combination therapy. Best serum IgM response was also lower, and hematocrit higher, in those patients who received maintenance rituximab. Among patients who received maintenance rituximab therapy, an increased number of infectious events, predominantly grade 1 or 2 sinusitis and bronchitis, was observed, along with lower serum IgA and IgG levels. A prospective study examining the role of maintenance rituximab has also been initiated by the German STiL Group.¹⁸⁴ In this study, patients received up to six cycles of bendamustine and rituximab, and responders were randomized to either observation or maintenance rituximab every 2 months for 2 years. Enrollment for this study is complete, and response outcome for maintenance rituximab therapy is awaited.

High-Dose Therapy and Stem Cell Transplant

The European Bone Marrow Transplant Registry (EBMT) reported the largest experience for both autologous as well as allogeneic SCT in WM.^{185,186} Among 158 patients with WM receiving an autologous SCT, which included primarily relapsed or refractory patients, the 5-year progression-free and overall survival rates were 39.7% and 68.5%, respectively.¹⁸⁵ Nonrelapse mortality at 1 year was 3.8%. Chemorefractory disease and the number of prior lines of therapy at the time of the autologous SCT were the most important prognostic factors for progression-free and overall survival. In the allogeneic SCT experience from the EBMT, the long-term outcomes of 86 patients with WM were reported.¹⁸⁶ A total of 86 patients received an allograft following either myeloablative or reduced-intensity conditioning. The median age of patients in this series was 49 years, and 47 patients had undergone three or more previous lines of therapy. Eight patients failed prior autologous SCT. Fifty-nine patients (68.6%) had chemotherapy-sensitive disease at the time of allogeneic SCT. Non-relapse mortality rates at 3 years were 33% for patients receiving a myeloablative transplant and 23% for those who received reduced-intensity conditioning. The ORR was 75.6%. The relapse rates at 3 years were 11% for myeloablative and 25% for reduced-intensity conditioning recipients. Five-year progression-free and overall survival for patients with WM who received a myeloablative allogeneic SCT were 56% and 62%, respectively, and for patients who received reduced intensity conditioning, the rates were 49% and 64%, respectively. The occurrence of chronic graft-versus-host disease was associated with improved progression-free survival and suggested the existence of a clinically relevant graft-versus-WM effect in this study.

Response Criteria in Waldenström Macroglobulinemia

Table 87.3 summarizes the response categories and criteria for progressive disease in WM based on the most recent consensus recommendations.¹⁸⁷ The term *overall response* is used to characterize all responses, including minor responses. *Major responses* include partial, very good partial, and complete responses. The attainment of very good partial or complete responses is associated with improved

progression-free survival.^{155,165,176,179,188} Response assessments in WM rely primarily on serum IgM or IgM paraprotein levels, though complete responses require disappearance of the IgM monoclonal protein, and resolution of evidence of BM and/or extramedullary disease.¹⁸⁷ An important concern with the use of IgM as a surrogate marker of disease is that it can fluctuate independent of tumor cell killing with some agents. By way of example, rituximab can induce a flare in serum IgM levels, whereas everolimus, bortezomib, and ibrutinib can suppress IgM levels independent of tumor cell killing in some patients, a phenomenon referred to as *IgM discordance*.^{158,159,162,181,183,189} Moreover, with selective B cell-depleting agents such as rituximab and alemtuzumab, residual IgM-producing plasma cells are spared and persist, thus potentially skewing the relative response and assessment to treatment.¹⁹⁰ Soluble CD27 levels have been investigated as an alternative surrogate marker in WM, given their correlation with WM disease burden, and may remain a faithful marker of disease in patients experiencing a rituximab-related IgM flare, as well as after plasmapheresis.^{60,191} The use of quantitative allele-specific PCR assays to assess serial MYD88^{L265P} burden in patients with WM is also under investigation.^{36,38}

Course and Prognosis

WM typically presents as an indolent disease. The presence of 6q deletions may have prognostic significance, although this is disputed.^{20,21} Age is an important prognostic factor (>65 years),^{192–194} but it is influenced by comorbidities. Anemia that reflects both marrow involvement and the serum level of the IgM monoclonal protein (because of the impact of IgM on intravascular fluid retention) has emerged as a strong adverse prognostic factor with hemoglobin levels of <9 to 12 g/dL associated with decreased survival in several series.^{192–194} Other cytopenias also may be significant predictors of survival.¹⁹³ The precise level of cytopenias with prognostic significance has not been determined. Some series have identified a platelet count of <100 to 150 × 10⁹/L and a granulocyte count of <1.5 × 10⁹/L as independent prognostic factors.^{193,194} The number of cytopenias in a given patient has been proposed as a prognostic factor.¹⁹³ Serum albumin levels also correlate with survival in patients

TABLE 87.3 Summary of Consensus Response Criteria for Waldenström Macroglobulinemia¹⁸⁷

Response Type	Abbreviation	Criteria
Complete response	CR	Absence of serum monoclonal IgM protein by immunofixation Normal serum IgM level Complete resolution of extramedullary disease (i.e., lymphadenopathy/splenomegaly if present at baseline) Morphologically normal bone marrow aspirate and trephine biopsy
Very good partial response	VGPR	Monoclonal IgM protein is detectable 90% reduction in serum IgM level from baseline or normalization of serum IgM level Complete resolution of extramedullary disease (i.e., lymphadenopathy/splenomegaly if present at baseline) No new signs or symptoms of active disease
Partial response	PR	Monoclonal IgM protein is detectable ≥50% but <90% reduction in serum IgM level from baseline Reduction in extramedullary disease (i.e., lymphadenopathy/splenomegaly if present at baseline) No new signs or symptoms of active disease
Minor response	MR	Monoclonal IgM protein is detectable ≥25% but <50% reduction in serum IgM level from baseline No new signs or symptoms of active disease
Stable disease	SD	Monoclonal IgM protein is detectable <25% reduction and <25% increase in serum IgM level from baseline No progression in extramedullary disease (i.e., lymphadenopathy/splenomegaly) No new signs or symptoms of active disease
Progressive disease	PD	>25% increase in serum IgM level from lowest nadir (requires confirmation) and/or progression in clinical features attributable to the disease

IgM, Immunoglobulin M.

TABLE 87.4 Prognostic Scoring Systems in Waldenström Macroglobulinemia

Study	Adverse Prognostic Factors	Number of Groups	Survival
Gobbi et al. ¹⁹²	Hgb <9 g/dL Age >70 years Weight loss Cryoglobulinemia	0–1 prognostic factors 2–4 prognostic factors	Median: 48 months Median: 80 months
Morel et al. ¹⁹³	Age ≥65 years Albumin <4 g/dL Number of cytopenias: Hgb <12 g/dL Platelets <150 × 10 ⁹ /L WBC <4 × 10 ⁹ /L	0–1 prognostic factors 2 prognostic factors 3–4 prognostic factors	5-year: 87% of patients 5-year: 62% 5-year: 25%
Dhodapkar et al. ¹⁹⁴	β ₂ M ≥3 g/dL Hgb <12 g/dL IgM <4 g/dL	β ₂ M <3 mg/dL + Hgb ≥12 g/dL β ₂ M <3 mg/dL + Hgb <12 g/dL β ₂ M ≥3 mg/dL + IgM ≥4 g/dL β ₂ M ≥3 mg/dL + IgM <4 g/dL	5-year: 87% of patients 5-year: 63% 5-year: 53% 5-year: 21%
Dimopoulos et al. ¹⁹⁵	Albumin ≤3.5 g/dL β ₂ M ≥3.5 mg/L	Albumin ≥3.5 g/dL + β ₂ M <3.5 mg/dL Albumin ≤3.5 g/dL + β ₂ M <3.5 or β ₂ M 3.5–5.5 mg/dL β ₂ M >5.5 mg/dL	Median: NR Median: 116 months Median: 54 months
Morel et al. ¹⁹⁷	Age >65 years Hgb <11.5 g/dL Platelets <100 × 10 ⁹ /L β ₂ M >3 mg/L IgM >7 g/dL	0–1 prognostic factors (excluding age) 2 prognostic factors (or age >65 years) 3–5 prognostic factors	5 year: 87% of patients 5 year: 68% 5 year: 36%

β₂M, β₂-microglobulin; Hgb, hemoglobin; IgM, immunoglobulin M; NR, not reported; WBC, white blood cell count.

with WM in some studies, using multivariate analyses.^{193,195} Elevated serum β₂-microglobulin levels (>3–3.5 g/dL) have also been shown to have strong prognostic correlation in WM.^{193–196} Several scoring systems have been proposed that are based on these analyses (Table 87.4), including the International Prognostic Scoring System for Waldenström macroglobulinemia (IPSSWM), which incorporates five adverse covariates: advanced age (>65 years), hemoglobin ≤11.5 g/dL, platelet count ≤100 × 10⁹/L, β₂-microglobulin >3 mg/L, and serum monoclonal protein concentration >7.0 g/dL.¹⁹⁷ Among 537 patients with WM evaluated in the development of IPSSWM, low-risk patients (27%) presented with no or one of the adverse characteristics and advanced age; intermediate-risk patients (38%) presented with two adverse characteristics or only advanced age; and high-risk patients (35%) presented with more than two adverse characteristics. Five-year survival rates for these three patient groups were 87%, 68%, and 36%, respectively. Importantly, the IPSS WM retained its prognostic significance in subgroups defined by age and treatment with alkylating agent and nucleoside analogues. Recent data from the Surveillance, Epidemiology, and End Results (SEER) database involving 7744 patients with WM showed that the relative survival of patients with WM has improved over time. Patients diagnosed during 2001–2010 had higher 5-year (78% vs. 67%) and 10-year (66% vs. 49%) relative survival rates versus patients diagnosed during 1980–2000. A Greek study that included 345 patients with WM failed to show any overall or cause-specific survival improvement in recent years, though the study might have been underpowered to detect any expected benefit.¹⁹⁶ A Swedish study of 1555 patients diagnosed with WM between 1980 and 2005 showed that the 5-year relative survival rate improved from 57% in 1980–1985 to 78% in 2001–2005.¹⁹⁸

IMMUNOGLOBULIN LIGHT CHAIN AMYLOIDOSIS (PRIMARY AMYLOIDOSIS)

Morie A. Gertz, Francis K. Buadi, Martha Q. Lacy, and Suzanne R. Hayman

Amyloidosis is defined as the clinical syndrome associated with deposition of amyloid. Amyloid in tissue is defined by its tinctorial properties of a homogeneous, eosinophilic, hyaline material when viewed by hematoxylin and eosin staining. Amyloid stains specifically with Congo red, demonstrating a deep pink amorphous composition. Although Congo red staining is the *sine qua non* for the diagnosis of amyloid, many pathology laboratories prefer the use of sulfated Alcian blue or crystal violet for screening. A second requirement is that the Congo red–positive histologic finding must demonstrate apple-green birefringence when observed under polarized light.

The term *amyloid* is a misnomer. The term was first used in 1838 by a German botanist because the tissue stained blue with iodine and was incorrectly thought to be starch-like, thus the terminology *amyloid*. In Vienna, Rokitsansky believed that the material was not starch but rather of lipid composition and used the term *lardaceous degeneration* for amyloid. Both were incorrect because all forms of amyloid appear to be protein-derived.

By electron microscopy, amyloid has been shown to be fibrillar in origin with an approximate diameter of 9.5 nm and as being linear nonbranching and comprised of protofilaments (Fig. 88.1). The Congo red binding occurs because the protein misfolds from the physiologic configuration of the α -helix into a β -pleated sheet, which is directly responsible for its insolubility and resistance to proteolysis. Amyloid is highly resistant to solubilization unless it is subjected to the harshest denaturation conditions. This insolubility in physiologic solution likely contributes to amyloid's ability to disrupt normal organ function and leads to the clinical disease amyloidosis, the clinical syndrome associated with deposition of amyloid.

EPIDEMIOLOGY

The incidence of immunoglobulin light-chain amyloidosis is estimated to be approximately 8 per 1 million per year. It is the cause of death in 0.58 of 1000 recorded deaths and is responsible for 0.8% of end-stage renal disease. At Mayo Clinic, amyloid light-chain (AL) amyloidosis represents 9% of all patients seen with monoclonal gammopathies. AL amyloidosis represents 60% of all patients seen with amyloidosis. However, hereditary amyloidosis now accounts for 10% of patients, localized amyloidosis 8.5% of patients, senile systemic amyloidosis 18% of patients, and secondary amyloidosis 2.5% of patients. All these forms of amyloidosis have the same tinctorial properties in histologic section and must be distinguished using other techniques.

The cause of the plasma cell dyscrasia that underlies light-chain amyloidosis remains unknown. There does not appear to be a linkage to any specific occupation or toxic chemical exposure. No environmental agents have been linked to the development of amyloidosis. However, the Veterans Administration in the United States considers amyloidosis in a veteran who was exposed to Agent Orange during the Vietnam era to have a service-connected illness.

Amyloidosis may be systemic or localized. The localized forms generally do not require any systemic chemotherapy. The distinction is, therefore, important so that patients for whom chemotherapy will not benefit are not inappropriately subjected to this form of therapy. Localized amyloidosis can be suspected, usually based on the location

of the deposits, as discussed in the “Clinical Manifestations” section below.

Familial amyloidosis is, for most patients, caused by an inherited mutation of transthyretin (TTR). It is difficult to distinguish from light-chain amyloidosis because the clinical manifestations may be quite similar. Other inherited forms of amyloidosis have been associated with apolipoprotein A1 mutations, fibrinogen A α mutations, and mutations of gelsolin.

Secondary systemic amyloidosis is amyloidosis that is usually a consequence of a sustained inflammatory process. The frequency of symptomatic secondary systemic amyloidosis has been in sharp decline for the past decade. Previously, secondary systemic amyloidosis was a consequence of an uncontrolled inflammatory process, typically inflammatory polyarthropathies such as juvenile rheumatoid arthritis, psoriatic arthritis, or ankylosing spondylitis. Another cause was long-standing inflammatory bowel disease. Amyloidosis as a consequence of these inflammatory processes has fallen sharply with the introduction of biologic agents that function as inhibitors of interleukin-1, interleukin-6, and inhibitors of tumor necrosis factor α (TNF- α). The ability to control these sustained inflammatory processes has resulted in the sharp decline in the recognition of secondary systemic amyloidosis. Sporadic patients are seen with multiple cutaneous abscesses, usually as a result of subcutaneous injection of contaminated narcotics. Patients can also be seen with chronic infections related to paraplegia or quadriplegia. Rare patients with lifelong bronchiectasis related to cystic fibrosis can develop systemic amyloidosis. There are also forms of inherited secondary amyloidosis associated with familial inflammatory syndromes such as familial Mediterranean fever or mutations of the TNF receptor gene (so-called TNF receptor–associated periodic syndrome).

PATHOBIOLOGY OF THE DISEASE

In immunoglobulin light-chain amyloidosis, the immunoglobulin fragments have specific thermodynamic instability that causes them to misfold into the insoluble amyloid configuration. The injection of immunoglobulin light chains purified from the urine of patients with multiple myeloma will not produce amyloid when injected into mice. However, when the light chains are extracted from the urine of patients with light-chain amyloidosis and injected into mice, it will produce amyloid deposits and organ dysfunction, suggesting that the specifics of the immunoglobulin light chain are important in determining its propensity to misfold into amyloid. Monoclonal immunoglobulin light chains can be converted in vitro to amyloid by in vitro digestion with pepsin. Historically, before it was clearly understood that amyloidosis was derived from a plasma cell dyscrasia with the development of “toxic” immunoglobulin light chains, the term *primary amyloidosis* was used as a consequence of the lack of understanding of the pathophysiology. This term should be abandoned, and the term *immunoglobulin light-chain amyloidosis* or *AL amyloidosis* (amyloid light chain) should be used. Many forms of localized amyloidosis are also derived from immunoglobulin light chains, but there is no evidence of a systemic plasma cell dyscrasia, and systemic therapy is contraindicated. Virtually all patients with systemic AL amyloidosis have a demonstrable clonal plasma cell disorder. In

Fig. 88.1 ELECTRON MICROGRAPH DEMONSTRATING THE CLASSIC FIBRILS OF AMYLOID.

Fig. 88.2 DISTRIBUTION OF HEAVY- AND LIGHT-CHAIN PROTEINS IN MYELOMA, MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE, AND AMYLOID LIGHT-CHAIN AMYLOIDOSIS. *AL*, Amyloid light chain; *Ig*, Immunoglobulin; *MGUS*, monoclonal gammopathy of undetermined significance.

monoclonal gammopathy of undetermined significance (MGUS) and multiple myeloma, two-thirds of the immunoglobulin light chains are κ type. In AL amyloidosis, nearly three-fourths of the light chains are of λ origin (Fig. 88.2), suggesting that there is a greater propensity for λ light chains to misfold into amyloid configuration. The λ_6 subgroup of light chains is exclusively associated with amyloid deposition. There are also abnormalities in amyloid-associated germline gene use. A preferential use of variable lambda (VL) germline genes is noted for AL κ and AL λ patients. There is a significant correlation between the use of V λ_6 germline, 6a, and renal involvement as well as the λ_3 gene, 3r, with soft tissue AL. Identification of the clonal VL gene in AL has important implications regarding clinical outcome.

Chromosomal aberrations of the plasma cells in amyloidosis have also been recognized. Interphase fluorescence in situ hybridization (FISH) has detected a gain of 1q21, predicting a poor overall survival, and is an independent prognostic factor. Patients with t(11;14) have a longer median overall survival. Deletion 13q14 and hyperdiploidy are prognostically neutral.

The pathobiology of organ dysfunction associated with amyloidosis has long been assumed to be caused by the direct effect of amyloid protein deposition in tissues. However, there is increasing evidence that the light chains themselves have a toxic effect on tissues as a soluble mediator. A zebrafish model of human light-chain cardiotoxicity has demonstrated that injection of light chains results in impaired cardiac function, pericardial edema, and increased cell death. Mitogen-activated protein (MAP) kinase activation may mediate this cardiotoxicity, and p38 MAP kinase inhibition reduces cell death and improves cardiac function.

Amyloidosis and multiple myeloma both share the presence in the bone marrow of a clonal population of plasma cells. The number of plasma cells and the immunoglobulin light chains that they produce are both important for prognosis. Patients who have an increased number of plasma cells in the bone marrow with light-chain amyloidosis have a worse prognosis and a shorter overall survival, regardless of whether they manifest any of the clinical criteria associated with multiple myeloma, such as hypercalcemia, renal insufficiency, anemia, or destructive bone lesions. There appears to be no survival difference between patients who have an elevated plasma cell count in their bone marrow and whether they have overt symptoms of myeloma. The therapeutic import of this finding is still being investigated.

CLINICAL MANIFESTATIONS

Patient 1

Patient 1 is a 46-year-old man who, 10 months prior to diagnosis, began to develop cramping abdominal pain associated with an unexplained 45-lb weight loss. Four months later, he began to develop episodes of orthostatic syncope and was documented to have an orthostatic drop in blood pressure from systolic 110 mmHg in supine to 66 mmHg when standing. As a consequence of his abdominal cramping, the patient underwent endoscopy and colonoscopy. Biopsies were obtained from the duodenum, proximal jejunum, colon, and rectum, all of which demonstrated amyloid deposits. Subsequently, a bone marrow biopsy was performed that showed 4% clonal plasma cells. A subcutaneous fat aspirate was positive for amyloid. The plasma cells showed a CCND1/IgH fusion t(11;14). The patient's hemoglobin level was normal, as were his creatinine, alkaline phosphatase, and urinary protein. The patient had a λ free light chain level of 92.8 mg/L, κ free light chain of 10.9 mg/L, and a ratio of 0.12.

Comment on Patient 1

This patient presented with amyloid autonomic neuropathy, leading to gastrointestinal (GI) tract dysmotility and pain as well as orthostatic hypotension. There was clear-cut evidence of a low-grade plasma cell dyscrasia. Orthostatic hypotension causing lightheadedness is a very nonspecific complaint, and syncope owing to amyloid orthostatic hypotension is easily overlooked because of its infrequency.

Patient 2

A 61-year-old man with a known immunoglobulin G λ MGUS of 0.6 mg/dL was monitored on an annual basis with no change in the level of the monoclonal protein over a period of 3 years. He developed progressive fatigue and shortness of breath. He was evaluated by a cardiologist, and his echocardiogram showed thickening that was interpreted to be related to hypertension, with a normal ejection

fraction. The patient was placed on lisinopril and did not improve. He returned and underwent catheterization with coronary angiography. His coronary arteries were normal, and he was diagnosed with deconditioning. His dyspnea continued, and he was referred to a pulmonologist, who recognized the long-standing monoclonal gammopathy and obtained light chain studies that showed a λ light chain of 41 mg/dL and κ of 10 mg/dL. The patient underwent a subcutaneous fat aspiration that demonstrated amyloid deposits, which, by mass spectroscopy, were found to be of λ origin. At this point, the patient had New York Heart Association class IV heart failure; he died within 3 months thereafter.

Comment on Patient 2

This case is an example of a classic failure to recognize that patients with monoclonal gammopathies should have amyloidosis included in the differential diagnosis. The fact that the monoclonal protein was stable would certainly argue against the development of multiple myeloma, but light-chain amyloidosis regularly occurs without any change in the M component over time. The failure to recognize the patient's progressive fatigue and shortness of breath as cardiac amyloid is not unusual. The echocardiographic findings of thickening were interpreted as being caused by hypertension, but, in fact, they were caused by infiltrative cardiomyopathy, and the cardiac catheterization and angiogram without an endomyocardial biopsy led to a missed diagnosis. Only an increased index of suspicion in patients with a known monoclonal protein allowed this diagnosis to be confirmed.

One of the major difficulties in the diagnosis of amyloidosis is that there is virtually no blood test or imaging study that is diagnostic of the disease. The most common symptoms associated with amyloidosis are fatigue, lower extremity edema (may be cardiac or renal), unexplained weight loss (often leading to search for occult malignancy), exertional dyspnea, orthostatic hypotension, and paresthesias. These symptoms are quite vague, and in a general medical practice, there are hundreds of disorders that are far more common and are responsible for light-chain amyloidosis. As noticed in Patient 2, the fatigue, which is often caused by early cardiac amyloid but is not associated with overt congestive heart failure, can be missed. Cardiac amyloidosis is a classic form of heart failure with preserved ejection fraction owing to the restrictive physiology associated with amyloidosis.

Edema in amyloidosis may be a manifestation of high right-sided filling pressures, leading to lower extremity edema, or it may be a consequence of renal involvement with the nephrotic syndrome (peripheral edema, hypoalbuminemia, hyperlipidemia, and proteinuria). Even when nephrotic range proteinuria is seen, amyloidosis, which is known to cause nephrotic syndrome in 10% of adults who are nondiabetic, is infrequently considered in the differential diagnosis, which would include minimal change glomerulopathy, as well as membranous and membranoproliferative glomerulopathy.

The physical findings that are known to be associated with light-chain amyloidosis include enlargement of the tongue (15%) (Fig. 88.3) and periorbital purpura (12%). These findings are highly specific when recognized. However, although they are highly specific, they lack sensitivity because nearly 80% of patients with amyloidosis lack both of these physical features. It is common for an enlarged tongue in amyloid to be misdiagnosed as suspect glossal cancer or a manifestation of acromegaly. Many patients with significant tongue enlargement needlessly undergo a painful and often hemorrhagic tongue biopsy, which could be avoided if the diagnosis was considered. Patients with enlargement of the tongue frequently have major indentations on the underside of their tongue from their teeth and from the continuous pressure that the tongue exerts against their lower jaw. The purpura is also quite specific, and the patient often will note the development of purpura simply by rubbing of the eyelids. However, these patients often undergo an evaluation for a coagulation disorder or are simply reassured that purpura is benign, and the physical findings do not trigger an investigation for light-chain amyloidosis (Fig. 88.4).

Fig. 88.3 ENLARGED TONGUE INFILTRATED BY AMYLOID DEPOSITS.

Fig. 88.4 CLASSIC AMYLOID PURPURA.

Hepatomegaly is seen in approximately 10% of patients with amyloidosis, but it is nonspecific, and imaging of the liver will show homogeneous enlargement without filling defects. Occasionally, patients will have widespread vascular amyloid that will result in claudication of the calf, buttock, upper extremities, and jaw. Occasionally, these patients will undergo temporal artery biopsy, which, when appropriately stained, will show amyloid. More often, these patients will be given an empiric diagnosis of polymyalgia rheumatica

and be placed on corticosteroids without appropriate screening. The rarest physical finding in amyloidosis is periarticular infiltration of the synovium in the upper extremities, leading to the “shoulder pad” sign. This causes a continuous, chronic, low-grade pain caused by the periarticular infiltration. Diagnosis in this setting requires arthrocentesis and the demonstration of Congo red–positive deposits in the synovial fluid.

LABORATORY MANIFESTATIONS

If the symptoms of amyloidosis are so vague as not to be helpful and the physical findings are specific but not sensitive, when should a clinician suspect amyloidosis and aggressively pursue this rare disorder? Amyloidosis should be considered in any patient who presents with (1) nephrotic range proteinuria; (2) fatigue, which may have a cardiac basis, including heart failure with preserved ejection fraction or restrictive cardiomyopathy; (3) unexplained hepatomegaly; (4) a peripheral neuropathy resembling chronic inflammatory demyelinating polyneuropathy (CIDP); and (5) “atypical” multiple myeloma or MGUS with unexplained fatigue, weight loss, and edema. Consulting patients with any one of these five syndromes should lead to the placement of light-chain amyloid in the differential diagnosis, and screening should commence.

Because all patients with systemic immunoglobulin light-chain amyloidosis have a plasma cell dyscrasia, the initial step should be screening by performing immunofixation of the serum, immunofixation of the urine, and an immunoglobulin free light-chain assay. Results of one of these three tests will be abnormal in 99% of patients with light-chain amyloidosis. If results of these three tests are negative, the likelihood is that one of the following conditions exists: (1) The patient does not have amyloidosis; (2) the chance of immunoglobulin light-chain amyloidosis is only 1%; (3) the patient has systemic amyloidosis, but it is not of immunoglobulin light-chain origin (familial amyloid or senile systemic amyloid); or (4) the amyloidosis is localized.

Alternatively, if a patient with nephrotic range proteinuria has a monoclonal protein or an abnormal free light-chain ratio, the diagnosis, which often includes minimal change glomerulopathy and membranoproliferative glomerulopathy, suddenly shifts to either (1) myeloma cast nephropathy, (2) immunoglobulin light-chain amyloidosis of the kidney (Fig. 88.5), or (3) κ light-chain deposition disease of the kidney. In this situation, a kidney biopsy could be avoided by doing less invasive diagnostic testing.

In a patient with fatigue, weight loss, or dyspnea on exertion, the finding of an immunoglobulin abnormality raises the suspicion of amyloid. Evaluation can be redirected to include echocardiography

with the specific inclusion of Doppler studies that accurately measure the restricted filling that occurs with amyloid infiltration (stiff heart syndrome). It may also include magnetic resonance imaging of the heart, which can show distinct endomyocardial enhancement following gadolinium injection, as well as myocardial nulling, which is specific for light-chain amyloidosis.

A patient with unexplained hepatomegaly who has a monoclonal protein can often avoid a liver biopsy, which rarely is associated with bleeding and occasionally with hepatic rupture. Fat aspiration is positive in over 75% of patients with hepatic amyloidosis.

In a patient with peripheral neuropathy who is found to have a monoclonal protein, consideration of amyloidosis in the differential diagnosis can prevent interventions such as plasma exchange or intravenous immunoglobulin infusions, which are ineffective in patients with light-chain amyloidosis but are often attempted in patients who have a monoclonal gammopathy and a peripheral neuropathy (presumed CIDP) if amyloidosis is not considered in the differential diagnosis.

All patients with MGUS need to be monitored for life for the development of myeloma and amyloidosis. Over 25 years, approximately 25% of patients will go on to develop a more serious plasma cell dyscrasia. In 21%, this represents multiple myeloma, but 4% of patients with MGUS will develop light-chain amyloidosis during the course of observation. If screening is limited to detection of changes consistent with multiple myeloma, such as anemia, bone pain, and hypercalcemia, amyloidosis will be overlooked because all three of these findings are unusual in light-chain amyloidosis. Patient 2, described above, was being followed by a hematologist for a monoclonal gammopathy, and when he developed fatigue in the absence of progressive anemia, amyloidosis was not considered.

Any patient with one of the five compatible clinical syndromes listed in Table 88.1 should be screened for monoclonal protein. If a monoclonal protein is not found, the likelihood of light-chain amyloidosis is very small. However, if a monoclonal gammopathy exists with an appropriate clinical syndrome, histologic demonstration of amyloid should be sought.

In patients who have renal, cardiac, hepatic, and peripheral nerve amyloid, biopsy of the affected organs has a very high sensitivity of demonstrating amyloid. However, these biopsies are not required if amyloid is considered in the differential diagnosis.

The first diagnostic studies that should be performed in patients with a compatible clinical syndrome and an immunoglobulin light-chain abnormality are a subcutaneous fat aspirate and a bone marrow biopsy. Subcutaneous fat aspirate in an experienced laboratory will demonstrate amyloid deposits in 75% of patients tested (Fig. 88.6). In a patient with light-chain amyloidosis, staining of the bone marrow biopsy for amyloid deposition in blood vessels is positive in 50%. A second advantage of the bone marrow biopsy is it provides the percentage of plasma cells in the bone marrow, which is prognostic and is an essential evaluation in patients with immunoglobulin light-chain abnormalities. When combining the subcutaneous fat aspirate and the bone marrow biopsy, nearly 85% of patients with light-chain amyloidosis will be identified. For the remaining 15%, direct biopsy of the involved organ would be indicated if the index of suspicion for light-chain amyloidosis remained high. Other centers have

reported success with biopsies of the minor submandibular salivary gland, skin biopsies, and endoscopic biopsies of the stomach. These procedures would be best undertaken in laboratories where there is extensive experience in the processing and staining of amyloid tissues.

Once amyloid has been demonstrated in histologic sections, it is imperative that the amyloid be typed to ensure it is of immunoglobulin light-chain origin because of the critical therapeutic implications. Although immunoglobulin light-chain amyloidosis is always associated with a monoclonal gammopathy, it is important to recognize that monoclonal gammopathies are common in the elderly population. On screening, 3% of adult patients over the age of 50 will have a monoclonal protein, and 5% of those over the age of 80 will have a monoclonal protein. Therefore, it is possible to have a positive biopsy for amyloid and a coincidental monoclonal protein when the amyloid itself is unrelated to immunoglobulin light-chain amyloidosis. Thus, when a pathologist reports amyloid-laden tissue, the task will not be complete until the specific type of amyloid is identified (Table 88.2). Historically immunohistochemistry was used to classify amyloid. This technique is being used less. First, the type of amyloid can be identified only if the appropriate antibodies are used. In patients with amyloid deposition, it would be very challenging to diagnose dialysis-related amyloid (β_2 -microglobulin type), insulin-type amyloid (found at the sites of insulin injection in diabetics), keratin amyloid (seen in skin biopsies), or TTR amyloid (seen in senile systemic amyloid). Most laboratories are not equipped with such a broad panel of antibodies. Second, even when light-chain amyloidosis exists, the use of anti- κ and anti- λ antibodies frequently will not be able to identify the type of amyloid in tissue section. There are two widely held hypotheses for this lack of sensitivity of immunohistochemistry in AL amyloidosis.

The first hypothesis is a reflection of the immunoglobulin in amyloid deposits. The light chain in amyloid is usually not the intact immunoglobulin light chain but usually represents a fragment. The average AL is approximately 12 kDa, approximately half the molecular weight of an intact immunoglobulin light chain. In most of these proteins, the constant portion of the light chain has been deleted. Most commercial antisera used in immunohistochemistry recognize the constant portion of the immunoglobulin light chain and, therefore, have no recognizable binding sites on the AL, owing to the deletions it undergoes as it is deposited.

The second hypothesis is that the immunoglobulin light chain, by definition, has undergone misfolding as it assumes the amyloid configuration in tissues. This misfolding can lead to the loss of available epitopes on the protein surface that commercial antisera bind to. It is for these reasons that it is common for immunohistochemistry, even in light-chain amyloidosis, to be equivocal or difficult to distinguish from background staining. At Mayo Clinic, immunohistochemistry has been abandoned as a modality to diagnose the

type of amyloidosis. Currently laser capture microdissection with mass spectroscopic analysis of amyloid deposits has supplanted immunohistochemistry in our practice. Amyloid deposits can be excised by laser microdissection directly from a glass slide and then can undergo mass spectroscopic sequencing. The results are compared with a library of proteins stored in a database and then identified. Virtually all amyloid proteins contain serum amyloid P protein, apolipoprotein E, and vitronectin. These findings are confirmatory of amyloid but are ancillary proteins and are not the specific primary protein. In patients with amyloidosis, sequencing will identify the specific protein composition. In a survey of over 4000 tissues, light chains were detected by mass spectroscopic analysis in 61.68%, but 24.5% were transthyretin-related hereditary amyloidosis, 3.7% were amyloid A, 3.6% were leukocyte chemotactic factor 2 amyloidosis (ALECT2) (renal amyloidosis in Mexican and Indian patients), insulin 1% (localized in diabetic), and the remaining comprised <1%. Due to its high sensitivity and specificity, mass spectroscopy is now our technique of choice.

In a survey of 143 heart biopsies, of which 81 were TTR (familial or senile systemic amyloid), an M protein was found in 20 patients, and free light chain abnormality was found in 8 of the 81 patients, indicating that the finding of an immunoglobulin protein does not prove that amyloidosis is AL in origin. Because senile systemic amyloidosis is a disease that causes heart failure in the elderly, the finding of a high prevalence of immunoglobulin abnormalities as a coincidental observation is not unusual. Box 88.1 provides a list of the diagnostic tests needed to evaluate in patients for whom amyloidosis is established as a diagnosis.

Other required diagnostic studies in patients with amyloidosis include cardiac biomarkers, which are extensively discussed in the section below on prognosis and screening measurements of the coagulation system. A unique and highly specific finding, albeit limited to no more than 5% of patients with light chain amyloidosis, is the development of deficiency of coagulation factor X. This is usually recognized as prolongation of the prothrombin time. The underlying mechanism of factor X deficiency in amyloidosis is direct binding of factor X to the amyloid deposit itself, which can

BOX 88.1 Recommended Diagnostic Evaluation for Amyloidosis

occasionally be associated with serious clinical bleeding and can complicate the systemic therapy of this disorder. If a prothrombin time is completely normal, it is not our habit to routinely screen for factor X deficiency, but any abnormality of the prothrombin time or international normalized ratio should lead to a screening for factor X deficiency, given its unique association with light chain amyloid. In our experience, factor X deficiency is most commonly seen in patients with hepatosplenic deposits of amyloid.

DIFFERENTIAL DIAGNOSIS

The path to the diagnosis of amyloid depends on the initial presentation. Many patients will present to a hematologist because of a monoclonal gammopathy and >10% plasma cells in the bone marrow, which will fulfill the diagnostic criteria for myeloma, even though the clinical manifestations and the drivers of outcome could all be related to amyloidosis. It therefore is incumbent upon practicing hematologists who see a patient with multiple myeloma or MGUS to inquire about progressive fatigue out of proportion to any anemia, intractable edema, unexplained elevation of the serum alkaline phosphatase, or the presence of a peripheral neuropathy. The index of suspicion should be heightened if the monoclonal gammopathy is of λ type relative to κ type because of the stronger association with light chain amyloidosis. Any of these findings should lead to staining of the bone marrow biopsy for Congo red and the performance of subcutaneous fat aspiration. If the fatigue is significant, echocardiography, specifically to look for amyloid, is indicated.

Conversely, any patient with a known cardiomyopathy should be screened with serum and urine immunofixation and immunoglobulin light-chain assay because a positive result will redirect the evaluation toward amyloidosis. Any patient with albuminuria and a light chain should not be assumed to have myeloma cast nephropathy. Rather, the pattern of the urinary protein, whether albumin-dominant or globulin-dominant, can help distinguish between the two syndromes. In a patient with a peripheral neuropathy and a monoclonal protein, it should not be assumed that this is MGUS neuropathy; rather, screening for amyloidosis, in the presence of associated autonomic neuropathy (rare in MGUS neuropathy, 20% of AL amyloidosis) or concomitant carpal tunnel syndrome (50% of amyloid neuropathy patients, uncommon in MGUS neuropathy) is required.

Excluding Localized Amyloidosis

Localized forms of amyloidosis are characterized by the presence of amyloid deposits in biopsy tissue without systemic organ dysfunction.

The typical sites associated with localized amyloidosis include skin, vocal cord, tracheobronchial tree, ureter, bladder, and urethra. Occasionally, GI biopsies, particularly polyps, or the edges of ulcers will show amyloid deposits and not be reflective of a systemic form of amyloidosis.

In some instances, mass spectroscopic analysis will demonstrate that the amyloid is not of immunoglobulin light-chain origin. However, there are a number of forms of localized amyloidosis that are of immunoglobulin light-chain origin but are not part of a systemic plasma cell dyscrasia. When a deposit is seen and is of light-chain origin but there is no evidence of a clonal plasma cell disorder in the bone marrow, and serum and urine immunofixation and light chain assays are normal, the index of suspicion should be that this is a localized form of amyloid for which systemic therapy is not indicated. Most forms of cutaneous amyloidosis do not require therapeutic intervention. Amyloidosis involving the vocal cords is most commonly treated by endoscopic resection of the deposits or yttrium-aluminum-garnet (YAG) laser vaporization of the deposits. Tracheobronchial amyloid deposits can be treated with laser vaporization of the deposits or, if the deposits extend beyond the reach of the bronchoscope, with external beam radiation, which has been reported to control the amyloid deposits successfully. Amyloids involving the ureter, bladder, and urethra are often diagnosed with a preoperative diagnosis of urothelial malignancy. Surgeons have often treated patients with ureteral resections for suspect transitional cell carcinoma only to find that amyloid is present. Bladder amyloid most commonly manifests with gross hematuria, and endoscopic resection will demonstrate amyloid deposits. Most patients can be controlled via cystoscopic resection and then surveillance. There are occasional patients who require subtotal cystectomy. There is experience with the use of instillation of dimethyl sulfoxide into the urinary bladder. Urethral amyloid can usually be treated with resection to prevent obstruction.

Systemic Forms of Amyloidosis Unrelated to Immunoglobulin Light Chain

The aging of the population is leading to increased recognition of senile systemic amyloidosis (formally known as *senile cardiac amyloidosis*). Autopsy studies in patients over the age of 90 shows that nearly one-third of patients have cardiac amyloid deposits, and approximately half of those deposits were responsible for clinically significant cardiac dysfunction. With the rising age of the population and increased application of echocardiography, it is expected that the recognition of senile systemic amyloid, also known as *native TTR amyloid* or *wild-type TTR amyloid*, will increase. Patients with this form of cardiac amyloidosis can develop congestive heart failure and commonly have conduction system abnormalities, including atrial fibrillation, first-degree heart block, and bundle branch block. The echocardiographic features are similar to those of light-chain amyloidosis, although extreme degrees of infiltration can be seen (septal thicknesses >20 mm), which are uncommon in light-chain amyloidosis. It should never be assumed that a patient with suspect cardiac amyloidosis has light-chain amyloidosis, particularly if the patient is over the age of 70. However, we have seen patients as young as 57 with senile systemic amyloidosis. Moreover, when patients are recognized by mass spectroscopy to have TTR cardiac amyloidosis, sequencing of the *TTR* gene is essential to exclude the possibility of a late-onset inherited form of amyloidosis. This is particularly the case because a specific mutation, ILE-122, is found in 4% of the African American population in the United States and is associated with the development of late-onset cardiac amyloidosis, and we have seen patients with inherited cardiac amyloidosis who have been inappropriately treated with systemic chemotherapy.

Familial amyloidosis represents a small but important subset of patients with systemic amyloidosis. The majority of cases are caused by mutations of *TTR* and can be recognized by identifying the *TTR* subunit by mass spectroscopy and by detection of the mutation by sequencing of the *TTR* gene using polymerase chain reaction

Fig. 88.7 TRANSTHYRETIN MUTATIONS SEEN AT MAYO CLINIC, BY AGE. TTR, Transthyretin.

amplification techniques (Fig. 88.7). Clinically, most patients present either with cardiac amyloid or with amyloid peripheral neuropathy and are not easily distinguished clinically from immunoglobulin light chain amyloid. Most of these patients will have no evidence of a systemic plasma cell dyscrasia. Only half of the patients in our practice actually have a positive family history for this autosomal dominantly inherited disorder. In many instances, this is simply because of a failure to recognize in a prior generation and misattribution of the etiology of cardiac death or neural disability.

There are forms of renal amyloidosis that are not immunoglobulin light chain in origin. The two most common are fibrinogen A α and ALECT2. Again, this requires mass spectroscopic identification of these subunit proteins to validate the diagnosis. The distinction for all forms of inherited amyloidosis are important because, in TTR amyloidosis, liver transplant has been demonstrated to be an effective technique; in other forms of non-TTR amyloidosis, organ transplant (renal transplant for apolipoprotein A1 amyloid renal failure) has been used for the management of renal and cardiac failure.

PROGNOSIS

The prognosis of immunoglobulin light-chain amyloidosis has been associated with abnormalities in lactate dehydrogenase, β_2 -microglobulin, genetics, circulating plasma cells, the fraction of plasma cells in S-phase, and the serum amyloid P scanning technique. The simplest and most powerful assessments of prognosis revolve around the importance of cardiac amyloid in determining outcome.

The most common cause of death in patients with cardiac amyloidosis is cardiac failure or sudden death, presumed to be caused by arrhythmia. However, the most common cause of death in renal, hepatic, and peripheral nerve amyloid is also cardiac amyloid. The presence of cardiac amyloid predicts for the fraction of patients unable to complete 3 months of therapy and remains responsible for the 1-year mortality of amyloidosis of 40%, which has not changed in 25 years, is the major driver of outcome, and emphasizes why earlier diagnosis of cardiac amyloid is essential to improvement of outcomes for patients with this disease. In addition, the burden of plasma cells, as measured both in the bone marrow and by the levels of involved and uninvolved immunoglobulin light chains in the serum, is key in assessing prognosis. Box 88.2 gives the outcomes for the four stages of immunoglobulin light-chain amyloidosis, based on the measurement of cardiac troponin T, N-terminal pro-brain natriuretic peptide (NT-proBNP), and the difference between the involved

BOX 88.2 Amyloid Staging

Patients are assigned a score of 1 point for each of the following:

1. FLC-diff ≥ 18 mg/dL
2. cTnT ≥ 0.025 ng/mL
3. NT-proBNP ≥ 1800 pg/mL

This creates stages I–IV with scores of 0–3 points, respectively

Median Survival (months):

- I. 94.1
 - II. 40.3
 - III. 14
 - IV. 5.8
1. Difference between the involved and uninvolved serum light chain levels
 2. Cardiac troponin T
 3. N-terminal pro-brain natriuretic peptide

cTnT, Cardiac troponin T; FLC-diff, difference between involved and uninvolved free light chains; NT-proBNP, N-terminal pro-B-type natriuretic peptide.

and uninvolved serum free light-chain levels (Box 88.2). These three blood tests have been converted into a very convenient staging system with dramatic differences in prognosis and almost equal distribution of patients into the four stages. Fig. 88.8 shows posttransplant overall survival for the four stages in 444 patients. Other important prognostic features, which are not currently part of the staging system, include echocardiographic Doppler studies of diastolic performance and mitral deceleration time. Echocardiographic strain, which measures the rate at which myocardial shortening occurs, has also been shown to be a powerful measure of outcome. Others have described a systolic blood pressure of <90 mmHg as being adverse, but this has not been effectively incorporated into the current staging system for amyloidosis.

THERAPY

Before one can understand the various therapies, it is important to understand how to interpret response in patients with amyloidosis. In amyloidosis, because there is both a plasma cell dyscrasia and organ dysfunction related to amyloidosis, there are now response criteria for both hematologic and organ responses. Hematologic responses parallel response criteria that have been established for multiple myeloma

Fig. 88.8 SURVIVAL BY STAGE FOLLOWING STEM CELL TRANSPLANT. Orange, stage 1; dark blue, stage 2; light blue, stage 3; pink, stage 4.

and rely heavily on the measurement of the involved and uninvolved immunoglobulin free light chain.

The immunoglobulin free light-chain assay has been summarized earlier as being critical in the recognition of the disease; it has been described as being important in prognosis; and its serial measurement is the key to assessing hematologic response. In fact, when both an intact immunoglobulin is present and an abnormal involved free light chain is detected, the latter is more important prognostically than changes in the intact immunoglobulin and is given preference when interpreting responses in treated patients and for assessment of the role of salvage therapies. A complete hematologic response is defined as a negative serum and urine immunofixation, a normal free light-chain ratio, and a normal bone marrow examination. A very good partial response is now defined as a difference between involved and uninvolved free light chain of <40 mg/L. A partial response is a 50% reduction in the difference between involved and uninvolved serum free light-chain levels, and less than 50% decrease is considered stable disease. A cardiac response in amyloidosis is defined not by changes in the echocardiogram but by changes in the NT-proBNP. A decrease of NT-proBNP of 30% and at least 300 ng/L is considered a response. However, the NT-proBNP level must be >650 ng/L to be considered measurable. The definition of renal response is a 50% reduction in the amount of urinary protein loss over a 24-hour period. This reduction is associated with longer survival. A 75% reduction in proteinuria is associated with markedly prolonged survival.

The therapy for amyloidosis is both supportive care and systemic chemotherapy against the plasma cell dyscrasia. Supportive care for cardiac and renal amyloidosis includes diuretic therapy to help reduce the elevated filling pressures in both the right and left sides of the heart and reduce pulmonary edema, as well as to relieve symptomatic lower extremity edema. Diuretics are also required for the management of the lower extremity edema associated with nephrotic syndrome. Many cardiologists at Mayo Clinic believe that bumetanide is a superior diuretic to furosemide in patients with amyloidosis and prefer it. For refractory edema, the addition of metolazone can be useful, but it can result in serious hypokalemia when combined with furosemide or bumetanide. There is no evidence that the use of lisinopril, as has been applied in the nephrotic syndrome of diabetic nephropathy, plays any role in the management of renal amyloidosis. In addition, afterload reduction, shown to provide survival benefit in patients with ischemic cardiomyopathy, has not been shown to be beneficial in patients with amyloidosis and can significantly aggravate hypotension in patients with poor filling during diastole. Finally, a number of patients in our practice have shown significant deterioration with the addition of β -blockade, and these agents are avoided in our patients as well.

Management of amyloid orthostatic hypotension involves the use of both fludrocortisone and midodrine, which can help reduce

orthostatic syncope but are associated with both fluid retention and supine hypertension, making their use a challenge. The diarrhea associated with GI amyloid is also challenging. It is common for these patients to fail imodium therapy and loperamide. We frequently will use tincture of opium to manage this. In refractory instances where fecal incontinence is common, the placement of a diverting sigmoid colostomy has no impact on the diarrhea but can provide the patient important improved quality of life and social relief.

Chemotherapy Treatment for Light Chain Amyloidosis

The chemotherapy treatment of light-chain amyloidosis requires a determination of whether the patients are candidates for high-dose therapy with stem cell transplant or are best served with conventional chemotherapy regimens.

It is now 40 years since melphalan and prednisone treatment was shown to benefit patients with amyloidosis, and two randomized clinical trials comparing melphalan and prednisone with colchicine regimens demonstrated a response rate of 15% and a 50% increase in median survival in responders. Melphalan has a significant impact on survival in patients without heart failure. The best responses to melphalan-containing regimens are in patients with renal amyloid nephrotic syndrome and preserved renal function.

Dexamethasone in high doses of 40 mg on days 1–4, 9–12, and 17–20 was demonstrated in three individual studies to result in organ improvement in amyloid patients for whom melphalan-containing regimens had failed. Subsequently, the combination of melphalan and dexamethasone was introduced, showing a 50% 5-year survival rate, a hematologic complete response rate of 24%, and organ improvement in 43%. Oral melphalan and dexamethasone can be administered to virtually any patient with amyloidosis and should be considered the standard with which all other therapies are compared. There is a strong correlation between organ improvement and hematologic response. In patients who achieve a hematologic complete response, organ improvement has been seen in 87% of patients. Organ response rates are $<15\%$ in the patients who do not achieve a hematologic partial response.

The introduction of proteasome inhibitors and immunomodulatory agents has broadened the horizon for patients with amyloidosis. Initial experience with thalidomide demonstrated that the administration of immunomodulatory drugs to patients with amyloidosis cannot be implemented solely on the basis of experience with multiple myeloma. In an early study of 16 patients with AL amyloidosis treated with thalidomide, grade 3 or greater adverse events were noticed in 50% of patients, including exacerbation of neuropathy and heart failure. When thalidomide was combined with cyclophosphamide and dexamethasone, the hematologic response rates were high, but the toxicity was significant.

Lenalidomide has demonstrated activity in AL as a single agent and in combination with steroids and the alkylating agents cyclophosphamide and melphalan. Lenalidomide appears to be better tolerated than thalidomide but produces significant increases in the NT-proBNP and symptomatic exacerbations of cardiac symptoms. In a phase II trial of 35 patients, 8 of 13 evaluable subjects had a hematologic response, but the maximum tolerated dose of lenalidomide was only 15 mg. Lenalidomide has been used as salvage therapy in patients who have progressed after melphalan, dexamethasone, and bortezomib combinations. Melphalan, lenalidomide, and dexamethasone in a relapsed setting produced hematologic complete response rates in 42% of patients. A phase II trial at Mayo Clinic of cyclophosphamide, lenalidomide, and dexamethasone also produced response rates of 50%, with 7% showing a complete response. Myelosuppression with the combination of melphalan and lenalidomide is significant. Cardiac arrhythmias were seen in 33%.

As salvage therapy in relapsing disease, lenalidomide has been combined with cyclophosphamide and dexamethasone in 35 patients. The median number of treatment cycles was six, and the hematologic response rate was 60%; in those receiving at least four cycles, the response rate was 87%. A median overall survival of 37.8 months has

been reported. In patients with amyloidosis, lenalidomide has been reported to worsen renal function even in patients whose amyloidosis spares the kidney. Recovery of renal function was reported in 44%. Lenalidomide salvage therapy after bortezomib achieves a hematologic response rate of 41%. Pomalidomide is a third-generation immunomodulatory drug with a toxicity profile that compares favorably with the other immunomodulatory drugs. In a single phase II trial, 29 patients previously treated received pomalidomide with a response rate of 38%. Three-fourths of the patients were alive at 1 year, and 56% were free of disease progression. The majority of these patients had previously received stem cell transplants, bortezomib, and thalidomide, indicating that this immunomodulatory drug is active and capable of producing durable remissions, albeit with significant toxicity.

Bortezomib

Bortezomib, which was the first proteasome inhibitor used for the treatment of amyloidosis, has the advantage of a rapid time to response and no modification required for renal dysfunction. In the first phase II trial, 14 of 18 patients with relapsed refractory AL amyloidosis had a hematologic response, with 16% achieving complete response. Schedules of weekly and twice-weekly bortezomib have been investigated with similar response rates and similar 1-year progression-free survival. The weekly form of bortezomib, however, does appear to have lower rates of treatment discontinuation and peripheral neuropathy. Bortezomib has been combined with dexamethasone with a hematologic response rate of 71%, complete in 25%. In previously untreated patients, bortezomib produces a complete response rate of 47%, although in one study the progression-free survival was only 5 months and the overall survival was 18.7 months, raising questions about how durable these responses are. Bortezomib has also been combined with stem cell transplant as induction therapy, as posttransplant consolidation therapy, and as part of the conditioning regimen. In a report of 19 patients for whom bortezomib was used after stem cell transplant to deepen the response, 67% of patients achieved a complete response, with organ responses in 60% using posttransplant consolidation with bortezomib. Data from 33 national centers were combined, with 94 patients having received bortezomib. A cardiac response was seen in 29% of patients. The NT-proBNP predicted survival. The median time to response was 7.5 weeks. Authors of a survey of European centers with 428 evaluable patients reported that bortezomib therapy achieved a lower difference between involved and uninvolved free light chains at the end of therapy compared with cyclophosphamide-thalidomide-dexamethasone, melphalan-dexamethasone, stem cell transplant, and cyclophosphamide-lenalidomide-dexamethasone.

Bortezomib had been combined with cyclophosphamide and dexamethasone. In a study of 17 patients, 10 of whom were therapy-naïve, a response rate of 94% was achieved, 71% complete. A second cohort of 43 patients achieved a hematologic response rate of 81%, with 42% achieving a complete response and a 2-year progression-free survival of 67% for newly diagnosed patients.

Despite the promising published results with bortezomib, a prospective randomized trial conducted in Europe of bortezomib, melphalan, and dexamethasone (BMD) compared with melphalan and dexamethasone failed to show any difference in organ response rates or in progression-free or overall survival in the bortezomib-containing regimen; yet grade 3 toxicity was seen in 27% of patients receiving BMD compared with only 12% treated with melphalan and dexamethasone. Moreover, day 100 all-cause mortality was 7.5% in the BMD arm and only 2.5% in the melphalan dexamethasone lenalidomide. The hematologic response rate was higher in the BMD arm at 77% vs. 52% ($p = .045$). A compilation of 230 patients in Europe who received cyclophosphamide, bortezomib, and dexamethasone showed a high level of effectiveness in low-risk amyloidosis patients with an at least very good partial response rate of 56% and no deaths seen in stage I patients.

A European collaborative study of treatment outcomes in 346 patients with cardiac stage III AL amyloidosis was reported. In this

cohort of patients with advanced cardiac amyloidosis, the median overall survival was 7 months with a 2-year overall survival of 29%. As is typical for this disease, 42% of patients died before their first response evaluation, and the overall hematologic response rate was 33% (12% complete). The overall survival rate was 88% at 2 years for complete responders, 53% for partial responders, and 22% for non-responders; 45% of responders achieved an organ response. The only factors predictive of survival were an NT-proBNP >8500 ng/L and a systolic blood pressure <100 mmHg. The regimens administered included melphalan and dexamethasone, alkylating agents thalidomide and dexamethasone, and bortezomib as well as lenalidomide combinations. Although this was not a prospective trial, the overall response rate for melphalan-dexamethasone-thalidomide-bortezomib combinations ranged from 60% to 64%. The response rate to lenalidomide combination therapy was 41% but included only 13 patients. The most common regimen administered was melphalan and dexamethasone, administered to 154 of the 286 patients evaluable for response.

Stem Cell Transplant

Unlike multiple myeloma, where visceral organ function tends to be normal with the exception of the kidney, and the bone marrow tends to be heavily involved, the converse is true in amyloidosis. In amyloidosis, the marrow shows minimal involvement, but organ dysfunction increases the morbidity as well as the mortality of high-dose chemotherapy and stem cell transplant. Ablative therapy can be more effective, and the response durability of patients who achieve a complete response is greater in amyloidosis than it is in multiple myeloma, the number one indication for autologous stem cell transplant in the United States. Stem cell transplant is not a suitable technique for patients with advanced cardiac disease, because these patients decompensate if they develop neutropenic infection during the phase of maximal immunosuppression. Careful patient selection becomes critical in ensuring a safe outcome for patients who undergo stem cell transplant. Over the past two decades, the treatment-related mortality associated with stem cell transplant has fallen from 10% to 2% because of improved supportive care and optimization of patient selection. As a general guideline, it has been our experience that patients whose NT-proBNP is >5000 pg/mL or whose troponin T is >0.06 ng/mL have too high a mortality associated with transplant and are better managed with standard-dosage chemotherapy, as outlined in the previous section. Systolic blood pressure >100 mmHg is also an important feature reflecting sufficient diastolic compliance to improve cardiac output during the stress of stem cell transplant. Patients who have stage III and stage IV cardiac amyloidosis are candidates for stem cell transplant if they fulfill the other criteria outlined.

At Mayo Clinic, approximately 20% of patients with newly diagnosed amyloidosis are eligible for high-dose melphalan. Melphalan 200 mg/m² and 140 mg/m² can both be used, but the response rates associated with lower-dose melphalan are decreased and may not be superior to the response rates reported with standard chemotherapies. The ability of stem cell transplant to produce a durable response is unmatched in the literature, with 43% of patients surviving 10 years or longer. Patients with more than two organs involved are oftentimes not considered adequate candidates for stem cell transplant, but some judgment is warranted because patients can have very mild involvement of three organs and be candidates, yet have advanced involvement of two organs and not be candidates (Fig. 88.9). The serum creatinine is predictive of the risk of requiring dialysis during the transplant, a major complication leading to serious morbidity. We are disinclined to perform transplant in renal amyloid patients whose serum creatinine is ≥ 1.8 mg/dL. Although age is not an absolute criterion, additional scrutiny is warranted above the age of 65. From January 1, 2013, through December 31, 2014, 85 amyloid patients underwent transplants; 35 were older than 65 years of age, and 11 were over age 70 years.

As with conventional chemotherapy, hematologic response is a predictor of survival, with complete responders having improved

Fig. 88.9 SURVIVAL AFTER STEM CELL TRANSPLANT, BASED ON NUMBER OF ORGANS INVOLVED. *Pink*, Soft tissue only, no visceral involvement; *orange*, 1 organ; *dark blue*, 2 organs; *light blue*, >2 organs.

Fig. 88.10 SURVIVAL BY RESPONSE DEPTH. *Orange*, Complete response; *dark blue*, partial response; *light blue*, no response.

outcomes compared with very good partial responders and partial responders (Fig. 88.10). The depth of hematologic response required to achieve optimal outcomes is not well defined in amyloidosis, because highly amyloidogenic light chains can continue to deposit even if the levels are sharply reduced. Unlike myeloma (where the monoclonal protein is a surrogate for tumor mass), in amyloidosis, the monoclonal protein is itself the problem, and to completely disrupt deposition, one may hypothesize that nearly complete eradication of the protein from the serum is required. In amyloidosis, hematologic response is used as a surrogate for organ response, which is the only outcome that improves survival by the prevention of progressive organ failure.

Most published information on high-dose therapy and stem cell transplant in amyloidosis has used melphalan at doses ranging from 100 to 200 mg/m² as the standard. The Boston Medical Center reported 250 patients with AL amyloidosis who underwent high-dose melphalan and autologous stem cell rescue. Two-thirds were alive at a mean follow-up of 23 months, with a 3-month all-cause mortality of 14%. Febrile neutropenia, GI tract hemorrhage, and dialysis-dependent renal failure were unique toxicities associated with transplant. However, the Boston group has demonstrated an improved quality of life for patients who respond. We have published our experience with 434 patients with amyloidosis. The hematologic response rate among those patients was 75%. The complete response rate was 38%, and the organ response rate was 46%. The most important predictor of outcome was the depth of hematologic

response. Median survival was not reached for patients who achieved a complete response, whereas it was 107 months for those with partial remission and 32 months for nonresponders (Fig. 88.10). There is a significant impact of pretreatment NT-proBNP levels on outcome. We do not use chemomobilization to obtain stem cells. The low number of plasma cells in the bone marrow allows growth factor–only mobilization to achieve the requisite goal. Plerixafor is not routinely used to mobilize stem cells; it is used only in patients who do not achieve a peripheral blood CD34 count >10/μL. We also do not routinely use granulocyte colony-stimulating factor to support engraftment following transplant, owing to fluid retention that is seen, and we have observed no increase in bacteremia or hospital days after ceasing use of posttransplant growth factor support. Among amyloid patients, approximately 30% will complete the procedure without requiring hospitalization. Adjuvant therapy has been used in patients who are the recipients of stem cell transplants. Both thalidomide-dexamethasone and bortezomib-dexamethasone has been used to consolidate response after transplant, and it has been demonstrated that deepening of the response can be achieved.

It is difficult to obtain category A evidence in support of high-dose therapy and stem cell transplant for amyloidosis. The only prospective controlled trial enrolled 100 patients and did not demonstrate survival differences between the two groups, whether in a landmark analysis or on an intention-to-treat basis. This study has been called into question because of a 24% treatment-related mortality in the transplant group. A subsequent metaanalysis of high-dose therapy in patients with AL amyloidosis also could not identify a survival advantage with stem cell transplant. Boston University has reported a 10-year survival of 25% in their transplant population, compared with 4% prior to the advent of high-dose therapy. A case-matched control study done at Mayo Clinic matched 63 transplanted patients with 63 nontransplanted patients and showed a survival advantage for patients who received a stem cell transplant.

Organ Transplantation

Both cardiac and renal transplant have been performed in patients with AL amyloidosis. Criteria to be considered in selecting patients for solid organ transplant include amyloidosis confined only to the organ that is to be transplanted. Also the patient should either have achieved a complete hematologic response with therapy or be a candidate for therapy who has a high likelihood of producing a complete hematologic response and thereby obviate the possibility of recurrent amyloid in the transplanted organ.

Three patients were reported with AL amyloidosis who had cardiac involvement, and the time from symptomatic onset to the diagnosis of AL amyloidosis ranged from 12 to 24 months. The times from the onset of heart failure to orthotopic heart transplant in these three patients were 4, 5, and 7 months, respectively. The patients then underwent stem cell transplant at 13, 16, and 13 months, respectively; all three are alive at 23+, 35+, and 39 months, demonstrating that in highly selected patients, heart transplant in those with dominant cardiac involvement followed by subsequent stem cell transplant can result in survival benefit. Authors of a report of six patients who underwent heart transplant for cardiac amyloidosis at Stanford stated that all patients received chemotherapy in the interval between heart transplant and autologous stem cell transplant. Five patients were alive up to 25 months after heart transplant without evidence of recurrent cardiac amyloid deposition, but chemotherapy actually began as early as 32 days after cardiac transplant. The three patients are alive 19, 24, and 25 months posttransplant, respectively.

Renal transplant has also been reported. Nineteen patients with AL underwent renal transplant, comprising living donor transplants in eighteen and a cadaveric transplant in one, with a median follow-up of 41.4 months; 79% were alive, and five patients had cellular rejection. Recurrent amyloidosis was diagnosed by a kidney biopsy in only one patient, indicating that renal transplant can be successfully performed in patients with AL amyloidosis in complete hematologic

response without a significant risk of recurrent amyloid when the primary hematologic disorder is controlled.

Nine cardiac transplants were reported from Boston, eight of whom subsequently received a stem cell transplant. Six of seven evaluable patients achieved a complete hematologic remission. One achieved a partial remission. At a median follow-up of 56 months, five of seven patients were alive without recurrent amyloid, comparable to patients who received heart transplants for nonamyloid heart disease. At Mayo Clinic, the median survival of patients who have received cardiac transplants for amyloid is approximately 50%, which is somewhat inferior to patients who receive hearts for cardiomyopathy without a systemic disorder. Eleven patients underwent heart transplant followed by autologous peripheral blood stem cell transplant. Two patients died as a result of transplant-related complications. Nine survived, but three died because of progressive amyloidosis. The 1- and 5-year survival rates were 82% and 65%, respectively. The median survival was 76 months from heart transplant and 57 months from stem cell transplant.

Organ transplant is a viable option for patients in whom complete suppression of light chain production can be achieved. Because of the shortage of organs, critical decisions regarding allocation must be made. Organ transplant has also been applied to familial amyloid polyneuropathy amyloidosis, usually combined with liver transplant. We have performed three cardiac transplants for familial amyloidosis, heart transplant for senile amyloid in 2 patients, heart-liver transplant for familial amyloid in 18 patients, and heart-liver-kidney transplant for familial amyloid in 4 patients.

CONCLUSIONS

Amyloidosis should always be considered in the differential diagnosis of a patient who presents with proteinuria and is nondiabetic. Any patient with unexplained fatigue or restrictive cardiomyopathy or heart failure with preserved ejection fraction should be screened for amyloidosis. Patients who fulfill criteria for chronic inflammatory demyelinating peripheral neuropathy, unexplained hepatomegaly, or atypical multiple myeloma should all be considered for the possibility of amyloidosis. When a patient with one of these five compatible syndromes is seen, screening with immunofixation of the serum or urine in a free light-chain assay should be performed (Fig. 88.11). If an immunoglobulin light-chain abnormality is found, it would be appropriate to do biopsies of the bone marrow and subcutaneous fat to stain for Congo red. Only if the index of suspicion is high should further biopsies be performed if the results of bone marrow and fat biopsies are both negative. It is critical to ensure that all amyloid deposits are typed. The gold standard is laser capture mass spectroscopy in an effort to ensure that all chemotherapy-treated amyloid is of immunoglobulin light chain origin. The prognosis of amyloidosis can be determined by measurements of the immunoglobulin free light chain, serum troponin, and NT-proBNP. We believe that stem cell transplant is the preferred technique for patients in whom it can be performed safely, but this should not be more than 20% of patients. For nontransplant candidates, melphalan-dexamethasone, melphalan-dexamethasone-bortezomib, and cyclophosphamide-bortezomib-dexamethasone are all legitimate options for induction therapy. For patients without

Fig. 88.11 DIAGNOSTIC ALGORITHM FOR USE WHEN AMYLOIDOSIS IS SUSPECTED.

TABLE 88.3**Active Nonchemotherapy Trials for Amyloidosis**

Drug	Mechanism	Amyloidosis Type	Trial Registration Number	Comments
Tafamidis	Misfolding interference	Mutant (Val122Ile) and wild-type TTR	NCT00935012	Double-blind, placebo-controlled trial
ALN-TTRSC	Suppress transthyretin expression	TTR wild type including cardiac involvement	NCT01994889, NCT01981837	None
ISIS-TTRRx	Suppress transthyretin expression	TTR neuropathy in ambulatory patients (use only one cane)	NCT01737398	Placebo-controlled
Doxycycline and tauroursodeoxycholic acid	Misfolding interference	TTR	NCT01171859	None
Doxycycline	Fibril disruption	AL and TTR	NCT01677286	None
NEOD001	Antibody-mediated fibril dissolution	AL	NCT01707264	None

AL, Light chain amyloid; TTR, transthyretin.

a response to their primary therapy, immunomodulatory drug-containing therapies such as melphalan-dexamethasone-lenalidomide, lenalidomide-dexamethasone, and cyclophosphamide-lenalidomide-dexamethasone are all appropriate combinations.

FUTURE DIRECTIONS AND SUMMARY

Some of the nonchemotherapy-based imitatives for amyloidosis treatment are listed in Table 88.3. Antibodies, small interfering RNA, and antisense oligonucleotides are all being explored. Combinations of anti-light-chain synthesis and therapies to prevent misfolding are likely the next generation of therapies.

**COMPREHENSIVE CARE OF PATIENTS
WITH HEMATOLOGIC MALIGNANCIES**

This page intentionally left blank

CLINICAL APPROACH TO INFECTIONS IN THE COMPROMISED HOST

Samuel A. Shelburne, Russell E. Lewis, and Dimitrios P. Kontoyiannis

Advances in the supportive care and treatment of hematologic malignancies have markedly improved the life expectancy of afflicted patients, but this progress is increasingly at the expense of developing a wider range of infectious complications often caused by drug-resistant organisms. The clinical approach to infections occurring among hematology patients involves understanding host immune system defects and anatomic barrier disruption that predispose patients to infection (Fig. 89.1). This chapter reviews specific hematologic conditions for their unique host defense defects and associated infections (Table 89.1) and the differential diagnoses of common infectious pathogens (Table 89.2). To demonstrate how periods of predictable anatomic defects combine with severe immune compromise, the prevention, diagnosis, and management strategies for infections occurring in the hematopoietic stem cell transplant (HSCT) recipient are presented as models.¹

HEMATOLOGIC CONDITIONS PREDISPOSING TO INFECTION

Malignant Hematologic Disorders

Antineoplastic Therapy

During antineoplastic treatment, cytotoxic agents frequently are administered in combination with other immunosuppressive therapies, such as corticosteroids or radiation therapy. Several cytotoxic agents, notably methotrexate, cyclophosphamide, 6-mercaptopurine, and azathioprine, impair cell-mediated immunity. Many of the drugs themselves (e.g., cyclophosphamide) also impair humoral responses and produce quantitative phagocyte defects. Fludarabine, a major therapy for chronic lymphocytic leukemia (CLL), can produce prolonged and profound defects in cell-mediated immunity, thereby increasing susceptibility to *Pneumocystis*, yeast, and herpes group viruses (herpes simplex virus [HSV], varicella-zoster virus [VZV], and cytomegalovirus [CMV]).

The use of monoclonal antibody therapy for hematologic disorders results in dysfunction of particular aspects of the immune system.² Rituximab results in a sustained depletion of B lymphocytes for 6 to 9 months and has been specifically associated with reactivation of hepatitis B virus infection.³ Alemtuzumab administration causes profound lymphopenia and an increased risk for a variety of viral and fungal infections.

Exogenous administration of glucocorticoids leads to increased susceptibility to infection. The degree of immunosuppression and the relative risk for infection depend on the dose and duration of use. The major effect of steroids on granulocyte function is a decrease in chemotactic activity. This accounts, in part, for the clinical observation that the signs and symptoms of severe infections may be masked or greatly reduced in patients receiving steroids. Steroids may enhance susceptibility to infection by means of negative effects on glucose homeostasis, wound healing, skin fragility, monocyte and lymphocyte function, production of cytokines, and humoral immune responses.

Radiation therapy has been associated with granulocyte dysfunction and delayed wound healing. Defects in cell-mediated immunity

may persist for more than 1 year after intensive radiation therapy or after HSCT.

Acute Leukemias

In patients with acute leukemias, a major cause of morbidity is infection due to drug-associated mucositis and therapy-induced neutropenia. Most infections occurring during neutropenia are bacterial, but patients with prolonged neutropenia are at additional risk for development of yeast and mold infections. Patients with acute leukemia who progress to advanced therapies, such as hematopoietic cell transplant, have added risk for infections associated with acquired deficiencies in cell-mediated and humoral immunity, such as *Pneumocystis jirovecii* and CMV infections.¹

Chronic Leukemias

Patients with chronic myeloid leukemia do not have prominent host defense impairments, so infections are limited unless patients proceed to aggressive chemotherapy or HSCT. Host defense defects with tyrosine kinase inhibitors, such as imatinib or dasatinib, have not been well defined. Chemotherapy for blast crisis resembles therapy for acute leukemia. Patients with CLL are predisposed to infection because of immunodeficiency related to the leukemia itself (humoral and cellular immune dysfunction) and to therapy-related immunosuppression.⁴ In early B-cell CLL, the infectious risk is mainly related to unbalanced immunoglobulin chain synthesis and resultant hypogammaglobulinemia. In patients with advanced CLL, particularly after the introduction of therapy with purine analogues and monoclonal agents (e.g., rituximab, alemtuzumab), neutropenia and defects in cell-mediated immunity are other factors predisposing to infection. The risk for infectious complications increases with the duration of CLL, reflecting the cumulative immunosuppression related to its treatment. The incidence of infection correlates with the serum levels of immunoglobulins (particularly IgG), which may be further impaired by use of anti-CD20 therapies.

Lymphomas

Hodgkin and non-Hodgkin lymphoma are commonly associated with impaired cell-mediated immunity. The degree of immune impairment may correlate with the extent of disease and often is compounded by administration of immunosuppressive therapy.³ The intrinsic impairment of cell-mediated immunity in Hodgkin lymphoma can persist even after apparent cure. Splenectomy-related infections occur with sepsis caused by encapsulated bacterial organisms at a median of 22 months but sometimes many years after surgery.

Myelodysplastic Syndrome

Neutrophils and band forms from patients with myelodysplastic syndrome are functionally defective and probably are derived from a

Fig. 89.1 CONSTELLATION OF FACTORS CONTRIBUTING TO INCREASED RISK FOR INFECTION IN IMMUNOCOMPROMISED HOSTS.

malignant clone of myeloid precursor cells. Neutrophils from patients with myelodysplastic syndrome have deficiencies in myeloperoxidase, elastase, and integrins. More than half of patients with myelodysplastic syndrome die within 3 years of diagnosis from infections, bleeding complications, or progression to acute leukemia.

Multiple Myeloma

Malignant plasma cells produce a variety of immunomodulatory molecules such as TGF- β that suppress B-cell function, so multiple myeloma is frequently associated with a variety of defects in humoral immunity.⁵ Patients having myeloma with IgG paraprotein have an increased rate of catabolism of normal and clonal IgG. They also may have defects in complement and granulocyte function. Cell-mediated immunity is not impaired by the disease but is compromised by corticosteroids or cytotoxic therapy.

Uncommon Malignancies

Patients with hairy cell leukemia develop mycobacterial disease relatively often, especially infection with atypical mycobacteria. Reversal of host cellular immune defects with effective therapy can lead to rapid clinical response with eradication of mycobacterial infection.

Defects in cell-mediated immunity have been postulated to explain the incidence of infection caused by intracellular pathogens in patients with the relatively rare T-cell malignancies mycosis fungoides and T-cell CLL.

Nonmalignant Hematologic Disorders

Aplastic Anemia

This blood dyscrasia is associated with decreased peripheral blood cell counts due to marrow failure. Chronic neutropenia is the main cause of recurrent bacterial and fungal infections among patients. Periodontal infections are particularly common. Treatment of the underlying hematologic disease is required to stop recurrent infections and cure some chronic infections.

Paroxysmal Nocturnal Hemoglobinuria

Patients with paroxysmal nocturnal hemoglobinuria are at some increased risk for bacterial infection due to a deficiency of decay-accelerating factor on the membrane of neutrophils. Modest and progressive granulocytopenia, progression to aplasia or leukemia may compound these risks. Vaccination against meningococcus is required before treatment with the terminal complement inhibitor eculizumab.

Granulocytic Phagocyte Disorders

The clinical approach to infections in patients with granulocytic phagocyte disorders is specific to each of these disorders and is beyond the scope of this chapter. However, chronic granulomatous disease is discussed because patients with this congenital immunodeficiency

TABLE 89.1**Malignant and Select Nonmalignant Hematologic Diseases and Their Associated Infection-Predisposing Host Defects**

Hematologic Condition	Infection-Predisposing Host Defects
Acute myeloid leukemia	Neutropenia; therapies such as dose-intensive chemotherapy and hematopoietic stem cell transplant may result in additional anatomic disruptions, cell-mediated defects, and humoral defects
Acute lymphocytic leukemia	Neutropenia; therapy effects similar to acute myeloid leukemia
Hairy cell leukemia	Neutropenia (also monocytopenia); abnormal humoral immunity; T-cell suppressing therapy
Chronic lymphocytic leukemia	Hypogammaglobulinemia; abnormal cell-mediated immunity
Chronic myeloid leukemia	No prominent host defects unless aggressive therapy, advanced stage, or postsplenectomy
Multiple myeloma	Hypogammaglobulinemia; other host defects may occur with aggressive therapy or advanced stage
Hodgkin/non-Hodgkin lymphomas	Abnormal cell-mediated immunity, therapy-related neutropenia, splenic dysfunction (if splenectomy or radiation)
Myelodysplastic syndromes	Functional or absolute neutropenia
Aplastic anemia	Neutropenia; abnormal cell-mediated immunity from immunosuppressive therapies (e.g., steroids, antithymocyte globulin, cyclosporine, hematopoietic stem cell transplantation)
Paroxysmal nocturnal hemoglobinuria	Deficient Fc receptor may contribute to abnormal cell-mediated immunity
Hemolytic states (thalassemia)	Gallstones may serve as a nidus for infection; splenic dysfunction or splenectomy
Sickle cell disease	Can be neutropenic with aplastic crisis; bone infarcts may serve as a nidus for infection; splenic dysfunction with poor complement activation and opsonization from autosplenectomy

who survive into adulthood are at risk for severe infections. Chronic granulomatous disease is a heterogeneous group of disorders resulting from defective or malfunctioning oxidative metabolism capacity of phagocytes. Recurrent infections with bacteria and fungi are common and occasionally life threatening, despite optimal antimicrobial therapy. Infections with *Staphylococcus* species and *Aspergillus* species can be particularly aggressive.⁶ Granulomata may form in response to infection, especially in the gastrointestinal (GI) and genitourinary tracts.

Erythrocyte Disorders

Glucose-6-phosphate dehydrogenase deficiency is a sex-linked disorder. Deficiency of this enzyme limits glucose metabolism through the hexose monophosphate shunt, resulting in an abnormal respiratory burst in neutrophils. Bacterial infections can occur if the deficiency is severe.

TABLE 89.2**Host Defense Impairments and Their Associated Infectious Pathogens**

Host Defense Defect	Pathogen Categories
Neutropenia	Enteric gram-negative organisms Gram-positive staphylococci and streptococci Anaerobes Yeast, particularly <i>Candida</i> species Molds, particularly <i>Aspergillus</i> species
Abnormal cell-mediated immunity	Atypical bacteria: <i>Legionella</i> , <i>Nocardia</i> <i>Salmonella</i> species <i>Mycobacteria</i> (<i>M. tuberculosis</i> and atypical mycobacteria) Disseminated infection from live bacilli Calmette-Guérin (BCG) vaccine Environmental fungi, including <i>Cryptococcus neoformans</i> , <i>Histoplasma capsulatum</i> , <i>Coccidioides immitis</i> Endogenous yeast, particularly <i>Candida</i> species Herpesviruses Infections from live-virus vaccines <i>Pneumocystis jirovecii</i> <i>Toxoplasma gondii</i> <i>Cryptosporidium</i> <i>Strongyloides stercoralis</i>
Immunoglobulin abnormalities	Gram-positive <i>Streptococcus pneumoniae</i> , <i>Staphylococcus aureus</i> Gram-negative <i>Haemophilus influenzae</i> , <i>Neisseria</i> species, enteric organisms Enteroviruses Disseminated infections from live-virus vaccines <i>Giardia lamblia</i>
Complement abnormalities C3, C5	Gram-positive <i>S. pneumoniae</i> , staphylococci Gram-negative <i>H. influenzae</i> , <i>Neisseria</i> species, enteric organisms
Complement abnormalities C5–C9	<i>Neisseria</i> species
Anatomic Disruption	Pathogen Categories
Oral cavity	α -Hemolytic streptococci, oral anaerobes <i>Candida</i> species Herpes simplex virus
Esophagus	<i>Candida</i> species, Herpes simplex virus, cytomegalovirus
Lower gastrointestinal tract	Enterococcus, gram-negative enteric organisms, Anaerobes (<i>Bacteroides fragilis</i> , <i>Clostridium perfringens</i>), <i>Candida</i> species, <i>Strongyloides stercoralis</i>
Skin (IV catheter)	Gram-positive staphylococci and streptococci, <i>Corynebacterium</i> , <i>Bacillus</i> Atypical mycobacteria
Urinary tract	Enterococcus, Gram-negative enteric organisms <i>Candida</i> species
Splenectomy	Encapsulated organisms: <i>S. pneumoniae</i> , <i>H. influenzae</i> , <i>Neisseria</i> , <i>Capnocytophaga canimorsus</i> <i>Salmonella</i> (especially sickle cell disease), <i>Babesia</i>

Hemoglobin Gene Variants

Patients with chronic hemolytic states may develop bilirubin gallstones, which can serve as a nidus for infection. Defects in cell-mediated immunity have been described in patients with thalassemia. Patients with sickle cell disease have an increased susceptibility to bacterial infections.⁷ Defective alternative complement pathway function, especially in conjunction with asplenia, contributes to the propensity to bacterial infection. Splenic involution results in depressed synthesis of alternate pathway factor(s) of complement and decreased phagocytic clearance of bacteria. Phagocytosis of *Streptococcus pneumoniae* is abnormal, in part because of an inability to use the alternate pathway for C3 fixation as a means of opsonization. An increased risk for *Salmonella* infection appears to be unique to the sickle cell population. Suppurative arthritis can occur after repeated episodes of hemarthrosis among patients with sickle cell disease.

Coagulation Disorders

Hemophilias are sex-linked deficiencies of clotting factor VIII or IX. Septic arthritis should be considered in the differential diagnosis of any hemophiliac with repeated episodes of hemarthrosis whose articular signs and symptoms fail to improve quickly after administration of appropriate coagulation factor replacement. Hemophiliacs who have acquired infection with human immunodeficiency virus (HIV)-1 from plasma-derived factor replacement therapy may develop severe impairment of cell-mediated immunity after this retroviral infection progresses to acquired immunodeficiency syndrome (AIDS).

Blood Groups

The Duffy blood group antigen serves as a receptor for *Plasmodium vivax* to invade erythrocytes. Blood group O is associated with *Helicobacter pylori* infection and an associated increase in peptic ulceration because the Lewis (b) blood group antigen mediates *H. pylori* attachment to human gastric mucosa.

Host Defense Impairment and Associated Infection Issues

Neutropenia

Profound or absolute neutropenia can occur in patients with aplastic anemia or leukemia or from chemotherapy used for treatment of various malignant diseases. Infection rates increase when neutrophil counts fall below $1000/\text{mm}^3$, but the patient is most at risk for spontaneous infection when the count is below $100/\text{mm}^3$ (Fig. 89.2). The patient who is neutropenic from cytotoxic therapy can serve as a basic model for predicting infections that could occur in other patients with qualitative or quantitative granulocyte defects.

Neutropenia predisposes to the development of bacterial and fungal infections but does not appear to increase the incidence or severity of viral and parasitic infections. Patients with profound and prolonged neutropenia who are at particular high risk for infection (e.g., cytopenic patients with acute myelogenous leukemia and severe mucositis following induction therapy) are likely to benefit from receiving prophylactic antimicrobials.^{8,9} However, patients with moderate granulocytopenia (i.e., absolute granulocyte counts in the range from 500 to $2000/\text{mm}^3$ that are not falling precipitously) should not receive prophylactic antimicrobial agents. Colony-stimulating factors (granulocyte colony-stimulating factor [G-CSF; pegylated filgrastim], granulocyte-macrophage colony-stimulating factor [GM-CSF, sargramostim]) are routinely used in the management of

Fig. 89.2 RELATIONSHIP OF SEVERITY AND DURATION OF NEUTROPENIA TO THE RISK FOR DEVELOPING A SERIOUS INFECTION. PMN, Polymorphonuclear neutrophil. (Courtesy GE Body.)

hematologic disorders. A number of functional granulocyte parameters may be enhanced by G-CSF or GM-CSF, including enhanced per-cell phagocytosis, oxidative metabolism, microbicidal activity, and antibody-dependent cytotoxicity.¹⁰ However, G-CSF or GM-CSF administration may decrease the motility of granulocytes, impair *in vivo* migration, and decrease bacteria-induced chemotaxis. The clinical significance of any of these effects remains to be established but is generally believed to be insignificant in light of the potency of these agents in shortening the depth and duration of therapy-induced neutropenia.

Defects in Cell-Mediated Immunity

Cellular immune dysfunction occurs in patients with lymphoid malignancies, in those with hematologic malignancies undergoing HSCT, and in patients with AIDS. The most frequently encountered pathogens are intracellular organisms because they can survive and even replicate inside macrophages in a nonimmune individual or in the absence of T-cell immunity. Specific pathogens associated with infection in patients with cell-mediated immunity include bacteria (including *Mycobacterium tuberculosis*, atypical mycobacteria, *Salmonella*, streptococci, *Legionella*, *Nocardia*, and *Listeria*); fungi (including the yeasts *Candida* and *Cryptococcus*; molds such as *Aspergillus*; endemic dimorphic fungi such as *Histoplasma* and *Coccidioides*; and *Pneumocystis*); viruses (including herpes group viruses [HSV, VZV, CMV] and respiratory viruses); and protozoa (*Toxoplasma gondii*, *Cryptosporidium*, and *Strongyloides stercoralis*).

Patients with defects in cell-mediated immunity or who are about to receive HSCT should undergo risk factor assessment for reactivation of tuberculosis. Patients with a known history of an untreated but positive Mantoux test or interferon-gamma release assay should receive prophylactic isoniazid to prevent reactivation and potential dissemination of tuberculosis. Patients without a prior Mantoux test but with risk factors for tuberculosis should undergo a screening test for latent tuberculosis before starting the conditioning regimen for HSCT.

Patients with defects in cell-mediated immunity are at risk for the development of disseminated infection due to live vaccines, even when the vaccine contains attenuated organisms. Accordingly, these patients should not receive vaccines containing bacillus Calmette-Guérin (BCG), vaccinia/smallpox, measles, mumps, rubella, yellow fever, or oral polio.¹¹ HSCT recipients are eligible for revaccination with some of the live virus vaccines 2 years after transplantation, provided the patient does not have graft-versus-host disease (GVHD) or is not receiving ongoing pharmacologic immunosuppression (see Chapter 110, Table 110.4).

Defects in the Humoral Immune System

Immunoglobulin and complement are components of the humoral immune system. Immunoglobulin and complement both have associated lytic and neutralizing activities. Patients with primary or secondary defects or deficiencies in humoral immunity are susceptible to recurrent pyogenic infections from polysaccharide-encapsulated bacteria, such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria* species. HSCT recipients who continue to receive immunosuppressants more than 100 days after transplantation should be given antimicrobial prophylaxis with coverage for encapsulated bacteria until immunosuppression is discontinued. Patients are also at risk for infections from enteroviruses and *Giardia lamblia*. Patients with low levels of circulating IgG may benefit from intravenous Ig (IVIg) infusions, although the benefit of using of IVIg infusions for routine prophylaxis must be weighed against the expense of this approach.

Abnormalities in Splenic Function

A number of hematologic disorders are complicated by either intrinsic splenic impairment or splenectomy. The spleen removes organisms from the blood that have been ineffectively opsonized by complement, serving an adjunctive role in fighting infection. It is involved in the regulation of the alternate complement pathway, and low levels of immunoglobulin and properdin have been reported in patients after splenectomy. Alternate pathway defects may be particularly important in patients with splenic dysfunction associated with sickle cell disease.

Asplenic or splenectomized patients are at increased risk for serious, frequently fulminant, bacterial infections, primarily for infections caused by *S. pneumoniae*, *H. influenzae*, *Neisseria*, *Babesia*, and *Capnocytophaga canimorsus*. The initial presentation of even overwhelming infection can be subtle, with fever often the only sign. Accordingly, all asplenic patients with underlying hematologic disease who present with fever should be managed initially as potentially septic. Overwhelming infection after splenectomy occurs in approximately 7% of postsplenectomy patients, with 50% of infection-related deaths occurring in the first 3 months. Prophylaxis against pneumococcal infection is used for asplenic patients who are small children or for those with increased immune impairment from malignant disease.

Pneumococcal, *H. influenzae* type b, and meningococcal vaccines should be administered to asplenic patients. Patients with an intact spleen may respond better to pneumococcal polysaccharide vaccine than do splenectomized patients, so immunization is recommended as early as possible before elective surgery. Additionally, immunization before splenectomy can result in protective pneumococcal antibody titers immediately after the operation. For patients with Hodgkin lymphoma, the antibody response to pneumococcal vaccine may not be affected by the timing of immunization relative to splenectomy. Immunizations reduce, but do not eliminate the risk for serious infection with encapsulated bacteria.

Anatomic Alterations in Host Defense

Immunocompromised patients frequently have disruptions in the skin and mucosa, which are important primary physical barriers against endogenous and exogenous sources of infections (Fig. 89.1). Disruption of skin and mucosa may result from invasion by malignant cells, from the effects of chemotherapy or radiation therapy, from use of invasive diagnostic or therapeutic procedures (e.g., intravenous catheters), and from the effects of local infections, such as oral HSV. Such alterations may provide a nidus for microbial colonization, a focus for localized infection, and a portal of entry for systemic invasion. Organisms associated with defects in skin or mucosal surfaces depend on the site of breakdown, local colonizing flora, and other factors. Gram-positive organisms are associated with isolated

disruption of the skin from an indwelling intravenous catheter, usually with coagulase-negative staphylococci, but also with *Corynebacterium jeikeium*, *Bacillus* species, and occasionally atypical mycobacteria.

GI mucosal integrity is frequently disrupted by chemotherapeutic agents. Because the GI tract normally is colonized by a multitude of organisms, this state can lead to infection by streptococci, aerobic gram-negative enteric and anaerobic bacteria, and yeast. Mucosal damage can allow normal flora to invade and become pathogens. Lower GI ulcerations permit infections by *Bacteroides fragilis* or *Streptococcus bovis*. Oral lesions are associated with HSV reactivation, ulceration, and possible bloodstream infection with other common oral flora such as α -hemolytic streptococci.

The genitourinary tract mucosa may be disrupted by tumors, invasive procedures, or cytotoxic therapy, with subsequent colonization and the potential for local or invasive infection. The most common urinary tract pathogens are enteric gram-negative bacilli, enterococci, and *Candida albicans*. Viral reactivation is common, predominantly from adenovirus and polyomavirus (BK virus), but also from the herpesviruses (HSV and CMV).

The lung, genitourinary tract, biliary tract, and auditory canal are potential sites of mechanical obstruction, increasing the risk for localized infection. Obstruction may lead to stasis of local body fluids, with resultant overgrowth of potentially pathogenic colonizing organisms. Patients with chronic hemolytic states are prone to gallstones that can become a nidus for infection.

Anatomic alteration can predispose to infection simply by providing a nidus for growth of organisms. Many patients with sickle cell anemia and hemophilia have underlying anatomic abnormalities of the bones and joints as a result of vasoocclusive crises causing infarction of marrow, bony cortex, or synovium. In turn, these changes may predispose to infection such as osteomyelitis or arthritis. Decreased local blood flow and increased bacterial adherence may be other contributing factors. Foreign bodies, such as prosthetic devices, can lead to persistent infection after even transient bacteremia.

Infection in Patients With Acute Neutropenia or Lymphopenia Following Chemotherapy or Transplantation

This section outlines predictable infections that can present during acute profound neutropenia/lymphopenia.

Fever

Despite the specific prophylactic measures directed against common pathogens, many fevers occur in neutropenic patients after transplantation or chemotherapy. Fever can be divided into three categories: infectious fever with an obvious source, infectious fever without an obvious source, and noninfectious fever. Risk factor assessment should include knowledge of the temporal relationship to blood product infusions; recent exposure to contagious infection; degree of fever and whether the fever is accompanied by chills, rigors, or diaphoresis; and response to antipyretics. Symptom assessment should include evaluation to assess sinus drainage, sore throat, ear pain, cough, sputum production, shortness of breath, abdominal pain, diarrhea, rash, and dysuria.

The initial workup of fever in a patient with neutropenia, regardless of whether an infectious or noninfectious source is suspected, is identical and includes blood culture, culture of symptom-related sites (e.g., sputum, urine, with/without stool, with/without cerebrospinal fluid), review of medication list for potential contributors to drug fever, review of recent transfusions, chest radiograph, and computed tomography (CT) scan of any symptom-related body systems. When feasible, blood cultures should be drawn through an existing indwelling catheter as well as peripherally because this can facilitate the diagnosis of a catheter-related bloodstream infection compared with

a bloodstream infection arising from a different source (e.g., the GI tract).¹²

Consensus guidelines on the management of patients with febrile neutropenia have been published.¹³ Empiric antibiotics are recommended for all febrile patients with neutropenia, but the type of antibiotics and the site of administration (i.e., hospital vs. outpatient) depends on the severity of immunosuppression, expected duration of neutropenia, and factors related to the local epidemiology and resistance patterns (Fig. 89.3). Patients defined as low risk using the Multinational Association for Supportive Care in Cancer (MASCC) index can be treated as outpatients, whereas other patients are generally admitted for intravenous therapy.¹⁴ Typical pathogens causing infection in this situation include Enterobacteriaceae, *Pseudomonas*, *Streptococcus*, and *Staphylococcus* spp. Thus antipseudomonal β -lactam antibiotics such as third-generation cephalosporins, piperacillin-tazobactam, and carbapenems are commonly employed as empiric

therapy.¹⁵ Vancomycin is administered if staphylococcal disease is suspected or if the patient is clinically unstable while cultures are pending. Severely ill patients are often also treated with an aminoglycoside for the first 48 to 72 hours of illness, although data in support of this approach are lacking.

Therapeutic changes to the antimicrobial regimens are made in response to culture results, but the cultures are negative about 50% of the time (Fig. 89.3). If the patient becomes afebrile, therapy is usually continued for 7 days. Persistent fever after more than 72 hours of empiric therapy suggests an untreated infection. If the patient is recovering his or her neutrophil count, no additional changes in antibiotics are typically needed. However, the persistently neutropenic and febrile patient may have an occult fungal infection such as candidiasis or aspergillosis. Thus initiation of empiric antifungal therapy with antimold activity (e.g., amphotericin B, caspofungin, voriconazole) is usually begun in such a situation.

a Hypotension, altered mental status, neurologic changes, respiratory failure, abdominal pain, hemorrhage, cardiac compromise or new arrhythmia, catheter tunnel infection, extensive cellulitis, acute renal or liver failure

b Institution sensitivity dependent, ciprofloxacin, levofloxacin, moxifloxacin

c Drug selection and dosing institution-specific: piperacillin tazobactam, ticarcillin/clavulanate

d Drug selection and dosing institution-specific: ceftazidime

e imipenem, cefepime/cilastatin, meropenem, doripenem

f Gentamicin, tobramycin, or amikacin

g Drug selection and institution institution-specific: vancomycin, linezolid, daptomycin, ceftaroline

TABLE 89.3 Pulmonary Infiltrates and Their Association With Specific Infectious and Noninfectious Etiologies

Radiologic Sign	Differential Diagnosis
Interstitial infiltrates	Pulmonary edema Diffuse alveolar damage Idiopathic pneumonia syndrome Respiratory viruses: respiratory syncytial virus, parainfluenza, influenza, adenovirus, enterovirus Herpes viruses: cytomegalovirus, herpes simplex virus, varicella zoster virus, human herpes virus type 6 <i>Pneumocystis pneumonia</i>
Focal airspace disease	Bacterial pneumonia Fungal pneumonia
Nodules	Fungal pneumonia (aspergillosis) <i>Nocardia</i> <i>Legionella</i> Septic bacterial emboli Mycobacterial infection (with cavitation) Epstein-Barr virus lymphoproliferative disorder Relapsed malignancy Pulmonary embolism (pleural based)
Halo sign or air crescent sign	Aspergillosis

Two common anaerobic infections occur during neutropenia at sites where biopsy is difficult or contraindicated. Neutropenic enterocolitis, also known as typhlitis, manifests as fever, abdominal pain, and tenderness. CT scan of the abdomen shows signs of right-sided colonic and ileal inflammation.¹⁶ Excessive soft-tissue swelling of the neck during mucositis can present as a Ludwig angina variant. Broadly active antianaerobic, aerobic, and possibly antifungal antimicrobial agents should be added for either of these clinical findings.

Pulmonary Infiltrates

Pulmonary infections are common in the immunocompromised host (see box on [Approach to Pulmonary Infiltrates](#)). Plain chest radiography is a good initial screen but lacks the sensitivity of CT, which generally provides more useful information in terms of characterizing the nature of an infiltrate and assists the pulmonologist in determining where to direct the bronchoscope for highest yield. A specific infectious and noninfectious differential diagnosis exists for certain radiologic signs ([Table 89.3](#)). For example, consolidative focal airspace disease is associated most typically with a bacterial pneumonia. A halo of interstitial changes around a pulmonary nodule or an air crescent above a pulmonary nodule is most likely due to aspergillosis ([Fig. 89.4](#)).¹⁷ Although 90% of pulmonary nodules are due to fungal pneumonia (mainly aspergillosis), 10% have various etiologies, including septic bacterial emboli, *Nocardia*, *Legionella*, mycobacterial infection (with cavitation), Epstein-Barr virus (EBV)-related lymphoproliferative disease, relapsed malignancy, and pulmonary embolism (pleural based). Interstitial infiltrates can be caused by either respiratory viruses during the winter season (except for parainfluenza virus, which is nonseasonal), herpes viruses, *Pneumocystis*, edema, or idiopathic. A complete differential of causes of interstitial pneumonitis (a pulmonary syndrome often associated with HSCT) is given in [Chapter 110](#).

Pulmonary and sinus infections from inhaled molds are more likely to occur as the duration of neutropenia lengthens, particularly beyond an initial 21-day window. For that reason, among HSCT recipients without graft failure, invasive tissue mold infections occur at a low rate (less than 3%) before engraftment because of the

Fig. 89.4 COMPUTED TOMOGRAPHY SCAN EXAMPLES OF DIFFERENT PULMONARY INFILTRATES IN IMMUNOCOMPROMISED PATIENTS. (A) Diffuse ground-glass opacities in a patient with *Pneumocystis jirovecii* pneumonia. (B) Cavitory lung lesion in a patient with *Pseudomonas aeruginosa* pneumonia. (C) Lung nodule with halo sign due to *Aspergillus*. For each panel, the arrow points to involved pulmonary parenchyma.

environmental preventive measures taken for air filtration. However, if endogenous occult aspergillosis infections are present before HSCT, the infection can rapidly escalate when the immune system is profoundly suppressed by the preparative regimen. This phenomenon manifests as early invasive aspergillosis (before day 40). Therefore patients with hematologic malignancy at risk for occult mold infections in the lungs, sinuses, and at times, the oral cavity should have CT scans of the lungs and sinuses before the onset of any profoundly immunosuppressive regimens, such as HSCT and select nontransplantation regimens. High-risk patients may be given mold-active antifungal prophylaxis to either prevent or suppress invasive mold infections.

Approach to Pulmonary Infiltrates

Pulmonary infiltrates can be divided into three general categories: consolidative, interstitial, and nodular. A consolidative infiltrate may be bacterial, even polymicrobial, so sampling of the infiltrate through sputum or endotracheal tube suctioning for bacterial and fungal cultures is required. If either of these methods does not provide an adequate sample from a consolidative infiltrate, or if these methods do not lead to a diagnosis, “early” (within 72 hours) bronchoscopy is indicated. If interstitial or nodular infiltrates are not peripheral (i.e., within the range of the bronchoscope), they should also be evaluated with timely bronchoscopy. An advantage of bronchoscopy, in addition to the ability to obtain a deep specimen, is that the samples usually are sent for a broad range of diagnostic tests. These tests usually are ordered from preprinted order sheets, which reduce errors. Most preprinted order sheets for bronchoalveolar lavage fluid will test for the following:

- Cytology, with the attendant Fite and Gomori methenamine silver stains
- Bacterial (Gram) stain and aerobic culture
- Mycobacterial (acid-fast bacillus) stain and culture
- Fungal (potassium hydroxide or calcofluor) stain and culture
- *Nocardia* culture
- *Legionella* culture
- Viral cultures for herpes viruses and respiratory viruses
- Rapid test for cytomegalovirus (shell vial or polymerase chain reaction [PCR])
- Rapid test for respiratory viruses during respiratory virus season (pooled respiratory virus shell vial, respiratory syncytial virus antigen, influenza A/B antigen)

Optional tests that can be requested from bronchoalveolar lavage fluid, some at significant extra expense, include the following:

- Mycobacterial stain (requires separate 5 mL volume that cannot be used later for culture)
- *Mycoplasma pneumoniae* PCR
- *Chlamydia pneumoniae* PCR
- Human herpesvirus type 6 PCR
- Human metapneumovirus PCR
- *Aspergillus* galactomannan antigen
- Any of the above first-tier tests that your institution does not send on a routine basis (e.g., *Nocardia* or *Legionella*)

Invasive sampling may be the only definitive means for making a diagnosis of peripheral nodules. The two main options are percutaneous fine-needle aspiration or open lung biopsy (usually obtained through video-assisted thoracoscopic surgical procedure). In toto sampling of a lung nodule permits enough material for the whole range of the above diagnostic tests as well as histopathology. Of note, fewer lobectomies of unilateral pulmonary nodular infiltrates have been reported in recent years, probably a result of the frequent use of a broad range of less toxic antifungal medications.

Bacteria

Because bacterial infections cause significant morbidity and mortality in neutropenic patients, broad-spectrum antibacterial prophylaxis is often used during periods of profound neutropenia. The exact agents used vary, but typical agents include a quinolone (e.g., levofloxacin) or a β -lactam (e.g., cefpodoxime). Institutional protocols and resistance patterns drive selection of specific prophylactic agents. Oral prophylaxis regimens are generally discontinued and substituted with intravenous antibacterials with enhanced activity against *Pseudomonas aeruginosa* with the first onset of fever. The use of oral antibiotics among low-risk, neutropenic patients with fever is guided by the use of standardized scoring systems (e.g., MASCC index).¹

Mucositis, with breakdown of oral and GI mucosal barriers, is common during this period. This condition can predispose to sepsis from bacterial and fungal organisms that typically colonize the GI tract. The most common serious infections occurring in neutropenic patients with mucositis are bacteremias due to viridans group streptococci and gram-negative bacilli. Such infections are particularly common during the first several weeks following HSCT, so broad-spectrum antimicrobial prophylaxis is generally given during this

time period. The propensity of viridans streptococci to develop resistance to quinolones and gram-negative bacilli to be resistant to quinolones and β -lactams means that there is no perfect preventive regimen.

Central venous catheter placement through the skin can lead to blood infection from colonizing gram-positive skin organisms, despite sterile, operative placement of these catheters and antiseptic cleansing procedures.¹⁸ Because the gram-positive bacteremias, including those caused by coagulase-negative *Staphylococcus* species, usually are not immediately life threatening, direct prophylactic coverage often is not immediately provided. During workup of a new fever, some treatment guidelines advocate the administration of vancomycin for several days until blood cultures demonstrate no gram-positive bacteremia. The use of antimicrobial-coated bloodstream catheters can be effective in reducing rates of catheter-related bloodstream infections.

Once a gram-positive bacterial infection is identified, vancomycin therapy is often used empirically until the susceptibility profile is available and targeted therapy can be provided. There are concerns about the efficacy of vancomycin in treating serious *S. aureus* infections because of relative or frank vancomycin resistance. Similarly, if the patient is known to be colonized with vancomycin-resistant enterococcus and the Gram stain indicates gram-positive organisms in chains, therapy for empiric vancomycin-resistant enterococcus is appropriate until the bacterial identification and susceptibility profile is available, usually with daptomycin or linezolid.

Once a gram-negative infection is identified, empiric therapy that includes *Pseudomonas* coverage is continued until the susceptibility profile is available. In the severely neutropenic host, serious gram-negative infections are often treated with combination therapy consisting of a β -lactam plus either an aminoglycoside or a quinolone depending on the antimicrobial sensitivity pattern and patient comorbidities.¹⁵ However, data demonstrating the superiority of combination therapy over β -lactam monotherapy are lacking. The emergence of extended-spectrum β -lactamase producing gram-negative bacilli is a particular concern in patients with significant antimicrobial exposure as are the development of infections with pan-resistant organisms, such as multidrug-resistant *Acinetobacter baumannii* (see box on [Treatment of Drug-Resistant Gram-Negative Bacilli](#)). For many infections, the regimen then can be tailored to a single agent and continued for 2 weeks after the last positive culture in clinically responding patients. Therapy with a carbapenem resistant to β -lactamase hydrolysis is required if an organism is isolated that is known to have an inducible β -lactamase enzyme (e.g., *Enterobacter*).

For bloodstream infections, repeat blood cultures should be drawn after 2 to 3 days of effective therapy to ensure that sterilization of the bloodstream has been achieved. Persistently positive blood cultures suggest the development of a deep-seated or endovascular site of infection such as infective endocarditis or suppurative thrombophlebitis. When a bloodstream catheter is proven to be the source of the infection,^{12,18} removal of the catheter may be required for most, but not all, infections. At the end of a 14-day treatment course beyond the last positive culture, the patient should be transitioned to an oral gram-negative prophylaxis regimen if still neutropenic.

Antimicrobial agents with anaerobic activity should be added for neutropenic enterocolitis, enlargement of neck soft tissues during mucositis (Ludwig angina variant), or culture-documented anaerobic infection. Infrequently, tuberculous and nontuberculous mycobacteria are responsible for infections in the bloodstream, catheters, and pulmonary tree. Infections of central catheters or catheter tunnels caused by rapidly growing atypical mycobacterial infections require a high index of suspicion, as well as specific culture media.¹⁹ Organism identification and drug sensitivities may take several weeks. Tuberculous disease can be empirically treated based on risk factors. For patients without risk factors for tuberculosis, recovery of acid-fast bacilli will prompt therapy for suspected nontuberculous mycobacteria, usually with clarithromycin and either a quinolone or ethambutol until specific susceptibility information is available. Tailored therapy is often continued for a minimum of 3 to 6 months.

Treatment of Drug-Resistant Gram-Negative Bacilli

The widespread use of antibiotic prophylaxis among immunocompromised patients has been associated with the development of antimicrobial drug resistance, which is especially problematic among gram-negative bacilli. Drug-resistant organisms can colonize the GI tract for prolonged periods of time and emerge to cause serious infections during periods of neutropenia or other medical stress (e.g., following admission to the intensive care unit).

- *Pseudomonas aeruginosa* is the paradigm for drug resistance among gram-negative bacilli and often rapidly develops pan-resistance to antimicrobials. Serious pseudomonal infections are generally treated with two antimicrobial agents, although convincing data supporting this approach are lacking.
- Extended-spectrum β -lactamase (ESBL) production among Enterobacteriaceae such as *Escherichia coli* and *Klebsiella pneumoniae* renders these organisms resistant to non-carbapenem β -lactam antibiotics. Treatment is generally with a carbapenem (e.g., meropenem), although a quinolone can sometimes be used.
- The presence of a *Klebsiella pneumoniae* carbapenemase (KPC) can occur among species other than *K. pneumoniae* and creates resistance to all β -lactam antibiotics including carbapenems. Resistance to quinolones is also typical, so therapy is limited to the polymyxins (e.g., colistin), or to tigecycline and the aminoglycosides depending on the organism's antibiotic susceptibility pattern.
- Like *P. aeruginosa*, *A. baumannii* can develop resistance to all known antimicrobials via a variety of mechanisms. This generally occurs among critically ill patients following prolonged stays in the intensive care unit. Treatment options may include polymyxins and sulbactam, a β -lactamase inhibitor that possesses some activity against drug-resistant *Acinetobacter*.
- *Enterobacter*, *Serratia*, and *Citrobacter* species can elaborate an AmpC β -lactamase following initiation of β -lactam therapy, which can result in a relapsing infection following an initial response. Thus clinicians treating such infections with penicillins or cephalosporins should closely monitor patients for the emergence of resistance. If resistance does emerge, AmpC-producing organisms can be treated with a carbapenem.
- Patients with multidrug-resistant gram-negative infections should be cared for in such a manner as to minimize spread of these dangerous organisms to other patients. Compliance with infection control protocols is paramount.
- Knowledge of the local epidemiology and antibiogram are important for preemptive and empiric antibiotic choices, especially against gram-negative rods.
- A carefully designed and executed antibiotic stewardship program could curtail unnecessary antibiotic use, thereby decreasing antibiotic selection pressure with a resulting decrease in bacterial resistance rates.

Viruses

Neutropenia per se is not a major risk factor for developing viral infections but concomitant lymphopenia is common and does predispose to infections with a range of viruses.²⁰ Respiratory virus infections are seasonal, except for parainfluenza. A frequent pathogen with clinical significance is respiratory syncytial virus, although influenza, parainfluenza, adenovirus, enteroviruses, the herpesviruses (including HHV-6), human metapneumovirus, and rhinovirus also produce diffuse interstitial infiltrates and pneumonitis.²⁰ HHV-6 and human metapneumovirus are not recovered with the usual tests ordered at the time of bronchoscopy, so a high suspicion for infection is required to order specific PCR testing. Documented infection with RSV prompts contact and droplet isolation precautions. Treatment components may include aerosolized ribavirin, IVIg, and in some cases, monoclonal antibody therapy. However, proof of efficacy of these treatments remains elusive, and the disease can cause significant morbidity and mortality.²¹ With respiratory syncytial virus infections, aerosolized ribavirin treatment appears safe, and trends of decreasing viral loads have been reported. Secondary graft failure or diffuse

alveolar hemorrhage associated with parainfluenza virus infection has been sporadically reported following transplantation.

Patients with lymphopenia are susceptible to a range of herpes virus family infections. Herpes simplex reactivation infections typically manifest as oral or genital ulcers, although more widespread involvement can occur, and are treated with low doses of acyclovir adjusted for renal function (e.g., 5 mg/kg IV every 8 hours) or oral valacyclovir (1 g bid). Reactivation of VZV can be severe in immunosuppressed persons and is treated with higher doses of acyclovir (e.g., 10 mg/kg IV every 8 hours or oral valacyclovir, 1 g three times a day). Use of acyclovir to prevent reactivation of HSV will also prevent VZV reactivation. Because many patients have not been exposed to acyclovir chronically (except for patients previously treated with recurrent courses of acyclovir for frequent outbreaks of genital herpes), there is little reason to expect resistance to acyclovir. However, HSV infections that appear or persist through acyclovir prophylaxis should be considered acyclovir resistant until viral sensitivity testing can be performed, and consideration should be given to initiating treatment with foscarnet or cidofovir.²² Reports of acyclovir-resistant varicella are extremely rare. Foscarnet infusions affect calcium homeostasis, so monitoring of ionized calcium and phosphorus levels is required during clinical use of the drug. The major side effect of cidofovir is renal toxicity, which can be reduced to some degree with probenecid and hydration. Clinically significant CMV infection can occur during neutropenia, but the antigenemia test cannot be used for diagnosis or monitoring of response to therapy in this situation, so DNA PCR methods are preferred in that setting.

Human herpesvirus type 6 (HHV-6) is ubiquitous, and reactivation commonly occurs in patients with significant immunosuppression. However, clinically significant disease due to HHV-6 occurs in only a small percentage of patients who have HHV-6 detected in their blood.²³ HHV-6 infection can manifest as fever or pancytopenia. Other recognized clinical syndromes include pneumonitis and encephalitis. Infection is diagnosed by quantitative PCR, although the exact levels of virus that indicate clinically significant disease are not known. Detection of virus in the first 3 weeks following transplantation may be associated with early skin maculopapular rash and acute GVHD, but it can also present without overt clinical symptoms. Prospective large-scale studies are needed to determine the role of HHV-6 infection. HHV-6 has 60% DNA homology with CMV, and treatment of documented infection usually is initiated with induction doses of foscarnet or ganciclovir. Responses to antiviral therapy are not universal, and benefits of foscarnet versus ganciclovir have not been determined.

Cidofovir, when combined with aggressive supportive measures, is considered an adjunct in treatment of BK and adenovirus-associated hemorrhagic cystitis. Similarly, cidofovir can be used to treat disseminated adenovirus infections typically three times a week at 1 mg/kg/day, along with probenecid and hyperhydration.

Fungi

Most yeast infections in immunosuppressed patients are caused by *Candida*.²⁴ Candidal organisms that colonize the mouth and gut proliferate when antibacterial agents suppress the coexisting bacterial flora population. Guidelines for the treatment of candidiasis have been issued.²⁵ Patients who are clinically stable generally can be treated with fluconazole unless there has been previous azole exposure or mold infection is also a concern. Unstable patients or those who have been receiving an azole are usually treated with an echinocandin. Prevention of candidemia among allogeneic HSCT recipients is generally achieved with fluconazole. However, fluconazole does not have activity against some nonalbicans *Candida* species (e.g., *C. glabrata*, *C. krusei*) and all molds (e.g., *Aspergillus*, *Fusarium*, the Mucorales species). Among patients colonized with yeast species other than *C. albicans* and among heavily pretreated patients who may have incubating mold infection, prophylaxis using a mold-active triazole (e.g., posaconazole) or an echinocandin is preferred.²⁶

Fig. 89.5 EXAMPLES OF ASPERGILLOSIS. (A) Cutaneous aspergillosis in a patient with lymphoma treated with high-dose steroids. (B) Invasive aspergillosis with organism invading into blood vessel wall (black arrows).

Although less common than *Candida* infections, mold infections in immunocompromised hosts are a significant source of mortality, with aspergillosis being the most common (Fig. 89.5). Because such infections are difficult to diagnose using standard microbiologic techniques, there has been significant interest in developing more effective screening tests. When used regularly, the serum *Aspergillus* galactomannan enzyme-linked immunosorbent assay (ELISA) may allow for earlier diagnosis of invasive aspergillosis in some patients.²⁷ The test is troubled by difficulties with both false-positive and false-negative results and thus needs to be interpreted as part of the overall clinical picture rather than as a stand-alone diagnostic tool. The development of a fungal infection in a patient receiving voriconazole should raise concern for mucormycosis, which is the second-most common mold infection in many transplant centers. Mucormycosis can rapidly disseminate through the lungs, sinuses, GI tract, and skin, which is uniformly fatal in patients with hematologic malignancies if not diagnosed early and aggressively treated.²⁸

Although in vitro antifungal susceptibility testing for yeasts is not as well established as antibacterial testing, susceptibility from

Use of Antifungal Agents in Combination

The development of new antifungal drugs gives the clinician more options for prophylaxis and therapy than in previous years. There is an overall level of simplicity to the drug choices once their mechanisms of action are understood. The polyenes, including amphotericin products and the topical agent nystatin, attach onto ergosterol in the fungal cell membrane and are considered fungicidal, because cytoplasm leaks out, and individual cells die. The azoles, including fluconazole, itraconazole, voriconazole, and posaconazole, prevent the formation of new ergosterol. Azoles are considered fungistatic, because removal of the drug permits cell regrowth. Theoretically, use of an azole together with a polyene may have an overall static effect for an established infection as the ergosterol target for the fungicidal polyene is depleted. However, this combination may have advantages in terms of enhanced spectrum of activity. The echinocandins, including caspofungin, micafungin, and anidulafungin, prevent interaction of the catalytic and regulatory subunits of the β -glucan synthesis enzyme, so less β -glucan is formed for the cell wall. The scaffolding for the fungal cell wall is not maintained, and a dividing cell may burst open when trying to extend the new cell wall over daughter cells. The echinocandins are considered fungicidal for yeasts but fungistatic for molds, because drug activity is concentrated at only the tips of the extending hyphae with little effect on less metabolically active subapical compartments of the fungus. Combination therapy may have the most effect when a cell wall agent (an echinocandin) is used together with a cell membrane agent (a polyene or an azole). There is no role for three-drug therapy (an echinocandin, a polyene, and an azole). Aside from cases of cryptococcal meningitis, in which the importance of combination therapy is well established, the benefits of frontline use of combination antifungal for molds remain controversial, although active investigation continues in clinical trials. The value of combination regimens as salvage therapy for refractory mold infections remains uncertain.

bloodstream or invasive isolates can be helpful in the management of infections, especially if the patient will require transition to longer-term oral therapy. Long-term treatment with newer azoles may be valuable in responding patients. Echinocandins cannot be used to treat *Cryptococcus* or Mucorales as monotherapy, but there may be a role for echinocandin in combination treatment for Mucorales. Mucorales species are generally susceptible to amphotericin B and posaconazole and isavuconazole, although there are interspecies variations in susceptibility. In the case of mold infections, echinocandin agents may be fungistatic, rather than fungicidal, because interruption of fungal cell wall synthesis is limited to areas of hyphal branch points and growing hyphal tips. Because susceptibility testing for the echinocandin agents is of uncertain reliability, use of an echinocandin after the susceptibility profile has returned should be limited to non-neutropenic patients with uncomplicated candidemia. At present, the efficacy of combination drug therapy is unproven, but such therapy is often used in situations associated with high mortality. Clinical experience, but little clearly documented evidence, supports the value of extended combination antifungal therapy. Molds that often are resistant to amphotericin but may be susceptible to voriconazole or posaconazole include *Fusarium*, *Scedosporium* or *Pseudallescheria*, and *Trichosporon* (see box on [Use of Antifungal Agents in Combination](#)).

Malignancy-Associated Fever and Drug Fever

Although fever usually indicates the presence of infection, relapsing malignancy, autoimmune-granulomatous, collagen vascular diseases, or immunologic drug reactions can also be sources of fever in the immunocompromised host.²⁹ Malignancy or drug-associated fevers are the most common causes of persistent noninfectious fevers in cancer patients, but these are “diagnoses of exclusion” that require extensive clinical, radiographic, and microbiologic workup for occult infection until a noninfectious cause is considered most likely. All too often, patients receive escalating empiric broad-spectrum antibiotic therapy during this workup, which should be discouraged in clinically stable patients. Several clinical clues may favor a diagnosis of

malignancy-associated fever, including (1) a prior history of fever at the time of initial malignancy diagnosis and (2) response of the fever to a trial of naproxen.² Patients with drug-associated fever often appear clinically well with relative bradycardia during periods of fever. Drug fevers typically develop 1 to 3 weeks after the start of a drug (β -lactams, sulfas, vancomycin, and phenytoin are among the most common inciting agents) and resolve, on average, within 48 hours of drug discontinuation unless the patient also has an accompanying rash. Drug-associated fever with rash and liver function test or complete blood count abnormalities (e.g., thrombocytopenia and eosinophilia) are often indicative of more severe reactions that should prompt immediate discontinuation or substitution of the likely offending medications.

INFECTION MANAGEMENT IN THE HEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENT: A MODEL OF SEVERE IMMUNE DEFICIENCY

Infection is a major cause of morbidity and mortality in HSCT recipients. Such patients are susceptible to a wide range of infections, but the risk for a particular infection depends on a multitude of factors, including the type of transplantation, the length of time since transplantation, and the development of GVHD. A summary of common infections occurring in HSCT recipients is shown in Fig. 89.6.

Pretransplantation Prophylactic Techniques in Hematopoietic Stem Cell Transplant Recipients

Over the four decades during which HSCT has evolved, antimicrobial prophylaxis regimens have advanced to prevent common or high-risk infections.³ This is balanced by problems associated with the preventive regimen, including toxicity, overgrowth of resistant organisms, and sometimes high cost. Algorithms for these preventive regimens evolve with changes in epidemiology, diagnostic methods, and new treatment agents for infections. Despite an overall preventive approach, infections still occur when a severe immune defect persists,

when the infecting inoculum of organisms is large, when diagnostic methods are not sensitive enough for early detection, or when infecting agents overcome the effect of the antimicrobial agents. Measures taken to prevent infection in the preengraftment HSCT patient include pretransplantation serostatus blood workup, environmental measures to prevent infection (including frequent handwashing), and common sense.

Assessment of Pretransplantation Serostatus

Current pretransplant serologic testing of donor and recipient includes assaying for latent viruses (herpesvirus antibodies, hepatitis panels, and human T-cell lymphotropic virus antibodies [human T-lymphotropic virus I/II and HIV 1/2]) and syphilis. Antibody tests that are checked variably among individual transplantation centers include VZV, EBV, and *Toxoplasma*.

Herpes Simplex Virus

If the antibody test for HSV indicates prior infection or if the patient provides a clinical history of prior HSV infection (i.e., mucosal sores), latent infection exists and has the potential to reactivate during periods of T-cell suppression and neutropenia. This patient requires prophylactic medication (e.g., acyclovir or oral valacyclovir), which targets HSV for the neutropenic phase of transplantation. HSV lesions can appear as black scabs on the outside of the lips, white- to yellow-based ulcers when found on oral mucosa, or as an unusually severe exacerbation of mucositis or esophagitis. HSV prophylaxis administered until recovery from neutropenia may be helpful even in patients receiving nontransplantation chemotherapy such as acute leukemia induction therapy.

Cytomegalovirus

If the candidate is CMV seropositive before transplantation, the recipient should be followed with periodic (usually weekly) diagnostic

Fig. 89.6 TIMING OF INFECTIONS FOLLOWING HEMATOPOIETIC STEM CELL TRANSPLANT. GI, Gastrointestinal; GVHD, graft-versus-host disease; HSV, herpes simplex virus.

monitoring tests (e.g., pp65 antigenemia or PCR) for 10 to 20 weeks. No special measures are needed during neutropenia because a detectable circulating white count usually is necessary for reactivation of CMV. If the patient is CMV seronegative before transplantation but the donor is seropositive, the same monitoring algorithm used for the CMV-seropositive patient is needed.

If the donor and recipient are CMV seronegative before transplantation, infection through blood products is possible; therefore exclusive use of CMV-seronegative blood products or other means of preventing CMV seroconversion, such as leukocyte depletion by filtration, are recommended. CMV monitoring should be followed weekly, but the duration of this testing can be shortened by 50%, to 6 to 10 weeks, because late infection in seronegative recipients is uncommon.

Varicella, Human Herpes Virus Type 6, and Epstein-Barr Virus

A history of chickenpox is an adequate surrogate for performing the VZV antibody test. As an alternative to ordering varicella serology on every patient, the test could be ordered in patients with no history of varicella infection or vaccination.

Acyclovir used to prevent reactivation of HSV during neutropenia will also prevent occurrence of clinical VZV infection in most transplantation recipients. Later after transplantation, when acyclovir prophylaxis may have been discontinued, VZV reactivations usually are recognized by their characteristic dermatomal distribution, and treated using acyclovir or valacyclovir.

Serology for HHV-6 is not tested before transplantation because more than 95% of adults are seropositive for the virus. The transplantation recipient receiving minimal herpesvirus antiviral therapy during the transplantation procedure is at risk for reactivation of HHV-6. Whether the CMV-seronegative or HSV-seronegative recipient with a CMV-seronegative donor who ordinarily would receive no antiviral prophylaxis is at highest risk is not known. Additionally, the consequences of asymptomatic and untreated HHV-6 reactivation are not known.

The vast majority of adult patients undergoing transplantation and their donors are EBV seropositive. EBV reactivation is in the differential diagnosis of any new mass, such as enlarged nodes or lung nodules after transplantation (Chapter 52). Now that sensitive quantitative EBV viral load tests and effective treatments, such as rituximab, are available, investigators are monitoring high-risk recipients with quantitative viral load studies.³⁰

Hepatitis B and C

Hepatitis B (core antibody, surface antibody, and surface antigen) and hepatitis C serologies are tested in donor and recipient before transplantation. Hepatic dysfunction from either hepatitis B or C after HSCT can lead to life-threatening liver complications, including venoocclusive disease and acute hepatic necrosis. Short-term complications are usually due to hepatitis B, whereas the long-term complication of cirrhosis is due to hepatitis C. The risk for hepatitis in the recipient can be reduced by antiviral therapy for recipients and donors who have detectable viral loads and by transfer of immunity from donor to recipient. A hepatitis-infected individual can be used as a donor if no alternative donor is available or if the intended recipient already is seropositive.

The risk for transmission is small when the hepatitis B-seropositive donor has an undetectable viral load; however, careful follow-up of recipients is recommended. A surface antigen-positive hepatitis B donor with a high viral load should be treated with lamivudine or another agent to reduce the circulating viral load before transplantation. High-circulating hepatitis C viral load in the seropositive donor for a seronegative recipient is an indication for antiviral therapy of the donor before HSCT.

If the potential recipient has serologic evidence of infection with hepatitis B or C before transplantation, viral load levels should be

checked before and monitored after HSCT. High hepatitis B viral load ($>10^5$ copies/mL) is the most important risk factor for reactivation in patients positive for surface antigen undergoing HSCT. High-circulating hepatitis B viral load in the intended recipient is an indication for lamivudine. There is no evident correlation between hepatitis C genotype and type or severity of liver disease after transplantation.

Human Immunodeficiency Virus

A positive donor HIV test for a recipient candidate not known to be seropositive is a contraindication for donation. If the screening test for HIV is positive, a Western blot study should be completed to confirm the result because of the potential for false-positive testing.

Syphilis

If the indirect screening test for syphilis returns positive and is confirmed by a direct test, high-dose penicillin treatment should be given for 10 days after transplantation.

Toxoplasma

Historically, 15% of patients who undergo transplantation in the United States are seropositive for *Toxoplasma*, but this percentage may be higher for European centers. The risk for reactivation among seropositive patients is 2%, for an overall incidence of less than 1% of HSCT recipients. It is suspected that low-dose sulfa-based regimens, such as those used to prevent *Pneumocystis* pneumonia, may be effective in preventing *Toxoplasma*.

Review of Commonsense Measures to Prevent Infection

Commonsense measures that should be discussed before transplantation or aggressive nontransplantation chemotherapy include attention to diet, travel, crowds, and pets. Additionally, a history of family or social exposure to tuberculosis should be used to guide whether or not a Mantoux test is applied before therapy.

Diet should be reviewed for herbal supplements or restricted foods. Patients may not recognize that most supplements will have to be discontinued after HSCT. Ground meat products need to be thoroughly cooked so that bacteria, distributed onto meat in the grinding process, are killed. Any fruits or vegetables that cannot be peeled should be washed. Salad bars are associated with occasional transmission of infections. Food products or supplements that inherently contain infectious organisms should be avoided, including undercooked eggs. Blue cheeses have molds spiked into the cheese wheel as they are curing and should be avoided. Soft cheeses carry the potential risk for *Listeria* infection. Yogurt contains *Lactobacillus* that, rather than causing gut problems, has been found to cause infection in other sites, including the lungs after aspiration events.

There are no particular travel restrictions, but strategies to minimize transmission of infectious diseases have been summarized. Some social situations, such as sitting in a crowded movie theater or classroom, increase the risk for acquiring a viral illness. Turning away from individuals who are coughing or sneezing may be helpful in preventing the transmission of infections. Patients need instruction to remember to complete the cycle of infection prevention by washing their hands as soon as possible after being close to such an individual. Given outbreaks of noroviruses (Norwalk-like viruses) on cruise ships and other types of outbreaks (e.g., *Staphylococcus*) commonly associated with the close living quarters during this type of travel, cruise ships should be avoided.

Healthy dogs and cats are considered acceptable pets. However, the immunosuppressed patient should not be responsible for scooping cat litter because of potential *Toxoplasma* cyst exposure. Similarly, the patient should not play in sandboxes because these areas are concentrated sites that feral outdoor cats may use as litter boxes. Because reptiles of many sorts have been reported to be infected with *Salmonella*, patients should not touch these animals or the insides or outsides of their cages or tanks. The heated water of tropical fish tanks carry *Mycobacterium marinum*. *Cryptococcus* and *Chlamydophila* (formerly *Chlamydia*) *psittaci* can be transmitted from large pet birds.

Environmental Measures to Prevent Infection

Persons entering the patient's room to perform an examination or touch the patient (including visitors as well as health care workers) should wash their hands outside the room. Ideally, the institution will have handwashing sinks in the hallways outside patient rooms for this purpose. During respiratory virus season, the infection control department often adds extra signs to doorways and other places in the wards to remind visitors of the importance of handwashing. Staff and visitors without control of body secretions should not be permitted to have direct patient contact.

Some infectious situations require special isolation procedures. Contact isolation (gloves and gowns) is used for patients with adenovirus, methicillin-resistant *S. aureus*, or *Clostridium difficile* infection. Droplet precautions are added to contact precautions for respiratory virus or varicella infection. Carriers of vancomycin-resistant *Enterococcus* are placed in contact isolation until they meet defined criteria for discontinuation of isolation.

Laminar airflow is a cumbersome and expensive isolation technique that has been largely outmoded with advances in airflow and isolation technology as well as current antimicrobial therapy. Historically, it has been most commonly used for patients with aplastic anemia or those receiving T cell-depleted transplants.

High-efficiency particulate air (HEPA) filtration has replaced laminar airflow as the means for preventing infection through ventilation. With at least 12 air exchanges per hour, HEPA filters are capable of removing particles greater than 0.2 μm in diameter, such as mold spores. Patients often ask whether they should purchase portable HEPA filters for the home or apartment they will occupy after hospitalization. In the broadest sense, this is an extra measure that can be used on an individual basis. If portable HEPA filters are used, they should be obtained for each room that the patient will occupy during the day and night, and each unit should be sized for the individual room. A beneficial effect of HEPA filtration in the outpatient setting has not been demonstrated.

Infection in the Hematopoietic Stem Cell Transplant Recipient Preengraftment

The major risk factors for infection in the preengraftment period include drug-induced mucositis, profound neutropenia, and the presence of indwelling catheters. Thus the major infections observed in this period are due to bacteria that colonize the skin and GI tract (e.g., viridans group streptococci and gram-negative bacilli), *Candida*, and respiratory viruses, especially in the winter months (see Fig. 89.6). Reactivation of latent or partially treated fungal infections can also occur, with *Aspergillus* being well recognized. The propensity of patients to develop such infections has led to widespread use of prophylaxis with an antiviral, antibacterial, and antifungal agent during this time period.

Infection in the Hematopoietic Stem Cell Transplant Recipient After Engraftment

Once engraftment has occurred, the major risk factors for infection include immunosuppression used to treat GVHD and mechanical

disruption of mucosal barriers, particular indwelling venous catheters. Viral infections that reactivate after engraftment often are related to defective T cell-mediated immunity and include CMV, adenovirus, and hepatitis viruses. Outpatient HSCT recipients inhale mold spores and *Pneumocystis* cysts from the environment, so common exogenously acquired infections include aspergillosis, mucormycosis, and *P. jirovecii* (previously *carinii*). Bacterial infections associated with defective cell-mediated immunity such as pneumococcosis, nocardiosis, and atypical mycobacterial disease can also occur in association with significant immunosuppression (Fig. 89.6).

Cytomegalovirus

CMV causes significant morbidity and mortality in transplant patients both directly and because of its immunosuppressive effects that predispose patients to concomitant or sequential infection with bacterial and fungal pathogens. Use of prophylactic ganciclovir at engraftment usually is avoided because it leads to myelosuppression and possibly a higher incidence of late CMV disease. Instead, the patient is treated with ganciclovir when weekly PCR or pp65 antigenemia monitoring test meets a positive threshold. Initial viral load levels do not predict disease. CMV infections are treated with an induction ganciclovir regimen followed by approximately 6 weeks of a maintenance regimen (half the induction dose). The duration of induction (1 to 3 weeks) varies by institution, but in general 1 week is used for low-grade infection, 2 weeks for high-grade infection, and 3 weeks for end-organ disease. A rising viral load, when checked weekly during the first month of preemptive therapy, signals the need for continued induction dosing or repeat induction dosing.

When the end-organ manifestation of CMV is pneumonitis (recovery of CMV from a deep lung specimen along with an interstitial infiltrate on chest radiograph), IVIg is added on an every-other-day basis for the duration of induction. When CMV manifests in an end organ other than the lungs, use of IVIg is not as clearly useful. Some centers add IVIg when the patient's total IgG level falls below 400 mg/dL. Dosing schedules vary from IVIg given once weekly for 3 weeks to every other day for the duration of induction, similar to therapy for pneumonitis. Ganciclovir resistance is uncommon, but when it occurs, foscarnet or cidofovir may be used.

Varicella-Zoster Virus

VZV reactivations from latency (zoster) usually are recognized by their characteristic dermatomal distribution. No temporal pattern is seen, viremia can occur concurrently, and multiple episodes are possible but uncommon. For patients who have been treated for a zoster episode after HSCT, some centers provide acyclovir prophylaxis until 1 year after HSCT. Less common VZV clinical manifestations that can result in severe infection and may require molecular testing or viral culture for diagnosis include hemorrhagic pneumonia, hepatitis, central nervous system disease, thrombocytopenia, and retinal necrosis.

HSCT recipients with a negative or unknown VZV disease history and a significant exposure to active varicella are susceptible to primary VZV infection. For these patients, varicella-zoster immune globulin should be provided within 96 hours of exposure. Patients with positive serology can become clinically reinfect after exposure and should be provided with acyclovir prophylaxis; however, such patients do not require varicella-zoster immune globulin.

Epstein-Barr Virus

EBV causes a spectrum of scenarios after stem cell transplantation, ranging from asymptomatic but detectable viremia, hemophagocytic syndrome, or posttransplant lymphoproliferative disorder (Chapter 52). The incidence of EBV-related complications is higher in

mismatched donors, patients with T cell–depleted transplants, and patients receiving intensive immunosuppression (e.g., antithymocyte globulin). Posttransplant lymphoproliferative disorder after allogeneic stem cell transplantation most often is of donor origin. Quantitative EBV viral load diagnostic testing is relatively new and not standardized, so the algorithms for monitoring and initiation of treatment vary. Recognition of greater than 1000 viral copies/mL of blood requires investigation, repeated testing, and possibly treatment, especially in high-risk patients. Direct antiviral agents have limited impact on reducing detectable EBV viral loads. General treatment approaches involve reduction of immunosuppression and rituximab or donor lymphocyte infusion (see [Chapter 52](#)).

Invasive Mold Infections

Invasive fungal infections are among the most feared complications of HSCT both because of their high mortality rates and the difficulty in establishing a diagnosis.⁴ Among HSCT recipients studied at autopsy, yeast and mold infections were common, seen in more than 25% of deaths. The probability of survival is higher in recent years, likely due to newer and more effective agents, as well as nonmyeloablative conditioning. Posaconazole has been shown to be effective in preventing invasive fungal infections during GVHD.⁵ Mold spores may initiate a localized infection in the lungs or sinuses that, after intensive immunosuppression for GVHD, may disseminate to the skin, abdominal organs, or central nervous system. Treatment of central nervous system infections should include voriconazole, which attains cerebrospinal fluid levels approximately 50% those of plasma or central nervous system tissue levels approximately 200% those of plasma. Infection with Mucorales organisms tends to have later onset than infection with *Aspergillus* (after day 90).⁴

Pneumocystis

The most common presenting symptoms of *Pneumocystis* infection are dyspnea, cough, and fever. Diagnosis requires demonstration of the organism in silver-stained specimens (bronchoalveolar lavage or lung biopsy) although PCR testing of bronchoalveolar lavage fluid is becoming a more common diagnostic method. Disease occurs by both new infection and activation of latent infection. Most patients present between day 40 and day 80 after HSCT, but cases as early as day 12 and as late as 42 months after HSCT have been reported. Once lymphocyte function is more reconstituted, *Pneumocystis* infections are rare. Prophylaxis options include trimethoprim-sulfamethoxazole, aerosol or intravenous pentamidine, dapsone, and atovaquone. Among patients treated with dapsone after transplantation, increased red blood cell and platelet transfusion requirements are noted. Prophylaxis is generally discontinued 1 to 2 years after HSCT, or later if immunosuppression is ongoing.

Parasitic Infections

Toxoplasma gondii is a ubiquitous pathogen that causes significant morbidity and mortality. Although relatively uncommon, toxoplasmosis is recognized as a cause of cerebral, ocular, and lung disease in immunocompromised patients. Accurate diagnosis of this treatable infection is critical. PCR-based testing has become an adjunct method for diagnosis, occasionally replacing tissue biopsy, and can be used to monitor patients with positive anti-toxoplasma serology prior to transplant.

Infection Issues in the Late Posttransplantation Period

Encapsulated Organism Prophylaxis

Penicillin prophylaxis has decreased the incidence of infection-related morbidity and mortality from polysaccharide-encapsulated bacteria

(*S. pneumoniae*, *H. influenzae* type b, *Neisseria meningitidis*). Penicillin-resistant pneumococcal infection has been reported, prompting consideration of alternate prophylaxis, such as a change from penicillins to quinolones. Prophylaxis is generally discontinued 2 years after HSCT, or later if GVHD and immunosuppression are ongoing at the 2-year time point. Once the patient is ready for vaccinations, conjugate pneumococcal, meningococcal, and *H. influenzae* type b vaccines are given.

Vaccination

Recipients of HSCT frequently lose antibody responses to viral and bacterial pathogens previously targeted by childhood vaccination. Although practice varies among transplantation centers, killed-virus vaccines are often given at 1 year after HSCT and live-virus vaccines approximately 2 years after HSCT for patients without GVHD.⁶ For adults, Tdap (formulation of reduced-antigen, combined diphtheria-tetanus-acellular pertussis vaccine) has replaced Td (diphtheria-tetanus booster vaccine) as a means for decreasing the adult reservoir of pertussis. For protection against hepatitis, the combined vaccine providing protection against both hepatitis A and B can be used. The efficacy of vaccination is influenced by the time elapsed since transplantation, the nature of the hematopoietic graft, the presence of GVHD, and the use of serial immunization. Guidelines have been published ([Chapter 110](#), [Table 110.4](#)).

PSYCHOSOCIAL ASPECTS OF HEMATOLOGIC DISORDERS

Matthew J. Gonzales, Dawn M. Gross, and Elizabeth Cooke

Major changes in the understanding and treatment of cancer have led to increased survival for people diagnosed with hematologic cancers. Regardless of the advances and concomitant survival increase, a diagnosis of a hematologic malignancy can have great impact on the psychosocial aspects of the lives of cancer survivors and their families. Diseases of the blood are perceived as serious and often fatal. Psychologic, existential, cognitive, social, and economic stressors are common experiences for cancer survivors. Despite the increasing attention by providers, policy makers, and the general public on long-term survivorship issues within the past 20 years, ongoing progress must continue to be made in identifying and testing interventions and services to meet the psychosocial aspects of quality cancer care for patients and their families.¹ Psychosocial interventions and services are those that enable patients, their families, and health care providers to optimize health care and health care outcomes by managing the psychologic, social, spiritual, and behavioral aspects of cancer and its consequences.

These psychosocial aspects may be intensified in patients with hematologic malignancies because of their association with an uncertain prognosis, a prolonged treatment course often involving numerous hospitalizations including periods of prolonged isolation, and the systemic nature of the diseases.² Involvement with a complex and fragmented health care system, the need for episodic and aggressive treatment, remissions and exacerbation of acute and distressing symptoms, functional limitations, family separation, financial burden, and role disruptions are a few of the issues that characterize the life of patients with hematologic malignancies, not to mention the threat to life imposed by these diagnoses. This chapter provides information on factors that affect psychosocial adjustment among patients with hematologic malignancies, the wide range of psychologic responses that are possible throughout the illness trajectory, and the efficacy of psychosocial interventions and services to minimize distress and promote adaptation. Some practical guidelines regarding patient management and identification of patients who may require formal psychiatric consultation are offered.

ACCOMPANYING TRENDS IN PSYCHOSOCIAL ISSUES

Within the past several decades there have been significant advances in oncology that have affected the psychosocial care of the cancer patient. The continued advances in quality-of-life research, survivorship, personalized medicine, patient-centered care, quality care initiatives; interest in the reduction of health care disparities, evidence-based medicine, and palliative medicine; and the increasing interest in psychosocial health for patients and caregivers are a few of the changes in cancer care.

Interest in health-related quality of life can be traced back to 1947 with the beginning of the first nonphysiologic outcome measure for cancer: the Karnofsky performance scale. Exponential growth in disease- and individual-specific tools for measurement of health-related quality of life continues to this day.^{3,4} Since the beginning of the survivorship movement, there has been increasing growth in legislation, education, and advocacy for cancer survivors. The focus on personalized medicine coupled with an interest in decreasing health care disparities has incorporated the idea of tailoring interventions to the needs of individual patients.⁵⁻⁷ The Institute of Medicine report the “Quality Chasm” has begun a dialogue of the patient-centered

view of medicine that is ongoing.⁸⁻¹⁰ The emergence of palliative medicine, a new specialty that overlaps symptom management and end-of-life care with oncology specialists, has made an impact on improving symptoms in oncology patients.^{11,12} The Institute of Medicine report *Cancer Care for the Whole Patient: Meeting Psychosocial Health Needs* lists 10 recommendations related to improving psychosocial health for patients and family members.¹³

CLINICAL COURSE OF HEMATOLOGIC MALIGNANCIES

The incidence, course, treatment, and survival for various hematologic malignancies vary widely, yet dramatic improvements in survival rates have been seen almost universally.

In contrast to treatment of many solid cancers, treatment of hematologic malignancies often involves intense regimens, highly technical therapies, lengthy hospitalizations, episodes of high infection risk, periods of unpredictability, and ongoing outpatient monitoring of the patient's condition. A number of patients respond to the curative attempts with long-term remission, remain well, and, after a period, are considered cured. However, some patients have an initial reduction in tumor burden in response to a curative attempt only to relapse at an unpredictable time later. Other patients begin treatment with a hope for a cure but their cancer does not dissipate often resulting in the individual's progressive decline. In some patients, the cancer is so advanced at the time of diagnoses that they experience a rapid progression of their disease. The remainder of this chapter proceeds through the common trajectories associated with hematologic malignancies including diagnosis, treatment, relapse, the end of life, and survivorship (Fig. 90.1).

Time of Diagnosis

Being diagnosed with a hematologic malignancy can be a devastating time of crisis. The time of diagnosis has been described by a cancer survivor as “a lightning bolt through a stop sign” or an existential plight.^{14,15} It is a time of intense stress and likened to a personal disaster in the patient's and family's life.¹⁵ Often these patients describe vague symptoms such as fatigue for weeks, even months, being treated in urgent care centers for presumed non-life-threatening illnesses, such as bronchitis or other uncomplicated infections. Families are often dismissed if they offer their concern, thus being unprepared and blind-sided by the ultimate diagnosis of an unexpected, catastrophic illness. More recent literature has continued to confirm the distress at diagnosis and advance the understanding to include potential psychiatric diagnosis such as depression and anxiety.¹⁶

The period from time of diagnosis through initiation of treatment is characterized by sometimes fast-paced medical evaluation and treatment, the development of new relationships with unfamiliar medical personnel, and the need to integrate a barrage of information that is at best frightening and confusing. Often patients with hematologic malignancies need immediate treatment intervention compared with those patients with solid tumors. But even with the advanced speed of information in this technologic age, patients have difficulty with information integration in a short period of time. Within the context of this anxiety-provoking situation, timely deci-

Fig. 90.1 CLINICAL COURSE OF A PATIENT WITH A HEMATOLOGIC MALIGNANCY. (Modified from Lesko LM: *Hematopoietic dyscrasias*. In Holland JC, editor: *Psychooncology*, New York, 1998, Oxford University Press, p 408.)

sions must be made regarding treatment, and patients may feel tremendous responsibility, concern, and isolation during this period.

There are multiple personal and cultural factors that may profoundly influence the patient's response to the cancer diagnosis. Being aware of the patient's exposure to cancer in the past and the meaning of their cancer experience may provide an insight into response. Literature does indicate that preexisting issues such as symptoms, psychiatric history, gender, social and psychologic factors, disability and avoidance coping may influence the reaction to the time of diagnosis.^{17–20} Although extreme and sustained psychologic reactions as the first response to a cancer diagnosis are unusual, careful assessment of the nature of the patient's reaction remains important. Initial reactions often are predictive of later adaptation.⁴³ Early assessment by clinicians can help to identify people who are at risk for later adjustment problems and in greatest need of ongoing psychosocial support^{21,22,27} (see Box 90.1). Because many clinicians are guarded about disclosing information until a firm diagnosis is established, patients may develop highly personal explanations that can be inaccurate and provoke intensely negative emotions. Ongoing involvement and consistent and repeated information from key health care providers help to minimize patients' uncertainty and the development of maladaptive coping strategies based on incomplete or inaccurate information.

Although the literature substantiates the devastating psychologic impact of a cancer diagnosis, it is also well documented that many patients cope effectively by embracing optimism. Also, contrary to the beliefs of many clinicians, denial has also been found to assist patients in coping effectively with a diagnosis of cancer, unless used to an excessive degree.²³ With the firm establishment of the cancer diagnosis, planning for treatment begins. If patients have been given a clear explanation of their condition while encouraged to maintain hope, the initial reaction of shock, fear, and desperation can give way to a sense of optimism. Health care providers have an important role in monitoring and possibly mediating psychosocial adjustment. Keeping patients informed and actively involved in their care and being aware of the unique meaning that people may associate with a

BOX 90.1 Factors That May Predict Poor Coping in Patients With Cancer

- Past psychiatric history
- Compliance issues
- Demographic factors such as younger age and female sex
- Limited social support or difficult social relationships
- Recent history of smoking cessation
- Substance abuse history
- Recent losses
- Advanced disease
- Uncontrolled symptoms
- Pessimistic outlook on life
- Multiple obligations
- Avoidance coping (escape-avoidance, distancing, and denial)
- Lower functional status
- Higher regimen-related toxicity

diagnosis of cancer are vital. Patients who have a pervasive and unyielding negative affect that persists long after the crisis of diagnosis may require ongoing psychosocial monitoring and referral for services and supportive interventions throughout their treatment and disease course.²⁴

In addition, family assessment during this phase is vital. Levels of family distress, depression, and anxiety are mediated by the functioning of the family at the time of diagnosis.²⁴ Studies have shown that caregivers and families share similar rates of psychosocial angst.²⁴ Families who have open expression of feelings and actions have reported lower depression; however, those families who have dysfunctional problem-solving abilities have higher depression.²⁴ Also, anxiety within the family increases with unclear communication.²⁴ Both anxiety and depression are easy to assess in patients and family members, and timely referral for assistance during this period may lay a foundation of adequate coping throughout the patient's course of illness. During this time, many providers are conveying large amounts of information. It is not always easy for patients to differentiate the importance of each communication and prioritize their problem-solving behaviors. Consequently, providers must repeat information at each contact and inquire about the patients' and families' understanding of facts and treatment options. Often patients and families describe that they are in a state of numbness and that information is not really processed, understood, or comprehended.

Treatment

Psychosocial factors are critical parameters in considering which treatment is best for an individual patient. The development of a treatment plan should include information about all aspects of medical/surgical treatments as well as what is known about the psychosocial sequelae. Often patients react to a diagnosis of cancer with feelings of fear and helplessness. Patients look to the primary oncologist for a curative treatment that also can preserve their quality of life. Patients may feel vulnerable and believe that complete reliance on the oncologist is essential. Combating feelings of helplessness during this period can help patients alleviate painful anxiety and possible depression.¹⁸ This is best done by a member of the health care team who has established a treatment alliance with the patient. The health care provider must make the patient feel like a partner in all aspects of care. This is especially true regarding decisions about treatment options. Giving information to patients and families often alleviates anxiety and uncertainty because patients feel more in control.

Active treatment of cancer usually initiates another acute phase of the cancer experience. It can occur while a patient is receiving treatment or as a complication of treatment. An important standard of clinical practice, based on extensive research, is to provide patients with information that will prepare them for what to expect during their treatment. Some providers wait until patients complain about

potentially expected side effects. When this happens patients may become skeptical about the completeness or accuracy of any future information given by the person. This threat to undermine a trusting relationship has important implications for decision making, patient choice of care setting in the future, and recommendations made by patients to others who are seeking a source of cancer care.

Often during the treatment phase increasing burdens are placed on the immediate caregiver and family to support the patient's schedule for treatment, multiple admissions, and increasing dependency.²⁵ The patient may be unable to work, and financial stressors accumulate. Sensitivity and awareness by providers to social, economic, and relationship stresses are needed to assist with referral for social services and other psychologic assistance. Support groups with other patients, families and caregivers, can be helpful during this time. Evidence clearly indicates that sharing a common experience in a support group can have psychologic benefit.²⁶

DECISION FOR HEMATOPOIETIC STEM CELL TRANSPLANTATION

Hematopoietic stem cell transplantation (HSCT) is increasingly becoming a standard treatment for many high-risk hematologic malignancies and nonmalignant diseases either as part of overall treatment or after relapse. The procedure for transplantation is complex and can cause intense psychologic distress and extreme social strain on the patient's caregiver, friends, and family members. Often the psychologic and social issues can be more challenging for the health care team than the medical issues. Because HSCT is an intense and distinctive experience for patients and families and has the potential to cause prolonged psychologic distress unlike other experiences with oncology patients, the issues unique to this population warrant a separate discussion.

HSCT patients may face unique physical and psychologic stresses consisting of recurrent infections, repeated hospitalizations, and social isolation for weeks to months during their initial recovery. Consequently a thorough pretransplant psychosocial evaluation is recommended to identify those patients at risk for development of psychosocial morbidity and to initiate timely interventions to optimize adaptation. Identified risk factors for psychosocial morbidity during and following transplant include previous psychiatric morbidity, pretransplant compliance issues, pretransplant physical and mental health problems, younger age, female sex, avoidant coping style, recent smoking cessation, lower functioning status on admission, problems with quality and presence of social support before transplant, perception of limited social support, and the presence of difficult relationships.^{21,27}

The time of transplantation when the infusion of cells occurs can be a special moment for patients, with patients often referring to the date of transplant as a "birthday" or special anniversary date. Often family members are gathered at the bedside to celebrate the long-awaited event of the transplant. However, the weeks following transplant can be difficult psychologically. Factors that can affect psychologic distress and subsequent coping include persistent symptoms following transplant, increased regimen-related toxicity, slower physical recovery, low performance status, longer length of stay, graft-versus-host disease (GVHD), negative appraisal of the transplant experience, body image disturbance, fears of relapse and secondary malignancies.²⁷⁻²⁹ The threat of death continues to be real, and patients experience social isolation, bodily discomfort, major body image changes, and a sense of loss of control. These issues lead to a myriad of emotions, including hope, anger, depression, anxiety, anticipation, guilt, and joy. Khan et al identified the following common psychiatric diagnoses with inpatient transplant patients: adjustment disorder (40%), depression (23%), generalized anxiety disorder (10%), acute psychotic disorder (10%), delirium (10%), and depressive psychosis (7%).³⁰ Kishi et al compared inpatient psychiatric consultations among transplant and nontransplant patients.³¹ Transplant patients differed on several characteristics: more frequently white, less likely to have a previous psychiatric history, longer time

period between admission to consult, more delirium, and more socioeconomic and health-related distress.

Patients are often not prepared for the long, gradual recovery. Patients are more familiar with recovery after surgery that takes days to weeks, and they are unprepared for and overwhelmed with the long recovery that can take weeks to months or even months to years. Typically patients perceived their quality of life to be worse the first year after transplant than before transplant.³² Patients continue to feel functional limitations, and both recipients of autologous and/or allogeneic transplants report common somatic symptoms, with fatigue being the most common distressing symptom.³³⁻³⁵ Patients who experience depression the first year have a higher mortality rate.³⁶ Periods when patients may be more psychologically vulnerable may occur at transition periods such as admission workup, directly before transplant, discharge from the inpatient setting, between 3 and 5 months, and between 6 and 9 months posttransplant.

The financial burden for patients who undergo HSCT can be overwhelming, including medical expenses for the patient and marrow donor in the case of an allogeneic HSCT, potential travel expenses, and loss of income for other caregiving family members.²⁶ Patients and their immediate families often are geographically far from their usual support systems because of the distance to the HSCT center. In some cases, family members who have not been close in the past may be forced to interact with each other, leading to additional stress.

Although the literature is clear that most patients return to a productive life with high quality of life, during the first few years after transplantation, patients and family members may continue to experience physical and psychologic sequelae.³⁷ One study reported that 43% of long-term HSCT survivors with an average of 3.4 years after transplant had clinically significant global psychologic distress.³⁸ Despite this distress, only 50% of the patients received mental health services.³⁹

Researchers have described the following factors as predictors of poorer quality of life in patients 1 to 5 years after transplant: diagnoses of anxiety and/or depression, younger age, long-term sequelae, chronic GVHD, unemployment, lower income, poor functional status, family/caregiver distress, and short follow-up by the treatment center.^{32,33,39}

Patient and families are ready to put the experience behind them, only to discover that the experience of transplant has forever changed the patient's outlook, priorities, and family network. Fear of recurrence and feelings of uncertainty related to future relationships, work, and financial strain continue.²⁶ There is discordance between the patients' pre-HSCT expectations and the everyday symptoms that limit their physical abilities. Besides fatigue, which continues to be the dominant symptom, another distressing issue is cognitive dysfunction as patients return to the workplace or reenter school.²⁶ Educating patients about some expected common short-term side effects can reduce anxiety. Neurocognitive side effects of treatment can be long term in high-risk patients but are mostly temporary, including diminished concentration, short-term memory loss, decreased speed of information processing, and loss of effective problem-solving abilities. Sexuality issues are another area of great concern for patients in the posttransplant period. Barriers for discussion and lack of referrals for supportive services in this area may be related to the patient's embarrassment, the clinician's lack of knowledge, or the focus on other issues that may be interpreted as more critical. Common sexual issues after transplant include vaginal dryness and distressing menopausal symptoms in women and erectile dysfunction in men.⁴⁰

Patients who experience physical symptoms after transplantation may be at risk for long-term psychologic distress.²⁵ Despite the fact that patients are followed by transplant physicians longer than patients with nonhematologic malignancies, this population often is referred back to primary care physicians 1 to 2 years after transplant. Primary care clinicians do not have the knowledge or experience to recognize physical complications related to the effects of chemotherapy, radiation, and GVHD, so ongoing communication between the providers and the transplant team and center is imperative.

Long-term effects may include persistent viral, bacterial, and fungal susceptibility, GVHD, dental caries, muscle atrophy, pneumonitis, gonadal dysfunction, sexual dysfunction, endocrine abnormalities, cataracts, ocular sicca syndrome, reduced bone mass, secondary malignancies, and cognitive dysfunction.⁴¹ In addition to monitoring physical complications, the American Society for Blood and Marrow Transplantation (ASBMT) consensus statement recommends annual evaluation of patients' psychologic status. Health care providers must have a high level of vigilance to assess depression in both the patient and family caregiver years after transplant, with clinical assessments recommended annually after transplant. Studies of transplant survivors beyond 10 years indicate possible issues with returning to work, physical fitness, impairment in social functioning and family life, insurance denial, and continued symptoms such as pain, depression, muscle stiffness/cramps, memory/attention problems, sleep disorders, sexual issues, and incontinence.^{42,43} In spite of the range of problems, only 9.8% of patients reported accessing psychologic support.⁴²

The concept of posttraumatic growth (PTG) after transplantation has been evolving. By definition, the potential for PTG requires that patients experience a stressful event and then subsequently experience positive psychologic outcomes or benefits. As early as 1996, Fromm identified that positive sequelae are possible after transplantation, including the development of a new philosophy of life, greater appreciation of life, making changes in personal characteristics, and improving relationships with family and friends.⁴⁴ Potential predictors of PTG among posttransplant patients include good social support, little avoidance coping, younger age, less education, greater use of positive reinterpretation, problem solving, seeking alternative rewards, more stressful appraisal of the experience, and more negatively biased recall of pretransplant levels of psychologic distress.^{22,45} Discussing the PTG potential with patients and making referrals for counseling to experienced clinicians who are aware of the potential for PTG are essential.

Although patients report long-term psychosocial effects after transplantation, they may be reluctant to accept help and fail to access psychologic resources and social support.⁴² These patients must be encouraged to use resources and seek psychologic support, because this experience may impair the patients' and families' ability to cope with life after transplant. In an article about HSCT patients' experiences with a support group, Sherman et al identified the themes of meaning and changing of perspectives as patients expressed their struggles with redefining themselves, their priorities, and their values.²⁶ Some patients wanted to change their former values and behaviors. The support group experience may be therapeutic for patients who often do not have physical signs of transplant to the untrained eye but continue to experience increasing or unresolved psychologic and physical issues.^{21,25} Sharing a common experience may encourage patients to believe that their symptoms and feelings are not unique and may decrease their feelings of isolation.

Immediate Period Following Diagnosis and Treatment

As the treatment and acute side effects improve and subside, patients often feel that the whirlwind has passed, only to be confronted with uneasy silence. Weeks and months of clinic and physician appointments, infusions, and admissions stop or trickle to a small stream of appointments. Families who have been functioning on a grinding schedule of crisis mode find the change almost paralyzing. Adding to this halt of activity, health care providers have a tendency to limit their contacts when the patients' physical status has stabilized. This is a critical time when psychosocial interventions and supportive services from other members of the health care team must be instituted for patients and family members to deal with the uncertainty and anxiety of waiting. Fears and anxieties change from fighting the disease to returning to life.⁴⁶ Because of less contact with the primary treatment hematologists, patients and families may perceive a withdrawal of support from the medical team. Long-term psychosocial health of the patient and family is affected by the meaning ascribed

to the cancer experience, fear of recurrence, support of the family, demographic factors, and financial stressors. This transition time is pivotal for patients' long-term quality of life. Surveillance with specific questions to access the need for referrals can have lasting outcomes.

Time of Relapse

The time of recurrence of cancer has been reported to be more distressing for patients and family members than the initial diagnosis. The recurrence of the disease can plunge the patient and family into despair and crisis as they realize that death may occur despite the ongoing fight to live. The psychosocial issues experienced by the person with cancer depend in part on the clinical course of the disease process. As the disease progresses, the person often reports an upsetting scenario that includes uncertainty, frequent pain, diminished functional ability, increased dependence, and disability.⁴⁷

The development of a relapse after a disease-free interval can be especially devastating for patients and those close to them. The medical workup often is difficult and anxiety provoking, and psychosocial problems experienced at the time of diagnosis frequently resurface, often with greater intensity.⁴⁷ Shock and depression can accompany relapse and require patients and family members to reevaluate the future. In spite of the overwhelming nature of the psychosocial responses, however, most patients cope effectively with progressive disease. It is essential to recognize that intense emotions do not necessarily equate with maladaptive coping. Investigators studying quality of life in patients with cancer have demonstrated a clear relationship between a person's perception of their quality of life and the presence of discomfort.^{48,49} As uncomfortable symptoms increase, perceived quality of life diminishes. An important goal in the psychosocial treatment of patients with advanced cancer is optimal symptom management.

An issue that repeatedly surfaces among patients, family members, and professional care providers is the use of aggressive treatment protocols in the presence of relapse and progressive disease. Currently there are newer agents that can induce remission even in the face of relapse. In addition, patients and families often request participation in experimental protocols, even when there is little likelihood of extending survival. Controversy continues about the efficacy of such therapies and the role health care providers can play in facilitating patients' choices about participating. Clear communication about treatment goals and expectations will assist in patient and family preparation.

Certain patients respond to investigational treatment with increased hope. It is vital to clarify the values, thoughts, and psychologic reactions of care providers, patients, and families to the delicate issues that evolve if individualized care with attention to the patient's psychosocial needs is to be provided.

Survivorship

The definition of a long-term survivor has evolved over time. Initially, individuals who had survived cancer-free for longer than 5 years were considered "survivors and cured." More recently the term *survivor* has been used to define individuals who have completed the acute phase of illness. Others use the term for all patients initially diagnosed with cancer. Some people would prefer changing the term to "thrivers," champions, or fighters.⁵⁰

Successful treatment of hematologic malignancies has resulted in cure for many patients and progressively longer lives for others. However, longer survival is not without significant psychologic sequelae.^{51–56} New treatments may result in unintended physical side effects such as infertility, treatment-related toxicity, persistent side effects, and organ system failure that can magnify and exacerbate the psychologic issues initially associated with diagnosis and treatment.^{48,49,57} The overwhelming evidence from the literature involving survivors with hematologic malignancies is that, on average, most do very well after the initial adjustment in the first 1 to 3 years after

treatment.^{32,52} Most long-term HSCT survivors express satisfaction with their quality of life and describe themselves as productive, stable, and well adjusted without significant physical, functional, psychologic, and social problems related to their disease or HSCT treatment. However, there is a group of patients with a high rate of psychosocial morbidity who are vulnerable to ongoing and intermittent psychosocial distress. Empiric evidence showed that as many as 9% to 30% of long-term survivors with hematologic malignancies experience significant psychologic distress, including anxiety, depression, and posttraumatic distress symptoms.^{53,55,58}

Psychologic aspects of survivorship may include concern over termination of treatment; fear of relapse; preoccupation with somatic symptoms; reentry into previous roles; lingering affinity with death; and financial, job, and insurance difficulties. These issues may manifest in a variety of ways, including denial of past illness, leading to medical compliance issues; ongoing problems with anxiety, panic, and depression; and inability to reenter or modify previous roles. Fear of recurrence by both patients and family members can severely affect quality of life.^{48,59} In her classic article "The Enduring Seasons in Survival," Dow stated that the season of extended survival is dominated by fear of recurrence.⁶⁰ In fact, Baker et al showed in a group of cancer survivors that "being fearful my illness will return," "concern about relapsing," "fears about the future," and "difficulty making long-term plans" were a problem 68%, 60%, 58%, and 41% of the time, respectively.³³ Mellon and Northouse found that the strongest predictors of quality of life 1 to 5 years after treatment were concurrent family stressors, family social support, family member fear of recurrence, family meaning of the illness, and patient's employment status.⁶¹

There is increasing interest in patients' experiences with post-traumatic stress disorder (PTSD). Studies have consistently described a higher incidence of PTSD in patients with hematologic malignancies than in the average population.⁶²⁻⁶⁴ Predictors of PTSD severity among patients with hematologic diagnosis include higher levels of distress and high avoidance coping coupled with low social support.²² These researchers describe how providers can assess coping and presence of family support and potentially mitigate the effects of a distressing experience with the cancer diagnosis. Considerable evidence indicates that the wide range of surgical, chemotherapeutic, and radiation therapies leaves permanent damage to organs and physiologic functioning and disfigurement across the different hematologic diagnoses (Table 90.1). Health care providers should be mindful of psychologic sequelae among patients, even within the context of remission and a hopeful prognosis, and refer patients and family members to a mental health specialist for further evaluation, as needed.

Terminal Stage and End-of-Life Care

Technologic advances in health care have improved the potential for cure of many previously fatal hematologic malignancies. However, many patients still have disease that is unresponsive to treatment, continues to progress, and is considered incurable. When cure is acknowledged to be impossible and alternative efforts to combat the progress of disease are exhausted, patients are recognized as terminally ill or dying. In the past, experts had advocated for the pursuit of hospice care at this point in time foregoing further active treatment and shifting the emphasis of medical care to control of distressing symptoms and maintenance of quality of life at an optimal level.^{59,65,66}

Over the past few years, the paradigm has shifted in the field of palliative care to initiating palliative care alongside curative treatment with the philosophy that it should be implemented across the illness trajectory. The ultimate goal is to improve the quality of life and facilitate relief of suffering over the course of one's illness.⁶⁷ In non-hematologic diseases such as severe heart failure or metastatic lung cancer, palliative care has been shown not only to improve quality of life but extend it.¹¹ The new World Health Organization definition states: "Palliative care is an approach to care which improves quality of life of patients and their families facing life-threatening illness,

TABLE 90.1 Long-Term Consequences of Therapies for Hematologic Cancers

Fertility

through prevention, assessment and treatment of pain and other physical, psychologic, and spiritual problems."⁶⁸

Palliative care began with the hospice movement. Since the concept of hospice was first introduced in England in the 1960s, hospice care has been recognized as the state-of-the-science end-of-life care, and hospice services are now available around the world. However, hospice care has not been integrated into the care of patients dying with hematologic malignancies.^{69,70} Despite the strong emphasis on providing end-of-life care in accordance with patients' wishes and empiric studies showing that most terminal patients prefer spending their final days of life and dying at home, hematologic malignancy is the only diagnosis that has been repeatedly and consistently shown to predict hospital death.^{71,72}

The reasons for such insufficiency have been attributed to many factors. Manitta et al in their article "Palliative Care and the Hemato-Oncologic Patient: Can We Live Together?" identified barriers between the expectations of two specialties: (1) the dying trajectory can be rapid with more unpredictability and more technology, (2) the various hematologic diagnoses are not uniform in response and treatment, (3) the goals of care can be unclear, (4) the focus on cure can preclude the focus on palliation, (5) lack of knowledge exists among hematologists about palliative care principles, and (6) the health care system does not encourage collaborative care.⁷³ Many of these issues are not unique to hematologic conditions, but are clearly challenges to be overcome. In our experience, one of the most significant barriers to initiation of hospice care for patients with hematologic malignancies is the ongoing need for blood product transfusions, which is often not provided by hospice agencies. Explorations around how much benefit these transfusions concretely provide are often helpful to bridging this gap. Additionally, partnering with insurance agencies to carve out blood products for ambulatory patients may be possible.

In addition to systematic barriers, personal barriers exist. Health care providers, first and foremost, must examine their own attitudes toward death and dying and avoid imposing their own values on patients and their families. Respecting patient and family wishes, appropriately managing and alleviating distressing symptoms, and providing care tailored to meeting patients' needs can help patients dying of hematologic malignancies reach the end of life with peace and dignity.

FACTORS THAT INFLUENCE PSYCHOSOCIAL ADJUSTMENT

Psychosocial responses to cancer vary widely and are influenced by several factors that clinicians should bear in mind when considering the responses of individual patients. A review of the literature points to key factors that may have an impact on psychosocial adjustment

and include individual patient, environmental, and disease-related factors.

Individual Patient Factors

Demographics, comorbid conditions including previous psychiatric morbidity, and previous coping strategies have been consistently documented as important predictors for psychosocial adjustment. Female sex and younger age are important predictors for worse psychosocial adjustment and poorer quality of life for patients with hematologic malignancies.^{21,74–76} As the population ages, there are more individuals diagnosed with cancer who already have comorbid diseases, which complicates treatment decisions and recovery.^{77,78} Many individual patient factors are interrelated; for example, higher anxiety scores and worse quality of life outcomes have been observed in women more than in men. Poor quality of life after treatment has been associated with higher age of the recipient at the time of the transplant, poorer self-image, decreased cognitive functioning, and inability to return to work.^{79,80} This makes it difficult to accurately predict psychosocial adjustment solely based on these factors.

One of the key predictors of psychosocial adjustment to cancer is the psychologic stability of the person before diagnosis. People with a history of poor psychosocial adjustment before development of cancer are at highest risk for psychologic decompensation and should be monitored closely throughout all phases of treatment.^{27,81} This is particularly true of people with a history of a major psychiatric syndrome, psychiatric hospitalization, or both.²⁷

Because a person's coping style is determined relatively early in life and tends to remain stable over time and across situations, it serves as a useful predictor of adjustment to cancer. Several investigators have identified specific personality characteristics, coping strategies, and life experiences that enhance or inhibit positive adjustment to cancer.^{82,83} Empiric evidence demonstrates the beneficial impact of positive coping strategies and personality attributes on long-term survival.^{84–86} Coping strategies found to be most effective include: having a “fighting spirit;” hopefulness and acceptance of the situation; a belief that life has purpose and coherence; and having a feeling of control over events. These strategies tend to result in active participation in treatment and engagement in daily life. By contrast, poor adjustment has been associated with avoidant coping strategies; anxious preoccupation and high distraction; prior negative sexual experiences; body image problems; and inhibition in discussing personal and sexual problems.⁸⁷ One study showed that patients who smoke are at higher risk for psychiatric morbidity, perhaps due to the potential development of depression and/or anxiety with withdrawal symptoms.⁸⁸ It is important to include smoking history in the patient's assessment of substance control use when preparing patients for treatment options.

Environmental Factors

Environmental factors include partner and family support as well as other forms of social support. The quality of spousal and family relationships has a significant impact on the psychologic health and even mortality of the patient.⁸⁹ Social support, network size, satisfaction with social support, and reliance on formal and informal social ties have consistently been found to influence a person's psychosocial adjustment to cancer.^{71,72} The ability and availability of significant others in dealing with a diagnosis and discussion of treatment options can significantly affect the patient's view of himself or herself. Patients diagnosed with all types of life-threatening chronic disorders experience a heightened need for interpersonal support. Those who are able to maintain close connections with family and friends during the course of illness are more likely to cope effectively with the disease than are those who are not able to maintain such relationships.^{69,86,90}

Often the transition out of the hospital posttransplant can be a fearful time for patients and families. Traditionally patients are not

referred routinely to formal home nursing care at discharge. An initial home visit can be invaluable in assisting patients and families with the transition, in addition to identifying areas in which ongoing assistance is needed. Given changes in the current health care system, informal family caregivers are increasingly expected to serve as the major providers of care outside the hospital. Hence referral for home care can be of significant support.

Disease-Related Factors

Disease-related factors including the type of disease, side effects of treatment, and residual symptoms all greatly affect psychosocial adjustment. Different treatment modalities introduce varying degrees of side effects, symptoms, and impact on quality of life. Without exception, the greatest difficulties in psychosocial adjustment were observed among patients who underwent allogeneic HSCT, followed by autologous HSCT recipients, and then patients who received conventional or maintenance chemotherapy. The latter groups experienced the least impairment in quality of life and psychologic distress. Patients who underwent transplant also had more psychiatric morbidity if they experienced lower functional status and higher regimen-related toxicity.²⁷

Time interval after treatment has been documented as an important predictor for psychosocial adjustment. Particularly, time since HSCT or completion of treatment was an important factor for facilitating psychosocial adjustment and improving quality of life. In general, during the first year after HSCT, patients perceived their physical and overall well-being as being at its worst, during which time they experienced more anxiety and total mood disturbance, and reported the highest degree of illness intrusiveness in every aspect of life.^{32,57,91–95} With the passage of time, improvements in functional status, quality of life, levels of anxiety, depression, and satisfaction with life were frequently observed after transplant.

DIFFERENTIATING PSYCHIATRIC COMPLICATIONS FROM EXPECTED PSYCHOLOGIC RESPONSE

Living with a chronic illness often requires continuing care and management by a team of specialists. Use of supportive care services has been related to improved quality of life; therefore it is in the patient's best interest to access services needed for psychologic distress early in the continuum of care.⁹⁰ Care usually is provided through follow-up visits to ambulatory or outpatient clinics and consulting rooms, rather than through hospitalization. However, several barriers that may impair the outpatient cancer survivor from accessing health care services include economic and financial constraints.⁹⁶ Differentiating a psychiatric complication from expected psychologic responses is imperative.

Although any individual experiencing the crisis of a cancer diagnosis may become clinically depressed or experience a panic attack, most patients do not experience a diagnosable psychiatric condition. Currently the rates of adjustment disorder, depression, anxiety, and PTSD are 40%, 25%, 10%, and 5%, respectively. The ability of health care providers to distinguish expected reactions from more severe psychiatric complications is crucial.

Unfortunately, non-mental health providers often miss clinically relevant and severe psychiatric syndromes. Being knowledgeable about common symptoms of adjustment disorder, depression, anxiety, and PTSD are helpful. [Table 90.2](#) provides a quick reference; also refer to the *Diagnostic and Statistical Manual of Mental Disorders*.

Another group of patients who are at high risk for developing adjustment problems includes those with coexisting severe mental illness including schizophrenia, bipolar disorder, schizoaffective disorder, and obsessive-compulsive disorder. Integrated care of psychiatry and oncology is the best option in treating these patients, first to stabilize the psychiatric illness and then to treat the cancer.^{97,98} Good communication, empathy, listening skills, and providing emotional support are all skills that benefit these patients and specifically those

TABLE 90.2 Common Symptoms of Psychiatric Disorders

Adjustment Disorder	Depression	Anxiety	Posttraumatic Stress Disorder
The development of emotional or behavioral symptoms in response to an identifiable stressor	Symptoms that are present for a 2-week period and a change from previous functioning	Excessive worry and anxiety for at least 6 months; the person finds it difficult not to worry	The person has been exposed to a traumatic event
1. Marked distress that is in excess of what would be expected for exposure to the stressor	1. Depressed mood most of the day	Anxiety and worry have to have three of the six following symptoms:	1. Reexperiencing symptoms such as images, thoughts, and perceptions
2. Significant impairment in social or occupational functioning	2. Marked diminished interest or pleasure	1. Restlessness	2. Persistent avoidance of stimuli and numbing of general responsiveness
	3. Significant weight loss or decrease or increase in appetite	2. Fatigue	3. Persistent symptoms of increased arousal: sleep issues, anger or irritability, difficulty concentrating, hypervigilance, and exaggerated startle response
	4. Insomnia or hypersomnia	3. Difficulty concentrating	
	5. Psychomotor agitation or retardation	4. Irritability	
	6. Fatigue	5. Muscle tension	
	7. Feelings of worthlessness or guilt	6. Sleep disturbance	
	8. Diminished ability to think or concentrate		
	9. Recurrent thoughts of death, suicidal ideation, or a plan for suicide

who have severe mental illness, who often have a history of disregard and neglect from providers.⁹⁹

Most patients manifest transient psychologic symptoms that are responsive to support, reassurance, and information about what to expect regarding the cancer course and its treatment. Some require more aggressive psychotherapeutic interventions, such as pharmacotherapy and ongoing psychotherapy. The following guidelines can assist the clinician in identifying those patients who exhibit behavior suggesting the presence of a psychiatric syndrome.

General guidelines designed to assist in distinguishing patients who should be referred for evaluation by a trained psychiatric clinician include the following:

1. History of psychiatric hospitalization or significant psychiatric/personality disorder.
2. Persistent refusal, indecisiveness, or noncompliance with regard to needed treatment.
3. Persistent symptoms of anxiety and depression that are unresponsive to usual support from health care providers or family members; symptoms may present in the form of constant fear associated with treatment and procedures or excessive crying and feelings of hopelessness that worsen rather than improve with time.
4. Abrupt, unexplained change in mood or behavior.
5. Insomnia, anorexia, diminished energy out of proportion to expected treatment effects.
6. Persistent suicidal ideation.
7. Unusual or eccentric behavior or confusion (may be indicative of an organic mental disorder).
8. Excessive guilt and self-blame for illness.
9. Evidence of dysfunctional family coping or complex family issues.

After referral to a psychiatric specialist, one or a combination of therapeutic modalities may be used. Cancer and its treatment may precipitate an exacerbation of an underlying mental illness to which a patient was predisposed and that may require extensive treatment (e.g., hospitalization for a psychosis, ongoing pharmacotherapy, or psychotherapy). A discussion of these specialized forms of treatment is beyond the scope of this chapter. The reader is encouraged to consult an appropriate standard textbook.¹⁰⁰

SCREENING FOR PSYCHOLOGIC DISTRESS

A number of tools have been developed to screen for psychologic distress, but adoption and consistent incorporation into clinical care has been slow.^{101,102} Most recently, National Comprehensive Cancer

Network (NCCN) guidelines have been updated to work towards implementing standard screening. Indeed these guidelines now clearly advocate for distress to be recognized, monitored, documented, and treated promptly at all stages of disease.¹⁰³ In a strong show of support for distress screening, the American College of Surgeons Commission on Cancer has required cancer centers to implement screening programs for psychosocial distress as a criterion for further accreditation.¹⁰⁴

One tool that is easy to administer and that patients report as capturing their problems is the *distress thermometer*.¹⁰⁵ The term “distress” was selected as it was felt to be more acceptable and less stigmatizing than other related terms (e.g., psychiatric, psychosocial, emotional). The tool is similar to pain measurement scales that ask patients to rate their pain on a scale from 0 to 10, and consists of two parts. The first part is a picture of a thermometer, and patients are asked to mark their level of distress. A rating of 4 or above indicates that a patient has symptoms indicating a need for evaluation by a mental health professional and potentially has a need for referral for services. On the second part, the patient marks items that relate to his or her distress from a six-item problem list (Fig. 90.2).^{105,106} Multiple studies have validated the use of this distress thermometer in various oncologic settings including stem cell transplant.^{107,108} Lee et al found that the distress thermometer was a useful tool for screening transplant patients before admission.¹⁰⁸ Interestingly, pretransplant distress appeared to be highly predictive of distress following transplant and was a feasible marker to screen patients for distress.¹⁰⁸ Yet controversy remains about whether distress screening is of critical importance as is highlighted in a recent systematic review that found that the distress did not improve in screened patients as compared with those who received usual care.¹⁰⁹

MANAGEMENT OF PSYCHOSOCIAL PROBLEMS

Interventions for these patients center on the uniqueness of the experience. In the initial phase of the experience, 50% of patients have psychologic distress, including both anxiety and depression.¹⁰⁶ A growing body of literature provides evidence that patients may experience PTSD.¹¹⁰ Increased length of survival from time of diagnosis has highlighted the need for psychopharmacologic, psychotherapeutic, and cognitive and behaviorally oriented interventions to reduce distress, promote adjustment, and improve quality of life for patients with hematologic malignancies. Cognitive behavioral therapy is a promising intervention that has been used with transplant patients and shown to decrease PTSD symptoms and overall distress.¹¹¹ Because of the increasing complexity of patient care, a

multidisciplinary approach that includes regular avenues and options for communication about patient management and status updates is imperative. Numerous studies have documented the efficacy of a variety of modalities in managing psychosocial problems for such patients. Psychologic distress that can be managed effectively include anxiety and depression; sexual dysfunction; body image disturbances; noncompliance, pain, and neurologic complications such as delirium and dementia induced by brain metastasis or treatment; anticipatory and posttreatment nausea and vomiting; anorexia and feeding problems; and marital and family difficulties.

Pharmacologic Interventions

Pharmacotherapy, as an adjunct to one or more of the psychotherapies, can be an important aid in bringing psychologic symptoms under control. For patients with severe anxiety, factors other than a psychologic state must first be evaluated. Metabolic abnormalities, pain, hypoxia, and drug withdrawal states all can present as anxiety. Many common medications are associated with anxiety and depression. Medications such as steroids and antipsychotics, often used to control nausea, can cause anxiety characterized by agitation and motor restlessness. After medical or drug-induced causes for anxiety

are ruled out, an anxiolytic agent is the treatment of choice, except for patients who present with panic episodes, in whom selective serotonin reuptake inhibitors are most efficacious. Medications are most effective when used at adequate dosages and as standing orders. Use of these medications may assist the patient with participating in psychotherapy, which can provide more lasting control over psychologic symptoms. All pharmacologic treatments must be monitored for effectiveness and side effects.

Patients commonly demonstrate transient depressive symptoms at various points in the disease trajectory. In patients who exhibit prolonged or severe depressive symptoms, a major depressive illness must be considered. Depression can be related to a recurrence of a past depressive disorder or the stress associated with treatment, or it can be a result of the illness process or treatment agents. Antidepressant medications are easily administered and are an effective treatment strategy. Disadvantages include the need for repeated visits to health care clinicians to monitor patient response and adjust the dosage, possible adverse side effects and medical reactions, potential use in suicide attempts, and the need for strict adherence to the medication schedule. Patients should be informed that most antidepressant medications must be taken for 4 to 6 weeks before a significant response is achieved. The clinician must be aware that patients at risk for suicide become more energized with

medications and appear to look better long before their depressive feelings and suicidal thoughts are relieved. Careful monitoring of suicidal ideation should continue for weeks after the patient appears improved.

A diagnosis of major depression in medically ill patients relies heavily on the presence of affective symptoms such as hopelessness, crying spells, and guilt; preoccupation with death or suicide; feelings of diminished self-worth; and loss of pleasure in most activities, such as being with friends and loved ones. The neurovegetative symptoms that usually characterize depression in physically healthy individuals are not good predictors of depression in the medically ill because disease and treatment can also produce these symptoms. A combination of psychotherapy and antidepressant medication often proves useful in treating major depression.¹¹² Patients may need ongoing support, reassurance, and monitoring in the period before the antidepressant effects of medication are achieved. Patients must be monitored closely by a consistent provider during the initiation and modification of psychopharmacologic regimens. In patients with a limited prognosis shorter than a few weeks, recent emerging data suggests that ketamine may be useful for the rapid treatment of depression. The average time to response is on the order of a few hours.¹¹³ It is important to note that although sadness may be present in the end-of-life period, major depression is not common and should be addressed.

Psychotropic drugs are highly effective for treatment of anxiety, depression, agitation, and confusion in patients with hematologic malignancies.¹¹⁴ It is beyond the scope of this chapter to include the current medications recommended for common psychiatric disorders. A comprehensive discussion of psychotropic drugs is summarized in the quick pocketbook reference for oncology clinicians.¹¹⁵ Medications specific for the management of anxiety, depression, and delirium also are presented.

Psychotherapeutic Modalities

“Returning to normal” is a prominent theme and desired goal in the clinical management of patients but is not always possible for patients with hematologic malignancies.^{92,116} Survivors of cancer continue to face challenges with long-term physical and psychologic symptoms long after treatment has ended, and data indicate that they report more contact with mental health providers than do people without cancer.⁹⁶ The ASBMT released a joint statement recommending screening and preventive practices for long-term survivors of hematopoietic cell transplantation. The recommendation states that “a high level of vigilance for psychologic symptoms should be maintained. Clinical assessment is recommended throughout the recovery period, at six months, one year, and annually thereafter, with mental health professional counseling recommended for those with recognized deficits.”⁴¹ The number of intervention studies designed with the hematologic population is limited; however, growing interest in survivorship is changing the research climate in this area.

Support groups can provide a therapeutic experience for patients and family members. Initial evidence suggests that support groups may help reduce health care costs along with depression, mood disturbance, and psychiatric symptoms in patients.¹¹⁷ Patients often feel alone in their distress and report that sharing a common experience normalizes their feelings, provides an avenue for emotional support, facilitates dialogue to problem solve, and offers opportunities to learn from other patients. Support groups facilitated by professionals such as social workers, nurses, or psychologists can provide a forum for health and psychologic education and provide patients with printed literature and online community-based resources. Sherman et al found that psychoeducational support groups facilitated by professionals were a helpful strategy for psychologic recovery in patients' post-HSCT.²⁶

Other modalities have been shown to be effective with patients.^{82,92} Studies have consistently shown that relaxation training with or without guided imagery or hypnosis may have some benefit with improving quality of life, symptom management, and

anxiety and depression management.^{116,118,119} It is a skill taught to patients that takes minimal time. It does, however, require that patients be motivated to learn and practice new techniques as a way of coping. Cognitive therapy/reappraisal, problem solving, and stress management training also have been shown to be helpful in the general cancer population.^{110,116,120} Fritzsche et al identified that a considerable need for psychotherapeutic treatment of inpatient hematology patients is best handled by mental health professionals.¹¹⁹ They described a psychosomatic liaison service that provides psychosocial support for patients with hematologic malignancies, including patients going through transplant. The service screened patients for anxiety, depression, poor coping, quality of life, and psychosocial openness for support, and provided psychotherapy, relaxation training, or group therapy as interventions. Although all transplant patients received support from the team, 23% of the hematology patients on the general ward received additional psychosocial interventions.

Other evidence-based interventions that have been found to be helpful in the general oncology population include individual and group counseling, family therapy, and music and art therapy. In comparison to patients with solid cancers, there should be a low threshold for referral for psychosocial support for patients and families faced with a hematologic malignancy because the primary treatment is intense and long and associated with sensitivity to potential barriers such as economic constraints, including loss of insurance. It has been estimated that one of six cancer survivors with mental health problems who need services are unable to access those services due to cost.⁹⁶ If cost is prohibitive and referral to a psychologist is not feasible, both patients and providers must investigate other potential providers, such as chaplains, art therapists, music therapists, social workers, and psychiatric advanced practice nurses who might be able to see patients as part of their work responsibilities. Other possibilities include online support groups and advocacy organizations, including local wellness communities.

Depending on the nature of the problem, the treatment modality may take the form of individual psychotherapy, group therapy, family therapy, marital therapy, cognitive or behaviorally oriented therapy, or some combination.¹³ Increasing evidence supports use of an aerobic exercise program for patients with hematologic malignancies.^{121–123} Researchers have concluded that fatigue and loss of physical performance in patients undergoing HSCT may improve with exercise.¹²² Others have found increased muscle strength with supervised weight bearing and lifting after allogeneic HSCT.¹²³ Table 90.3 outlines the major psychotherapeutic modalities and their advantages, goals, and indications.

FUTURE DIRECTIONS

The psychosocial issues faced by people diagnosed with and treated for hematologic malignancies are influenced by individual, environmental, and disease-related factors. Because involvement in decision making clearly is a positive aspect of current cancer therapies, great care should be taken to ensure that communication is timely, repeated, relevant, and consistent with the patient's needs, tolerance for information, and comprehension. A multidisciplinary approach is necessary to guarantee the communication of timely and essential information to patients and family members. Patients should be given the opportunity to speak with multiple members of the multidisciplinary treatment team and other patients who have experienced similar management and treatment protocols. Care should be taken to provide needed information from a variety of expert perspectives while respecting the unique characteristics, psychosocial profiles, needs, and desires of each individual. In treatment settings with limited resources, every effort should be made to enlist the help and support of providers and services that can assist patients with treatment decisions and their complex management. Referral to community resources and support services after discharge from the hospital often is helpful, even for patients who cope well with initial treatment.¹²⁴

TABLE
90.3

Therapeutic Modalities Useful for Patients and Family Members

Modality	Selected Indications	Goals and Advantages	Comments
Individual psychotherapy	Prolonged adverse reactions to diagnosis, treatment, and other aspects of chronic illness (e.g., anxiety, depression)	Supports patients and enhances ability to cope with distressing feelings Short-term therapy; focused and goal directed	Pharmacology and family involvement are useful adjuncts in some cases
Support groups	Patients desire contact with others who are experiencing chronic illness	Supports patient and enhances coping ability Patients benefit by observing coping strategies of others Usually does not involve a fee	Expands social network of patients with limited support systems
Family and marital therapy	Relationship problems secondary to illness (e.g., family tension, role changes, conflict, sexual problems)	Assists couples with clarifying problems and facilitates solving them together Addresses role changes in the family system	Problems, issues, and concerns about relationships including children can be addressed
Mind-body therapies, including progressive muscle relaxation, yoga, guided imagery, Reiki, meditation, hypnosis, and biofeedback	Patients desire assistance with control of pain, anxiety, anticipatory and posttreatment nausea and vomiting, fears associated with medical procedures	Increases sense of control and participation in treatment Individualized to meet patient's preferences and circumstances Time limited and goal directed Evaluated in terms of observable changes in symptoms and self-efficacy	Realistic goals should be stated explicitly (Some patients may view these therapies as a cancer cure)

Most patients undergoing cancer treatment, as well as their families, experience expected periods of psychologic turmoil that occur at transition points along the clinical course of cancer. In a small proportion of patients, more severe psychiatric complications may occur, warranting referral to a psychiatric specialist, including psychiatrists, social workers, psychologists, and psychiatric nurses. Screening for ongoing psychiatric problems must become standard care. A variety of psychotherapeutic modalities are useful for helping patients work through the expected psychologic responses to cancer as well as more severe responses.¹⁵ Supportive psychotherapeutic measures should be used routinely because they minimize distress and enhance feelings of control and mastery over self and environment. For these reasons alone, their value in the care of patients with cancer is paramount.

Throughout the clinical course of cancer, the patient's relationship with health care providers and the presence of a supportive social network are important factors that can ensure successful management of the many physical and psychosocial demands imposed by a cancer diagnosis and treatment. As scientific inquiry continues to produce vast but sometimes conflicting information regarding etiology and treatment of cancers, concurrent research regarding the psychosocial aspects of hematologic malignancies is crucial. This line of inquiry will, at the very least, assist in promoting psychosocial well-being in patients and family members faced with an extreme and unexpected life crisis. At best, expanding the knowledge base relative to the psychosocial aspects of cancer may provide some "missing links" regarding psychosocial adaptation and quality of life and the impact of cancer on patients' survival. The Institute of Medicine report that recommends that all cancer care should ensure the provision of appropriate psychosocial health services, states that at a minimum, patients must be screened for emotional distress and evaluated for additional services.

PAIN MANAGEMENT AND ANTIEMETIC THERAPY IN HEMATOLOGIC DISORDERS

Shane E. Peterson, Kathy J. Selvaggi, Bridget Fowler Scullion,
and Craig D. Blinderman

Relieving pain in patients with hematologic disorders requires a multifaceted approach.^{1,2} This chapter will provide the clinician with the tools to perform a systematic evaluation of the pain complaint and propose a rational, evidence-based, strategy. After the source and type of the pain has been identified and assessed, appropriate nonpharmacologic and pharmacologic therapies can be initiated. The approach to managing pain in hematologic disorders is largely based on the approach for managing cancer-related pain. We do not address the neurosurgical or anesthetic procedures for managing pain; those interested in these techniques are referred to several excellent reviews.¹⁻⁵ We will also review the pharmacologic strategies for managing nausea in patients with hematologic disorders undergoing treatment.

TAXONOMY OF PAIN

Although there is no one standardized classification system for cancer pain, several systems have been proposed. Cancer pain syndromes, and thus by analogy, pain syndromes in hematologic disorders, may be classified temporally, pathophysiologically, and etiologically, according to distinct clinical-anatomical entities, or any combination thereof. It is important to determine both the etiology and inferred pathophysiology in the assessment of the pain complaint because this may suggest the use of specific therapies. Pain can be categorized as *nociceptive* (somatic or visceral), *neuropathic*, or *idiopathic*.⁶ Nociceptive pain is pain that is sustained predominantly by tissue injury or inflammation. Nociceptive somatic pain is described as sharp, aching, stabbing, throbbing, or pressure-like. Nociceptive visceral pain is poorly localized and is usually described as crampy pain (e.g., obstruction of hollow viscus) or as aching and stabbing (e.g., pain secondary to splenomegaly). Neuropathic pain is sustained by abnormal somatosensory processing in the peripheral or central nervous system (CNS). Sensations described as “burning,” “shock-like,” and “electrical” typically suggest neuropathic pain. On physical examination, patients may have allodynia (pain induced by nonpainful stimuli) and hyperalgesia (increased perception of painful stimuli). In the absence of evidence sufficient to label pain as either nociceptive or neuropathic, we may use the term *idiopathic*. However, in patients with hematologic disorders, this term should lead to additional workup and a search for an underlying etiology and pathophysiology.

EVALUATION OF THE PAIN COMPLAINT

Initial Evaluation

Effective pain management requires a comprehensive assessment of the patient's pain. The clinical presentation of a patient with chronic pain is very different from that of a patient in acute pain. The patient with chronic pain does not present with the common autonomic manifestations of acute pain (e.g., tachycardia, sweating, elevated blood pressure) or facial grimacing, but often is withdrawn, quiet, depressed, or irritable; moves very little spontaneously; and complains of discomfort when moved. When the pain is relieved, these patients

often exhibit completely different behaviors, becoming mobile, engaged, and involved with other people. The first component in the assessment is to believe the patient's complaint.

Patient reports of pain are valid, reliable, and reproducible.¹ A variety of assessment tools that can be completed within 5–10 minutes are available.^{1,7} The pain complaint should be characterized by a number of descriptors, including the pain location, intensity, quality, onset, and duration; location and patterns of radiation; and what relieves or exacerbates the pain and its functional consequences (including how the pain affects the patient's ability to sleep or eat and how it affects physical activity, relationships with others, emotions, and concentration). Most patients with chronic cancer pain also experience periodic flares of pain, or “breakthrough pain.”^{7,8} An important subtype of breakthrough pain is “incident pain,” which is caused by voluntary activity. The initial evaluation should determine the extent to which the patient has breakthrough pain and if it is provoked by movement (nociceptive) or tends to be paroxysmal in nature (neuropathic). This subjective information, combined with the physical examination and diagnostic studies, may identify a specific pain syndrome and its implied pathophysiology.

In a patient with a hematologic disorder, the cause of pain may be the disease itself, the specific therapy for the disease, diagnostic procedures related to the disease, or unrelated disorders (Table 91.1). Splenomegaly, bone injury (e.g., infarction, infection, hemarthroses, and infiltration), leptomeningeal infiltration, and spinal cord compression frequently accompany hematologic diseases. Chemotherapy and radiation therapy can cause mucositis, typhlitis, hemorrhagic cystitis, and peripheral neuropathy; corticosteroid withdrawal may cause myalgias. Immunosuppression, caused by the diseases themselves or by the therapies used to treat them, may lead to painful infections such as perirectal abscesses, herpetic or candidal esophagitis, and herpes zoster. Patients with sickle cell disease have a number of causes for both acute and chronic pain (Table 91.2).

Distress, however, may arise from nonanatomic sources. The pain complaint may represent the patient's only means of expressing nonspecific feelings of distress to the physician. Chapman recognized three categories of this distress: anxiety, arising from fear of disfigurement or of uncontrollable pain, fear of loss of social position or of self-control, or fear of death; anger at the failure of the physicians to provide a cure; and depression from the loss of physical ability, a sense of helplessness, and the impact of financial problems. In addition to these psychological, social, and financial contributions, spiritual concerns may exacerbate any concomitant painful sensations.⁹ Alleviating them may significantly reduce distress and decrease the need for pain medications or other interventions.

Sometimes there may be a disparity between the patient's expression of pain and the patient's family or friends' appreciation of the impact of the pain. The following observation may help to begin a conversation around this issue: “You seem to show a different perspective about the pain from those of your family and friends. Help me to understand *what the pain is like for you* and why you think your family and friends feel differently.” Differences in cultural backgrounds may also affect the expression of pain, and thus may vary within a family, as well as in different families.⁹

TABLE 91.1 Common Pain Syndromes in Hematologic Malignancies

Procedure-Related Pain	
Deep somatic pain	Bone marrow aspiration, biopsy, and harvest Headache following lumbar puncture
Superficial somatic pain	Venepuncture (needle insertions) Central catheter placement/positioning
Therapy-Related Pain	
Deep somatic pain	Bone marrow expansion and/or sensitization by granulocyte colony-stimulating factor, osteoporosis (e.g., from corticosteroids use), myalgias (e.g., from corticosteroid withdrawal), myopathy
Superficial somatic pain	Oropharyngeal mucositis (e.g., from chemotherapy or radiotherapy)
Visceral pain	Enteritis, typhlitis, hemorrhagic cystitis
Neuropathic pain	Drug-related neuropathies (e.g., from chemotherapy agents)
Headache	Drug related (e.g., due to tretinoin)
Pain From Hematologic Malignancy	
Somatic pain	Bone infarct or necrosis, osteomyelitis, compression fracture, hemarthrosis
Visceral pain	Tumor involvement, splenomegaly, lymphadenopathy, or lymphadenitis
Neuropathic pain	Paraproteins with antimyelin properties, amyloid infiltration, peripheral nerve compression, spinal cord compression
Mixed pain	Headache, meningeal infiltration or infection, brain metastasis, or primary tumor

TABLE 91.2 Classification of Pain Syndromes in Sickle Cell Disease

Pain secondary to the disease itself
Acute pain syndromes
Acute chest syndrome
Calculus cholecystitis (pigment stones)
Hand-foot syndrome (in children)
Hepatic crisis
Priapism
Pulmonary infarction
Recurrent acute painful episode
Splenic sequestration (in children)
Chronic pain syndromes
Arthropathies or arthritis
Avascular necrosis
Chronic osteomyelitis
Intractable chronic pain
Leg ulcers
Neuropathic pain
Pain secondary to therapy
Loose prosthesis (in patients after arthroplasty for avascular necrosis)
Opioid withdrawal
Postoperative pain
Pain caused by comorbid conditions

Continued Assessment

A standardized measurement tool, such as a verbal rating scale (VRS) or a visual analog scale (VAS), should be consistently used during follow-up visits.^{1,7,10} These measurements are thought to be more accurate than mere qualitative descriptors, such as: “The pain is

better.” Using, for example, a scale of 0 (no pain) to 10 (the worst pain one can imagine), a decrease in pain intensity from 10 to 8 indicates that the patient could benefit from additional dose titration, but a decrease from 10 to 3 suggests that the current dose is effective. A pain goal should be assessed by asking the patient, “What level of pain would be acceptable to you?” The ongoing assessment should also pay attention to changes in the phenomenology of the pain, new occurrences of pain, or a change in the location of pain—all of which may suggest progression of disease in the patient with a hematologic disorder.

The successful outcome of pain therapy should be more than simply the lowering of pain intensity scores, but the impact on function, the minimization of side effects from treatment, and the prevention of opioid misuse. Passik and Weinreb developed a useful mnemonic device for the assessment of pain therapy in chronic nonmalignant pain known as the “4 As”: analgesia, activities of daily living, adverse events, and aberrant drug-taking behaviors (e.g., repeated dose escalation or noncompliance, hoarding drugs, or acquiring drugs from other medical sources).¹¹ By focusing on these relevant domains in the continued assessment of the pain therapy, the clinician is able to determine if the therapy makes a true difference in the patient's life, stabilizes or improves psychosocial functioning, manages side effects, and provides a means of assessing for aberrant drug behaviors. Ultimately, the goal should be to lower the pain *to a level acceptable to the patient* and to improve the patient's level of functioning.

THERAPY DIRECTED AT THE UNDERLYING ETIOLOGY

A major component of pain therapy is to ameliorate the underlying cause of the pain, when possible. Surgery, chemotherapy, radiation therapy, immunosuppression, and antibiotics may all be used. Attention to patient comfort should be maintained regardless of the diagnostic or treatment interventions proposed.

NONPHARMACOLOGIC METHODS OF PAIN MANAGEMENT

Cognitive-Behavioral Interventions

Education and Reassurance

Patients with serious hematologic disorders are often required to undergo extensive diagnostic testing, which can include painful procedures. A rehearsal of the planned test or procedure, including a discussion (or view) of the appearance of the room and the length of time to be spent in the test apparatus, can minimize the patient's anxiety. Such explanations, offered preoperatively, lessen the need for postoperative medication and shorten the patient's hospital stay. If conscious sedation is not planned, a pleasant distraction may be helpful to divert attention from certain procedures (e.g., bone marrow aspiration or biopsy) that take place in the physician's office or in the patient's room. For example, a physician might present a patient with an electronic tablet-guided relaxation training session while the physician is preparing for a procedure. The patient is able to utilize the relaxation techniques recently acquired during the procedure in order to diminish pain.¹²

Hypnosis

Hypnosis can be a useful adjunct in the management of pain, including for patients undergoing painful procedures.⁹ The hypnotic trance, a state of heightened and focused concentration, allows one to manipulate the perception of pain and diminish sleeplessness, anxiety, and anticipation of discomfort. Hypnotic training of patients with sickle cell anemia or hemophilia decreases the frequency and pain intensity of painful crises or bleeding episodes, respectively. In a

controlled trial comparing hypnosis with cognitive-behavioral therapy in relieving mucositis after a bone marrow transplant, patients using hypnosis reported a significant reduction in pain control compared with patients who used cognitive-behavioral techniques.¹²

In the absence of a formal hypnotic induction, words used by a practitioner to describe procedures are very important. For example, suggesting that the numbness and coolness of a local anesthetic will persist may diminish the discomfort of a bone marrow biopsy. Using the phrase: “You will feel something; I’m not sure what you will feel because everyone feels this a little differently” in place of “This is going to hurt a lot!” gives the patient permission to alter the sensation and may also diminish the experience of pain.¹³

Meditation

Meditation has long been utilized as a method for controlling pain. Given the wide range of meditation practices and methods, it has historically been difficult to conduct evidence-based research into the effectiveness of meditation. Some research has shown that using meditation to increase focus and clarity does improve pain symptoms and appears to correlate with decreased pharmacologic requirements.¹⁴

Cognitive-Behavioral Techniques and Counseling

The cognitive-behavioral approach addresses a number of psychosocial and behavioral factors that contribute to patients’ experience of pain.^{7,9,15} These techniques have demonstrated clinical utility for patients with a wide range of chronic pain syndromes. Psychological counseling as part of a multidisciplinary approach to pain treatment provides education, support, and skill development for patients with pain. It can improve patients’ abilities to communicate their pain to health care personnel and may be effective in overcoming anxiety and depression. Spiritual counseling may help patients who have lost hope, can find no meaning in their lives, or believe they are being punished or have been forsaken by God.⁹ They may interpret their pain in light of these feelings. Through counseling, they can regain a sense of worth and belonging. As they recast the pain in its true light, its intensity is often diminished.

Cutaneous Techniques

Acupuncture, massage, vibration, and applying cold or heat to the skin over injured areas are often very effective. Cold wraps, ice packs, or cold massage using a cup filled with water that has frozen into a solid piece of ice relieve the pain of muscles that are in spasm from nerve injury. Heat from heating pads, hot wraps, or paraffin treatments can soothe injured joints but should not be used over areas of vascular insufficiency.

EMLA, a cream containing two topical anesthetics (2.5% lidocaine and 2.5% prilocaine) is used, especially in children, to decrease the pain of superficial cutaneous procedures (e.g., venous cannulation or skin anesthesia before lumbar puncture, bone marrow aspiration, or biopsy).⁹ In adults, it is used before access of implanted vascular access devices or CNS ports. To achieve anesthesia, the EMLA cream must be applied 1–1.5 hours before the planned procedure in a mound under a semipermeable dressing such as Opsite or Tegaderm. When EMLA is used as directed, methemoglobinemia has not been a problem even in infants as young as 3 months old. Skin blanching occurs, sometimes exceeding or equaling the frequency of that found with placebo moisturizing cream placed under the occlusive dressing. ELA-Max, a cream containing 4% lidocaine, is available over the counter and is an alternative to EMLA cream. Because it does not contain prilocaine, there is no risk of methemoglobinemia.

Lidocaine patches can be used over areas of hyperesthesia, as can occur in patients with postherpetic neuralgia (PHN) or nerve entrapment by vertebral body collapse.⁹ The patch is applied to the affected area for no more than 12 consecutive hours a day and can be cut to

size. Use should be avoided over areas of broken skin and in patients undergoing radiation therapy. Extended application of lidocaine patches has been safely applied for up to 24 hours/day for up to 4 days with minimal systemic absorption in healthy volunteers and in patients with PHN.

Neuromodulation

Transcutaneous electrical nerve stimulation (TENS) devices are indicated for patients with dermatomal pain, such as PHN or radiculopathy from spinal cord compression.^{9,16} For optimal effect, a physiatrist or physical therapist familiar with the device should train the patient in its use. The efficacy of TENS therapy for patients with cancer pain remains controversial.

Radiation Therapy

Radiation therapy is commonly used in the management of painful bone lesions, spinal cord compression, bulky lymphadenopathy, and symptomatic splenomegaly in patients with hematologic malignancies.^{9,17} Radiotherapy is the treatment of choice for local metastatic bone pain in most situations, although patients with underlying pathologic fractures may require surgical fixation before radiotherapy. Randomized trials have shown that single-fraction radiotherapy is as effective as multifraction radiotherapy in relieving pain caused by metastases. However, there are higher rates of retreatment, and single-fraction radiotherapy may not prevent pathological fractures or spinal cord compression.¹⁷ In patients with poor performance status or a short life expectancy, a single dose (8 Gy) of radiation or a hypofractionated course (20 Gy/5 fractions) may be preferable and less burdensome.

Vertebroplasty and Kyphoplasty

Vertebroplasty and kyphoplasty are both minimally invasive techniques used to stabilize vertebral compression fractures and reduce pain. Vertebroplasty is a procedure in which bone cement, usually polymethylmethacrylate, is injected into the vertebral body. With kyphoplasty, a balloon is first inserted into the vertebral body followed by inflation and then deflation before cement is added. Balloon kyphoplasty has been shown to stabilize pathologic vertebral fractures caused by multiple myeloma and significantly reduce pain.¹⁸

Anesthetic Techniques

Trigger-point injections, nerve blocks, and neurolytic procedures are useful for acute and chronic localized pain. After excisional biopsy of an axillary lymph node, for example, a burning, constricting pain in the posterior arm and chest wall may develop; this pain is often promptly relieved by trigger-point injection.

Lymphoma or multiple myeloma may involve the spine and lead to vertebral collapse or pain from progressive disease that is refractory to antineoplastic therapy. Such pain is often particularly difficult to manage. Insertion of temporary or permanent indwelling epidural or intrathecal catheters to deliver opioids, local anesthetic agents, clonidine, or combinations of these and other agents can be very effective, especially in relieving lower thoracic or lumbar spine pain, as well as pelvic and lower extremity pain.¹⁹ Reviews of the indications for and techniques of the anesthetic and neurolytic procedures are available.⁴

PHARMACOTHERAPY

Drugs useful for pain relief include nonopioid analgesics, opioids, and adjuvant analgesics. Most patients require a combination of medications for optimal pain relief (Fig. 91.1).²⁰

Fig. 91.1 STRATEGY FOR PHARMACOLOGIC MANAGEMENT OF PAIN USING A MODIFIED (FOUR-STEP) WORLD HEALTH ORGANIZATION ANALGESIC LADDER. Multiagent therapy is usually required for optimal pain management. Patients with mild pain should be started on a nonopioid analgesic, and those with moderate pain should be started on a step 2 opioid. Many patients can benefit from the addition of a nonopioid to the opioid (e.g., for bone pain) or an adjuvant agent to the opioid (e.g., for neuropathic pain). If this combination does not produce adequate relief or the patient presents with severe pain, step 3 opioids should be begun initially. Toradol (Ketorolac) is a nonsteroidal antiinflammatory drug (NSAID) with the pain-relieving potency of a step 3 opioid. Many patients can benefit from the addition of nonopioid analgesics or adjuvants, if indicated. *Oxycodone in combination with products. It has been suggested that if opioids with nonopioid analgesics and adjuvants is unsuccessful in providing relief that an additional “4th step” of interventional/intraspinal delivery systems should be initiated.²⁰ ASA, Aspirin; NSAID, nonsteroidal antiinflammatory drug; WHO, World Health Organisation.

Management of Mild-to-Moderate Pain

Nonopioid analgesics should be given to patients with mild-to-moderate pain.^{1,9} Aspirin and nonsteroidal antiinflammatory drugs (NSAIDs), including cyclooxygenase-2 (COX-2) inhibitors, are especially useful as antiinflammatory agents because they decrease local prostaglandin release through the inhibition of COX (although the mechanisms for their analgesic properties are not as clear).²¹ Acetaminophen is an effective analgesic but only a weak antiinflammatory agent. Daily intake of acetaminophen should not exceed 4 g because of the potential hepatic toxicity (see [box on Management of Severe Pain](#)). It is important to prescribe an adequate dose of acetaminophen or NSAID at regular intervals, switching to another nonopioid analgesic only when maximal doses of the first have become ineffective.²¹

Ketorolac tromethamine (Toradol) is an NSAID of particular value in relieving moderate-to-severe acute pain.²² A parenteral dose of 30 mg of ketorolac equals the pain-relieving potency of a parenteral dose of 15 mg of morphine, and acute toxicity is minimal if the total daily dose is under 100 mg. Oral ketorolac is considered less potent. Ketorolac has all of the side effects of the NSAIDs and is not recommended for use beyond 5 days because of an increased risk of renal toxicity. If that degree of pain relief is needed chronically, an opioid agent should be substituted.

Because NSAIDs can cause renal insufficiency in a significant number of patients, renal function should be assessed 1–2 weeks after initiation of any of these agents. NSAIDs should be used with caution in patients with a history of aspirin allergy or asthma because they

can precipitate bronchospasm in as many as 20%. Significant edema can occur in patients with cirrhosis or congestive heart failure.²¹ The relatively selective COX-2 inhibitors, such as meloxicam, celecoxib, and nabumetone, have been shown to cause similar gastrointestinal side effects as nonselective NSAIDs.²³ If NSAIDs are required in patients with a history of significant gastritis or ulcer disease, or who are older than 70 years, COX-2 inhibitors or a concomitant proton pump inhibitor should be considered. Cardiotoxicity is well described in the literature for COX-2 selective inhibitors.²⁴ Recently, the cardiac risk associated with traditional NSAIDs has been questioned. In a metaanalysis that included naproxen, ibuprofen, diclofenac, and several COX-2-specific inhibitors, ibuprofen and diclofenac demonstrated an increased risk of stroke. Diclofenac was also associated with an increased risk of cardiovascular death. Naproxen was not noted to increase risk in this study.²⁴ Nonopioid analgesics should be continued when opioid analgesics are added because they can potentiate the pain-relieving effect of the opioid (see [Fig. 91.1](#)).²⁵ However, when aspirin or acetaminophen is included in a fixed drug combination (e.g., Percodan, Percocet), toxicities may develop if the patient uses the medication more frequently than prescribed. The metabolism of salicylates is limited by the capacity of the hepatic microsomal system.⁹ After it is saturated, salicylate levels are dependent on renal clearance. Small increases in maintenance doses can lead to serious salicylism. Patients with low albumin levels or acid urine are particularly susceptible to the development of salicylate toxicity.

Tramadol, which both weakly inhibits norepinephrine and serotonin reuptake, and weakly binds to μ -opioid receptors and has opioid-like side effects, can be used for mild-to-moderate pain. A dose of 100 mg is more effective than 60 mg of codeine. Tapentadol (Nucynta) also had both μ -receptor agonism and norepinephrine reuptake inhibition. Studied in moderate-to-severe acute postoperative pain, osteoarthritis, and low back pain, doses of 50–100 mg every 4–6 hours are comparable to oxycodone 10–15 mg every 4–6 hours with less nausea, vomiting, and constipation.

Management of Moderate-to-Severe Pain

Opioid therapy is the cornerstone of management of patients with moderate-to-severe pain.

In patients with acute moderate-to-severe pain (i.e., $>4/10$ on VRS), intravenous dosing should be started with the goal of rapid titration (see, for example, National Comprehensive Cancer Network [NCCN] guidelines for Adult Cancer Pain).²⁶ In opioid-naïve patients, morphine 2–5 mg or its equivalent (see [box on Relative Potencies of Commonly Used Opioids](#)) should be dosed every 15 min (peak effect ~15 min). The patient should be reassessed for analgesic effect and side effects. If pain is not relieved, then the dose can be increased by 50%–100%; if the pain score decreases to an acceptable level, then the same dose can be continued and given as a standing dose “around the clock.” Alternatively, a patient-controlled analgesia (PCA) can also be used in these situations and can provide the patient with significant control over their pain experience. Similarly, the PCA demand dose can be calculated over a 24-hour period to determine the “basal dose” of opioid the patient will need for stable analgesia. This can be provided as a basal rate on the PCA, or given the clinical situation, as a long-acting formulation equivalent to the amount of demand doses received. In opioid tolerant patients, a dose equivalent to 10%–20% of the patient’s total 24-hour oral requirement should be administered as an intravenous bolus (see [box on Relative Potencies of Commonly Used Opioids](#)) and titrated, as above, every 15 minutes until pain is controlled and acceptable to the patient. For example, a patient receiving oxycodone sustained release 60 mg twice daily, should be prescribed morphine 5–10 mg intravenously every 15 minutes as needed (oxycodone 120 mg is approximately equivalent to 180 mg of oral morphine, or 60 mg of intravenous morphine; take 10%–20% of this dose). The long-acting opioid should be continued or converted to a continuous infusion, or given as a basal rate via a PCA.

Once the patient has an acceptable level of analgesia, this dose can be converted to a sustained release formulation, or to another equivalent long-acting opioid. If morphine is used, for example, the patient will need three times the parenteral dose that was effective. For example, a patient who requires 10 mg of morphine per hour (i.e., 240 mg/24 hours given intravenously) will need 720 mg/day of the oral sustained-release agent (240 mg every 8 hours). This can also be given orally as 360 mg every 12 hours. Short-acting immediate-release morphine should be available for rescue dosing at 10% of the total daily dose. For this patient, 60–90 mg every 3–4 hours is recommended. If the amount of opioid taken as a rescue dose is significant (>25% of the daily dose) for 1 or 2 days, the total dose of long-acting agent is adjusted upward accordingly.

In the outpatient setting, patients with chronic, moderate-to-severe pain can be treated with oral pain medications, e.g., morphine 5–15 mg (or an equianalgesic dose, e.g., oxycodone 5–10 mg), and titrated in a similar fashion. Note the peak effect of most oral opioids is approximately 60 minutes, so the patient should be reassessed 60 minutes following the dose for analgesic efficacy and side effects. The same strategy as above can be used for opioids-tolerant patients, i.e., 10–20% of the basal dose can be given for additional analgesia and titrated to effect.

Agents to prevent side effects should be started once opioids are initiated. All patients should be prescribed a stimulant laxative, e.g., senna (one or two tablets orally daily to twice daily, up to a maximum of eight pills per day), plus or minus a stool softener, e.g., colace 100 mg three times per day. If a more potent laxative effect is needed, lactulose (15–30 mL) or polyethylene glycol (17 g) is added. In opioid-naïve patients, prochlorperazine (Compazine 10 mg taken orally two or three times daily) is prescribed as needed to treat nausea.

Opioid Analgesics

Patient Education

To ensure patient compliance with an opioid prescription, education of members of the health care team, the patient, and the family is often required to dispel the many misconceptions associated with opioid therapy.⁹

Fear of addiction is a common cause of inadequate prescribing of opioids and a barrier to their acceptance by patients.⁹ Patient adherence can be improved by providing a full explanation of the differences between addiction and physical dependence, education regarding the appropriate use, storage, and disposal of opioid medications, and the risks factors for opioid misuse. Patients may also fear that if they take opioid medications for moderate pain, the medications will no longer be effective if more severe pain occurs. Because this fear, if unexpressed, can lead to undertreatment, the topic should be addressed even if the patient does not raise the question. A functional goal of therapy, such as returning to a favorite activity or reinstituting normal activities of everyday life, may enable the patient and the family to accept the opioid. Misconceptions about religious teachings may prevent health care personnel, patients, and their families from giving or accepting adequate pain medication. Catholics, for example, may not be aware of the church's position, as stated in the current catechism, that opioids may be used at the approach of death even if their use ultimately shortens the patient's life. The church does not consider this use of pain medication to be a means of suicide or euthanasia.⁹

Choice of Medication

Because a wide variety of medications are available, pharmacokinetic considerations and side-effect profiles should be considered when choosing opioid agents. Intermittent moderate-to-severe pain lasting hours to several days is amenable to oral analgesics with short half-lives (3–4 hours) with appropriate potency (e.g., immediate-release oxycodone, morphine, hydromorphone [Dilaudid], or oxymorphone

Relative Potencies of Commonly Used Opioids

Drug	Epidural	SC or IV (mg)	PO (mg)
Morphine	1	10	30
Codeine		130	200
Oxycodone		N/A	20
Hydromorphone	0.15	1.5	7.5
Methadone ^a		^a	
Oxymorphone		1	10
Levorphanol		2	4
Fentanyl		0.1	N/A
Meperidine (Demerol) ^b		75	300

^aMethadone is approximately half as potent orally as it is intravenously. It is usually not given SC because of local irritation. Standard equianalgesic tables do not reflect methadone's potency when used in repeated doses.

^bNot recommended for patients with chronic pain.

IV, Intravenous; N/A, not applicable; PO, oral; SC, subcutaneous.

Conversions Between the Transdermal Fentanyl Patch and Morphine

Fentanyl (μg/hour)	Morphine (mg/24 hours)	
	Oral	IM or IV
25	50	17
50	100	33
75	150	50
100	200	67
125	250	83
150	300	100

IM, Intramuscular; IV, intravenous.

Data from Miaskowski C, Cleary J, Burney R, et al: Guideline for the management of cancer pain in adults and children, Aps clinical practice guidelines series, No.3. Glenview, IL, 2005, American Pain Society.

[Opana] when available). Severe pain of relatively constant intensity should be treated with oral sustained-release morphine or oxycodone taken every 8 or 12 hours,^{1,7} hydromorphone (Exalgo) taken every 24 hours, oxymorphone (Opana ER) taken every 12 hours, hydrocodone (Zohydro ER, Hysingla ER) taken every 12 hours, methadone taken every 6–8 hours, or transdermal fentanyl renewed every 48–72 hours. Twelve- to 24-hour formulations of oral morphine (e.g., Kadian, Avinza) are also available; for patients unable to take pills, the capsule can be opened and the pellets sprinkled on food or suspended in water and given through a feeding tube⁹ (see [boxes on Relative Potencies of Commonly Used Opioids and Choice of Medication](#)).

Practical Considerations When Using Opioids

Drugs with short half-lives should be used for “rescue doses” given for incident pain (i.e., pain with movement) and for between-dose pain exacerbations often referred to as “breakthrough pain.” The dose of the rescue medication is usually calculated as 10%–20% of the total 24-hour dose, although there is no evidence for this heuristic.^{27,28} For example, if a patient is receiving 300 mg of oral sustained-release morphine twice each day, the rescue dose is 10%–20% of 600 mg, which is 60–120 mg of short-acting morphine. Agents with short half-lives should also be used in elderly patients and in patients with impaired renal or hepatic function.⁹ For patients with a history of drug abuse, agents with longer half-lives, such as methadone, are preferred.

There is considerable variability with respect to the side effect profile of the various opioids in each patient. Therefore it is often useful to switch to another agent if a patient is experiencing dose-limiting side effects with the initial opioid chosen. For example, if the

patient on morphine experiences persistent or debilitating nausea, the rotation to another opioid at an equianalgesic dose should be considered (see [box on Relative Potencies of Commonly Used Opioids](#)). Because of incomplete cross-tolerance, the initial dose for patients taking higher doses of opioids should be reduced by approximately 25%–50%. The short-acting rescue medication can provide relief if this initial dose does not prove adequate.

Methadone is increasingly used for patients with moderate-to-severe pain. It is by far the least expensive of the opioids; can be given by the oral, sublingual, rectal, intravenous, and epidural routes; and may have particular usefulness in patients with poor tolerance to other opioids. Methadone has anecdotally been used for neuropathic pain; however, recent clinical trials have not demonstrated this benefit.²⁹ Methadone is structurally unrelated to morphine and fentanyl, and can be used in the rare case of true allergy to these medications. It is also helpful when patients have neurotoxic side effects of other opioids. Methadone is a potent μ -opioid receptor agonist. The l-isomer has higher binding affinity for delta opioid receptors, which reduces tolerance, while the d-isomer has *N*-methyl-D-aspartate (NMDA) receptor antagonism and 5-hydroxytryptamine and norepinephrine reuptake blockade, which may be helpful in providing analgesia.²⁹ Patients with neuropathic pain and patients taking opioids chronically have increased levels of NMDA receptors in the dorsal horn of the spinal cord. NMDA antagonizes the activity of the opiate receptors. Blocking the NMDA receptors therefore enhances the analgesic effect of externally administered opioids. Ketamine, a pure NMDA antagonist, similarly enhances opioid efficacy but is associated with more cognitive side effects than methadone.

Methadone interacts with inducers and inhibitors of the cytochrome P450 system. It is extensively metabolized by CYP1A2, CYP3A4, and CYP2D6; the first two are induced by a number of drugs and other substances (e.g., cigarette smoke), and the last enzyme has a genetic polymorphism. Drug levels of desipramine and zidovudine increase when patients are receiving methadone. Drugs that lower the levels of methadone include phenytoin (by 50%), phenobarbital, carbamazepine, rifampicin, and risperidone, each of which has precipitated withdrawal symptoms.³⁰ Drugs that raise the serum methadone levels include ketoconazole, fluconazole, fluoxetine, and fluvoxamine. The selective serotonin reuptake inhibitors (SSRIs) (except venlafaxine) may raise methadone levels in CYP2D6 rapid metabolizers.

Methadone can cause prolongation of the QT interval. A mean methadone dose of 400 mg/day (standard deviation: 283 mg) was found in 17 patients with torsades de pointes. In an evaluation of reports of methadone-related adverse events to the US Food and Drug Administration (FDA), approximately 1% of the greater than 5000 reports were of QT prolongation or torsades de pointes. The median dose was 345 mg with a range of 29–1680 mg. Drugs that also prolong the QT interval, such as metoclopramide and olanzapine, should be used with caution in patients receiving significant doses of methadone. Gabapentin, the drug used most often as a neuropathic pain adjuvant, does not interact with methadone metabolism. There is insufficient evidence to recommend a screening interval or dose threshold for detecting methadone-induced QTc prolongation.³¹

Other difficulties with using methadone lie in its variable and long biologic half-life, and the controversy about its equianalgesic dosing range. Some studies have reported that the equianalgesic dose of morphine to methadone varies as the dose of morphine increases.⁹ Dose ratios vary from 4:1 at morphine doses of 30–90 mg, to 6:1 at 90–300 mg, and to 8:1 at doses of more than 300 mg of morphine. Other studies report a ratio of 20:1 for doses of oral morphine equivalents greater than 1000 mg. Some physicians advise a 3-day conversion to methadone. On the first day, the dose of the old opioid is reduced by one-third, and one-third of the calculated dose of methadone is given; the second day, the dose of the remaining opioid is reduced by half, and the dose of methadone is only increased if the patient is experiencing moderate-to-severe pain; the third day, the old opioid is discontinued, and the standing dose of methadone is

adjusted to reflect the rescue doses.³⁰ When converting patients directly from intravenous fentanyl to intravenous methadone, a conversion ratio of 25 μ g/hour of fentanyl to 0.1 mg/hour of methadone has been found in a pilot study to be a safe and effective initial infusion rate.³²

A relatively new opioid to the US market that is now available in both extended release and immediate release is oxycodone. Oxycodone extended release has been found to provide safe and effective pain relief for cancer pain.³³ Oxycodone extended release is dosed twice daily and is about twice as potent as oxycodone.³⁴

Levorphanol, which is chemically similar to dextromethorphan (an NMDA antagonist and cough suppressant), is a potent opioid that may be considered for patients with severe cancer pain. It was originally synthesized as an alternative to morphine more than 40 years ago. It has a greater potency than morphine, approximately five times as potent in its oral formulation. Analgesia is achieved through its agonistic activity at μ -, δ -, and κ -opioid receptors, as well as by its antagonism of NMDA receptors. Levorphanol can be given orally, intravenously, and subcutaneously.

Buprenorphine has long been used to treat patients with addiction as an alternative to methadone. It is available buccal/sublingually, intravenously, and now as a transdermal patch. Buprenorphine has been shown to be very effective in treating cancer pains (including neuropathic) and provides several important advantages over other opioids: It is associated with less cardiotoxicity (does not significantly prolong the QTc interval), respiratory depression, cognitive impairment, and constipation, and is one of the safer opioids to use in elderly patients or patients with renal dysfunction.³⁵

Meperidine is eight to 10 times less potent than morphine and has a short duration of action, approximately 2–3 hours. Normeperidine, an active metabolite which induces dysphoria, is excitatory to the CNS and can cause agitation, tremors, myoclonus, and seizures, especially in high doses, with prolonged use or in renal failure.⁹ Normeperidine has a half-life of 13–24 hours, which can lengthen with renal failure. The seizure incidence is further increased if the opioid antagonist naloxone (Narcan) must be given. Therefore meperidine is not recommended for use in patients with long-lasting moderate-to-severe pain.^{1,7}

Routes of Delivery

Opioids can be delivered noninvasively (orally, rectally, transmucosally, or transdermally) or invasively (subcutaneously, intravenously, or by spinal infusion). For patients switched from one route to another such as oral or rectal to parenteral or spinal medication, or vice versa, the dose must be converted accordingly to avoid overdose or undertreatment (see [box on Relative Potencies of Commonly Used Opioids](#)).

Oral Route

Most patients can achieve excellent pain relief with short-acting and/or sustained-release oral opioid preparations. The typical onset of short-acting opioids via the oral route is 45 minutes to 1 hour, with a typical duration of action around 3–4 hours. When tablets and capsules are not feasible, many liquid forms are available in various concentrations. Some solutions do contain alcohol, which can be irritating to patients with oral lesions.

Rectal Route

Rectal opioids (i.e., morphine, oxycodone, and hydromorphone) replace subcutaneous injections in patients who are suddenly unable to take oral medications. They have about the same potency and half-life as orally administered agents⁹ and must therefore be administered frequently. Oxycodone has been shown to have a similar mean bioavailability but with a large interpatient variability but longer duration of activity (8 hours). Although not approved by the FDA, in single-dose bioavailability studies of sustained-release morphine preparations, despite delayed absorption from the rectal route, total

morphine absorption over 24 hours was equivalent, whether the drug was given orally or rectally.⁹

Transdermal Route

The transdermal fentanyl patch delivers the lipophilic fentanyl into the fat-containing areas of the skin. The drug diffuses continuously from the patch's reservoir through a rate-controlling membrane and is absorbed from the skin depot into the bloodstream, where it is rapidly metabolized.⁹ The onset of pain relief is delayed about 12 hours, and a relatively constant plasma concentration of fentanyl is not reached until about 14–20 hours after the initial patch is placed.⁹ Liberal rescue medication must therefore be provided during the first 24 hours of use of the patch. Similarly if a patient develops signs of fentanyl overdose, naloxone (Narcan) must be given until the skin reservoir has become depleted. About 50% of the drug is still present 24 hours after patch removal. Converting patients from oral or parenteral medication to the patch is easily accomplished⁹ (see [box on Relative Potencies of Commonly Used Opioids](#)). A new patch is applied every 72 hours, although up to 25% of patients require a new patch every 48 hours.

The transdermal system is an effective method of delivering pain relief for patients with a stable level of chronic moderate-to-severe pain, no oral route available, or no desire to take pills. Side effects include those caused by the contact adhesive along with those commonly associated with other opioids, but they may be better tolerated than those caused by morphine.

The transdermal system should not be used in patients with sepsis, those experiencing acute pain, those with markedly fluctuating opioid requirements, cachectic patients, or individuals with significant dermatologic insults (i.e., skin graft-versus-host disease [GVHD] or diffuse varicella). When the patient's temperature rises to 40°C, drug absorption from the skin can increase by as much as 35%. If hepatic function is impaired or sepsis or shock develops and blood flow to the liver decreases, plasma concentrations may rise sharply. Patients with cachexia lack the subcutaneous tissue necessary for formation of a drug reservoir. Lower doses may also be required in elderly patients and in those with respiratory insufficiency.

Transdermal buprenorphine (Butrans) patches have been shown to be safe and effective in patients with cancer pain.³⁶ They can be used alone or in combination with other opioids without reported problems, and unlike other opioids, which can cause a hyperalgesia effect from long-term use, buprenorphine has been described to exert an antihyperalgesic effect. A lack of immunosuppression and safety in renal insufficiency make buprenorphine ideal for the treatment of cancer patients. Due to the risk of QTc prolongation the transdermal patch carries an FDA warning against exceeding 20 µg per hour.

Transmucosal Route

Transmucosally administered fentanyl induces rapid analgesia with a short duration of effect (≈1 hour) and is an effective treatment in the management of breakthrough pain.³⁷ Oral transmucosal fentanyl citrate (Actiq), fentanyl buccal tablet (Fentora), fentanyl buccal soluble film (Onsolis), and fentanyl sublingual tablets (Abstral), as well as a fentanyl nasal spray (Lazanda) are the available transmucosal fentanyl products. They have been found to be both efficacious and safe in the treatment of cancer-related breakthrough pain.

Subcutaneous and Intravenous Routes

Subcutaneous or intravenous administration of opioids can provide pain relief in the shortest amount of time with minimal oversedation. The drugs can be delivered by portable infusion pump that is initiated or continued in the home.⁹ Guidelines for their use are available. PCA systems for subcutaneous or intravenous drug delivery have the advantage of responding to the individual patient's threshold for pain while eliminating delays when nurses must administer supplemental medication. The pumps can administer a continuous fixed infusion of the opioid chosen and allow the patient to self-administer boluses of additional medication at frequencies chosen by the physician. By recording the additional amounts of self-administered medication,

the devices also facilitate the adjustment of the continuous dose required for pain relief.

Spinal Route

Epidural or intrathecal opioid infusions can be helpful for select patients. The infused opioids block pain transmission by binding to receptors in the dorsal horn of the spinal cord. Because the drug is being infused in close proximity to the spinal cord, only a small amount of opioid is needed, and the systemic side effects are reduced. Problems with this delivery system in patients who are not opioid naive include pruritus, respiratory depression, and sedation. If tolerance to the opioid develops and higher doses are required for relief, the incidence of side effects may approach that of systemically administered opioids.^{38,39} Addition of local anesthetic or α-adrenergic agent (e.g., clonidine) or other agents¹⁹ to the epidural opioid infusion allows for fairly rapid lowering of the opioid concentration and reestablishing opioid sensitivity but can cause hypotension.⁴⁰

Management of Opioid-Related Side Effects

Sedation

The addition of 2.5–7.5 mg of dextroamphetamine or methylphenidate⁹ (taken orally twice daily) has been shown to reduce opioid-induced sedation and at times allow for escalation of opioid doses without sedation. These medications also improve cognitive function and symptoms of depression. Methylphenidate may also enhance the analgesic effects of opioids.⁹ They should be avoided in patients with anxiety, moderate-to-severe hypertension, agitation, thyrotoxicosis, tachyarrhythmias, severe angina pectoris, and closed-angle glaucoma. Modafinil (Provigil), a novel psychostimulant with a mechanism of action different than the amphetamine derivatives, which is approved for narcolepsy and fatigue related to multiple sclerosis, has also been found to be effective for opioid-related sedation.⁹

Constipation

Constipation is the most common opioid-induced side effect.⁷ Laxatives should therefore be given routinely, not on an as-needed (PRN) basis,^{1,7,9} to patients treated with any of the drugs listed in the box on Relative Potencies of Commonly Used Opioids. Detailed bowel preparation recommendations can be found, but no regimen has been studied in a controlled fashion. Commonly used stool softeners and stimulants include docusate sodium, senna, lactulose, and polyethylene glycol. A combination of a stool softener and laxative seems to be a rational choice for patients taking chronic opioids (e.g., docusate sodium with senna). Promotility agents most directly counter the mechanism of opioid-induced constipation. Bulk-forming laxatives such as psyllium and methylcellulose should be avoided because they increase stool volume without promoting peristaltic action. For refractory opioid-induced constipation, a trial of oral naloxone, methylnaltrexone, or alvimopan may be initiated.⁹ These µ-opioid receptor antagonists (RAs) act locally to reverse the effects of opioids on the gut. There is minimal systemic absorption with oral naloxone and subsequently a low risk of precipitating opioid withdrawal or worsening pain at low-to-moderate doses (1.6–12 mg/day). Methylnaltrexone (administered subcutaneously)⁹ and alvimopan (oral) do not cross the blood–brain barrier and therefore do not cause opioid withdrawal or worsening pain.

Nausea

Prochlorperazine (10 mg taken two or three times daily) or metoclopramide (10 mg taken three to four times daily) can prevent the nausea that occurs in most patients during the first days of opioid therapy. Relieving constipation or changing the opioid (e.g., from morphine to oxycodone) often eliminates the later development of

nausea. Rarely, patients need oral or intravenous ondansetron (8 mg taken two or three times daily).

Respiratory Depression

Naloxone (Narcan), given intravenously, reverses opioid-induced respiratory depression, although repeated doses are often required.⁹ Respiratory depression can occur in patients with mild-to-moderate pain during the initial use of opioids, although it is rare in patients with severe pain and in those chronically receiving opioids. Caution should be exercised before administering naloxone to patients who are chronically receiving opioids to avoid precipitation of severe pain and withdrawal. In such cases, it is inadvisable to administer the usual 0.4 mg/mL dose. Rather, 0.4 mg of naloxone should be diluted with 9 mL of saline and 1–2 mL (0.04–0.08 mg) of this dilute mixture given every 2–3 minutes until the patient is rousable and breathing at least 10 times/min. Do not give enough to fully waken the patient or withdrawal is likely to ensue.¹ In a comatose patient, endotracheal tube placement is recommended to prevent aspiration from the salivation and bronchial spasm that will be induced.¹ Naloxone should not be administered to an alert patient.

Adjuvant Analgesics

Adjuvant analgesics are a diverse class of medications, which typically have indications for conditions other than pain. They have analgesic properties and are often used when an opioid regimen alone is unable to provide sufficient analgesia or is associated with dose-limiting side effects.

Neuropathic Pain

Adjuvant agents for patients with neuropathic pain include anticonvulsants, antidepressants, α_2 -adrenergic agonists, corticosteroids, topical agents, γ -aminobutyric acid (GABA) agonists, and NMDA RAs.^{1,7,9,41} However, the analgesic antidepressants and anticonvulsants are typically preferred for treating neuropathic pain secondary to cancer.⁴²

The anticonvulsants gabapentin (Neurontin) and pregabalin (Lyrica) have the fewest side effects and are very effective for patients with neuropathic pain from tumor, peripheral neuropathy from tumor or treatment, and PHN.⁴¹ Despite their names, they have no effect on GABA receptors, but rather bind to the α -2-delta subunit of the N-type calcium channels in neurons within the dorsal horn, thus inhibiting calcium influx and diminishing neuronal hyperactivity. To minimize sedation, doses should be low at first (e.g., gabapentin 100 mg three times daily or 300 mg at bedtime; pregabalin 50 mg twice a day) and should be increased as tolerated every 3–5 days until analgesia is achieved. The effective dose of gabapentin varies between 900 and 3600 mg/day in divided doses and that of pregabalin is 150–300 mg twice a day. The pharmacokinetics of gabapentin are unique in that it has a ceiling effect related to a saturable transport mechanism in the gut, such that the effects of this drug may plateau during dose escalation.⁴² The most common dose-limiting side effect is sedation. Gabapentin and pregabalin need to be renally dosed in patients with decreased creatinine clearance. Peripheral edema related to gabapentin or pregabalin may require diuretics. Pregabalin's gastrointestinal absorption is proportional to the dose throughout the effective dose range, making titration simpler. Other, generally less effective anticonvulsants used for neuropathic adjuvants include phenytoin, carbamazepine, lamotrigine, topiramate, and tiagabine.

The tricyclic antidepressants (TCAs; e.g., amitriptyline, nortriptyline) are effective agents for neuropathic pain.⁹ The TCAs, when used as adjuvant analgesics, are effective faster and at lower doses than when they are used as antidepressants (e.g., amitriptyline is effective within 2–3 days at 50–100 mg/day). However, because of their anticholinergic side effects they should be started at doses of 10–25 mg

at bedtime and used with caution in elderly patients and in patients who have cardiac conduction abnormalities or bladder outlet obstruction. Combination therapy with gabapentin and nortriptyline has been shown to be more effective than either drug alone in patients with diabetic neuropathy and PHN.⁴³

Selective serotonin and norepinephrine reuptake inhibitors (SSNRIs; e.g., venlafaxine and duloxetine) have been shown to be analgesic for a number of neuropathic pain syndromes. There is less evidence supporting the use of SSRIs for neuropathic pain.

Corticosteroids given epidurally, intravenously, or orally are useful as antineoplastics (e.g., in leukemia, lymphoma, and myeloma) and can also provide nonspecific relief for patients with spinal cord compression and plexus infiltrations. Doses of 16–100 mg of dexamethasone are needed to reduce vasogenic edema in spinal cord compression,⁹ but lesser doses (6–20 mg/day) can be helpful in patients with plexus injuries. Patients must be monitored for the development of oral or esophageal candidiasis and steroid-induced delirium.

Bone Pain

Adjuvants for bone pain include NSAIDs, corticosteroids, bisphosphonates, receptor activator of nuclear factor κ -B ligand inhibitors (e.g., denosumab), and the radiopharmaceuticals strontium chloride (⁸⁹Sr) and samarium 153-lexidronan.⁹ Multiple studies have demonstrated the efficacy of bisphosphonates in reducing skeletal complications and pain from bone metastases.⁹ Pamidronate and zoledronate are recommended for patients with multiple myeloma and other hematologic malignancies with painful bone lesions. Calcium and sometimes vitamin D supplementation (especially for denosumab) are often needed.⁴⁴ Also, the long-term use of bisphosphonates is associated with a small but meaningful risk of osteonecrosis of the jaw.⁴⁴ The limitations of radiopharmaceuticals include cost and cytopenias.⁹ Given the limited evidence available, a recent Cochrane review did not support the use of calcitonin for control of pain from bone metastases.

Cannabinoids

Long used empirically for their analgesic and antiemetic properties in a wide range of illnesses, cannabis and cannabinoid therapies have been subjected to an increasingly large number of controlled clinical trials (of varying size and quality) over the last several decades.⁴⁵ Oral cannabis, used for breakthrough pain, was studied in a recent multicenter randomized controlled trial, involving 360 patients, who were started on a long-acting opioid. The study showed analgesic efficacy in the low and medium dose ranges, which were also well tolerated.⁴⁶ Inhaled cannabis, used for nausea and vomiting secondary to active cancer chemotherapy, was studied in three randomized controlled trials, involving 43 subjects in total, which demonstrated inhaled cannabis to be an efficacious antiemetic. Additional studies have provided evidence for its effect on spasticity, appetite stimulation, and insomnia.

SPECIFIC CLINICAL PROBLEMS

Oral Complications

Oral complications of chemotherapeutic and bone marrow transplant regimens can be frequent causes of pain. A thorough dental evaluation and prompt treatment of infections can minimize the discomfort arising from underlying periodontal disease and caries; secondary bacterial, viral, and fungal infections; and mucositis.⁴⁷ Preventive regimens include saline, sodium bicarbonate, chlorhexidine gluconate rinses, acyclovir, antifungals, and ice. Palifermin (recombinant human keratinocyte growth factor [KGF-1]) is used for the prevention and treatment of mucositis induced by conditioning

regimens for hematopoietic stem cell transplants (SCT).⁹ Amifostine is a thiol compound that is a selective cytoprotective agent approved for salivary gland protection in patients receiving radiation therapy.⁴⁸ The benefit of using colony-stimulating factors in the treatment of oral mucositis has been confirmed in at least four controlled trials.⁴⁹ They have not achieved widespread use, possibly because of their high cost.

Anesthetic cocktails composed of agents such as viscous lidocaine (Xylocaine), dyclonine hydrochloride, or a slurry of sucralfate, provide temporary relief from oral mucositis-related oral pain. A variety of mucosal-coating agents have been used to protect mucosal surfaces of the oral cavity including Orabase, Episil, oral antacids, and Gelclair. There is little evidence from randomized trials to support any benefit from these preparations. Gelclair, a bioadherent gel that adheres to the oral surface, creating a protective barrier for irritated tissue, showed a reduction in oral discomfort within 5–7 hours of initial treatment in an uncontrolled, open-label study of 30 hospice patients (only three of whom had chemotherapy-related mucositis).⁵⁰ The more severe cases, occurring in bone marrow transplant recipients, usually require infusional opioid therapy delivered by standard drip or PCA. Pilocarpine (5–10 mg three times daily 1 hour before meals) may improve xerostomia from neck irradiation. However, caution is warranted because of reported side effects of glaucoma and cardiac problems. Sugar-free hard candy is also useful for opioid-induced xerostomia and dysgeusia.

Postherpetic Neuralgia

PHN, defined as pain persisting beyond 4 months from the initial onset of the rash, can be a difficult problem for patients with hematologic disorders and has been the subject of several reviews. The anticonvulsant medications gabapentin, pregabalin, and valproic acid are especially useful in reducing the lancinating component of the various pain syndromes generated by this infection. A 2011 systemic review identified four placebo-controlled randomized trials, with two trials evaluating immediate-release gabapentin at doses between 1800 and 3600 mg daily showing benefit compared with placebo for the outcome of “much or very much improved” (38% vs. 20%).⁵¹ Pregabalin in randomized studies with patients with PHN has shown improvement in sleep and decrease in pain at doses of 150–600 mg daily.⁵² Because of the risks associated with physical dependence, tolerance, addiction, and overdose, many experts consider opioids as second- or third-line options for PHN.⁵³

TCAs are effective for PHN.⁵⁴ One trial concluded that nortriptyline was better tolerated than amitriptyline.⁵⁵ Elderly patients, however, often do not tolerate the anticholinergic side effects, principally sedation and dry mouth, and therefore nortriptyline (Pamelor), a less anticholinergic TCA, may be useful in these patients. Topical lidocaine (5%) has been used for the relief of pain associated with postherpetic neuralgia; however, its role has not been established.⁵⁶ There are limited data on the efficacy of topical capsaicin (0.075%).⁵⁷ Available evidence of botulinum toxin injection for PHN has not been well studied, but available evidence suggests it is effective and well tolerated.⁵⁸ Patients with severe pain refractory to these therapies may benefit from a combination of intrathecal methylprednisolone and lidocaine.⁵⁹

Sickle Cell Anemia

Patients with sickle cell anemia have chronic and episodic pain despite optimal medical therapy, and 60% of patients with sickle cell anemia will have an episode of severe pain each year. Chronic arthritic pain can be treated with physical therapy and full doses of antiarthritic medication, but some patients require low doses of chronic opioid therapy to maintain independent functioning. Several studies have confirmed the safety and efficacy of long-term opioids in the treatment of pain of nonmalignant origin. In some cases, joint replacement may be required.

When a patient with sickle cell anemia experiences pain, it is important to attempt to define the precise cause of the pain before attributing it to a vasoocclusive crisis. Acute vasoocclusive pain may occur along with the chronic pain caused by the long-term complications of compression fractures, avascular necrosis, arthropathies, fractures, avascular necroses, and leg ulcers.⁶⁰

Treating patients with sickle cell pain is complex and requires understanding that much of the pain in adults with this illness is chronic with intermittent, recurring painful episodes. For mild pain, nonopioid therapy such as NSAIDs or acetaminophen with oxycodone or hydrocodone should be considered. However, because of possible compromise of renal blood flow in these patients and the risk of acute renal failure, NSAIDs should probably not be used beyond 5 days.⁷ Uncontrolled severe pain accounts for more than 90% of hospital admissions in adults with sickle cell disease. Using short-acting analgesics on an “as-needed” basis exposes the patient to periods of insufficient analgesia, anticipation, and anxiety. Their repeated requests for medication to relieve their ongoing pain may be mistakenly interpreted as “drug-seeking behavior,” and they may be unfairly stigmatized. Thus, intravenous analgesics should be started as a continuous infusion or with PCA. When adequate analgesia is obtained, a long-acting opioid or a sustained-release opioid may be initiated with intermittent use of rescue medication. In adult patients with frequent episodes of painful crisis, the use of long-acting opioid medications reduced visits to the emergency department and hospitalizations, and shortened the lengths of stay in hospital. Meperidine should be avoided in this population and has been associated with seizures in 1%–12% of these patients.

Patients With Opioid Addiction

In order to identify and treat patients with opioid addiction, the Food and Drug Administration Amendments Act (FDAAA) of 2007 established the requirement for postmarketing studies and mandated the implementation Risk Evaluation and Mitigation Strategies (REMS).⁶¹ Statewide Prescription Drug Monitoring Programs (PDMP) were established to track patients with prescriptions for controlled substances from multiple practitioners (e.g., I-STOP in New York State). These systems allow the practitioner to easily reference which scripts a patient has filled from which practitioner. Many guidelines for treating non-malignant chronic pain with opioids exist. Patients with cancer are not immune to the risks of opioid misuse and some patients may have a history of substance abuse. It is important to screen all patients for a history of or ongoing substance misuse. Patients with risk factors should be managed more strictly with the use of medication management agreements, urine toxicology screening, pill counts and possibly more frequent visits with prescriptions for shorter durations.

Bone Marrow Transplantation

While some studies have reported pain after bone marrow transplantation, thought to be secondary to bone marrow expansion during the engraftment phase,⁶² other studies have incidentally reported improvement in pain in patients with sickle cell disease after completion of successful bone marrow transplantation. While there are no studies that specifically look at pain outcomes, several studies report positive results. One study, which involved fifty children (26 with long-term follow-up) with stem cell transplants (SCT), reported that 22 of the children experienced no further episodes of pain after transplantation. It is notable that the age range was 4–14 years of age, which is likely to be too young to start developing the serious long-term effects of sickle cell disease.⁶³ Subsequent studies have demonstrated similar results in children who undergo SCT.⁶⁴ A recent study of adult patients with sickle cell disease who underwent SCT demonstrated that while these patients do continue to take opioids, they use them at lower doses. Pain in these

TABLE 91.3 Classification of Transplant-Related Pain Syndromes

Deep somatic pain	Bone marrow expansion and/or sensitization related to the engraftment, pneumonia, pleuritic, deep abscess
Superficial somatic pain	Oral ulcers and skin lesions associated with acute and chronic GVHD; superficial abscess, ocular lesions associated with chronic GVHD
Visceral pain	Gastrointestinal GVHD, neutropenic enterocolitis, visceral involvement by HZV and CMV
Neuropathic pain	HZV outbreak and PHN

CMV, Cytomegalovirus; GVHD, graft-versus-host disease; HZV, herpes zoster virus; PHN, postherpetic neuralgia.

patients is thought to be secondary to sickle cell disease injury prior to SCT.⁶⁵

Graft-Versus-Host Disease

For patients who have undergone bone marrow transplantation, GVHD can be a significant problem. The usual triad of GVHD includes hepatitis, dermatitis, and gastroenteritis. Patients are usually unable to take oral, rectal, subcutaneous, or transdermal opioids because of the effects on the skin (GVHD), lining of the gastrointestinal tract (mucositis, infection, and GVHD), and thrombocytopenia. Polyarthritides and musculoskeletal manifestations can cause significant pain (Table 91.3). Therefore pain management with intravenous opioids is a necessity. The intestinal involvement that usually causes the most physical pain includes abdominal cramping and voluminous diarrhea. Treatment often begins with intravenous opioids given through a PCA pump. Addition of octreotide continuous infusion at 50–100 µg/hour intravenously or intermittent dosing at 500 µg subcutaneously every 8 hours may be effective in decreasing the volume of diarrhea and level of abdominal pain.⁹

Peripheral Neuropathy Caused by Chemotherapy Agents

Several chemotherapy agents used in the treatment of hematologic malignancies can cause painful sensory peripheral neuropathy. The vinca alkaloids, most notably vincristine, are neurotoxic, but they are not always associated with painful neuropathy. Thalidomide, lenalidomide, pomalidomide, bortezomib, carfilzomib, cisplatin, oxaliplatin, and paclitaxel are all commonly used agents that carry a significant risk of causing painful peripheral neuropathy. The most common mechanism of neuropathy is damage to the axons starting with the most distal branches and is a result of chemotherapy's ability to damage DNA replication, leading to apoptosis. The major manifestations are burning paresthesias of the hands and feet, and loss of reflexes. Paclitaxel also causes a motor neuropathy, which predominantly affects proximal muscles.

Studies have evaluated numerous agents for prevention of painful peripheral neuropathy, although there have not been any magic bullets. Most of the research has focused on taxane and platinum-based chemotherapy agents. The American Society of Clinical Oncology (ASCO) has published a review of the available literature for prevention and treatment of chemotherapy-induced peripheral neuropathy (CIPN). Many vitamins and dietary supplements have been studied; however, most have not consistently shown benefit in larger randomized trials.⁶⁶ Specifically, the ASCO review indicates that acetyl-L-carnitine, vitamin E, all-*trans* retinoic acid, glutathione, and

calcium and magnesium infusions should not be utilized in the prevention of CIPN. Chemoprotectants have also not withstood scrutiny; amifostine, nimodipine, and others are not recommended. Although amitriptyline has not been shown to prevent CIPN, carbamazepine, oxcarbazepine, and venlafaxine have shown promise, although further evaluation is warranted.

Treatment of chemotherapy-induced painful peripheral neuropathy includes the usual agents used for patients with neuropathic pain from any etiology (i.e., anticonvulsants, TCAs, and occasionally tramadol or opioids). Duloxetine, a serotonin and norepinephrine reuptake inhibitor (SNRI), has been shown to improve CIPN at a dose of 60 mg daily.⁶⁷ In addition to treating these painful symptoms of neuropathy, the doses of the chemotherapy often require reduction or even discontinuation of therapy.

Problems in Elderly Patients

Pain management in elderly patients is a highly prevalent problem. It is complicated by difficulties in pain assessment and by the altered pharmacokinetics of opioids and of psychotropic adjuvant medications. Elderly patients may underreport pain because of misconceptions that pain is part of the aging process or fears of addiction.⁶⁸ Physicians may ascribe observed limitations in social contacts and physical activities to age-related changes when they are pain-induced limitations.

Elderly patients are particularly susceptible to the side effects of NSAIDs and opioids, and patients taking them should be monitored closely.⁶⁹ In elderly patients (70–89 years old), the volume of distribution for opioids is generally smaller, the drugs have longer plasma half-lives, and renal and hepatic clearances are decreased, all of which can prolong the duration of effect. The effective doses for these patients are half to one-fourth of those needed in younger patients. Drugs with short half-lives (e.g., morphine, oxycodone, hydromorphone) should be used, and initial doses should be low. Patients should be monitored carefully for the development of sedation or confusion, especially if they are receiving antihistaminic agents (e.g., famotidine, diphenhydramine), drugs with anticholinergic activity, or hypnotics.

Neuropathic pain syndromes are common in older adults, and the adjuvant analgesics gabapentin and pregabalin are often used. Common side effects include somnolence, dizziness, fatigue, and weight changes that can be problematic in the geriatric population.⁷⁰ Treatment should be initiated at 100 mg of gabapentin or 50 mg of pregabalin at bedtime, and close monitoring for side effects should occur before dose escalation. Acute urinary retention caused by opioids (especially in patients with prostatic hypertrophy) and the hypotension and tachycardia caused by tricyclic compounds can occur more frequently and be more clinically severe in this population. The starting dose of nortriptyline should be low (usually 10 mg at bedtime), and the dose should be slowly increased as tolerated. Treatment of opioid-related urinary retention may include generic Proscar (5 mg/day) in patients with benign prostatic hypertrophy and bethanechol (10–50 mg three times daily) to help increase bladder smooth muscle tone.

PATHOPHYSIOLOGY OF NAUSEA AND VOMITING

Nausea is the subjective sensation that precedes vomiting. It is caused by stimulation of one or more of four sites—the gastrointestinal tract, the vestibular system, the chemoreceptor trigger zone in the area postrema of the floor of the fourth ventricle, or higher centers in the CNS (Fig. 91.2). The gastrointestinal tract can activate the vomiting center by stimulation of mechanoreceptors or chemoreceptors on glossopharyngeal or vagal afferents (cranial nerves IX and X), or by release of serotonin from gut enterochromaffin cells, which in turn stimulates serotonin (5-HT₃) receptors on vagal afferents. The vestibular system activates the vomiting center when stimulated by motion or disease (e.g., labyrinthitis) or when sensitized by

Fig. 91.2 PATHOPHYSIOLOGY OF NAUSEA AND VOMITING. DKA, Diabetic ketoacidosis; GABA, γ -aminobutyric acid; GVHD, graft-versus-host-disease; 5-HT3, serotonin; 5-HT3 R, serotonin receptor.

medication (e.g., opioids). Histamine (H1) and acetylcholine (M1) receptors are present on vestibular afferents. Endogenous or exogenous blood-borne toxins may activate chemoreceptors in the area postrema of the floor of the fourth ventricle via dopamine type 2 receptors. Finally, higher CNS centers may activate or inhibit the vomiting center. In addition, there may be direct activation of H1 receptors in the meninges secondary to increased intracranial pressure.

The means by which chemotherapy agents induce vomiting are still incompletely understood, but the most likely mechanism is believed to include stimulation of the chemoreceptor trigger zone.⁹ Other causes of nausea and vomiting in hematologic patients include stimulation of the cerebral cortex, gastritis and gastroesophageal reflux disease, delayed gastric emptying, radiation enteritis, constipation, esophageal candidiasis, inner ear processes, hypoadrenalism, hypercalcemia, changes in taste and smell, and anticipatory nausea.

Although the sites of emetic action of the chemotherapeutic agents have not been identified, blocking agents directed against type 3 serotonin receptors (5-HT3 receptors), dopamine (D2) receptors, and neurokinin (NK-1) receptors have been effective in inhibiting chemotherapy-induced nausea and vomiting (CINV).⁹ Higher centers in the brain, such as the cortex, are also believed to be involved in producing anticipatory nausea and vomiting (ANV). Cognitive therapy, as well as anti-anxiety and amnesic agents, may provide effective antiemesis.

PATIENT ASSESSMENT

Risk factors for developing CINV include age younger than 60 years, female gender, history of motion sickness, and hyperemesis gravidarum.⁸ Patients who have a history of alcohol intake of more than five alcoholic drinks per day (>100 g of alcohol) tend to have less nausea and vomiting. This has been studied carefully in patients

receiving high-dose cisplatin therapy but has been anecdotally observed in patients receiving other agents.

Anticipatory Nausea and Vomiting

ANV is believed to be a classic conditioned response.⁹ Chemotherapy administration (the unconditioned stimulus) results in nausea and vomiting (the unconditioned response). Clinic sights, smells, and sounds are the conditioned stimuli. After frequent pairings of chemotherapy administration and the clinic's sights, smells, and sounds, the responses (nausea and vomiting) can be triggered in the absence of any chemotherapy by the clinic's sights, smells, or sounds, or simply by seeing clinic personnel even at a location distant from the site of treatment.

Patients who are at risk for developing ANV are those who have already experienced posttreatment nausea and vomiting. The risk of developing ANV increases with the increasing frequency, severity, and duration of the symptoms. Other possible predisposing factors include susceptibility to motion sickness, awareness of tastes or odors during infusions, younger age, lengthier infusions, greater autonomic sensitivity, and general anxiety or emotional distress.⁹

Acute and Delayed Chemotherapy-Induced Nausea and Vomiting

Acute CINV is defined as nausea, vomiting, or both occurring within 24 hours of administration of the agent. Although most drugs produce emesis 1–2 hours after they are given (in patients who have never before received chemotherapy), the onset of emesis from high-dose intravenous cyclophosphamide is delayed until 9–18 hours after treatment, and nausea and vomiting from high total doses of cisplatin can occur 24–72 hours later.

THERAPY

Antiemetic

A number of effective antiemetic therapies are used to prevent the nausea and vomiting induced in patients by treatment of their hematologic disorders with chemotherapy or radiation therapy. These antiemetic therapies markedly improve patients' quality of life. The vast majority of patients can expect complete control of vomiting,⁷¹ and most patients also are free of nausea.

Most studies of the potent antiemetic agents have been conducted in patients receiving therapy with cisplatin, a drug of high emetic potential. Although cisplatin is not generally used to treat patients with hematologic malignancies, the data are included in the following discussion because the findings can be extrapolated to other drugs of equivalent or less emetogenic potential. When available, data regarding efficacy in patients receiving radiation therapy or emetogenic drugs commonly used to treat hematologic disorders are reviewed. The choice of antiemetic agents depends on the emetogenic potential of the chemotherapy or radiation therapy regimen, the side effect profiles of the antiemetic agents, and patient preferences and characteristics.

The emetogenic potentials of commonly used chemotherapeutic agents are outlined in the NCCN Clinical Practice Guidelines in Oncology Antiemesis Guideline (www.nccn.org). For patients being treated with chemotherapeutic agents with low or minimal emetogenic potential, no antiemetic therapy may be needed, or a single agent such as dexamethasone or metoclopramide may be sufficient. For drugs with higher emetogenic potential, standard antiemetic treatment usually includes combinations of several antiemetic agents along with agents designed to treat anxiety.

Combination Antiemetic

These combinations include a 5-HT₃ RA such as ondansetron and a corticosteroid such as dexamethasone for moderately emetogenic regimens.⁷¹ For highly emetogenic combination chemotherapy or regimens that include two moderately emetogenic agents, such as cyclophosphamide and adriamycin, an NK-1 inhibitor such as aprepitant should be added to the antiemetic combination.⁷¹ Optional lorazepam may be added for anxiety-related symptoms. It is important to give antiemetic therapy before administering chemotherapy agents and to continue for about 24–72 hours after the drugs have been given to prevent emesis. Patient-specific factors and preferences regarding degree of alertness can help the health care provider choose an antiemetic regimen, as can the level of anxiety the provider observes in the patient. For instance, younger patients have a higher incidence of CINV and of metoclopramide-related acute dystonic reactions; trismus or torticollis was seen in only 2% of patients older than 30 years of age but in 27% of younger patients. Therefore even if they are receiving only moderately emetogenic therapy, they may require an antiemetic regimen for high-emetogenic drugs.⁷¹ Younger patients find cannabinoids (e.g., Marinol) more effective than do older patients because they can better tolerate the side effects associated with the therapeutic doses of these agents. Elderly patients also have high risks of extrapyramidal side effects and are more susceptible to anticholinergic and sedating side effects. 5-HT₃ RAs are therefore preferred to regimens containing metoclopramide and diphenhydramine.

The antiemetic evidence behind the utilization of different medications changes over time. We recommend utilizing the ASCO clinical practice guidelines for recommendations on combination antiemetic regimens: <http://www.instituteforquality.org/practice-guidelines>.

Serotonin Receptor Antagonists: Ondansetron, Granisetron, and Palonosetron

Ondansetron, granisetron, and palonosetron are the best studied of the 5-HT₃ RAs. This class also includes the drugs dolasetron and tropisetron. Several studies of patients receiving regimens that

included cyclophosphamide, methotrexate, or doxorubicin showed significant efficacy and the superiority of ondansetron over placebo.

Ondansetron also demonstrates efficacy in patients with emesis (induced by non-cisplatin-containing chemotherapy) that has been refractory to standard antiemetics, with complete control achieved in 50% of these patients. When dexamethasone is added, the rate of control is as high as 91%.

Ondansetron effectively prevents nausea and vomiting in patients treated with highly emetogenic agents for acute leukemia or multiple myeloma (i.e., high-dose melphalan) or who are being prepared for bone marrow transplantation with cyclophosphamide and total-body irradiation.^{71,72} In the transplantation recipients, 83% of patient-days were without any vomiting or retching, and in another 10%, there were no more than two emetic episodes. Ondansetron is also effective in preventing emesis induced by single- or multiple-fraction radiation therapy.⁹ Ondansetron is as effective as high-dose metoclopramide in preventing nausea induced by cisplatin, cyclophosphamide alone, or doxorubicin chemotherapy.

Oral granisetron has shown equivalence to ondansetron in studies of patients receiving cisplatin- or carboplatin-based regimens. In patients receiving moderately emetogenic therapy, oral granisetron with dexamethasone was as effective as intravenous ondansetron and dexamethasone. Oral or intravenous granisetron and dexamethasone were effective in a bone marrow transplantation program in which patients were treated with Cytoxan and total-body irradiation, and these agents, along with oral prochlorperazine, were also effective in patients undergoing peripheral blood SCT for which patients received Cytoxan, VP-16 or thiotepa, and cisplatin.

Palonosetron is a second-generation 5-HT₃ RA with higher potency, stronger receptor-binding activity, and longer half-life than the other drugs in this class.⁹ Palonosetron 0.25 mg intravenously has been studied in moderately and highly emetogenic chemotherapy. Several subgroup analyses of the registrational noninferiority trials have been reported in which palonosetron was superior. Palonosetron has been identified as the preferred 5-HT₃ RA in prevention of nausea and vomiting from moderately emetogenic regimens. Ondansetron and the other 5-HT₃ RAs have far fewer side effects than high-dose metoclopramide. Reports of extrapyramidal reactions are rare,⁹ and sedation, dystonic reactions, akathisia (e.g., severe restlessness, “ants-in-the-pants” feeling), and tardive dyskinesias do not occur. Patients can develop constipation, mild headache, QT prolongation, and elevated levels of transaminases.

Corticosteroids

The mechanism of the antiemetic action of corticosteroids remains undefined. Corticosteroids are effective when used alone to prevent emesis induced by agents of moderate or low emetogenic potential.^{71,72} They are also a useful component of antiemetic therapy regimens that include ondansetron, granisetron, aprepitant, or metoclopramide and add efficacy in randomized controlled trials.^{71,72}

The recommended specific corticosteroid drug, dose, and duration of therapy has not been determined. Dexamethasone and methylprednisolone are the best-studied agents, but no trials have demonstrated the superiority of one corticosteroid over another. Using anecdotal evidence recommendations for dexamethasone 4–8 mg orally (PO) two to three times per day, methylprednisolone 16–32 mg PO two to three times per day, or prednisone 20–30 mg PO two to three times per day have all been suggested.

Metoclopramide

Metoclopramide is a substituted benzamide that promotes gastric motility and reduces the emetic activity of chemotherapy agents by blocking dopamine receptors (at low-to-moderate doses) and 5-HT₃ receptors (at high doses) in the chemoreceptor trigger zone. Because of a more favorable side effect profile, 5-HT₃ antagonists have replaced high-dose metoclopramide. At lower doses (5–10 mg orally or intravenously every 6 hours) metoclopramide is useful in treating mild-to-moderate and delayed nausea and vomiting. Delivery of the drug on a schedule that maintains adequate levels during expected emesis appears to be important.

The side effects, which may be caused by the interaction of metoclopramide with dopamine receptors, can be quite troublesome. They include akathisia, dystonic reactions (age related), sedation, and diarrhea. Benzodiazepines such as lorazepam and β -blockers such as propranolol can prevent or reverse the akathisia, and diphenhydramine or benztropine can prevent or reverse the dystonias. However, these agents induce additional side effects, including dry mouth and sedation. Short-term, high-dose metoclopramide or long-term use at usual doses has been associated with persistent and disabling movement disorders, especially tardive dyskinesias.

Neurokinin-1 Inhibitors

Substance P can cause emesis, and it appears to play a role in chemotherapy-related nausea and vomiting. Its effects are mediated through NK-1 receptors.⁹ Agents that cross the blood–brain barrier and inhibit NK-1 activity (e.g., aprepitant, netupitant) are more effective than a 5-HT₃ RA and dexamethasone alone in moderating acute chemotherapy-related nausea and vomiting, and they are particularly effective in decreasing delayed nausea and vomiting occurring after highly and moderately emetogenic chemotherapy (HEC and MEC).^{9,71} Aprepitant is an inhibitor of CYP3A4 and therefore may cause elevation of chemotherapy agents primarily metabolized by this route; however, these elevations are not considered clinically significant, and there are no recommended dose adjustments. Aprepitant can cause significant decreases in the prolongation of the international normalized ratio induced by warfarin and increases the area under the curve of dexamethasone. The maximum dose of dexamethasone in combination with aprepitant is 12 mg. Fosaprepitant, the intravenous prodrug of aprepitant, has demonstrated equivalent efficacy to the 3-day oral regimen as a single dose at 150 mg on day 1. Oral netupitant has been studied in HEC and MEC regimens as part of a single-dose combination product with oral palonosetron. These studies have demonstrated similar safety and efficacy when compared with combination antiemetic therapy including aprepitant.⁷³

Olanzapine

Olanzapine has been shown to improve control of both acute and delayed nausea and vomiting in HEC and MEC when used in combination with dexamethasone and a 5-HT₃ RA. Olanzapine is also shown to be superior to standard antiemetics in the breakthrough CINV setting.⁷⁴

Anticipatory Nausea and Vomiting

The treatment of ANV is best achieved through prevention with aggressive antiemetic therapy and treatment of anxiety with the appropriate agents (see Benzodiazepines). However, in patients for whom this approach has not been successful and in whom ANV develops, a variety of behavioral techniques have been helpful.⁹ These include hypnosis, progressive muscle relaxation with guided imagery, systemic desensitization, and distraction. Results may be optimized if a therapist trained in these techniques works with the patient, but patients can use progressive muscle relaxation with guided imagery on their own.

Benzodiazepines

The benzodiazepine lorazepam has only mild antiemetic activity when used as a single agent. It is used frequently in the treatment and prevention of nausea and vomiting, particularly when anxiety is associated with the nausea and vomiting. It markedly decreases anxiety and the akathisia associated with metoclopramide therapy, and induces dose-related memory loss and marked sedation.

Cannabinoids

Currently two pharmaceutical tetrahydrocannabinol-containing agents are available via prescription. Nabilone and dronabinol are both FDA approved for the treatment of CINV. Synthetic

cannabinoids are mostly reserved for patients with difficult-to-treat, refractory nausea and vomiting or as a rescue agent. Younger patients find cannabinoids more effective than do older patients, likely due to better tolerated side effects associated with the therapeutic doses of these agents. The cannabinoids cause ataxia, dry mouth, orthostatic hypotension and dizziness, euphoria (or dysphoria), and a feeling of being “high.”⁷⁵

Other Drugs

Other agents that are more active than placebo include the butyrophenones haloperidol and droperidol, and the phenothiazine prochlorperazine. These agents are less effective drugs than the agents previously mentioned, and all cause sedation. The butyrophenones produce dystonic reactions, akathisia, and occasionally hypotension. Scopolamine, a centrally acting anticholinergic, can be effective for patients with a vertiginous component to their nausea.

CONCLUSION

Pain remains one of the most distressing and debilitating symptoms in patients with hematological disorders. Whether secondary to the disease process, iatrogenic, diagnostic, or therapeutic interventions, or related complications, pain is frequently underappreciated and undertreated. A methodological approach to evaluate and manage pain is recommended. Knowledge of the wide range of pharmacologic and nonpharmacologic interventions is essential for the clinician managing pain. Pain refractory to standard approaches should be referred to pain or palliative care specialists.

Nausea and vomiting are common side effects of chemotherapy and should be treated aggressively to assure patient comfort during the treatment of their hematologic illness. A number of targeted therapies exist and should be used based on the emetogenic potential of the agents used and the patient's clinical condition and comorbidities. Severe or refractory nausea should involve palliative care consultation.

PALLIATIVE CARE

Kristen G. Schaefer, Janet L. Abrahm, and Joanne Wolfe

Palliative care is an approach to care for children and adults provided by an interdisciplinary team with a focus on individual patient and family goals, values, preferences, and relief of suffering in the face of serious illness. In a seminal 2003 report,¹ and again in the recent *“Dying in America: Improving quality and honoring individual preferences near the end of life”*,² the Institute of Medicine (IOM) defined the unique role of palliative care for children and adults with serious illness: *“Palliative care seeks to prevent or relieve the physical and emotional distress produced by a life-threatening medical condition or its treatment, to help patients with such conditions and their families live as normally as possible, and to provide them with timely and accurate information and support in decision making.”* The IOM report also outlined the need to improve patient access, education of health professionals, and research in palliative care (Table 92.1). In 2006, hospice and palliative medicine was accepted as a specialty by the American Board of Medical Specialties. In 2007, the Accreditation Council for Graduate Medical Education began accrediting fellowship programs, and the first qualifying examination in hospice and palliative medicine was given in 2008. Palliative care subspecialists provide clinical support in more complex situations and are also responsible for improving palliative care education, innovation and research, but all clinicians should integrate high-quality palliative care into their care of patients with serious illness.³

Palliative care practitioners have expertise in communication, in treatment of physical symptoms, and in relieving social, psychological, and spiritual and existential distress. Such care and assistance is not limited to people thought to be dying and should be available concurrently for patients receiving curative or life-prolonging treatments. Emerging evidence suggests that concurrent palliative care in serious illness can decrease costs and improve outcomes, and patient access to high-quality specialty-level palliative care is becoming the standard of care at most academic cancer centers.^{2,4} However, overall rates of referral to palliative care remain low, particularly for patients with hematologic malignancies.⁵

Recently published oncology consensus clinical guidelines⁶ highlight the integral role of specialty-level palliative care throughout the cancer trajectory, and align with increasing public demand for better advance care planning and more timely referral to specialty-level palliative care and hospice.² This chapter will review core elements of palliative care for children and then for adults in each section, with specific attention to growing awareness and understanding of palliative care needs in patients with hematologic malignancies.

PEDIATRIC PALLIATIVE CARE: SPECIFIC ISSUES

I just wish that I had armfuls of time.

— (4-year-old child)⁷

Pediatric palliative care is an emerging frontier in the comprehensive care of children.⁸ Specific issues related to palliative care for pediatric patients and their families include the following:⁹

- The heterogeneity of illnesses, many rare, requires the involvement of many disciplines and specialists.
- Many children have genetic diseases, so there may be more than one affected child in a family.
- The time course of some illnesses can be extremely variable. Pediatric palliative care may extend over years, even decades.
- A broad developmental spectrum is represented, including changes in the individual child through time.
- The underlying principles and ethics of palliative care are universal across the life span. However, as in all specialties, children bring with them unique issues and dilemmas.
- A child or adolescent diagnosed with a life-threatening or life-limiting illness throws an assumed sequence out of order. A time of role reversal is expected, when children will care for dying parents. When parents instead find themselves watching their child face death, a sense of tragic absurdity prevails. Not only is time shortened, but its order is shattered. A child or adolescent with a life-threatening illness represents a premature separation to the family. Even before the child has become a differentiated individual through a natural developmental sequence, that child is wrenched away. There is little preparation for separation by death when a psychological separation has not yet been effected. The adolescent who is beginning to negotiate an independent existence is often the hardest to face when that “moving forward” is irreversibly halted, or at least disrupted. A child has not even had the time to begin to form life goals.
- The necessity for palliative care—the concept and the clinical approach—may emerge at different points in the illness trajectory, depending on the prognosis for the child, the decisions that must be made in choosing treatment options, and always, the management of pain and suffering in the provision of optimal quality of life. One of the foremost goals is to initiate palliative care for children earlier in the illness trajectory—in a proactive manner—so that effective care planning can be implemented. Care of the family, with a particular focus on the young siblings, is a priority.

COMMUNICATION

Good communication can dispel fears of abandonment. Breaking bad news and discussing prognosis with patients with advanced disease are occasions when clinicians can demonstrate their commitment to an ongoing partnership with patients and families. Conversations must demonstrate respect for cultural differences and the conviction that psychosocial and spiritual growth can occur even at the end of life. If done well, the groundwork will be laid for further discussions of patient hopes and fears, goals, values, and spiritual concerns that form the basis of decisions about resuscitation and artificial life support. These conversations should be documented in the medical record, and recorded as a physician order when possible, for example, a signed MOLST (Medical Order for Life-Sustaining Treatment) or POLST (Physician Order for Life-Sustaining Treatment) form.²

Communication with a child...

When I first heard my diagnosis, one question kept going around and around in my head: “How long do I have, Doc?”

— (12-year-old child)⁷

TABLE 92.1**Summary of the Institute of Medicine Report: *When Children Die: Improving Palliative and End-of-Life Care for Children and Their Families*****Improve Organization and Delivery of Care**

Emphasis is placed on the development of care guidelines and protocols in all pediatric settings, the development of regional information programs and resources in rural areas, and policies and procedures for involving children in decision making

Reform Financing of Palliative Services and Hospice Care

Vast changes in public and private health coverage: add hospice, change eligibility rules, provide outlier payments, extend coverage for counseling family members and for bereavement follow-up

Better Prepare Health Professionals

Create educational experiences and curricula that will provide basic and advanced competence in palliative, end-of-life, and bereavement care

Strengthen Research Base for Effective Care

Emphases include appropriate quality-of-life measures, effective symptom management, impact of perinatal death on parents and siblings, impact of sudden death on family and professional caregivers, efficacy of bereavement interventions, models for provision of care, financing alternatives, effective strategies for educating professionals

From Institute of Medicine: *When children die: Improving palliative and end-of-life care for children and their families*, Washington, DC, 2003, National Academy Press.

Children with serious hematologic disorders have usually lived with the illness over a prolonged period of months or years. Their knowledge, understanding, and awareness of their precarious life situation is often profound, at physical, cognitive, and emotional levels.

The doctors think my bone marrow is fine for now—and for now is for now.

— (8-year-old child)⁷

The protective stance of the past stated that disclosure to the child of his or her prognosis (and even, in some instances, the diagnosis) would cause increased anxiety and fear. Since the 1980s, however, a shift toward open communication has been evident.¹⁰ To shield the child from the truth may only heighten anxiety and cause the child to feel isolated, lonely, and unsure of whom to trust.

In communication with the life-threatened child at any juncture in the illness, the precedent for a climate that enables such honest interchange is created from the time of diagnosis. The individual child's competence and vulnerability serve as the context for decisions regarding disclosure at any point in the illness trajectory. Considerations about what or how much to tell include the child's age, cognitive and emotional maturity, family structure and functioning, cultural background, and history of loss.⁷ These same factors apply at the end of life, with extreme sensitivity to how the parents have chosen to inform the child throughout the illness experience, how the child has understood and processed information up to this time, and what the child is now asking—implicitly and explicitly—about his or her situation.

For adult patients with advanced cancer, having had a discussion about end-of-life wishes with one's physician has been shown to correlate with less aggressive medical care near death, earlier hospice referrals, cost savings at the end of life, and improved bereavement adjustment for caregivers.² Furthermore, having had conversations about end-of-life wishes is not associated with higher rates of major depressive disorder or more worry. Proactive, direct communication with patients and their families about approaching and managing the end of life can be a satisfying and rewarding part of patient care. However, more training in palliative care clinical and communication skills is needed during hematology/oncology fellowship and in continuing medical education settings to ensure competency in these areas.

TABLE 92.2**Breaking Bad News**

1. Make yourself, the patient, and the family comfortable
2. Find out what they know
3. Indicate that you are planning to tell them something that is unpleasant and may be disturbing
4. Find out whether they want to be told, or whether they want someone else to be told
5. Find out how much they want to know (i.e., the big picture versus all the details)
6. Tell them in words they can understand, allowing time for questions along the way
7. Respond to their feelings
8. Let them know that this is only the first of many discussions with you
9. Ask them to summarize what they heard you say; ask if they have further questions
10. Arrange your next meeting with them

From Abraham JL: Update in palliative medicine and end-of-life care, *Annu Rev Med* 54:53, 2003; and Back A, Arnold R, Tulsky J: *Mastering communication with seriously ill patients: Balancing honesty with empathy and hope*, New York, 2009, Cambridge University Press.

Breaking Bad News

I just wanted to be told the truth and not too bluntly, but the truth nonetheless. So that I could make a decision myself, be able to accept it, decide what I was going to do about it.

— Adult cancer patient seeking a second-opinion hematologic-oncology consultation¹¹

Table 92.2 contains an outline of the suggested steps to take when breaking bad news.¹² For patients with advanced disease, the goal is to establish or strengthen trust, and reassure them that the physician is committed to caring for them even though their disease cannot be cured. To do this well, physicians need to believe that they have not failed the dying patient, even if medicine has.

Prognosis and Decision Making

Surveys of bereaved parents indicate that physician communication about prognosis is not optimal. At the same time, emerging data suggest that bereaved parents consider high-quality communication as the most important value when reflecting on physician quality of care.² Parents value clear information that is communicated sensitively and includes the child, when developmentally appropriate. When it comes to discussing prognosis, a majority of parents want as much information as possible.¹³ Furthermore, although many parents find prognostic information about their child upsetting, they still want prognosis to be discussed. The data suggest, however, that parents are overly optimistic about the child's chances of cure in comparison to physicians, and this is especially true when the prognosis is uncertain. Being aware of these trends may help physicians to discuss prognosis with greater clarity.

One side of my head says: "Think optimistic." The other side says: "What if this treatment doesn't work?"

— (11-year-old-child)⁷

The child is often aware of the diminishing curative or life-prolonging options that he or she faces. It is at this time that the child may ask anxiously: "What if this medicine doesn't work? What will you give me next?" The child experiences a profound sense of loss of control. It is at this time that families are confronted with a series of decisions regarding the nature and intensity of medical interventions they wish to pursue. This process can be excruciating: they do not want their child to suffer more, yet they often cannot tolerate the thought of

missing an opportunity for a cure or prolonged time. The physician and team's role shifts from leadership in recommending a curative treatment plan to the clarification of experimental and palliative options and consequences. In most instances, the parents make the decision; however, to varying degrees, when asked in a sensitive manner, children as young as 10 years of age are able and willing to talk about their experiences and end-of-life decisions.⁸

During the last decade there has been increased recognition of the child's participation in making treatment decisions. Crucial to this process is an assessment of the child's or adolescent's ability to appreciate the nature and consequences of a specific medical decision. This becomes particularly complex when the wishes of the child differ from those of the parents. Because actual assessment tools are only in the early stages of development, professionals must rely exclusively on their clinical judgment to assess children's understanding of the contingencies they are facing. This is often a juncture when input from members of the interdisciplinary team can be crucial: children often express their understanding, awareness, and thoughts about treatment options and living or dying to individuals other than their parents or primary physician.

The following example illustrates the remarkable capacity of a young child to address the transition towards end of life.

*A 7-year-old girl told her parents that she was too tired to fight anymore, and that she wanted to give up. She added: "If I have to continue suffering, I would rather be in heaven." These statements were major determinants in the parents' choosing a palliative care plan without any further attempts at life-prolonging treatment. She went home on hospice care and died peacefully several weeks later.*⁷

Adult patients and families also want to be prepared for the end of life, to be able to name someone to make decisions, know what to expect about their physical condition, have financial affairs in order, know that the physician is comfortable talking about death and dying, feel that the family is prepared for their death, have funeral arrangements in place, and have treatment preferences in writing.¹² For this to happen, patients must know how long they are likely to have left to live. For adults with refractory hematologic malignancy, prognostic uncertainty about when to stop therapy in pursuit of cure and when end-of-life begins can be a barrier to palliative care referral.¹⁴

The median survival of older adults with leukemia is not that different from advanced pancreatic cancer or stage IV lung cancer ... but we are stuck with this tail and so what do we do with that? We live on the tail, this 5% to 10% tail.

— (Hematologic oncologist at an academic cancer center)¹⁵

Although most patients report wanting prognostic information from their oncologist, patients with advanced refractory disease may not ask about their prognosis, and oncologists often do not initiate the discussion. In one recent observational study of patients after their first oncologic visit for a hematologic malignancy,¹⁶ only half of patients were told unambiguous prognostic estimates for mortality or cure.

Discussions of prognosis can be very painful for clinicians, who may experience feelings of guilt, failure, or sadness. Clinicians interested in improving their skills may refer to practical educational handbooks and articles that outline how to discuss these issues both with patients who want to know their prognosis and with those who do not or are ambivalent.¹⁷ Online resources for communication in serious illness training include the Center to Advance Palliative Care (capc.org) and VitalTalk (vitaltalk.org).

Impact on Hope

The rigors of treatment regimens and the physical and emotional demands of the complex care required for patients with advanced disease tend to isolate patients and their families and focus all their

hopes on disease remission. They may have forgotten how to hope for anything else. Physicians and the teams they work with can help patients with advanced hematologic diseases develop new kinds of hope by encouraging them to reintegrate into activities that were meaningful before their disease began and they rearranged their lives around treatment schedules. Paradoxically, discussion about limited prognosis can lessen fears of abandonment and strengthen the trust patients have in the oncology team.¹² As disease progresses, despite ongoing treatment, patients who have begun to reengage in non-treatment-related activities and who have developed a broader relationship with their physicians are more likely to understand that the physician is not abandoning them when he or she says that the goals of treatment should be comfort.

CAREGIVERS

People who are not caregivers don't understand the continuous burden of the role ... the stress feels as if I'm constantly holding my breath.

— (Family member about caring for a loved one with advanced disease)²

Families and other nonprofessional caregivers, who provide the vast majority of care for patients with advanced cancer, are stressed by the patient's disability and degree of suffering, the lack of coordination of care, and underlying family, work, or financial pressures.¹⁸ As many as 32% of these caregivers either have a major psychiatric condition (panic disorder, major depression, posttraumatic stress disorder, or generalized anxiety disorder) or access mental health services after the patient's diagnosis.² Caregivers are likely to need the support of many members of the team therefore to continue in their difficult role.

RELIEF OF SUFFERING

Suffering includes physical, psychological, social, and spiritual or existential dimensions.

Symptom Management in Children

Therapist: If you could choose one word to describe the time since your diagnosis, what would it be?

— Child: PAIN.⁷

Maintaining patient comfort is a critical issue throughout treatment, as well as during the end stages of life. Although effective pain control is a hallmark of palliative care, pain is only one of many distressing symptoms. The spectrum of physical symptoms includes (although it is not limited to) dyspnea, fatigue, seizures, loss of appetite, nausea and vomiting, constipation, and diarrhea. Early studies among bereaved parents or children who died of cancer indicate that optimal symptom management is still far from being achieved, even in major pediatric teaching centers,¹⁹ and in one study more than 10% of parents had considered hastening their child's death; this was more likely if the child was in pain.²⁰ A recent study among children with advanced cancer confirmed high suffering from physical and psychosocial symptoms according to the children themselves.²¹ Relief of a child's end-of-life distress may have long-lasting implications for bereaved parents, who are negatively affected by the child's experience of pain years beyond the death.

Psychologic symptoms such as depression and anxiety are also prevalent in children at the end of life.¹⁹ Children also experience existential concerns. Creating opportunity for communication around these sources of distress involves using creative strategies that incorporate the developmental stage of the child. Strategies may involve verbal communication using open-ended questions such as "What are you hoping for?" and "What are you worried about?"

However, many children communicate best through nonverbal means such as artwork and music. Children may be more willing to

“talk things over” with puppets or stuffed animals rather than real people. Importantly, euphemistic expressions about death can be confusing or even frightening (for instance, equating death with sleep may result in the child’s being afraid of going to bed) and should be avoided.

Needless to say, parents of children with hematologic malignancies also experience distressing symptoms such as anxiety, depression, and spiritual and psychosocial concerns. Recognition of these by the pediatric clinician may serve families well while the child is alive and during bereavement.

Symptom Management in Adults

Patients with hematologic malignancies experience a high physical and psychologic symptom burden, similar to patients with metastatic solid tumors, especially during periods of treatment, when hospitalized, or with advanced disease.²² Pain and antiemetic therapy for adults is reviewed elsewhere in this volume (see [Chapter 91](#)). Anxiety, depression, delirium, and control of symptoms occurring in the last days of life are reviewed subsequently.

Among social sources of distress are financial concerns and, with increasing debility, loss of independence and sense of contribution and efficacy. Worries about burdening the family or that the family will fail them when they really need them may lead patients to request physician-assisted suicide. Social workers are the key team members who can help alleviate or at least ameliorate these sources of distress, and can help the caregivers cope.

Physicians should also explore religious and spiritual concerns, and understand what rituals will be important at the end of life. Spiritual and existential distress occur when individuals are unable to find sources of meaning, hope, love, peace, comfort, strength, and connection in life, or when there is dissonance between their beliefs and what is happening to them. Patients who use “positive” religious coping (e.g., prayer, feeling a sense of connectedness to a religious community, having a positive relationship with God) have been found to have better mental health status, growth in the spiritual dimension with stress, and a better overall quality of life. Patients who use “negative” religious coping (e.g., ascribe their illness to a punishing God or one who has abandoned them) have a poorer quality of life.²³ Clinicians should therefore include either a formal or informal spiritual assessment for all patients diagnosed with serious illness.

PSYCHOLOGIC CONCERNS

Clinicians must assess and attend to patients’ and families’ psychosocial distress, including developmental issues, meaning and impact of illness, coping style, impact on sense of self, relationships, stressors, spiritual resources, economic circumstances, and physician–patient relationship; they must be able to distinguish normal human reactions of grief, sadness, despair, fear, anxiety, loss, and loneliness in patients facing the end of their lives, from clinical anxiety and depression.²⁴ Up to 50% (or more) of patients with advanced cancer meet criteria for a psychiatric disorder when the diagnosis of adjustment disorder is included.²⁵

Anxiety and Depression

It is noteworthy that depression and anxiety are often not recognized as symptoms in children, and in many instances are inadequately addressed. Significant anxiety is found in approximately 25% of adult patients with cancer,²⁵ and anxiety symptoms can interfere with their ability to receive care. Patients with panic disorders, agitated depression, phobias, obsessive-compulsive disorder, delirium, posttraumatic stress disorder, or adjustment disorders can all present with anxiety. Anxiety in dying patients may arise from worries about the future (uncontrolled symptoms, family concerns, or concerns about death),

isolation from loved ones, sepsis, hypoxia, metabolic abnormalities, withdrawal from alcohol, opioids or benzodiazepines, drug reactions (e.g., akathisia from metoclopramide, phenothiazines, and butyrophenones; paradoxical agitation from benzodiazepines and olanzapine), and uncontrolled pain. Nonpharmacologic treatments, such as relaxation training, hypnosis, supportive psychotherapy, and counseling, are very effective. Pharmacologic treatments usually include benzodiazepines (e.g., the short-acting lorazepam, starting dose 0.5–2 mg every 8 hours as needed; or long-acting clonazepam, starting dose 0.25–0.5 mg orally (PO) two-times daily), selective serotonin reuptake inhibitors (SSRIs; see later), and, when there is evidence of delirium, neuroleptics (see later).

It is estimated that 5–26% of patients with advanced cancer meet criteria for a major depressive disorder, and patients with high symptom burden such as patients facing bone marrow transplantation are at higher risk.²⁵ It can be difficult to discern which patients with advanced disease are depressed or grieving. The usual somatic signs of depression or grief (e.g., anorexia, sleep disturbances, fatigue, or weight loss) are common in this population. Depressed patients, however, will be anhedonic and feel worthless, guilty, hopeless, or helpless. Grieving patients, in contrast, are very sad, but they are able to find happiness in some circumstances and can plan for the future.²⁵ Pain, a past or family history of substance abuse, depression, or bipolar illness are major risk factors for depression. Terminally ill patients responding “Yes” to the screening question “Are you depressed?” are very likely to be confirmed as depressed in a more comprehensive evaluation. Useful follow-up questions include “How do you see your future?” “What do you imagine is ahead for yourself with this illness?” “What aspects of your life do you feel most proud of? Most troubled by?”

As part of the treatment of depression, pain must be brought under control. Counseling can explore patient fears, provide emotional support, and help patients review their lives and find the meaning and areas of accomplishment in them. A variety of models of therapy are used, and none has been shown to be superior over the others. The psychostimulants dextroamphetamine and methylphenidate (2.5–5 mg, 8 AM and noon; maximum dose 60 mg daily) often act within a few days. The SSRIs are the first choice when immediate onset is not needed because they usually take several weeks to show effect. Useful agents include citalopram (Celexa) and paroxetine (Paxil; 10 mg PO daily initially; maximum 40 mg PO daily); escitalopram (Lexapro; 10 mg PO daily initially; maximum 20 mg PO daily); sertraline (Zoloft; 50 mg PO daily initially; maximum 200 mg PO daily); fluoxetine (5–10 mg PO daily initially; maximum 60 mg PO daily); and the serotonin–norepinephrine reuptake inhibitor venlafaxine (Effexor; 37.5 mg PO twice daily initially; maximum 225 mg PO daily). Venlafaxine inhibits norepinephrine, serotonin, and dopamine reuptake. Major side effects of the SSRIs include hyponatremia, sexual dysfunction or loss of libido, and gastrointestinal complaints (e.g., nausea, diarrhea, and foul-smelling flatus). Modafinil may also be an effective adjuvant agent to reduce SSRI-related sedation. The exact mechanism of action of mirtazapine (Remeron; 15 mg PO at bedtime initially; maximum 45 mg PO at bedtime) is unknown.

If the patient is expected to live longer than weeks to a few months, a stimulant and an SSRI should be started simultaneously, and the stimulant can be titrated off several weeks later. Tricyclic antidepressants are less useful in these patients because of their side-effect profile.

If the patient does not respond to first-line agents, a psychiatrist should be consulted. Referral to a psychiatrist is also necessary when the physician is unsure of the diagnosis; the patient is psychotic, confused, or delirious; the patient previously had a major psychiatric disorder; the patient is suicidal or requesting assisted suicide; or there are dysfunctional family dynamics.

Delirium

Delirium occurs in up to 80% of patients dying from advanced cancer and can cause distress and anxiety in caregivers.¹² Delirious

patients can be agitated, hypoactive, or vacillate between the two. Symptoms of delirium include insomnia and daytime somnolence, nightmares, restlessness or agitation, irritability, distractibility, hypersensitivity to light and sound, anxiety, difficulty in concentrating or marshaling thoughts, fleeting illusions, hallucinations and delusions, emotional lability, attention deficits, and memory disturbances.

Validated delirium screening and severity tools are available, but a comprehensive psychiatric evaluation is recommended to exclude other disorders, such as anxiety, minor depression, anger, dementia, or psychosis. The cause of delirium is often never determined and is frequently multifactorial. Medications, especially opioids, nonsteroidal antiinflammatory drugs, and high-dose corticosteroids, commonly contribute. Opioid-induced central nervous system toxicities are more common in patients with renal dysfunction, on high doses of opioids for long periods of time, with impaired cognition before starting the opioids, with dehydration, or taking other psychoactive drugs. Other causes include metabolic abnormalities (hypercalcemia, hyperglycemia, or uremia), malnutrition, hypoxia, fever, infection, uncontrolled pain, hepatic failure, primary brain tumor, and brain metastases.

Treatment for delirium should begin while the underlying cause(s) are being treated. In addition to the medications listed in Table 92.3, it is helpful to make the patient's surroundings as familiar as possible, restore aids to hearing and sight if they are needed, reorient the patient frequently, and have family members, friends, or well-known caregivers present.

MANAGEMENT CONCERNS DURING THE LAST DAYS OF LIFE

Evidence suggests that children with advanced cancer who receive concurrent home-based palliative care have improved quality of life at the end of life and are more likely to die at home.²⁶ For some

families, there is the possibility of planning ahead and choosing a setting for their child's death—home, hospice, or hospital. The child may express a preference about where he or she feels safe or prefers to be. Clear information about how the child is likely to die and professional support to validate the family's choice are crucial. Even more important is the explicitly stated "permission" from all members of the professional team that the family may change their choice freely at any time—that all options remain open and that no decision is irrevocable. In the past, siblings were rarely included in these discussions and were often inadequately prepared for the eventuality of a child dying at home. It is only recently that their voices are beginning to be heard.

The Dying Child

Therapist: Are you in any pain? Does anything hurt?

Child: My heart.

Therapist: Your heart?

Child: My heart is broken. I miss everybody.⁷

The distillation of anticipatory grief to its essence marks the imminence of death. At times imperceptibly, at other times dramatically, the child who has been living with the illness is transformed into a dying child.

The end point of the terminal phase is often marked by a turning inward on the part of the child, a pulling back from the external world. Cognitive and emotional horizons narrow, because all energy is needed simply for physical survival. A generalized irritability is not uncommon. The child may talk very little and may even retreat from physical contact. Although such withdrawal is not universal, a certain degree of quietness is almost always evident. The child is pulling into himself or herself, not away from others. This behavior is a normal and expectable precursor to death—a form of preparation for the ultimate separation that lies ahead.⁷

TABLE
92.3

Treatment of Delirium (Adult Patient)

Drug	Dose	Comment
Typical and Atypical Antipsychotics		
Haloperidol	1–4 mg PO, or 0.5–2 mg SQ, IV qhs or bid to tid	Do not exceed 20 mg in 24 hours Can add the same dose q4h prn Maintain the patient on the effective dose (divided into a bid dose) for 3–4 days, then taper over 1 week, as tolerated Oral dose is 60–70% as potent as parenteral dose
Quetiapine	25–200 mg PO qhs	Particularly useful in elderly patients with evening delirium Start 25 mg hs for 3–4 days
Olanzapine	2.5–5 mg PO/SL	Start 2.5–5 mg PO/SL qhs to bid (2.5 mg for elderly patients); can use q 4–6 hours prn agitation Maintain the patient on the effective dose (divided into a bid dose), then taper over 2 weeks, as tolerated; also antiemetic
Aripiprazole	5 mg PO qd	Do not exceed 30 mg Does not prolong and may shorten QTc
Chlorpromazine	12.5–1000 mg PO/IV/PR	Sedating; may cause significant hypotension
Benzodiazepines^a		
Lorazepam	0.5–1 mg q 1–2 hours	Add to antipsychotic for patients with an agitated delirium Tablets can be used PR for terminal delirium
Diazepam	5–10 pm PO bid	Useful PR for patients unable to take oral medication
Clonazepam	0.5–5 mg PO/SL bid to tid	Tablets have been used PR for terminal delirium; do not exceed 20 mg/24 hours
Midazolam	30–100 mg IV/SQ over 24 hours	IV drip or subcutaneous infusion for terminal delirium

^aCaution: Any benzodiazepine may exacerbate delirium, especially in older adults (>70 years of age).

q, Every; hs, at bedtime; d, day; bid, twice a day; tid, three times a day; prn, as needed; IM, intramuscularly; IV, intravenously; PO, orally; SL, sublingual; PR, rectally; SL, sublingually; SQ, subcutaneously.

Modified from Abraham JL: *A physician's guide to pain and symptom management in cancer patients*, ed 3, Baltimore, 2014, Johns Hopkins University Press; and Miovic M, Block S: Psychiatric disorders in advanced cancer. *Cancer* 110:1665, 2007.

TABLE 92.4**Treatment of Common Problems in the Final Days (Adult Patient)**

Problem	Agent(s)	Routes, Doses
Baseline pain	Concentrated oxycodone or morphine solution Morphine or hydromorphone tablets Fentanyl ^a Methadone liquid Acetaminophen, naproxen Dexamethasone (requires compounding)	PO/SL q4h around the clock; individualized PR q4h; individualized Transdermal; individualized PO; individualized PR tid to qid PR daily to bid
Breakthrough pain	Concentrated oxycodone or morphine solution Fentanyl ^a	PO or per gastric tube q4h around the clock; individualized Transmucosal (buccal, sublingual); individualized
“Death rattle”	Scopolamine Hyoscyamine Glycopyrrolate Atropine	Transderm Scop patch 1–3q3 days; gel 0.125–0.25 SL tid to qid 0.2–0.4 mg IV tid to qid or 1–2 mg po bid to tid 0.4 mg SL q4–6h
Dyspnea (anxiety)	Lorazepam Chlorpromazine	1 mg PO, SL, q2–4h 25 mg PO, PR q4–12h; or 12.5 mg IV q4–8h
Dyspnea (other)	Morphine/oxycodone Morphine	5–10 mg SL oral concentrate q2h 2–4 mg IV q1h
Nausea	Combinations of lorazepam, metoclopramide, dexamethasone, and/or haloperidol	PR q6h; compounded suppositories with desired agents (depending on presumed cause of nausea)
Anxiety	Lorazepam Diazepam suppository	1 mg PO, SL, q2–4h 5–10 mg PR daily

All liquid PO medications can be given per gastric tube.

^aFentanyl only for opioid tolerant patients.

h, Hour; IV, intravenously; PO, orally; PR, rectally; q, every; qid, four times a day; SL, sublingually; tid, three times a day.

Modified from Abraham JL: *A physician's guide to pain and symptom management in cancer patients*, ed 3, Baltimore, 2014, Johns Hopkins University Press.

Adults

Common physical symptoms that occur in the last week to days before an adult's death from cancer include pain (70%), noisy or moist breathing (60%), urinary incontinence or retention, dyspnea, and nausea and vomiting.¹² Patients may also experience fatigue. Hunger and thirst are unusual. Treatments for problems at the end of life are reviewed in Table 92.4. Patient and family wishes and options about the setting for end-of-life care should be explored. Some evidence suggests that patients with cancer who die at home have better quality of life, and their caregivers have better bereavement outcomes than cancer patients who die in the hospital. However, given the potentially high symptom burden in the final moments of life, such as bleeding or dyspnea, more research is needed to understand barriers to hospice care and patient and family outcomes in hematologic malignancies.²⁷

HOSPICE PROGRAMS

In the four weeks prior to his death, my father lived under the care of five different institutions in two states. Only the last place, the hospice, appeared willing or able to provide care and comfort to a man who was obviously at the end of his life.²

— (Bereaved family member)

In the United States, most hospice care takes place in the home, although patients can be admitted to nursing homes for brief periods (usually 5 days) to provide a respite for the family caregivers, or to the hospital (usually for up to 14 days) if symptoms cannot be controlled at home. Early referral to hospice programs improves outcomes, and in many cases hospice care is the only effective way to support these patients and families at home at the end of life. The Medicare Hospice Benefit does not require a do not resuscitate status, but it does require that the attending physician and the hospice medical director certify that the patient has a prognosis of 6 months or less to live if the disease follows its usual course. Medicare

reimburses hospice programs about \$186 per day per patient (as of fiscal year 2013) to provide the routine care described in Table 92.5. Therefore, the cost of transfusions typically required for many patients with hematologic malignancies, even at the end of life, may make it difficult for hospice programs to enroll patients insured by Medicare alone. Other insurance programs may allow their patients to receive transfusions and hospice care. Notably, many children are not referred to hospice because their illness experience is inconsistent with hospice specifications—prognosis is uncertain; there is a blending of goals, which can result in more costly health care; and providers lack pediatric expertise. Importantly, the Patient Protection and Affordable Care Act now requires state Medicaid programs to allow children with a life-limiting illness to receive both hospice care and curative treatments concurrently; the full effect of this change remains to be seen.

BEREAVEMENT

Bereavement follow-up by the professional team is an intrinsic component of comprehensive pediatric palliative care. Bereaved families often express the sentiment of a double loss: loss of their child and loss of their oncology team whom they have known and trusted, often over months and years. Parental grief has been recognized as more intense and longer lasting than other types of grief. Contact from a team member after the child's death can assuage the family's sense of abandonment and the palliative care team can serve a crucial preventive role by identifying families at particular risk for prolonged grief disorders and identifying resources for them.

Each bereaved person's loss is unique, but many people manifest similar symptoms of grief, some of which become less persistent as they rebuild their lives. Recurrent intense symptoms typically occur at the anniversary of the death of the patient but can occur at unpredictable times, induced by reminders of the deceased. Survivors appreciate calls or letters from the patient's physician and nurses. For patients enrolled in hospice programs, a formal bereavement program is offered for the family throughout the first year after the patient's

TABLE 92.5 Specialty Level Palliative Care Versus Hospice Care

Palliative Care	Hospice Care
Interdisciplinary Model of Care - Clinical specialty, offers expert: - Symptom management and communication - Psychosocial and spiritual care - Inpatient, outpatient and home care consultations to the primary team - Coordination of care among treating teams	Interdisciplinary Program of Care - Medicare hospice benefit, delivers: - Symptom management and communication - Psychosocial and spiritual care - Home, inpatient, or respite care in a nursing home under the direction of the patient's physician - Continuity with referring care team
Eligibility - Any patient with serious or life-threatening illness - Any stage the illness - Concurrent with curative or disease-directed therapies	Eligibility - Estimated 6 months or less prognosis - Eligible for Medicare or secondary insurance - Focus is quality not life prolongation
Interdisciplinary Consult Team Palliative care physicians, advance practice nurses, physician assistants, nurses, social workers, chaplains, and bereavement counselors and others	Interdisciplinary Care Team Hospice medical director (physician), advance practice nurses, physician assistants, nurses, social workers, home health aides, chaplains, volunteers, administrative personnel, medical consultants, occupational therapists, physical therapists, speech therapists, and bereavement counselors.

death. After the formal program ends, the bereaved are welcome to continue to participate in any bereavement activities that have been meaningful to them.

At the time of death, survivors may seem numb, confused, or dazed and experience disbelief. By the second month after the death, yearning has replaced disbelief. During the next months, disbelief, depressed mood, and yearning decline gradually, and by 6 months after the death, most people will have accepted the reality of the death and are beginning to think about reengaging in relationships and work, discovering new meaning and purpose. Siblings are especially vulnerable in the year following a child's death.²⁸ By a year or two, most survivors have accommodated to their loss. They become aware of the changes that must be made if they are to resume old relationships and responsibilities, or to establish new ones and risk recurrent loss.

About 10–20% of survivors, however, suffer either from depression and/or from a symptom complex previously called *complicated grief*, now identified as *prolonged grief disorder*.¹² Patients with depression manifest symptoms of sadness, anhedonia, and psychomotor retardation, but they are not yearning for the deceased or unable to accept the death. Depressed survivors benefit from counseling and consideration of pharmacologic treatment. Patients with prolonged grief disorder, in contrast, have grief symptoms that last beyond 6 months and cause functional impairments. Such patients are at increased risk for medical and psychiatric illness and should be referred for psychiatric or spiritual counseling. Persons at higher risk for this disorder include those with a history of attachment disorders (childhood abuse, childhood separation anxiety), aversion to lifestyle changes, being unprepared for the death and unsupported after it, and a particularly interdependent relationship with the deceased.

SELF-CARE FOR CLINICIANS

Even while providing steady care for the patient and family, professional caregivers are often experiencing their own distress in a sort of parallel process. The professional often feels anguish and helplessness in witnessing a child endure pain and suffering—physical or psychic. He or she often identifies with the parents of the child. This reaction intensifies when the caregiver is also a parent, especially if his or her healthy child is the same age as the patient. For the caregiver who does not yet have children, the specter of a fatally ill child may loom threateningly. In surveys, medical and nursing staff often cite the personal pain of losing a child as the most difficult experience in their work with dying children. Special attention should be paid to the

grief experienced by trainees with little previous experience with death and dying. Interns are in special need of emotional support following a patient's death. Reviewing each death on the next morning's rounds provides the needed debriefing and shows respect for the patient who has died. When possible and it feels appropriate, clinicians can write a card or attend the funeral or memorial service, which may facilitate closure.

For all these reasons, the professionals who engage in this extraordinarily rich and demanding work articulate significant needs for support themselves. Otherwise, the toll of cumulative unresolved grief exacts a heavy toll in their personal and professional lives. A cohesive team and/or the opportunity for individual and group consultation are crucial for those who are intimately engaged in repeated cycles of attachment.

CONCLUSION AND FUTURE DIRECTIONS

Patients with hematologic malignancies and their families face unique challenges compared with patients with solid tumors. These challenges include: the need to undergo high-risk treatments with significant symptom burden and prolonged hospitalization to achieve cure; significant prognostic uncertainty; difficult decisions about the benefits and burdens of life-sustaining transfusions of blood products when the prognosis of the cancer is weeks to months; increased likelihood of receiving more aggressive care in the last month of life; and more deaths in the hospital.^{5,22,27}

There is growing evidence that integration of palliative care into the care of patients with hematologic malignancies is achievable and can improve patient and family outcomes.²⁹ Appropriate triggers for members of the hematologic oncology team to request a palliative care consultation could include patients with high risk of refractory symptoms (e.g., severe graft-versus-host disease) or high mortality risk (e.g., relapse after bone marrow transplant, or hospitalized patients with end-stage disease). Research is needed to characterize and alleviate the symptom burden of patients with hematologic malignancy at all points in their illness trajectories,³⁰ and measure the effectiveness of specialty-level palliative care interventions to relieve patients' and families' suffering.¹⁴

LATE COMPLICATIONS OF HEMATOLOGIC DISEASES AND THEIR THERAPIES

Wendy Landier and Smita Bhatia

The past three decades have seen a marked improvement in survival for patients with hematologic malignancies. The 5-year survival is as follows: leukemia, 58%; Hodgkin lymphoma (HL), 87%; non-Hodgkin lymphoma (NHL), 71%; and multiple myeloma, 43%.¹ As a consequence, the population of long-term cancer survivors continues to grow. As of January 1, 2014, there were 316,210 leukemia survivors living in the United States, 197,850 HL survivors, and 569,820 NHL survivors.²

Attendant with this success is an increasing awareness of the occurrence of long-term morbidity and mortality associated with the very treatments responsible for the improvement in survival. The subject of long-term morbidity suffered by cancer survivors has been the topic of numerous reports.^{3–12} These reports demonstrate that survivors are at risk for developing adverse outcomes, including premature death, subsequent neoplasms, organ dysfunction (e.g., cardiac, pulmonary, gonadal), reduced growth, decreased fertility, impaired intellectual function, difficulties obtaining employment and insurance, and overall reduced quality of life.

Hematopoietic cell transplantation (HCT) is the treatment of choice for patients with hematologic malignancies experiencing disease recurrence after conventional regimens and for those with disease characteristics associated with poor prognosis if treated with conventional chemotherapy and radiation regimens. Complications observed after HCT often have a multifactorial origin encompassing issues related to prior cancer therapy, intensity of the preparative regimen, graft-versus-host disease (GVHD), and other posttransplantation complications.^{13–22}

This chapter summarizes select adverse outcomes among individuals treated for hematologic malignancies with conventional therapy alone or with HCT. Recommendations for providing ongoing follow-up care to this population of survivors are also reviewed.

CARDIOVASCULAR DISEASE

One of the more serious adverse events encountered in survivors of hematologic malignancies is the development of late-occurring cardiovascular events, which include coronary artery disease (CAD) (myocardial infarction, atherosclerotic heart disease, and angina pectoris) and cardiac disease (cardiomyopathy and congestive heart failure [CHF], valvular disease, conductive abnormalities, and constrictive pericarditis). These complications are more common than expected,^{23,24} and often occur earlier than would be expected for the general population.^{13,25,26}

Cardiac Disease

The anthracycline class of drugs is a well-known cause of late-onset cardiomyopathy. Anthracyclines are directly toxic to the myocardium through a variety of mechanisms, including free radical-mediated oxidative damage and induction of cellular apoptosis. Compared with the general population, survivors of childhood cancer are at a 15-fold increased risk of developing CHF⁶ and at a sevenfold increased risk of premature death due to cardiac causes.²⁷ There is a strong dose-dependent relationship between anthracycline exposure and risk of

CHF. Among childhood cancer survivors, the incidence of CHF is less than 5% with cumulative anthracycline exposure of less than 250 mg/m², approaches 10% at doses between 250 mg/m² and 600 mg/m², and exceeds 30% for doses higher than 600 mg/m².^{28–30} However, cumulative anthracycline exposure as low as 101–150 mg/m² may be associated with a 3.9-fold increased risk for cardiomyopathy when compared with those unexposed to anthracyclines.³¹

Among survivors of adult-onset cancer, the incidence of CHF has been estimated at 7.5% to 26% with a dosage of 550 mg/m².³² However, this cumulative anthracycline exposure has considerably higher dosages than the 300 mg/m² typically used for patients treated with six cycles of doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine (ABVD) or rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP); the cardiac effects of moderate-dose doxorubicin, given as part of ABVD or R-CHOP to young adults, are less clear. Small case series either show no cardiac toxicity^{33,34} or significant deterioration in several echocardiographic measures of ventricular function with 6 months of exposure.³⁵ In addition, 5-year cumulative risks of significant cardiac events and CHF were 19% and 10%, respectively.³⁶ Among survivors older than 65 years of age, the risk of late-onset CHF was 29% higher among those exposed to doxorubicin, compared with those not treated with doxorubicin, and an increase in the number of cycles of doxorubicin-containing chemotherapy was significantly associated with increasing risk of CHF.³⁷ In a clinical trial designed to evaluate cardiac toxicity after R-CHOP for diffuse large B-cell lymphoma (DLBCL) (median age at treatment: 68 years), 6% of the patients developed CHF after six to eight cycles.³⁸

Among HCT recipients, the risk of CHF is highest after autologous HCT, approaching 10% at 15 years after HCT.²⁴ Autologous HCT survivors are at a nearly fivefold risk of CHF when compared with age-matched and sex-matched individuals from the general population. Outcome after post-HCT CHF is poor, with less than 50% of patients surviving 5 years after a diagnosis of CHF.³⁹ The risk of late-occurring CHF is primarily due to pre-HCT exposure to anthracyclines.^{24,39} A recent study found that a doxorubicin dose ≥ 300 mg/m² and a cardiac radiation therapy (RT) dose greater than 30 Gy were independent risk factors for left ventricular systolic dysfunction.⁴⁰

Modifying Factors for Cardiac Disease

Young age at exposure is a significant modifier of anthracycline-related cardiotoxicity.^{41,42} Females treated in childhood are at greater risk of developing doxorubicin-induced ventricular dysfunction than are males.²⁸ The combined use of doxorubicin and chest radiation has been associated with a greater risk of late cardiac toxicity than either treatment given alone. For men treated for HL at age 40 years, the estimated 15-year rate of cardiac-related hospitalization was 9.8% (standardized incidence ratio [SIR]: 1.92) following mantle RT (median dose: 35 Gy) and 16.5% following combined doxorubicin with mediastinal RT (SIR: 2.80).^{33,34} Another study found the addition of anthracyclines to mediastinal RT significantly increased the risk of CHF (relative risk [RR]: 2.81) vs mediastinal RT alone.³³

The presence of one or more conventional cardiac risk factors (diabetes, dyslipidemia, smoking, and hypertension) has a significant effect on the incidence of heart disease among both HL survivors and older patients with DLBCL.^{33,37} The risk of post-HCT anthracycline-related cardiotoxicity also increases significantly among individuals with one or more conventional cardiac risk factors.^{23,24,43,44}

Arterial Disease

Radiation to the chest produces late-onset intimal thickening of the coronary arteries and microvascular damage that causes reduced myocardial perfusion. Several cohort studies have shown that patients who received mediastinal irradiation for HL had an increased risk of CAD compared with the respective general populations.^{45–51} The risk of radiation-related CAD is generally higher among men and among younger patients. A large, retrospective cohort study reported the risk of deaths related to myocardial infarction to be 2.5-fold higher among HL patients when compared with an age-matched and sex-matched general population. While the RR declined with increasing age of the HL cohort, the absolute excess risks of death from myocardial infarction increased with older age up to age 65 years at first treatment. The statistically significantly increased risk of myocardial infarction mortality persisted through to 25 years after first treatment. Risks were increased statistically significantly for patients treated with supradiaphragmatic radiation, anthracyclines, or vincristine. Patients treated with the doxorubicin, bleomycin, vinblastine, and dacarbazine regimen were at a 9.5-fold increased risk of mortality due to myocardial infarction. Among those exposed to supradiaphragmatic radiation and vincristine and followed for 20 or more years after first treatment, the risk was 14.8-fold that of the general population.⁵²

Arterial disease in the transplant setting is related to an accelerated atherosclerosis, attributed to pre-HCT and conditioning-related radiotherapy, and is compounded by the development of cardiovascular risk factors (hypertension, diabetes, and dyslipidemia) in the early post-HCT period.^{43,53} The cumulative incidence of arterial events such as clinically overt CAD or stroke among allogeneic HCT recipients is 10% at 15 years and the risk exceeds 20% at 20 years.^{25,26} In this population, the median age at first myocardial infarction is as low as 53 years (range: 35–66 years),^{44,54} which is earlier than would be expected for the general population (67 years)⁵⁵ or that reported for survivors of autologous HCT (61 years).^{44,54}

Cardiovascular Risk Factors

The risk of developing cardiovascular risk factors such as hypertension, diabetes, and dyslipidemia is especially high in allogeneic HCT recipients when compared with autologous HCT recipients, as well as age-matched and sex-matched individuals in the general population.^{44,56} The 10-year cumulative incidence of hypertension, diabetes, and dyslipidemia in allogeneic HCT recipients was 37.7%, 18.1%, and 46.7%, respectively; the risk for multiple (>2) cardiovascular risk factors approached 40% (compared with 26% in survivors of autologous HCT).

Conditioning with total body irradiation (TBI) has been associated with an increased risk of dyslipidemia and diabetes in pediatric^{57,58} and adult⁵⁶ survivors of HCT. Abdominal radiotherapy possibly contributes to insulin resistance and/or metabolic syndrome, suggesting a role for radiation-induced pancreatic or hepatic injury.^{59,60} The increased risk of diabetes and dyslipidemia among HCT survivors with prior exposure to TBI could potentially be due to the combined effects of abdominal radiotherapy and post-HCT gonadal dysfunction.⁶¹

Prevention of Cardiotoxicity

Given the known cardiac complications of cancer therapy, prevention of cardiotoxicity is a focus of active investigation. There is strong

evidence for dexrazoxane as a cardioprotectant. Dexrazoxane decreases oxygen free radicals through intracellular iron chelation.⁶² In two metaanalyses, dexrazoxane was associated with 60% to 80% fewer clinical and subclinical cardiac events during and after anthracycline-based therapy.^{63,64} Overall, toxicity and measures of tumor response were similar between patients exposed and unexposed to dexrazoxane.⁶³ Currently, the Food and Drug Administration approves dexrazoxane for women with metastatic breast cancer who have received 300 mg/m² of doxorubicin and who need additional anthracycline-based therapy. The American Society of Clinical Oncology also recommends considering dexrazoxane for adults with any history of cancer who have already received 300 mg/m² of doxorubicin-based therapy.⁶⁵

Intermediate or surrogate endpoints in randomized clinical trials show that dexrazoxane reduces cardiotoxicity in children exposed to anthracyclines.^{66,67} Among 206 children with acute lymphoblastic leukemia (ALL), those receiving dexrazoxane had fewer episodes of elevated cardiac troponin T (cTnT) concentrations after anthracycline treatment (21% vs. 50%, $p < .001$).⁶⁷ Longer term follow-up data demonstrate that various echocardiographic indices of left ventricular (LV) structure and function are worse in those not receiving dexrazoxane.⁶⁶ Girls benefit from dexrazoxane more than boys, particularly with respect to changes in the LV end-diastolic thickness-to-dimension ratio, a marker of pathologic LV remodeling. Dexrazoxane was also found to demonstrate cardioprotection in children treated with doxorubicin for T-cell ALL and lymphoma.⁶⁸ A recent report demonstrates no impact on late mortality among HL patients randomized to dexrazoxane.⁶⁹ However, comprehensive longer term follow-up is required to document that dexrazoxane does indeed have a cardioprotective effect while maintaining comparable event-free survival.^{70,71}

Previous reports have suggested that doxorubicin-induced cardiotoxicity can be prevented by continuous infusion of the drug.^{72–74} Lipshultz et al⁷⁵ compared cardiac outcomes in children with leukemia receiving bolus or continuous infusion doxorubicin and reported that continuous doxorubicin infusion over 48 hours did not offer a cardioprotective advantage over bolus infusion. Both regimens were associated with progressive subclinical cardiotoxicity. Several other studies have reported no statistically significant difference in echocardiographic characteristics of children with cancer 5–7 years after treatment with either continuous infusion (over 6–24 hours) or bolus infusion of anthracyclines.^{76,77}

Liposome-encapsulated anthracyclines have been explored for their propensity to result in a lower incidence of cardiotoxicity. The premise behind this theory is as follows: liposome-encapsulated anthracyclines escape the capillaries with wide endothelial gaps in the tumor, thus reaching high concentrations in the interstitial fluid of the tumor bed, but are less likely to escape the tight capillary junctions of the heart. Biopsy results have confirmed the relative safety in clinical use.^{78,79} Data on the potential cardioprotection associated with liposomal formulations of anthracyclines is limited. A phase I study of liposomal daunorubicin in 48 children reported no cardioprotection.⁸⁰

Specific recommendations for monitoring, based on age and therapeutic exposure, are delineated within the Children's Oncology Group Long-Term Follow-Up Guidelines⁸¹ (COG LTFU guidelines) available at <http://www.survivorshipguidelines.org>.⁸² According to these guidelines, patients exposed to anthracyclines need ongoing monitoring for late-onset cardiomyopathy using serial noninvasive testing (echocardiogram) and physical examination. The frequency of echocardiograms can range from yearly to every 5 years, depending on cumulative anthracycline dose, age at exposure, and treatment with mediastinal radiation. Pregnant women previously treated with anthracyclines should be closely monitored, because changes in volume during the third trimester could add significant stress to a potentially compromised myocardium. In addition to monitoring for cardiomyopathy, survivors who received radiation involving the heart field also need monitoring for potential early-onset atherosclerosis. Heart-healthy lifestyles should be encouraged for all survivors, including implementation of a regular exercise program, dietary

recommendations, and screening for dyslipidemia. Joint recommendations for monitoring long-term survivors of HCT by the European Group for Blood and Marrow Transplantation (EBMT)/Center for International Blood and Marrow Transplant Research (CIBMTR)/American Society for Blood and Marrow Transplantation (ASBMT) suggest that at a minimum, cholesterol and high-density lipoprotein-cholesterol (HDL-C) should be checked at least every 5 years for men starting by age 35 years and women starting at 45 years of age. It is suggested that screening for dyslipidemia should start at 20 years of age for smokers, patients with diabetes, or patients with a family history of heart disease. Abnormalities (total cholesterol >200 mg/dL or HDL-C <40 mg/dL) should be followed up with a full fasting lipoprotein profile.⁸³

PULMONARY EFFECTS

Compromise of pulmonary function among survivors of hematologic malignancies has been reported after conventional therapy.^{13,14,84–86} Impairments evident by pulmonary function testing include reductions in total lung capacity (TLC), forced vital capacity (FVC), forced expiratory volume in the first second of expiration (FEV₁), and gas transfer (diffusing capacity of lung for carbon monoxide [DLCO]), suggesting obstructive and restrictive defects. Risk factors include exposure to certain chemotherapeutic agents (particularly bleomycin), radiation to the chest, underlying lung disease, female sex, and a younger age at exposure to the pulmonary-toxic therapeutic agents. In a recent study, Armenian et al⁸⁷ demonstrated an elevated risk of pulmonary compromise among childhood cancer survivors when compared with healthy controls and identified populations at increased risk for pulmonary toxicity. Compared with healthy controls, childhood cancer survivors were 6.5-fold more likely to develop restrictive defects and 5.2-fold more likely to develop diffusion abnormalities. Among childhood cancer survivors, higher radiation dose (>20 Gy) and younger age at exposure (<16 years) was associated with restrictive disease. Female sex and higher chest radiation dose were associated with diffusion abnormalities. Importantly, over a period of 5 years, diffusion capacity declined among females and those exposed to high doses of chest radiation.

Pulmonary complications, both infectious and noninfectious, are common after HCT. Multiple factors are thought to contribute to pulmonary complications, including the type and duration of immunological defects produced by the underlying disease and treatment, the development of GVHD, and the conditioning regimens employed. These complications are classified as early or late, depending on whether they occur before or after 100 days from transplantation. Early noninfectious pulmonary complications typically include pulmonary edema, upper airway complications, diffuse alveolar hemorrhage, and pleural effusion. Bronchiolitis obliterans, venoocclusive disease, and secondary malignancies occur late after HCT. Idiopathic pneumonia syndrome, GVHD, and radiation-induced lung injury can occur in early or late periods after HCT (reviewed in Khurshid and Anderson).⁸⁸

The following pulmonary function tests are noted to decline after HCT: FEV₁/FVC, forced mid-expiratory flow, TLC, DLCO, residual volume (RV), functional residual capacity, and RV/TLC. Older age at the time of allogeneic HCT is associated with lower FEV₁/FVC and DLCO, and higher RV/TLC. Bronchiolitis obliterans syndrome is a progressive, insidious lung disease occurring after allogeneic HCT and results in progressive circumferential fibrosis and ultimate cicatrization of the small terminal airways, manifesting as new fixed airflow obstruction (reviewed in Williams et al).⁸⁹ Bronchiolitis obliterans has been shown to have a strong correlation with chronic GVHD and has been reported in up to 6% of HCT recipients. Most patients present when the degree of airflow is severe, causing significant dyspnea on exertion and a persistent nonproductive cough. Lung biopsy findings demonstrating damage to the bronchiolar epithelium, obliteration of bronchiolar lumens, inflammation between the epithelium and the smooth muscle, and pulmonary fibrosis are characteristic. The National Institutes of Health definition of bronchiolitis

obliterans requires the following: (1) absence of active infection, (2) decreased FEV₁ (<75% of predicted value), (3) evidence of airway obstruction with a ratio of FEV₁ to FVC of less than 0.7, (4) elevated RV of air (>120% of predicted normal), or (5) an expiratory chest computed tomographic (CT) scan or lung biopsy results that reveals air trapping or bronchiectasis. Recommended therapy includes high-dose systemic steroids for a protracted course, with or without the addition of other immunosuppressants. Leukotriene inhibitors have emerged as a potential therapy because of the elevated levels of leukotrienes implicated in bronchiolitis obliterans.

The COG LTFU guidelines recommend monitoring for pulmonary dysfunction in childhood cancer survivors that includes assessment of symptoms such as chronic cough or dyspnea on annual follow-up. Risks of smoking and exposure to second-hand smoke should be discussed with all patients. The best approach to chronic pulmonary toxicity of anticancer therapy is preventive and includes respecting cumulative dosage restrictions of bleomycin and alkylators, limiting radiation dosage and port sizes, and avoidance of primary or second-hand smoke. Pulmonary function tests are recommended as a baseline upon entry into long-term follow-up for patients at risk, repeated as clinically indicated in symptomatic patients and in those with subclinical abnormalities identified on screening evaluation. Repeat evaluation should also be considered for at-risk patients before general anesthesia. Influenza and pneumococcal vaccines are encouraged in survivors at risk for pulmonary compromise.⁸² Joint recommendations for monitoring long-term survivors of HCT by the EBMT/CIBMTR/ASBMT suggest: (1) routine clinical assessment at 6 months, 1 year, and annually thereafter, (2) institution of active smoking cessation programs, and (3) pulmonary function tests and focused radiologic assessment at 1 year after allogeneic HCT for patients with signs or symptoms of lung compromise or earlier as clinically indicated. Annual testing is recommended thereafter for patients with recognized defects or appropriate clinical circumstances. For autologous HCT recipients, pulmonary function testing should be performed for those with known deficits before HCT or with those exposed to radiation or other pulmonary toxic agents during or after transplantation. Chest radiographic studies are indicated based on symptoms or abnormal pulmonary function test results.⁸³

ENDOCRINOLOGIC EFFECTS

Thyroid

Patients with hematologic malignancies treated with cranial, craniospinal, or mantle irradiation are at increased risk for thyroid complications. Among survivors of HL, and to a lesser extent leukemia, abnormalities of the thyroid gland, including hypothyroidism, hyperthyroidism, and thyroid neoplasms, have been reported to occur at rates significantly higher than those found in the general population.^{73–75} Hypothyroidism is the most common nonmalignant late effect involving the thyroid gland.⁹⁰ After exposure to radiation at doses above 15 Gy, laboratory evidence of primary hypothyroidism is evident in 40% to 90% of patients with HL and NHL^{91–93}; risk increases with radiation dose.⁹⁴

In an analysis of 1791 5-year survivors of pediatric HL (median age at follow-up: 30 years), Sklar et al⁹⁵ reported the occurrence of at least one thyroid abnormality in 34% of subjects. The risk for hypothyroidism was increased 17-fold compared with sibling controls; increasing dose of radiation, older age at diagnosis of HL, and female sex were identified to be significant independent predictors of increased risk. The actuarial risk for hypothyroidism for subjects treated with 45 Gy or more was 50% at 20 years after diagnosis of HL. Hyperthyroidism was reported to occur in only 5%. In a seminal study of 1677 patients with HL treated at Stanford University Hospital between 1961 and 1989 with irradiation involving the thyroid (mean age at diagnosis: 28 years; mean duration of follow-up: 9.9 years), the actuarial risk for developing thyroid disease was 52% at 20 years and 67% at 26 years after treatment. In this population, the actuarial risk for developing overt or subclinical hypothyroidism

was 44% by 25 years after therapy; the risk for developing thyroid cancer was 1.7% (15.6 times the expected risk).⁹¹ Most cases of overt hypothyroidism after HCT result from primary hypothyroidism caused by radiation injury. The incidence of hypothyroidism after HCT depends on the type of myeloablative conditioning regimen, ranging from 10% to over 50% after fractionated TBI, to as high as 90% after exposure to single-dose TBI.^{16,96}

Thyroid nodules are common in patients treated with neck radiation for HL, but the majority of these do not undergo malignant transformation.^{97,98} In a study of 647 children treated for HL, 67 developed thyroid nodules during or after therapy (median time between diagnosis of HL and thyroid nodule was 10.5 years, with a range of 0.2–24.8 years). All but one of these patients had received neck radiation as part of their therapy, with a median dose to the thyroid of 35 Gy. Seven (10%) of the 67 nodules were malignant.⁹⁷

Monitoring for survivors at risk for thyroid complications should include yearly thyroid examination as well as yearly measurement of free thyroxine and thyroid-stimulating hormone.⁸²

Growth

Poor linear growth and short adult stature are common complications after successful treatment of hematologic malignancies in childhood. The adverse impact of central nervous system (CNS) irradiation on adult final height among childhood leukemia patients has been well documented, with final heights below the fifth percentile in 10% to 15% of survivors.^{99–102} The effects of cranial irradiation appear to be related to age and sex, with females and children younger than 8 years at the time of therapy being more susceptible.^{103,104} The precise mechanisms by which cranial irradiation induces short stature are not clear. Disturbances in growth hormone production have not been found to correlate well with observed growth patterns in these patients.^{105,106} The phenomenon of early onset of puberty in girls receiving cranial irradiation may play some role in the reduction of final height.^{107,108} In childhood leukemia survivors not treated with cranial irradiation, there are conflicting results regarding the impact of chemotherapy on final height.^{100,109}

Impaired linear growth after HCT is likely due to an interaction of multiple factors, including host characteristics (young age), treatment exposures (prior cranial irradiation, TBI), and post-HCT complications, such as chronic GVHD.⁹⁶ Findings suggest that final height is unaffected in children who receive busulfan or cyclophosphamide as pretransplant conditioning.¹¹⁰

Survivors should be monitored using standardized growth curves until final height is achieved. An endocrine consultation should be obtained for children who received cranial radiation in doses ≥ 30 Gy and for those whose height is less than the third percentile, or who have poor growth for age or pubertal stage.^{82,104}

Obesity

An increased prevalence of obesity has been reported among survivors of childhood ALL.^{111–113} In an analysis from the Childhood Cancer Survivor Study, Oeffinger et al¹¹⁴ compared the distribution of the body mass index (BMI) of 1765 adult survivors of childhood ALL with that of 2565 adult siblings of childhood cancer survivors. Survivors were significantly more likely to be overweight (BMI of 25 to <30) or obese (BMI ≥ 30). Risk factors for obesity were cranial irradiation, female sex, and age 0–4 years at diagnosis of leukemia. Females diagnosed under the age of 4 years who received a cranial radiation dose of more than 20 Gy were found to have a 3.8-fold increased risk for obesity. In a recent report of survivors of standard-risk childhood ALL treated without cranial radiation, there was no increased risk of overweight or obesity compared with general population health data.¹¹⁵ Obesity has the potential to adversely impact the overall health status in survivors and is associated with insulin resistance, diabetes mellitus, hypertension, and dyslipidemia. The prevalence of growth hormone deficiency related to cranial radiation in

childhood ranges from 29% to 39%,¹¹⁶ with increased risk at higher doses and longer time from treatment,¹¹⁶ and may predispose adult survivors of childhood ALL, particularly females, to abdominal obesity¹¹⁷ and metabolic syndrome.¹¹⁸ Yearly monitoring of BMI is recommended for all survivors.

Gonadal Dysfunction

Treatment-related gonadal dysfunction has been well documented in male and female patients after therapy for hematologic malignancies and there is a reasonable body of research that provides a basis for counseling patients regarding the long-term gonadal effects of radiation and chemotherapy.

Radiation effects on the ovary are age and dose dependent. It has been estimated that there is a 50% depletion in oocytes after exposure of the ovaries to 2 Gy.¹¹⁹ Amenorrhea develops in approximately 68% of prepubescent females treated for HL with ovarian doses of 12–15 Gy, whereas 100% of adult females older than 40 years of age will sustain irreversible ovarian failure after doses of 4–7 Gy.¹²⁰ Spinal irradiation for the treatment of childhood leukemia appears to result in clinically significant ovarian damage in some survivors,¹²¹ and cranial irradiation in young girls is associated with an increased risk for premature puberty.¹²²

The effects of radiation on testicular function, including germ cell number and Leydig cell function, have been investigated. Reduced sperm production has been observed after testicular doses of 1–6 Gy and follows a dose-dependent pattern.¹²³ Azoospermia has been reported among HL patients with calculated testicular irradiation exposures ranging from 1–3 Gy.¹²⁴ Testicular doses between 4–6 Gy have been associated with prolonged azoospermia and decreased testicular volume.¹²⁵ Spermatogenesis is impaired in 75% to 100% of male childhood HL survivors in whom radiation and chemotherapy were combined.⁹⁰ Leydig cells, although also affected by radiation in a dose-dependent fashion, require higher exposure levels to sustain damage than those seen for the germ cells.¹²⁶ Testicular doses of 24 Gy among prepubertal males have been reported to be associated with delayed pubertal development and abnormal testosterone and gonadotropin levels.^{127–129}

Ovarian and testicular damage can also result from chemotherapeutic agents, with alkylating agents showing the strongest association. Effects of chemotherapy on gonadal function are typically sex, age, and dose dependent. While older studies have suggested that the ovaries tend to be less sensitive to the effects of alkylating agent exposure compared with the testes,¹³⁰ this may have been due to a lack of reliable markers for measuring ovarian function.⁹⁰ Ovarian dysfunction has been well documented in HL patients treated with alkylating agents, singly or in combination (e.g., MOPP regimen consisting of mechlorethamine, vincristine [Oncovin], procarbazine, and prednisolone, or a COPP regimen consisting of cyclophosphamide, vincristine [Oncovin], procarbazine, and prednisolone).^{150–153} MOPP and COPP regimens have been reported to result in azoospermia in more than 90% of exposed males,¹³⁴ with a negative correlation seen between cumulative doses of alkylating agents and sperm concentration.¹³⁵ Even with a reduction in the dose of cyclophosphamide in the hybrid COPP/adriamycin, bleomycin, and vinblastine (ABV) regimen for HL, the majority of young males are infertile, likely due to the procarbazine component in this regimen.¹³⁶ In a study of 6224 male survivors of childhood cancer between 15 and 44 years of age, those with a diagnosis of hematologic malignancy were significantly less likely to sire a pregnancy compared with sibling controls; those with a diagnosis of HL were least likely to sire a pregnancy (RR of fertility: 0.34; 95% confidence interval [CI]: 0.28–0.41), followed by NHL (RR: 0.60; 95% CI: 0.48–0.74), and leukemia (RR: 0.70; 95% CI: 0.59–0.84); $p < .001$ for all comparisons.¹³⁷

Young boys and adolescent males with aplastic anemia who receive standard-dose cyclophosphamide alone (200 mg/kg) as the pretransplant conditioning regimen appear to retain normal Leydig cell function, as do males who receive busulfan and cyclophosphamide, with normal plasma concentrations of luteinizing hormone and

testosterone, and normal progression through puberty.⁹⁶ Evidence of germ cell damage can occur and is more likely among patients treated after puberty.¹³⁸ Semen analyses have been normal in approximately two-thirds of men after high-dose cyclophosphamide and several men have fathered normal children. Men treated with TBI-based regimens who have not received prior testicular irradiation generally retain normal Leydig cell function, regardless of their age at treatment.¹³⁸ Germ cell dysfunction occurs in all men treated with TBI-based regimens and azoospermia is the rule; however, some younger males (age <25 years at HCT) without chronic GVHD have showed some degree of spermatogenesis following standard-dose TBI.¹³⁹

Female patients treated with high-dose cyclophosphamide alone retain normal ovarian function regardless of age at exposure, although these subjects may be at an increased risk for early menopause as they reach the third decade of life.¹⁴⁰ These individuals can sustain a normal pregnancy resulting in normal offspring. Females treated with busulfan and cyclophosphamide are at very high risk for ovarian failure and premature menopause.¹⁴¹ The outcome of ovarian function after TBI appears to be determined by the age at exposure. Approximately 50% of prepubertal girls receiving fractionated TBI enter puberty spontaneously and premature ovarian failure is seen in all patients who are older than 10 years of age when treated with TBI.⁹⁶ Pregnancies among survivors of TBI are at an increased risk for spontaneous abortion, premature labor, and low-birthweight offspring.¹⁴²

Assessment for gonadal dysfunction includes a thorough history and physical examination; additionally, a morning serum testosterone level in males and serum estradiol, follicle-stimulating hormone level, and luteinizing hormone level in females, should be obtained during early adolescence and as clinically indicated in patients with delayed or arrested puberty or who have symptoms of gonadal dysfunction. Semen analysis may be obtained in sexually mature males desiring to know their fertility status.^{82,143,144}

PREGNANCY OUTCOMES

Offspring of survivors of childhood hematologic malignancies do not appear to be at increased risks for cancer or congenital malformations.^{145,146} In a study of 593 adult survivors of childhood ALL, 15.7% (93 out of 593) of survivors (mean age: 22.6 years) had given birth to or fathered a total of 140 live-born offspring, compared with 29.8% (122 out of 409) of sibling controls (mean age: 25.2 years). There was no significant difference in the rate of birth defects between offspring of survivors (3.6% [5 out of 140]) versus sibling controls (3.5% [8 out of 228]; RR: 1.02; 95% CI: 0.34–3.05).¹⁴⁷ In a review of pregnancy outcomes of participants in the Childhood Cancer Survivor Study,¹³³ the offspring of survivors were more likely to be premature (born before 37 weeks' gestation) compared with the survivors' female siblings (odds ratio [OR]: 1.9; 95% CI: 1.4–2.4; $p < .001$); and the offspring of women who received uterine radiation at a dose of more than 5 Gy were more likely to be small for gestational age (OR: 4.0; 95% CI: 1.6–9.8; $p = .003$). The frequency of premature birth was not related to prior maternal exposure to alkylating agents, but prior exposure to doxorubicin or daunorubicin increased the risk for low birthweight independent of pelvic irradiation history.¹³³ There were no significantly increased rates of congenital anomalies¹⁴⁶ or genetic diseases¹⁴⁸ in the offspring of survivors who received potentially mutagenic therapy (i.e., radiation or alkylating agents).

MUSCULOSKELETAL EFFECTS

Osteonecrosis is a painful and debilitating condition that develops when the blood supply to the bone is disrupted, usually in areas of terminal circulation. The condition is believed to be the result of vascular compromise with resultant death of bone and cell tissues or disruption of bone-repair mechanisms.^{149,150} Osteonecrosis has been reported after conventional therapy for hematologic malignancies,

particularly after exposure to dexamethasone between the ages of 10 and 20 years. This complication usually develops during or shortly after completion of therapy but may progress over time.^{151–153} Mattano et al¹⁵¹ described the magnitude of risk and associated risk factors for development of osteonecrosis in children with ALL treated on Children's Oncology Group therapeutic protocols. The cumulative incidence was 9.3% at 3 years; the incidence was higher in older patients (14.2% for patients ≥ 10 years of age vs. 0.9% for patients <10 years of age) and higher among whites than African Americans. Furthermore, the incidence was higher among patients randomized to receive two 21-day dexamethasone courses versus one course.

Osteonecrosis is increasingly being reported among HCT recipients.^{154–157} Campbell et al¹⁵⁸ conducted a retrospective cohort study and described the cumulative incidence of osteonecrosis to be 2.9% among autologous HCT recipients, 5.4% among allogeneic HCT recipients, and 15% among unrelated donor HCT recipients. Among allogeneic HCT recipients, male sex, presence of chronic GVHD, and exposure to cyclosporine, tacrolimus, prednisone, and mycophenolate mofetil rendered patients at increased risk, in particular among patients with a history of exposure to three or more drugs. The mean latency period was 18 months. The hip joint was the most commonly involved joint (80%); however, the knee, wrist, and ankle joints were also affected. The cumulative incidence of surgery (mainly arthroplasty) approached 31% at 1 year from osteonecrosis diagnosis. Li et al¹⁵⁷ conducted a case-control study of children who underwent allogeneic HCT and found that children at highest risk included those who underwent transplant during the period of rapid pubertal growth and those who received myeloablative conditioning and immunosuppression for treatment of GVHD.

Osteopenia (bone density 1–2.5 standard deviations below mean) or osteoporosis (bone density >2.5 standard deviations below mean) is commonly seen in survivors of hematologic malignancies.^{159–161} Risk factors include therapy with corticosteroids, methotrexate (at higher doses), and cranial irradiation with resultant pituitary insufficiency or gonadal dysfunction. Survivors of HCT are also at increased risk for reduced bone mineral density; identified risk factors in these patients include treatment with corticosteroids for chronic GVHD, prior cranial irradiation (resulting in growth hormone deficiency), and gonadal failure.⁹⁶ Lifestyle factors that increase the risk for osteopenia include lack of regular weight-bearing exercise, inadequate calcium and vitamin D intake, smoking, and excessive alcohol consumption.^{162,163}

Detection and diagnosis of musculoskeletal sequelae depend largely on anticipating these issues in vulnerable hosts, on taking a careful history, and on performing a thorough physical examination. Pain or a history of fractures may be the only indication of osteonecrosis or osteoporosis. Because of progress with various interventions (including the use of calcium supplementation, calcitonin, bisphosphonates, and hormone replacement in patients with gonadal failure), the COG LTFU guidelines recommend a baseline dual-energy x-ray absorptiometry or quantitative CT scan for survivors a minimum of 2 years following completion of treatment, with repeat studies as clinically indicated.⁸² Joint recommendations for monitoring long-term survivors of HCT by the EBMT/CIBMTR/ASBMT suggest a screening dual-photon densitometry performed at 1 year after transplantation in adult women or for any patient who has received prolonged treatment with corticosteroids or calcineurin inhibitors.⁸³ Screening for osteonecrosis is not recommended^{82,83}; however, clinicians should maintain a high level of suspicion for patients with exposure to irradiation or prolonged corticosteroids.

NEUROCOGNITIVE EFFECTS

Childhood cancer survivors are at increased risk for neurocognitive impairment. Cranial radiation has long been associated with neurocognitive late effects.^{164–166} typically a dose of 24 Gy is associated with cognitive deficits,¹⁶⁷ although antimetabolite chemotherapy and corticosteroids have also been implicated as potential contributors to neurocognitive impairment.^{168–171} Additional risk factors include

increased treatment intensity, younger age at treatment exposure, and female sex.^{169,172–176} Neurocognitive deficits usually become evident within 1–2 years following cranial radiation and are progressive in nature. The decline over time is typically reflective of the child's failure to acquire new abilities or information at a rate similar to peers, rather than because of a progressive loss of skills and knowledge. Survivors of childhood ALL are at risk for neurocognitive problems, generally characterized by reduced attention, processing speed, executive function, and global intellectual function.¹⁷⁴ Affected children with information-processing deficits exhibit academic difficulties and are prone to problems with receptive and expressive language, attention span, and visual and perceptual motor skills. The deficits observed after chemotherapy alone are restricted to attention, executive function, and complex fine-motor functioning; global intellectual function is relatively preserved. Neurocognitive function in long-term survivors of childhood cancer appears particularly vulnerable to the effects of fatigue and sleep disruption.¹⁷⁷ The neurocognitive impairment observed in survivors of childhood ALL persists into adulthood; this impairment is associated with reduced educational attainment and unemployment,¹⁷⁸ independent living, and health care use.¹⁷⁹

A spectrum of neuropathological syndromes related to leukoencephalopathy¹⁸⁰ may occur in survivors of childhood hematologic malignancies, including radionecrosis, necrotizing leukoencephalopathy, mineralizing microangiopathy and dystrophic calcification, cerebellar sclerosis, and spinal cord dysfunction, manifesting clinically as ataxia, spasticity, dysarthria, hemiparesis, or seizures. Imaging abnormalities may or may not be evident in these patients. Leukoencephalopathy has been primarily associated with methotrexate-induced injury of white matter. However, cranial irradiation may play an additive role through disruption of the blood–brain barrier, allowing greater exposure of the brain to systemic therapy. Although some abnormalities have been detected by diagnostic imaging studies, the abnormalities observed have not been well demonstrated to correlate with clinical findings and neurocognitive status. In a recent study, brain grey and white matter volume and diffusion tensor imaging was compared between survivors treated with and without radiation and healthy controls. ALL survivors had a lower ratio of white matter to intracranial volume in frontal and temporal lobes compared with control subjects. ALL survivors treated with chemotherapy alone performed worse in processing speed, verbal selective reminding, and academics compared with population norms but performed better than survivors treated with cranial RT on verbal selective reminding, processing speed, and memory span. There were significant associations between neurocognitive performance and brain imaging, particularly for frontal and temporal white and grey matter volume. ALL survivors treated with chemotherapy alone demonstrated significant long-term differences in neurocognitive function and altered neuroanatomical integrity.¹⁸¹

Long-term survivors of childhood HL may also be at risk for neurocognitive impairment. This is associated with radiologic indices suggestive of reduced brain integrity and occurs in the presence of symptoms of cardiopulmonary dysfunction.¹⁸²

Many survivors of adult-onset hematologic malignancies also experience impairments of neurocognitive function, including memory loss, distractibility, and difficulty performing multiple tasks. These patients may also concurrently suffer from mood disturbances and symptoms that compromise their ability to function adequately, including fatigue and pain.¹⁸³

HCT survivors are also at risk for neurocognitive late effects. Prospective, longitudinal evaluations of intellectual and adaptive functioning of children receiving a transplant have revealed declines in intellectual function, particularly among those less than 6 years of age at transplantation.¹⁸⁴ Among the adult populations, a prospective longitudinal study design was used to describe neurocognitive function over 5 years after allogeneic HCT for cancer survivors and compared with matched controls.¹⁸⁵ Survivors recovered significant cognitive function from posttransplantation (80 days) to 5 years in all tests except verbal recall. Between 1 and 5 years, verbal fluency improved, as did executive function, but motor dexterity did not, remaining significantly below population norms. Over 40% of the

survivors had mild or greater deficits, a proportion that was significantly higher than that among the controls (17.5%). Neurocognitive sequelae among adults undergoing HCT include slowed reaction time, reduced attention and concentration, and difficulties in reasoning and problem solving, memory impairment, problems with executive functioning and processing speed, and cognitive impairment.^{186–189} Reduced memory function is associated with older age, longer interval since HCT, chronic GVHD, and long-term cyclosporine use.¹⁹⁰ Other predictors include fatigue and poor physical functioning. Lower education level and poorer social functioning appear to impact cognitive performance. It is therefore prudent to query post-HCT patients regarding perceived deficits in neuropsychological functioning and to refer patients with these problems to a neuropsychologist who is experienced in the follow-up care of HCT patients.

The COG LTFU guidelines recommend a baseline neuropsychological evaluation for patients who received therapy that may affect neurocognitive function. This should be repeated as clinically indicated and at key transition points (e.g., transitioning from grade school to middle/high school); an annual assessment of their vocational or educational progress should also be monitored.⁸² Joint recommendations for monitoring long-term survivors of HCT by the EBMT/CIBMTR/ASBMT suggest that all recipients of HCT should undergo clinical evaluation for symptoms or signs of neurologic dysfunction at 1 year after HCT. Additional tests such as neuropsychologic testing may be warranted for those with symptoms or signs.⁸³

OTHER TOXICITIES

Ocular Effects

Survivors of hematologic malignancies are at risk for the development of cataracts as a consequence of therapy with corticosteroids, cranial irradiation,^{191,192} TBI,¹⁹³ or busulfan.¹⁹⁴ In a cohort of childhood ALL survivors who were treated with chemotherapy with or without cranial radiation and received a mean cumulative prednisone equivalent dose of 5.2 gm/m², cumulative incidence of cataracts was 26 ± 8.1% at 25 years; cranial radiation was the only significant risk factor.¹⁹⁵ Belkacemi et al¹⁹⁶ studied 1063 patients who underwent HCT for acute leukemia; the overall 10-year incidence of cataracts in this group of patients was 50%. Single-dose TBI was associated with a 60% incidence of cataracts, fractionated TBI was associated with a 43% incidence for those receiving six or fewer fractions, and a 7% incidence was reported for those receiving more than six fractions. Factors independently associated with an increased risk for cataract formation in this cohort were older age (>23 years), allogeneic bone marrow transplantation, higher dose rate (>0.04 Gy/min), and steroid administration for longer than 100 days. Xerophthalmia may also occur as a late complication because of decreased lacrimation resulting from damage to the lacrimal gland during radiation or, in HCT patients, from chronic GVHD.¹⁹⁷ Westeneng et al¹⁹⁸ followed 101 adults up to 24 months after allogeneic HCT and reported ocular GVHD in 54% of patients, manifesting mainly as xerophthalmia and conjunctivitis; blepharitis and uveitis were encountered less often. Tabbara et al¹⁹⁹ reported major ocular complications in 13% of 620 patients (age range: 9–65 years) after allogeneic HCT; complications included chronic ocular GVHD, corneal ulcers, cataracts, glaucoma, cytomegalovirus retinitis, fungal endophthalmitis, and the acquisition of allergic conjunctivitis from atopic donors.

Audiologic Effects

Survivors of hematologic malignancies who received platinum chemotherapy, those who had cranial irradiation at a young age (especially during infancy),²⁰⁰ and those who required supportive therapy with aminoglycoside antibiotics²⁰¹ are at risk for therapy-related hearing loss. Hearing loss associated with ototoxic agents is generally sensorineural in origin and is usually irreversible. Although a low incidence

of hearing loss has been reported in survivors of HCT performed in childhood, the risk is elevated threefold to fourfold over that in the general population.¹⁹³ Data are beginning to emerge regarding genetic polymorphisms associated with increased susceptibility to platinum-related hearing loss; these data may prove useful in identifying future patients who are at increased risk for hearing loss as a consequence of platinum-based chemotherapy.²⁰²

Dental Effects

Children whose teeth have not completely developed at the time of cancer treatment are most vulnerable to dental complications and treatment with chemotherapy during early childhood may result in qualitative problems with enamel and root development.²⁰³ However, patients of all ages who received RT involving the head or neck (including cranial irradiation and TBI) are susceptible to dental complications, most often manifesting as increased susceptibility to dental caries and gingivitis as a result of diminished salivary gland function. Patients who have undergone HCT are at increased risks for dental caries, gum disease, and xerostomia²⁰⁴; abnormalities of tooth development are seen in survivors who underwent HCT during childhood.²⁰⁵ Younger age at transplantation (especially under 6 years) and TBI doses above 10 Gy are associated with the greatest risk.²⁰⁵

Hepatic Effects

Although acute hepatic dysfunction may be seen with certain chemotherapeutic agents, including antimetabolites and anthracyclines, there has generally been a low reported incidence of delayed hepatotoxicity in patients receiving these agents.²⁰⁶ However, reports of chronic hepatotoxicity and portal hypertension have emerged in survivors of childhood ALL who received 6-thioguanine-based maintenance therapy,^{207–210} and these survivors require long-term surveillance for this complication.^{82,211} Chronic viral hepatitis, resulting from transfusion of contaminated blood or serum products, should be considered in the differential diagnosis of all survivors with persistently elevated alanine aminotransferase levels. Hepatitis C is the most prevalent type of hepatitis seen in survivors transfused before universal screening of the blood supply for this infection (implemented in the United States in July 1992).^{212,213} Cirrhosis and hepatocellular carcinoma are potential sequelae of untreated chronic viral hepatitis and potential causes of morbidity and mortality in this population. In addition, iron overload associated with HCT for hematopoietic malignancies may also be a contributing factor to hepatotoxicity in survivors.^{214,215}

Second and Subsequent Malignancies

Second or subsequent malignancies are defined as histologically distinct cancers developing after the occurrence of a first cancer. Subsequent malignancies are conventionally categorized into two major types: therapy-related myelodysplastic syndrome/acute myeloid leukemia (t-MDS/AML) and solid tumors. The latency between diagnosis and treatment of the primary cancer and the development of t-MDS/AML is generally short, whereas nonhematopoietic malignancies or solid tumors seem to have a longer latency, and the risk continues to rise for three or more decades. A wide variety of factors influence the risk for subsequent malignancies.

Several large epidemiologic studies have attempted to determine the magnitude of the burden of subsequent malignancies after adult-onset primary cancer. For example, 470,000 cancer patients registered between 1953 and 1991 in Finland were followed for the development of a second cancer.²¹⁶ Overall, the cohort was not at an increased risk for developing a second cancer when compared with the risk for cancer in an age-matched and sex-matched healthy population. However, patients less than 50 years of age at the diagnosis of their

primary cancer were at a 1.7-fold increased risk for developing a second cancer. Another cohort of 633,964 cancer patients diagnosed between 1958 and 1996 in Sweden and followed for the development of subsequent cancers revealed a modestly increased risk (less than twofold), when compared with the general population.²¹⁷ The Swedish family-cancer database was used to analyze site-specific risk of second primary malignancies following 53,159 hematologic malignancies diagnosed between 1958 and 1996. Among 18,960 patients with NHL, there was a 1.2-fold significant increase in risk of subsequent malignancies. Among the 5353 patients with HL, there was a 1.7-fold significant increase in subsequent malignancies. Among the 8098 patients with ALL, there was a 1.3-fold increased risk of subsequent malignancies.²¹⁸

However, when we examine the risk of subsequent neoplasms among childhood cancer survivors, a somewhat different picture emerges. The cumulative incidence of subsequent malignant neoplasms (SMNs) exceeds 20% at 30 years after diagnosis of the primary cancer.²¹⁹ The cumulative incidence is 9% for nonmelanoma skin cancer (NMSC) and 3% for meningioma. The cumulative incidence is 8% for SMNs excluding NMSC; this represents a sixfold increased risk of SMNs among cancer survivors compared with the general population. HL survivors demonstrate the highest risk of subsequent malignancies (8.7-fold compared with the general population). Treatment with RT and specific chemotherapeutic agents is associated with increased risk of subsequent malignancies; female sex, older age at diagnosis, and earlier treatment era modify that association. Breast cancer is the most common subsequent malignancy, followed by thyroid cancer.²¹⁹ Subsequent malignancies are the leading cause of nonrelapse late mortality.²²⁰ The risk of subsequent malignancies remains elevated for more than 20 years from diagnosis of the primary cancer. Multiple subsequent neoplasms are common among aging survivors of childhood cancer. Cumulative incidence of a second subsequent malignancy was reported as 47% at 20 years after the first SMN. A first SMN of NMSC identifies a population at high risk for a subsequent invasive SMN.²²¹

The magnitude of risk for subsequent malignant neoplasms after HCT ranges from fourfold to 11-fold that of the general population. Several host and clinical factors are associated with an increased risk for subsequent malignant neoplasms after HCT. These include age at HCT, pre-HCT exposure to chemotherapy and radiation, exposure to TBI as part of conditioning, infection with oncogenic viruses (Epstein-Barr virus and hepatitis B and C viruses), prolonged immunosuppression after HCT, autologous versus allogeneic HCT, and original cancer.

The cumulative incidence of solid tumors after allogeneic HCT ranges from 7% to 11% at 15 years posttransplantation.^{222–225} The magnitude of risk of solid tumors exceeds twofold that of an age-matched and sex-matched general population; the risk reaches threefold among patients followed for 15 or more years after HCT. Solid tumors are unequivocally related to the RT used to treat the primary cancer, typically have a long latency, and the risk is high among those exposed to irradiation at a young age. Thus among patients exposed to radiation at an age less than 30 years, the risk is ninefold that of the general population, whereas for those older than 30 years it approaches that of the general population. Solid tumors commonly seen after HCT include melanoma, cancers of the oral cavity and salivary glands, brain, liver, cervix, thyroid, breast, bone, and connective tissue.

t-MDS/AML is the major cause of nonrelapse mortality in patients undergoing autologous HCT for patients with a primary diagnosis of HL or NHL.^{226,227} The cumulative probability of t-MDS/AML ranges from 1.1% at 20 months to 24.3% at 43 months after autologous HCT, with a median latency of 12–24 months after HCT (range: 4 months to 6 years). Using the World Health Organization classification, two types of t-MDS/AML are recognized, related closely to the therapeutic exposure: alkylating agent/radiation and topoisomerase II inhibitor.²²⁸ The alkylating agent-related t-MDS/AML typically develops 4–7 years after exposure. Cytopenias are common. Roughly 65% of the patients present with myelodysplasia; the remaining present with AML but carry myelodysplastic features.

Abnormalities involving chromosomes 5 (-5/del[5q]) and 7 (-7/del[7q]) are frequently seen. AML secondary to topoisomerase II inhibitors presents as overt leukemia, without a preceding myelodysplastic phase. The latency is brief, ranging from 6 months to 5 years, and is associated with balanced translocations involving chromosome bands 11q23 or 21q22.

Subsequent Malignancies Among Survivors of Acute Lymphoblastic Leukemia

Evaluation of large cohorts of patients with childhood ALL entered on Children's Oncology Group therapeutic trials have shown that the cumulative incidence of second and subsequent malignancies approaches 4% at 15 years from diagnosis of ALL.²²⁹⁻²³¹ CNS tumors, the most common subsequent malignancy observed among survivors of childhood ALL, are predominantly associated with exposure to cranial irradiation.²³² Histologically, radiation-related late-occurring neoplasms include high-grade gliomas (glioblastomas and malignant astrocytomas), peripheral neuroectodermal tumors, ependymomas and meningiomas, and basal cell carcinomas (BCCs).^{229,230,233,234} Other commonly reported subsequent malignancies among ALL survivors include thyroid cancer and t-MDS/AML. Secondary thyroid malignancies are generally associated with radiation exposure to the thyroid gland as part of CNS irradiation, either prophylactic or for treatment of CNS leukemia. Thyroid malignancy has been reported to represent between 6% and 17% of secondary cancers among large cohorts of ALL survivors^{229,230,232} and typically develops 10 or more years from treatment. The risk of t-MDS/AML after therapy for ALL is generally low, except among those patients treated with epipodophyllotoxin therapy, where a cumulative risk of 3.8% at 6 years has been reported.²³⁵ Therapy-related AML associated with topoisomerase II inhibitors is characterized typically by a shorter latency period (3–5 years from therapeutic exposure) than that seen for t-MDS/AML after alkylating agents, lack of a myelodysplastic phase, and the presence of 11q23 rearrangements with mutations in the mixed-lineage leukemia (*MLL*) gene. Epipodophyllotoxin-associated secondary AML depends more on the schedule of drug administration than total cumulative dose.²³⁶

Subsequent Malignancies Among Survivors of Hodgkin Lymphoma

Survivors of HL demonstrate the highest risk for subsequent malignancies. This is particularly true for patients treated in the earlier eras with predominantly radiation-based therapies; these patients are at 10-fold increased risk when compared with the general population.²³⁷ A number of studies, with cohorts ranging from 499 to 5925 HL patients, have reported the cumulative incidence of second malignancies to range from 7.6% at 20 years to 18.0% at 30 years.^{232,238-242} The sex difference in a 30-year cumulative incidence of any SMN of 10.9% among males and 26.1% in females ($p < .001$) is driven by the incidence of invasive breast cancer.²⁴²

Early studies of HL identified the increased risk for t-MDS/AML among patients treated with MOPP-based therapy, which included mechlorethamine and cyclophosphamide.^{243,244} These alkylating agent-associated t-MDS/AMLs are characterized by a relatively short latency period, presence of chromosomal abnormalities involving chromosomes 5 and/or 7, and are often preceded by a phase of myelodysplasia. The risk for t-MDS/AML usually does not extend beyond the first 10–15 years after therapeutic exposure. Extended follow-up studies of early cohorts have already reported excess risks for lung and gastrointestinal cancers.^{237,245-248} More recent studies, with longer follow-up of cohorts, demonstrate that the most frequently observed solid second malignancies include breast cancer, thyroid cancer, and bone/soft tissue sarcomas.^{237,248-250} Compared with the general US population, SIRs are highest for bone cancer 22.3 (95% CI: 10.0–49.6), thyroid cancer 17.6, and breast cancer 17.0 per 10,000 person-years, respectively. Cumulative incidence of

invasive breast SMN at 30 years after diagnosis is 18.3%, with no apparent plateau in incidence within the cohort at this time.²⁴²

With extended follow-up of cohorts of young HL survivors, increased risks for common adult carcinomas, including colorectal, lung, and stomach, have emerged, and these cancers are being diagnosed at younger ages than observed in the general population.²³⁷ In a large population-based study of solid tumor risk among 18,862 5-year survivors reported to 13 registries, breast, lung, and gastrointestinal cancers accounted for almost two-thirds of the estimated excess number of cases.²⁵¹

Subsequent Breast Cancer

Breast cancer is the most common solid SMN after HL, largely due to chest radiation for treatment of HL. The risk of radiation-related breast cancer among female HL survivors ranges from 25-fold to 55-fold that of the general population.* For female HL patients treated with chest radiation at less than 16 years of age, the cumulative incidence of breast cancer approaches 20% by age 45 years.^{237,242}

The latency after chest radiation ranges from 7 to 10 years, and the risk of breast cancer increases in a linear fashion with radiation dose, with an estimated RR of 6.4 at a dose of 20 Gy and 11.8 at a dose of 40 Gy.^{242,258} Moreover, 40% of identified cases were found to have developed contralateral disease. Among women treated for childhood cancer with chest RT, those treated with whole-lung irradiation have a greater risk of breast cancer than previously recognized, demonstrating the importance of radiation volume.²⁵⁹ There appears to be a protective effect of early menopause either because of alkylating agents or radiation dose above 5 Gy to the ovaries, suggesting that ovarian hormones play an important role in promoting tumorigenesis once an initiating event has been produced by radiation.^{257,258,260} The 25-year cumulative incidence of breast cancer is reported to be 11% after allogeneic HCT.²⁶¹ Allogeneic HCT survivors are at a 2.2-fold increased risk for developing breast cancer when compared with an age and sex-matched general population. The median latency from HCT to diagnosis of breast cancer is 12.5 years. The incidence is higher among those exposed to TBI (17%) than among those who did not receive TBI (3%). The risk is increased among those exposed to TBI at a younger age. The substantially increased RRs of breast cancer observed at 10–20 years postdiagnosis are not sustained into ages at which the risk of breast cancer in the general population becomes substantial; among women who survived to an age of at least 50 years, there is currently no evidence of an increased risk of breast cancer compared with the general population.²⁶² Importantly, mortality associated with breast cancer after childhood cancer is substantial; breast cancer–specific mortality at 5 and 10 years was 12% and 19%, respectively.²⁵⁹

Travis et al²⁶³ developed estimates of cumulative absolute risk for use in counseling patients. For example, the cumulative absolute risks for an HL survivor who was treated at age 25 years with a chest radiation dose of 40 Gy or more without alkylating agents were estimated to be 1.4% after 10 years, 11% after 20 years, and 29% after 30 years.

Subsequent Thyroid Cancer

Thyroid cancer is observed after neck radiation for HL, ALL, and brain tumors, and after TBI for HCT.^{219,232,264} The risk of thyroid cancer has been reported to be 18-fold that of the general population.⁹⁵ RT at a young age is the major risk factor for the development of thyroid cancer. A linear dose–response relationship between thyroid cancer and radiation is observed up to 20 Gy, with a decline in the OR at higher doses, demonstrating evidence for a cell kill effect.^{265,266} Female sex, younger age at exposure, and longer time since exposure are significant modifiers of the radiation-related risk

*References 219, 232, 237, 238, 248, 249, 252–257.

of thyroid cancer.²⁶⁷ Thyroid cancer develops after a latency of 8.5 years and is associated with an excellent outcome.

Subsequent Central Nervous System Tumors

Meningiomas and gliomas develop after cranial radiation for management of CNS disease among ALL or NHL patients. Gliomas occurred a median of 9 years from the original diagnosis; for meningiomas, the latency is 17 years. For gliomas, the excess RR per Gy was highest among children exposed at less than 5 years of age. The overall SIR was 8.7 for the gliomas, and the excess absolute risk was 1.9 per 1000 person-years.^{219,230,232,268–272} The risk for second brain tumors demonstrates a linear relation with radiation dose; the dose–response appears weaker for gliomas than for meningiomas.^{268,269,273} Possible effects of chemotherapy on the risk of second brain tumors have also been described by some.²⁶⁹ Increased exposure to intrathecal methotrexate significantly increases risk of meningioma.²⁷³

Therapy-Related Myelodysplastic Syndrome/Acute Myeloid Leukemia

Several studies have described an increased risk for t-MDS/AML after autologous HCT, particularly for HL or NHL; pretransplantation therapy with alkylating agents, topoisomerase II inhibitors, and RT; use of peripheral blood hematopoietic cells; stem cell mobilization with etoposide; difficult stem cell harvests; conditioning with TBI; number of CD34⁺ cells infused; and a history of multiple transplants.^{224,226} Thus t-MDS/AML after autologous HCT is the result of cumulative toxicity that includes pre-HCT chemotherapy (alkylators and topoisomerase II inhibitors), topoisomerase II inhibitors used for stem cell mobilization, and transplantation-related conditioning. The diagnosis of t-MDS/AML after autologous HCT confers a uniformly poor prognosis, with a median survival of 6 months in patients treated with conventional chemotherapy.

Subsequent Skin Cancer

Among allogeneic HCT recipients, the incidence of BCCs is 6.5% at 20 years, whereas the incidence for squamous cell carcinoma (SCC) is 3.4%.²⁷⁴ TBI increases the risk for BCC, especially in younger patients. SCC risk is increased among patients with acute GVHD, whereas chronic GVHD is associated with both BCC and SCC.²⁷⁵ Immunologic alterations predispose patients to SCC of the buccal cavity particularly, hence the association with chronic GVHD.²⁷⁴ In patients with prolonged immunosuppression, oncogenic viruses such as human papillomavirus contribute to SCC of the skin and buccal mucosa.²⁷⁴ BCC is one of the most frequent SMNs in childhood cancer survivors.^{219,276} Childhood cancer survivors are at a fivefold increased risk of NMSC compared with the general population.²⁷⁷ Ninety percent of patients have previously received RT; 90% of tumors occur within the radiation field. Radiation is associated with a sixfold increase in risk.²⁷⁸

Recommendations for Screening and Follow-Up

The elevated risk of breast cancer noted among survivors of childhood and adolescent cancers supports the importance of evidence-based screening guidelines for this high-risk group.²⁵² Because outcome after breast cancer is closely linked to stage at diagnosis, close surveillance resulting in early diagnosis should confer survival advantage. Mammography, the most widely accepted screening tool for breast cancer in the general population, may not be the ideal screening tool by itself for radiation-related breast cancers, occurring in relatively young women with dense breasts, hence the American Cancer Society recommends including adjunct screening with magnetic resonance imaging.²⁷⁹ Thus the following are recommendations

for females who received radiation with potential impact to the breast (i.e., radiation doses of 20 Gy or higher to the mantle, mediastinal, whole lung, and axillary fields): monthly breast self-examination beginning at puberty; annual clinical breast examinations beginning at puberty until age 25 years; and a clinical breast examination every 6 months, with annual mammograms and magnetic resonance images beginning 8 years after radiation or at age 25 years (whichever occurs later). Females who received TBI or cumulative chest radiation doses of 10–19 Gy should be counseled regarding the benefits and risks/harms of screening; if a decision is made to screen, the same recommendations apply as for those women who received radiation doses of 20 Gy or higher.⁸² Screening of those at risk for early-onset colorectal cancer (i.e., radiation doses of ≥30 Gy to the abdomen, pelvis, or spine) should include colonoscopy every 5 years beginning at age 35 years or 10 years following radiation (whichever occurs last).⁸² Joint recommendations for monitoring long-term survivors of HCT by the EBMT/CIBMTR/ASBMT suggest that all recipients of HCT should be advised of the risks for subsequent malignancies and encouraged to perform screening self-examinations, such as breast and skin examinations. All patients should be advised to avoid high-risk behaviors, including avoidance of tobacco or excessive unprotected exposure of skin to ultraviolet light.⁸³

Late Mortality

Childhood cancer survivors remain at risk for disease-associated and treatment-associated late mortality, and the excess mortality persists long after diagnosis.^{220,280,281} Overall mortality among survivors has been described to be eightfold that of the general population. Recurrent disease is the most common cause of premature death. Increases in cause-specific mortality are seen for deaths due to SMNs, cardiac, and pulmonary causes. Extended follow-up of these cohorts demonstrates changing patterns of cancer-specific mortality with increasing time from diagnosis.^{27,280} Thus excess risk for deaths from recurrence declines with time, while the excess risk for deaths from SMNs and cardiovascular causes increases; subsequent to 45 years from diagnosis, recurrence accounted for only 7% of the excess number of deaths while SMNs and cardiovascular causes accounted for 51% and 26% of the excess number of deaths respectively.²⁸⁰ Childhood cancer survivors are at a 15-fold increased risk of SMN-related deaths, 8.8-fold increased risk of pulmonary deaths, and 7-fold increased risk of death due to cardiac causes when compared with the general population.²²⁰ The high burden of morbidity carried by HCT recipients can result in premature death. Mortality rates are fourfold to ninefold higher than in the expected population for at least 30 years following HCT, producing an estimated lower life expectancy of 30% compared with the general population, regardless of current age.²⁸² Relapse of primary disease and chronic GVHD are the main causes of premature death. Nonrelapse-related mortality is greater among patients who are over 18 years of age when undergoing HCT, as well as among those with chronic GVHD. Compared with the general population, allogeneic HCT recipients are 3.6 times more likely to die of SMNs, 15.1 times more likely to die of pulmonary complications, and 2.3 times more likely to die of a cardiac compromise. However, the conditional survival probability at 10–20 years after allogeneic HCT exceeds 80% for those individuals who were alive and disease free 2–5 years after HCT.^{283,284} On the other hand, autologous HCT recipients demonstrate a conditional 5-year survival that approaches 75% among those who have survived 2 or more years and approaches 90% among those who have survived 10 years after HCT. Among those who survive the first 10 years, nonrelapse-related mortality exceeds relapse-related mortality.²⁸⁵ Primary disease and subsequent malignancies are the most common cause of death.²²⁷

Psychosocial Effects

Survivors of hematopoietic malignancies are at risk for adverse psychosocial outcomes that may affect their overall quality of life,

including anxiety, depression, posttraumatic stress disorder, and barriers to accessing the healthcare system because of problems obtaining health insurance coverage. The impact of cancer therapy on psychosocial functioning is dependent on many variables, including intensity and duration of therapy, treatment-related complications, family functioning, developmental processes, and treatment-specific sequelae such as altered cognitive or physical functioning.²⁸⁶

Results from an analysis of 5736 long-term survivors of childhood leukemia and lymphoma demonstrated that although a relatively low proportion reported symptoms indicative of depression (4.6%) and somatic distress (10.8%), they were significantly more likely to report these symptoms when compared with sibling controls.²⁸⁷ In a study of 6542 childhood cancer survivors (55% of whom were survivors of leukemia/lymphoma), the risk for posttraumatic stress disorder was increased by 4.6-fold, 4.1-fold, and 3.8-fold for survivors of HL, NHL, and leukemia respectively, compared with sibling controls; increased risk was associated with lower educational level (high school or less), lower income (<\$20,000 annually), being unmarried, being unemployed, and having had more intensive treatment.²⁸⁸ Long-term survivors of adult-onset HL report poorer health-related quality of life, primarily in physical health, when compared with a healthy general population.²⁸⁹ Survivors of HL also appear to be at increased risk for psychosocial distress when compared with acute leukemia survivors; areas of greatest impact for these patients include impaired family and sexual functioning.²⁹⁰ There is growing interest in the reported occurrences of fatigue and sleep disturbances among cancer survivors, particularly those with HL,^{291–293} which may contribute to depression.

Fatigue, psychological distress, psychiatric symptoms, mood disturbances, and sexual difficulties are commonly reported by HCT survivors.²⁹⁴ Risk factors for impaired health-related quality of life include older age, advanced disease at transplantation, presence of chronic GVHD, and lower level of education. Fatigue and sleep disturbances have been reported in up to 65% of the patient cohorts studied,²⁹⁵ and sexual disturbances are prevalent in 25% of HCT survivors²⁹⁶ (see box on *Evaluating Survivors for Potential Late Effects*).

POTENTIAL LATE EFFECTS BY DIAGNOSIS

Therapeutic approaches to hematologic malignancies vary widely depending on the patient's age at diagnosis, biologic subtype and staging of disease, year (era) of diagnosis, initial response to therapy, and physician/institutional preference. Even though two patients may share an identical diagnosis, their risks for late effects may differ

Evaluating Survivors for Potential Late Effects

To diminish the incidence and severity of untoward late effects and to improve the quality of survival for patients with hematopoietic malignancies, systematic evaluation of outcomes with subsequent modification of current and future therapies is required. To decrease late morbidity and mortality rates and to meet the specialized healthcare needs of this group of patients, ongoing comprehensive follow-up care with attention to early detection and intervention for late effects are essential.

Patients are generally eligible to enter formal long-term follow-up care when the risk for relapse of their primary disease is minimal. For most hematologic malignancies, this occurs when a patient is at least 2 years off therapy. When a patient enters long-term follow-up, the focus of care shifts from vigilant surveillance for disease recurrence to a survivorship model of health maintenance or promotion and management of treatment-related late effects. Effective management of these late effects requires ongoing surveillance, early intervention, and when possible, prevention.

The long-term complications of treatment for which an individual survivor is at risk are determined by several factors, including the patient's diagnosis, age at treatment, specific chemotherapeutic agents received (including cumulative doses), specific radiation fields and doses, therapy-related complications, degree of psychosocial support received, genetic predisposition, and current health-related behaviors (e.g., diet, physical activity, tobacco, and alcohol use).

significantly because of differences in therapy, age at exposure to therapy, or pharmacogenetics. General associations of late effects with conventional treatment for common hematologic malignancies are reviewed in [Tables 93.1–93.3](#). The risk for specific late effects in survivors who have undergone HCT depends on the conditioning regimen, donor source, complications experienced during the transplantation process, presence or absence of GVHD, and prior cancer therapy. Transplantation-related sequelae have been reviewed throughout the text of this chapter.

Acute Lymphoblastic Leukemia

ALL is a heterogeneous disease. Therapy for ALL ranges from a relatively innocuous, antimetabolite-based approach for low-risk childhood ALL²⁹⁷ to marrow-ablative therapy followed by HCT for very high-risk disease in all age groups.^{298,299} The risk for long-term complications for individual survivors varies widely and is dependent on the specific therapy received as well as the patient's age at time of treatment.^{300,301} Potential late effects that may occur as a consequence of conventional therapy for ALL are listed in [Table 93.1](#).

Acute Myeloid Leukemia

Therapy for AML is generally more intense and of shorter duration than that used for treatment of ALL. Higher doses of anthracycline chemotherapy are often employed, as is consolidation therapy

TABLE 93.1

Late Effects Associated With Conventional Therapy for Acute Lymphoblastic Leukemia and Non-Hodgkin Lymphoma

Common Therapeutic Exposures	Potential Late Effects
Vincristine	Peripheral neuropathy, Raynaud phenomenon
Corticosteroids	Cataracts, osteopenia, osteoporosis, avascular necrosis
Asparaginase	No known late effects
Mercaptopurine	Hepatic dysfunction (rare)
Thioguanine	Portal hypertension, hepatotoxicity (when used continuously in maintenance therapy)
Methotrexate (systemic)	Osteopenia, osteoporosis, osteonecrosis, renal dysfunction (rare), hepatic dysfunction (rare)
Methotrexate (intrathecal, high dose), or cytarabine (high dose)	Neurocognitive deficits, clinical leukoencephalopathy
Cranial or craniospinal irradiation	Neurocognitive deficits, clinical leukoencephalopathy, cataracts, hypothyroidism, second malignant neoplasm in radiation field (e.g., skin, thyroid, brain), short stature, scoliosis or kyphosis, obesity
Anthracyclines	Cardiomyopathy, arrhythmias, subclinical left ventricular dysfunction, secondary AML
Cyclophosphamide	Hypogonadism, hemorrhagic cystitis, dysfunctional voiding, bladder malignancy, secondary AML or MDS
Blood products	Chronic viral hepatitis, HIV

AML, Acute myeloid leukemia; HIV, human immunodeficiency virus; MDS, myelodysplastic syndrome.

TABLE 93.2 Late Effects Associated With Conventional Therapy for Acute Myeloid Leukemia

Common Therapeutic Exposures	Potential Late Effects
Anthracyclines	Cardiomyopathy, arrhythmias, subclinical left ventricular dysfunction, secondary acute myeloid leukemia
Corticosteroids	Cataracts, osteopenia, osteoporosis, avascular necrosis
Asparaginase	No known late effects
Cytarabine (high dose)	Neurocognitive deficits, clinical leukoencephalopathy
Blood products	Chronic viral hepatitis, human immunodeficiency virus infection

TABLE 93.3 Late Effects Associated With Conventional Therapy for Hodgkin Lymphoma

Common Therapeutic Exposures	Potential Late Effects
Anthracyclines	Cardiomyopathy, arrhythmias, subclinical left ventricular dysfunction, secondary AML or MDS
Corticosteroids	Cataracts, osteopenia, osteoporosis, avascular necrosis
Bleomycin	Pulmonary dysfunction
Vincristine, vinblastine	Peripheral neuropathy, Raynaud phenomenon
Procarbazine, mechlorethamine, dacarbazine	Hypogonadism, infertility, secondary AML or MDS
Cyclophosphamide	Hypogonadism, infertility, hemorrhagic cystitis, dysfunctional voiding, bladder malignancy, secondary AML or MDS
Mantle irradiation	Hypothyroidism, premature cardiovascular disease, cardiac valvular disease, cardiomyopathy, arrhythmias, carotid artery disease, scoliosis or kyphosis, second malignant neoplasm in radiation field (e.g., thyroid, breast), pulmonary dysfunction
Inverted Y irradiation	Hypogonadism, infertility, adverse pregnancy outcome, second malignant neoplasm in radiation field (e.g., gastrointestinal)
Splenectomy	Acute life-threatening infections
Blood products	Chronic viral hepatitis, HIV

AML, Acute myeloid leukemia; HIV, human immunodeficiency virus; MDS, myelodysplastic syndrome.

with HCT.^{301,302} Typically patients with AML receive less CNS-directed therapy than those with ALL. Examples of potential late effects associated with conventional therapy for AML are listed in Table 93.2.

Hodgkin Lymphoma

Therapy for HL relies on the use of alkylating agents, antitumor antibiotics (including anthracyclines and bleomycin), corticosteroids, and RT. Some patients may be aplenic as a consequence of the staging procedures performed in the earlier era.³⁰³ Examples of potential late effects associated with conventional therapy for HL are listed in Table 93.3.

Late Effects Research: What Is Needed

Medical Issues Faced by This Population

- Premature death.
- Second malignancies.
- Organ dysfunction (e.g., cardiac, pulmonary, gonadal).
- Impaired growth and development.
- Decreased fertility.
- Neurocognitive impairment.
- Difficulties obtaining employment and insurance.
- Overall reduced quality of life.

Issues to Be Considered by Physicians Providing Care to This Population

- Providing long-term follow-up care for cancer survivors.
- Models of care delivery.
- Guidelines for ongoing screening and management.

Major Clinical and Research Challenges

- Cancer survivorship research continually changing because of new;
 - Therapeutic agents or combinations of agents (including targeted therapies).
 - Radiation oncology techniques.
 - Surgical procedures.
 - Supportive care techniques.

Future Directions

- Research is needed to;
 - More clearly define survivors at greatest risk for specific outcomes.
 - Identify genetic predispositions to certain key outcomes and the role of gene–environment interactions.
 - Identify the role of lifestyle choices (e.g., alcohol, tobacco, diet, exercise) in modification of risks for late adverse outcomes.
 - Understand the potential long-term impact of cancer therapy in order to effectively counsel survivors.
 - Develop effective intervention strategies to prevent or minimize the impact of adverse late effects.
 - Develop scientifically valid, evidence-based recommendations for clinical follow-up of survivors, which should include screening for potential late effects and application of proven approaches for health promotion.
- Much of the current information available relates to outcomes within the first decade after treatment, and only minimal data address the longer term outcomes that may subsequently occur. Large sample sizes within the context of well-characterized cohorts with complete long-term follow-up remain the greatest challenge to sound survivorship research.

Non-Hodgkin Lymphoma

The potential late effects after therapy for NHL are therapy specific and similar to those experienced by survivors of ALL (see Table 93.1).³⁰³ Those patients whose treatment included HCT are also at risk for transplantation-related sequelae.

Chronic Myeloid Leukemia

Long-term survivors of CML have usually either undergone HCT or are receiving tyrosine kinase inhibitors long term. Among HCT recipients, there is a significant risk for late effects as a result of the transplantation-conditioning regimen, as well as treatment for and sequelae of GVHD.¹⁷ With the transition in the early 2000s to tyrosine kinase inhibitor therapy for CML as the predominant treatment modality, the long-term effects of these agents will need to be studied in detail in the growing cohort of CML survivors³⁰⁴ (see box on Late Effects Research: What Is Needed and the section Providing Clinical Care to Survivors).

PROVIDING CLINICAL CARE TO SURVIVORS

A summary of cancer treatment and a survivorship care plan are critical components of care provision for survivors of hematologic malignancies (see box on [Survivorship Care Plans](#)). Guidelines for long-term follow-up of survivors of hematologic malignancies and those who underwent HCT in childhood, adolescence, or young adulthood have been developed by the Children's Oncology Group⁸² and are available at <http://www.survivorshipguidelines.org>; HCT long-term follow-up guidelines have also been developed by an international group of transplant experts.⁸³ In order to provide risk-based guideline-directed follow-up care, a comprehensive treatment summary is needed (Table 93.4) and a copy should be given to each survivor with instructions to share this information with all healthcare providers. Survivors should undergo annual comprehensive, multi-disciplinary health evaluations (Fig. 93.1) with special attention to the detection of potential late effects specific to the patient's diagnosis and treatment history (Table 93.5). Because certain late effects have prolonged asymptomatic intervals before becoming clinically evident (e.g., late-onset CHF as a result of anthracycline-induced cardiomyopathy), ongoing evaluation is important to identify and provide early intervention for these potential complications. Health education regarding potential health risks and risk-reduction measures should be provided to each survivor. Targeted health education materials related to potential late complications of therapy during childhood, adolescence, or young adulthood have been developed by the Children's Oncology Group³⁰⁵ and are available at <http://www.survivorshipguidelines.org>. After completion of each annual evaluation, identified late effects should be systematically recorded, and recommendations for any additional testing and for health maintenance and promotion should be shared with the patient and his or her primary healthcare provider. To optimize future follow-up care for all survivors, patients should be invited to participate in any relevant research studies for which they are eligible (see box on [Late Effects Research: What Is Needed](#)).

FUTURE DIRECTIONS

Better understanding of treatment-related toxicity has not only guided the design of less toxic therapies, but also the development of

Survivorship Care Plans

Survivorship care plans have been identified by the Institute of Medicine^{309,310} as an important tool to facilitate follow-up care. Survivorship care plans should include both a summary of cancer treatment and a follow-up plan that can be used to enhance communication between care providers, coordinate care, and encourage health monitoring and promotion.³⁰⁶ Specific elements of the survivorship care plan should include:

- Diagnosis, including histologic subtype and stage if relevant.
- Contact information for all cancer care providers and institutions where care was received.
- Surgical procedure(s) with dates.
- Chemo/biotherapy drugs received and completion dates for each.
- Radiation treatment dates with anatomical area(s) treated.
- Ongoing toxicities or treatment side effects.
- Genetic/hereditary risk factors or predisposing conditions, if relevant, including genetic testing results if performed.
- List of potential late and/or long-term effects.
- List of possible symptoms of cancer recurrence and surveillance testing schedule.
- Follow-up visit schedule, including who will provide care, and schedule of recommended screening/testing as indicated.
- Recommendations regarding general health maintenance/promotion.
- Information regarding common survivorship issues (e.g., emotional, financial, work/employment).

TABLE 93.4

Comprehensive Treatment Summary

Topic	Specific Information to Include
Demographics	Name Record number or patient identification number Date of birth Sex Race or ethnicity
Diagnosis	Date or age at diagnosis Referring physician or institution Treating physician or institution Presenting symptoms Past medical history Family history (including cancer in first- or second-degree relatives) Physical examination findings at presentation Initial diagnostics (complete blood cell count, chemistry panel, radiographic studies) Diagnostic procedures (biopsies, cytologic studies) Pathology (morphology, histology, cytochemistry, flow cytometry) Cytogenetics Central nervous system status (if applicable) Stage (if applicable) Metastatic sites (if applicable) Initial response to therapy (e.g., RER, SER, date first complete remission achieved) Relapse(s) dates, age at relapse(s), relapse site(s)
Treatment	Date of initial treatment (initiated and completed) Date(s) for treatment of relapse (initiated and completed) Final off-therapy date Chemotherapy agents received, including route of administration (list all) Cumulative doses (in mg/m ²) and age at treatment for all alkylators, anthracyclines, and heavy metals Dose ranges for cytarabine and methotrexate (e.g., standard dose vs. high dose >1000 mg/m ²) Radiation fields, doses, shielding, age at treatment Surgical procedure(s) Transfusion(s), including all blood or serum products Stem cell transplantation(s), including donor source, preparative regimen, GVHD prophylaxis or treatment
Acute complications	Significant therapy-related complications (e.g., tumor lysis, septic shock, typhilitis, acute GVHD) Significant treatment required for complications (e.g., hemodialysis, amphotericin, aminoglycosides)
Complications after therapy	Significant complications after completion of therapy (e.g., herpes zoster, acute life-threatening infection after splenectomy)

GVHD, Graft-versus-host disease; RER, rapid early response; SER, slow early response.

Fig. 93.1 ANNUAL COMPREHENSIVE MULTIDISCIPLINARY HEALTH EVALUATION FOR THE CANCER SURVIVOR.

TABLE 93.5 Monitoring for Potential Late Effects

Potential Late Effects	Therapeutic Exposure	Recommended Monitoring	Suggested Interventions
Adverse psychosocial effects (e.g., depression, anxiety, posttraumatic stress disorder, limitations in healthcare access, risky behaviors, psychosocial disability due to pain, fatigue)	Diagnosis and treatment for hematologic malignancy	Clinical interview: yearly	Psychologic or social work consultation if indicated
Dental abnormalities (abnormal tooth development, increased susceptibility to caries and gum disease)	Chemotherapy Cranial irradiation TBI	Dental examination: every 6 months	Professional dental cleaning every 6 months; use of fluoridated toothpaste; topical fluoride applications as indicated; Panorex radiograph before orthodontic or dental procedures for patients treated before completion of tooth development
Peripheral neuropathy Raynaud phenomenon	Vincristine Vinblastine	Neurologic examination if symptomatic	Physical therapy if indicated; advise patient to protect against precipitating factors (e.g., cold environment)
Neurocognitive deficits	Methotrexate (intrathecal, high-dose systemic) Cytarabine (high-dose systemic) Cranial irradiation TBI	Formal neuropsychologic testing: baseline on entry to long-term follow-up; repeat as clinically indicated if evidence of impaired performance Clinical interview yearly, including assessment of educational and vocational progress	Referral for specialized educational services, curricular modifications, or vocational training programs if indicated

**TABLE
93.5****Monitoring for Potential Late Effects—cont'd**

Potential Late Effects	Therapeutic Exposure	Recommended Monitoring	Suggested Interventions
Clinical leukoencephalopathy	Methotrexate (intrathecal, high-dose systemic) Cytarabine (high-dose systemic) Cranial irradiation	Clinical evaluation: yearly Brain MRI or CT if clinically indicated	Neurology consultation if clinically indicated
Cataracts	Corticosteroids Busulfan Cranial irradiation TBI	Funduscopy examination and visual acuity evaluation: yearly Ophthalmologic examination: yearly for patients who received TBI or cranial radiation ≥ 30 Gy; every 3 years for cranial radiation < 30 Gy	Ophthalmology consultation if abnormalities detected
Xerophthalmia	Chronic GVHD related to HCT	History and eye examination yearly	Artificial tears, ophthalmology consultation if indicated
Xerostomia	Cranial irradiation Chronic GVHD related to HCT	Dental evaluation: every 6 months	Meticulous oral hygiene Artificial saliva products if indicated
Hearing loss	Platinum chemotherapy Aminoglycoside antibiotics Cranial irradiation	History and physical examination: yearly Audiogram: baseline at entry into long-term follow-up, then as clinically indicated; every 5 years if cranial radiation dose ≥ 30 Gy	Audiology consultation if indicated
Hypothyroidism Thyroid nodules Thyroid malignancy	Cranial, cervical, spinal, mantle, or mediastinal irradiation; TBI	Free T ₄ , TSH, thyroid examination: yearly	Endocrine or surgical referral as indicated
Cardiomyopathy Arrhythmias Subclinical left ventricular dysfunction	Anthracyclines Chest or thoracic irradiation (e.g., mantle, mediastinal)	Detailed history of exertional tolerance (e.g., dyspnea on exertion, chest pain): yearly ECG (for evaluation of QT interval): baseline on entry into long-term follow-up; ECHO: baseline on entry into long-term follow-up, then every 1–5 years as indicated based on age at therapy and total anthracycline or radiation dose	Cardiology consultation if indicated; additional cardiology evaluation of patients who are pregnant or planning to become pregnant if patient received ≥ 300 mg/m ² of an anthracycline, radiation dose ≥ 30 Gy, or any dose of anthracycline combined with irradiation
Pericarditis Pericardial fibrosis Valvular disease Premature atherosclerotic heart disease	Chest or thoracic irradiation (e.g., mantle, mediastinal)	Consider cardiology consultation 5–10 years after irradiation to evaluate risk for coronary artery disease in patients who received doses ≥ 40 Gy Fasting glucose or hemoglobin A1c and lipid profiles: every 2 years	Cardiology consultation if indicated; additional cardiology evaluation in patients who are pregnant or planning to become pregnant if patient received anthracycline combined with radiation, ≥ 300 mg/m ² anthracycline, or radiation dose ≥ 30 Gy
Pulmonary dysfunction (fibrosis, interstitial pneumonitis)	Bleomycin Busulfan Chest/thoracic irradiation TBI Chronic GVHD related to HCT	Pulmonary function testing: baseline at entry into long-term follow-up and as clinically indicated for patients with progressive dysfunction	Pulmonary consultation for symptomatic patients; influenza and pneumococcal vaccine; counsel patients to avoid smoking and avoid scuba diving
Thrombosis Vascular insufficiency Infection of retained cuff or line tract	Central venous catheter	History and physical examination: yearly as clinically indicated	Surgical referral as indicated
Hepatic dysfunction	Mercaptopurine, thioguanine, methotrexate (systemic), HCT	ALT, AST, bilirubin: baseline on entry into long-term follow-up; repeat if clinically indicated	If abnormal results for baseline studies, obtain prothrombin time (to assess hepatic synthetic function) and viral hepatitis screening
Chronic viral hepatitis	Blood products	Hepatitis C antibody and HCV RNA by PCR: once if transfused before universal screening of blood supply (1992 in the United States) Hepatitis B surface antigen and core antibody: once if transfused before universal screening of blood supply (1972 in the United States)	Gastroenterology or hepatology consultation and annual AFP for patients with chronic hepatitis; hepatitis A and B immunizations in patients lacking immunity

Continued

TABLE 93.5 Monitoring for Potential Late Effects—cont'd

Potential Late Effects	Therapeutic Exposure	Recommended Monitoring	Suggested Interventions
HIV infection	Blood products	HIV-1 and HIV-2 antibodies: once if transfused before universal screening of blood supply (1985 in the United States)	Infectious disease consultation for patients with confirmed infection
Life-threatening infection	Splenectomy Splenic radiation ≥ 40 Gy Chronic active GVHD	Physical examination at time of febrile illness to evaluate degree of illness and for potential source of infection	Counsel patients regarding risk of life-threatening infections and indication for medical alert bracelet Administer parenteral antibiotics and continue close medical observation in patients with temperature $\geq 38.3^{\circ}\text{C}$ (101°F) or other signs of serious infection; immunize with pneumococcal, meningococcal, and Hib vaccines
Iron overload	HCT (and patients requiring multiple red blood cell transfusions)	Serum ferritin: at entry into long-term follow-up	If abnormal, consider chelation, or repeat as clinically indicated until within normal limits
Bowel obstruction Chronic enterocolitis Fistulas and strictures	Abdominal surgery Abdominal or pelvic irradiation Chronic GVHD related to HCT (esophageal strictures, vaginal stenosis)	History and physical examination: yearly and as clinically indicated Serum protein and albumin levels: yearly in patients with chronic diarrhea or fistula	Surgical and gastroenterology consultations as clinically indicated
Renal insufficiency	TBI Abdominal or splenic irradiation Ifosfamide Platinum chemotherapy Methotrexate	Blood pressure: yearly Urinalysis: yearly BUN, creatinine, electrolytes, calcium, magnesium, phosphorus baseline and repeat as clinically indicated	Nephrology consultation for proteinuria, hypertension, progressive renal insufficiency
Hemorrhagic cystitis Bladder fibrosis Dysfunctional voiding Bladder malignancy	Cyclophosphamide Ifosfamide Irradiation of abdomen, pelvis, iliac, inguinal sites	Voiding history: yearly	Urinalysis and urology consultation as clinically indicated for incontinence, dysfunctional voiding, macroscopic hematuria (culture negative)
Growth hormone deficiency	Cranial irradiation TBI	Height, weight: every 6 months during puberty until growth is complete Obtain bone age in poorly growing children	Endocrine referral for patients failing to follow normal growth curve
Overweight/obesity	Cranial irradiation	BP, growth percentile, BMI: yearly	Endocrine referral as indicated
Dyslipidemia	TBI	Lipid profile every 2 years	
Hypogonadism Infertility	Alkylating agents Cranial irradiation Abdominal or pelvic irradiation Testicular irradiation Spinal irradiation >25 Gy TBI	Menstrual history, sexual function, height, weight: yearly Pubertal history, Tanner stage: yearly until maturity FSH, LH, estradiol: baseline at age 13 (females); Testosterone: baseline at age 14 (males); or at entry into long-term follow-up and for clinical symptoms of estrogen or testosterone deficiency Semen analysis: as indicated or requested by patient	Endocrine referral for hypogonadal patients (for hormone-replacement therapy); reproductive endocrinology referral for patients desiring evaluation of fertility options
Precocious puberty	Cranial irradiation	Physical examination, height, weight, Tanner stage: yearly until maturity LH, FSH, estradiol, or testosterone: as clinically indicated in patients with accelerated pubertal progression Obtain bone age in rapidly growing prepubertal children	Endocrine referral as indicated
Adverse pregnancy outcomes (e.g., spontaneous abortion, premature delivery, low-birthweight infant)	Irradiation of abdomen, pelvis, iliac, inguinal, paraaortic sites TBI	History: yearly and as clinically indicated	High-risk obstetric care

TABLE 93.5**Monitoring for Potential Late Effects—cont'd**

Potential Late Effects	Therapeutic Exposure	Recommended Monitoring	Suggested Interventions
Osteopenia, osteoporosis	Corticosteroids Methotrexate (high-dose systemic) HCT	Bone-density study (DEXA scan or quantitative CT scan): baseline at entry into long-term follow-up, repeat as clinically indicated	Calcium and vitamin D supplementation; weight-bearing exercise; treatment of exacerbating conditions (e.g., hypogonadism); consider pharmacologic intervention (e.g., bisphosphonates)
Avascular necrosis	Corticosteroids Methotrexate (systemic) HCT	History: yearly; MRI if clinically indicated	Orthopedic consultation if indicated
Scoliosis/kyphosis	Irradiation of trunk (e.g., mantle, spine, abdomen, pelvis)	Physical examination of spine: yearly (every 6 months during pubertal growth spurt) Radiologic imaging of the spine if clinical evidence of scoliosis or kyphosis	Orthopedic referral
Joint contractures	Chronic GVHD related to HCT	Physical examination yearly	Orthopedic referral if indicated
Chronic infection	Chronic GVHD related to HCT	History: yearly	Prophylactic antiinfective agents; infectious disease consultation if indicated
Vitiligo Scleroderma Joint contractures Nail dysplasia Dysplastic nevi Skin cancer Secondary benign or malignant neoplasms in radiation field	Chronic GVHD related to HCT Irradiation (any field)	Physical examination: yearly Careful physical examination, inspection and palpation of irradiated skin and soft tissues: yearly	Dermatology or rehabilitation consultation if clinically indicated Dermatology or surgical referral and radiographs if indicated for any suspicious lesions
Bone malignancies Brain tumor	Cranial irradiation	History and physical examination: yearly Brain MRI: baseline at maturity for all patients and as clinically indicated	Neurosurgical consultation as indicated
Breast cancer	Chest or thorax irradiation ≥20 Gy (mantle radiation field) TBI or chest or thorax irradiation 10–19 Gy (mantle radiation field)	Clinical breast examination: yearly until age 25, then every 6 months Mammogram and breast MRI: yearly beginning at age 25 or 8 years after irradiation (whichever comes last) Discuss benefits and risks/harms of screening; if decision is made to screen, follow above recommendations	Teach breast self-examination; instruct patient to perform monthly self-examination and report changes immediately; surgical consultation if clinically indicated
Gastrointestinal malignancy	Abdominal, pelvic, spinal irradiation ≥30 Gy	Colonoscopy every 5 years beginning 10 years after radiation or at age 35, whichever comes last; or more frequently as clinically indicated	Surgical consultation if indicated
AML (preceding myelodysplastic phase associated with alkylating agents)	Anthracyclines Epipodophyllotoxins Alkylating agents Stem cell priming with etoposide Autologous transplantation for NHL or Hodgkin lymphoma	Physical examination: yearly for 10 years after therapy CBC and differential and bone marrow evaluation if clinically indicated	Counsel patient to report fatigue, bruising, bleeding, bone pain

AFP, α -Fetoprotein; ALT, alanine aminotransferase; AML, acute myeloid leukemia; AST, aspartate aminotransferase; BMI, body mass index; BP, blood pressure; BUN, blood urea nitrogen; CBC, complete blood cell count; CT, computed tomography; DEXA, dual-energy x-ray absorptiometry; ECG, electrocardiogram; ECHO, echocardiogram; FSH, follicle-stimulating hormone; GFR, glomerular filtration rate; GVHD, graft-versus-host disease; HCT, hematopoietic cell transplantation; HCV, hepatitis C virus; hemoglobin A1c, glycosylated hemoglobin; HIB, *Haemophilus influenzae* type B; HIV, human immunodeficiency virus; LH, luteinizing hormone; MRI, magnetic resonance imaging; NHL, non-Hodgkin lymphoma; PCR, polymerase chain reaction; RNA, ribonucleic acid; T₄, thyroxine; TBI, total body irradiation; TSH, thyroid-stimulating protein.

Modified from Children's Oncology Group: *Long-term follow-up guidelines for survivors of childhood, adolescent, and young adult cancers*, version 4.0, 2013, Children's Oncology Group. <http://www.survivorshipguidelines.org>

treatment summaries,⁸² survivorship plans,³⁰⁶ and efforts to harmonize survivorship guidelines worldwide³⁰⁷ that serve as a model for the survivorship care of adult patients with cancer. It is important that more recent cohorts of cancer survivors continue to be followed to determine how therapy modifications impact the prevalence and spectrum of late effects. It is important to apply known interventions

that can reduce the impact of cancer and treatment-related late effects on quality of life, morbidity, and mortality, as well as to develop and test new interventions. For example, survivors of HL who are treated with chest radiation have an increased risk of developing lung cancer, and tobacco use increases this risk 20-fold. Successful smoking prevention and cessation strategies among survivors can decrease the risk

of this prevalent and highly morbid cancer of adulthood, while also decreasing the development and progression of atherosclerosis and other SMNs. Screening of young women at increased risk of breast cancer due to chest radiation has already been mentioned. Survivors of childhood cancer, particularly those who received radiation to the hypothalamic–pituitary axis, are also at risk of obesity. Obesity can, in turn, exacerbate the increased risks of cardiovascular disease associated with anthracycline chemotherapy and RT to the chest. Modifiable cardiovascular risk factors, such as hypertension, can potentiate the risk of major cardiac events and both behavioral and medical interventions can potentially reduce these risks. Research to define optimal intervention strategies and well-integrated survivorship care models are needed. Execution of these intervention strategies in the setting of clinical trials would permit evaluation of interventions in early detection, leading to a reduction in morbidity and mortality and, ultimately, improvement in the overall quality of life of cancer survivors.

The advantages of studying outcomes in cancer survivors, including detailed knowledge of the therapeutic exposures coupled with close follow-up after these exposures, enables researchers to study testable hypotheses and determine the effects of host and therapy-related factors in the development of adverse outcomes ranging from carcinogenesis and organ dysfunction to psychosocial consequences. Opportunities also exist to explore gene and environment interactions that may modify susceptibility to develop adverse outcomes, thus providing insights into the identification of high-risk populations.

The growing population of cancer survivors carries a significant burden of morbidity, necessitating comprehensive long-term follow-up of these survivors.³⁰⁸ This follow-up should ideally begin at the completion of active therapy, with a documented summarization of therapeutic exposures and recommendations for follow-up, thus ensuring standardization of care received by the survivors.^{306,309,310} However, many barriers prevent effective follow-up, the most fundamental being the lack of knowledge regarding survivorship issues demonstrated by both the long-term survivors and the primary care physicians caring for them. Shortcomings of the healthcare system also pose potential barriers, and include logistical issues such as a lack of capacity within centers, training and educational deficiencies, inadequate communication between pediatric oncologists, and primary care physicians that subsequently provide the large bulk of follow-up. Finally, a major obstacle faced by cancer survivors in the United States has been the difficulty in obtaining affordable health insurance, especially for young adults, which has made it difficult for survivors to seek and obtain appropriate long-term follow-up care. The enactment of the Patient Protection and Affordable Care Act (ACA) in the United States in 2010 included several provisions designed to broaden coverage and potentially transform patterns of health care for previously uninsured survivors; the impact of this change on healthcare received by the cancer survivors is beginning to emerge.³¹¹

Despite these unique opportunities, conduct of survivorship research faces several challenges. Cancer survivorship research can be expected to evolve during the next several years as better treatment options, new agents, and combinations of agents are developed for the cancer patients who do not now survive. Targeted therapies will contribute to increased survivorship. Evaluation of their late effects will need to keep in step with their increased usage. Refinements in RT and minimally invasive surgeries are intended to minimize late effects. Evidence-based research will need to determine whether they will live up to this expectation. Advances in supportive care, including transfusions and hematopoietic growth factors, also require ongoing surveillance for identification of late effects. Furthermore, the influence of genetic profiles on susceptibility to late effects, as well as their interaction with lifestyle exposures such as tobacco, alcohol, and diet, is of growing interest and has not been fully explored. However, the

multifactorial etiology of the adverse effects, coupled with the heterogeneous nature of the patient population, necessitates large sample sizes within the context of well-characterized cohorts with complete long-term follow-up, and this remains the greatest challenge to sound survivorship research.

CELL-BASED THERAPIES

This page intentionally left blank

OVERVIEW AND HISTORICAL PERSPECTIVE OF CURRENT CELL-BASED THERAPIES

Leslie E. Silberstein and Helen E. Heslop

The discovery in 1900 by Karl Landsteiner of the ABO blood group system paved the way for transfusion therapy, that is, the ability to safely infuse living blood cells as a therapeutic modality (see [Chapters 95–109](#)). Thus, the discipline began with the collection by venipuncture of whole blood, which required anticoagulation and storage at refrigerated temperatures. These procedures were optimized when it became possible to isolate different cell populations, such as red blood cells, platelets, and granulocytes. The term *blood banking* refers to collection and storage of blood products, both of which are highly regulated by the United States Food and Drug Administration (FDA).

The pioneering work by E. Donnall Thomas and others between 1950 and 1970, demonstrating the feasibility of transfusing bone marrow cells (i.e., bone marrow transplantation) as a treatment modality marked the next significant development of cellular therapies (see [Chapters 103–109](#)).¹ The success of bone marrow engraftment is related to the presence of hematopoietic stem and progenitor cells in the bone marrow; immune cells in the graft, including T cells and natural killer cells, mediate graft-versus-tumor effects in patients transplanted for hematologic malignancy. Hematopoietic stem cell populations, currently used for therapy of malignant and nonmalignant disease, can be isolated from bone marrow, from (mobilized) peripheral blood, and from umbilical cord blood (see [Chapter 95](#)). An exciting new development in hematopoietic stem cell transplantation is the genetic manipulation/transduction of the hematopoietic stem cell to correct hereditary disorders such as the congenital immunodeficiencies and hemoglobinopathies (see [Chapter 98](#)).^{2,3} More recently, the ability to isolate and expand cell populations in culture has led to the evaluation of a number of cell therapy strategies. Only one approach, a dendritic cell vaccine, has so far been approved by the FDA in the United States,⁴ but several CD19 CAR products have obtained breakthrough designation and will likely be approved soon.⁵ Infusions of other cells expanded ex vivo or significantly manipulated are conducted as experimental procedures through the FDA's Investigational New Drug application process. Many such studies use autologous cells, which do not have a risk for transferring communicable disease, but (because they are patient-specific products) make late-stage clinical trials more challenging. The use of allogeneic cells requires careful assessment of donor eligibility because of the risk for infectious disease transmission or transfer of immune reactivity ([Table 94.1](#)).⁶ Allogeneic cells may also be used to produce a patient-specific product in some clinical settings, such as treatment of relapse postallogeneic transplant in which full HLA matching is required. In other applications, however, third-party cells may have benefits, including the advantage of broad applicability since a larger number of patients can receive a product generated from a single donor.

A broad range of cell types are currently being evaluated in clinical trials (see [Chapters 97–101](#)). Immune cell populations with distinct biologic properties are being infused to treat cancer and infectious diseases, and some approaches have progressed to late-phase testing (see [Chapters 100 and 101](#)). Nonhematopoietic stromal cells from bone marrow have attracted considerable interest recently for use in tissue repair and immunomodulation, largely because of their multilineage differentiation potential and their secretion of cytokines and chemokines (see [Chapter 99](#)). Their use, while experimental, is promising. Thus, significant experience in cell-based therapies

involving hematopoietic/bone marrow-derived cells has evolved, similar to blood banking and transfusion medicine, into a highly regulated discipline with oversight by several regulatory agencies, including the FDA and the National Institutes of Health Recombinant DNA Advisory Board (see [Chapters 96 and 97](#)).

TABLE 94.1 Evaluation of Allogeneic Donor for Eligibility to Provide Cell Therapy Product

Evaluation/Test ^a	Rationale/Purpose
Complete history and physical	To review the donor's medical and social history for risk factors for communicable disease agents and diseases. To review for clinical evidence of risk factors or diseases.
Donor questionnaire	To evaluate risk factors for communicable disease (using uniform donor questionnaire ^b drafted by an international task force).
CBC, platelets, differential	To evaluate for evidence of hematologic abnormalities.
Electrolytes, BUN, creatinine, glucose, total protein, albumin, total bilirubin, alkaline phosphatase, ALT, AST, LDH	To evaluate for evidence of liver or electrolyte abnormalities.
ABO typing	To confirm identity.
HLA typing	To conduct HLA matching for some indications. To confirm identity.
HIV-1 antibody, HIV-2 antibody, HIV NAT, HTLV-1/2 antibodies, HBs antigen, HBc antibody, HCV NAT, CMV antibody, serologic test for syphilis, West Nile virus NAT, Chagas disease (if indicated by region)	To exclude communicable disease agents. Must be collected at the time of recovery of the cells or tissue from the donor; or up to 7 days before or after recovery. For donors of peripheral blood stem/progenitor cells, oocytes and bone marrow may be collected for testing up to 30 days.

^aThe donor eligibility rule requires human cell and tissue products establishments to screen and test cell and tissue donors for risk factors for, and clinical evidence of, relevant communicable disease agents or diseases. Additional Investigational New Drug-specific tests may also be mandated. All facilities need to use United States Food and Drug Administration-approved testing.

^bFoundation for the Accreditation of Cellular Therapy (FACT) Standards: HPC Donor History Questionnaire <http://www.factwebsite.org/Inner.aspx?id=163>
ALT, Alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; CBC, complete blood cell count; CMV, cytomegalovirus; HBc, hemoglobin C; HBs, hemoglobin S; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HLA, human leukocyte antigen; HTLV-1/2, human T-lymphotropic virus-1/2; LDH, lactate dehydrogenase; NAT, nucleic acid testing.

The next frontier of cellular therapies is being driven by the discovery and ability to culture stem cell populations from various other adult tissues (retina, cornea, heart, lung, etc.), embryonic stem cells, and inducible pluripotent stem cells. The therapeutic application of these cell populations, although intensely investigated worldwide, is regarded as preliminary at present and guidelines have been published for clinical development.⁷ Similarly, gene editing is also being used to modify hematopoietic stem cells and immune effector cells in preclinical studies, but there are ethical considerations with transfer to the clinic.⁸

PRACTICAL ASPECTS OF HEMATOLOGIC STEM CELL HARVESTING AND MOBILIZATION

Scott D. Rowley and Michele L. Donato

Hematopoietic stem cell (HSC) products for autologous or allogeneic transplantation are available from bone marrow, peripheral blood, or umbilical cord blood (UCB) sources. Bone marrow was the original source of cells for transplantation because of the ease and reliability of collecting adequate numbers of cells for transplantation, and it remains the standard with which other sources of HSCs are compared.

Peripheral blood stem cell (PBSC) products have virtually replaced bone marrow as the HSC component for autologous transplantation and are frequently used for allogeneic transplantation. Virtually all patients undergoing autologous HSC transplantation will have PBSCs as the source of HSCs, based on the advantages of ease of scheduling of collections, greater quantities of HSCs resulting in faster hematologic recovery and shorter and less costly hospital stays,¹⁻⁶ and potentially lower risks for tumor cell contamination of the graft. The rapid engraftment kinetics of PBSCs compared with bone marrow is widely recognized. Median times to achieve an absolute neutrophil count greater than 500/ μ L and platelet transfusion independence after PBSC transplantation typically are approximately 11 to 14 days. The allogeneic donor has a wide range of options, including marrow, PBSC, or UCB products from human leukocyte antigen (HLA)-compatible or partially compatible related or unrelated donors. The availability of HLA-matched related or unrelated donors is the primary consideration in the selection of a donor, but donor health or donation preferences may restrict what products will be available to the recipient. The patient's physician may select a stem cell source based on the expected transplant outcomes. PBSC products, for example, have the greatest quantity of HSCs and will result in faster hematologic recovery compared with marrow or UCB transplants. Bone marrow transplantation has a higher risk of graft failure, resulting in a twofold higher probability of second harvest request compared with PBSC donation.⁷ In some reports, PBSC transplantation also results in a survival advantage. However, PBSC transplantation is associated with a higher risk for difficult-to-control chronic graft-versus-host disease (GVHD) and may not be appropriate for use in patients who would not benefit from a robust graft-versus-leukemia effect, such as those treated for nonmalignant diseases. The transplant recipient may request a source of cells, but the donor has the right to decide about the method of donation. Although GVHD prophylaxis with posttransplant methotrexate will slow engraftment, the kinetics of engraftment for the allogeneic PBSC recipient is similar to that experienced by the autologous PBSC recipient. A number of phase III studies involving either autologous or allogeneic HSC transplantation confirmed the more rapid engraftment kinetics for recipients of PBSCs,⁸⁻¹¹ and this effect is not limited to HSCs collected from the peripheral blood, because cytokine administration to the patient or donor before marrow harvesting will also increase the number of HSCs collected and result in quicker hematologic recovery.¹²⁻¹⁴ The disadvantages to use of PBSC components compared with bone marrow or UCB for autologous or allogeneic transplantation include the possible need for multiple days of collection (especially for autologous transplantation), the inability to collect adequate components from all patients and donors, and a possibly higher risk for chronic GVHD or the occurrence of chronic GVHD that is more difficult to control¹⁵ (see box on [Choice of Hematopoietic Stem Cell Product for Transplantation](#)).

UCB from public banks has the advantage of being immediately available, reducing the time to transplantation. Targeting collection of UCB products from ethnic populations not well represented in donor registries will facilitate treatment of ethnic minority patients. The relative immunologic naïveté of the cord blood donor allows use of HLA-mismatched products without an undue increase in GVHD risk.¹⁶ The much smaller quantity of HSCs in the cord blood product results in slower hematologic recovery and a higher risk for primary engraftment failure, which may be partially offset by infusion of multiple products, and the older adult patient, in particular, may also be at greater risk for posttransplant infections because of the relative immature immune system of the donor.

SELECTION AND EVALUATION OF THE STEM CELL DONOR

Selection of the Stem Cell Donor

The primary selection criterion for the patient undergoing autologous HSC collection and transplantation is the diagnosis of an illness amenable to treatment with a dose-intensive regimen requiring HSC support. Extensive prior treatments, especially with marrow-toxic chemotherapy regimens or with radiotherapy, may prohibit collection of adequate quantities of autologous HSCs, which would exclude a patient from this treatment option. Proper management of patients with a disease amenable to dose-intensive therapy should include provisions for HSC collection before extensive marrow-toxic agents are administered. In general, however, any serious comorbid illnesses that would preclude either marrow or PBSC collection would also disqualify the patient from treatment with dose-intensive regimens used in preparation for autologous HSC transplantation.

The selection of the allogeneic HSC donor is more complex. The HLA major histocompatibility complex is the primary consideration in selection of a donor for allogeneic HSC transplantation, since its loci contribute significantly to host-versus-graft (leading to immunologic rejection of donor HSCs) and to graft-versus-host (leading to GVHD and graft-versus-leukemia) reactions.^{17,18} Donor age, gender, and parity are secondary considerations in the selection of an allogeneic HSC donor.^{18,19} Mismatching for killer-cell immunoglobulin-like receptor ligands may reduce the risk for posttransplant relapse of disease.²⁰ More than 30% of allogeneic HSC transplants from related or unrelated donors will involve ABO-disparate donors and recipients, and donor and recipient pairs may also differ for other red blood cell antigens, with no clear evidence of deleterious effect on engraftment, survival, or GVHD.²¹ Cancer, autoimmune disorders, and genetic diseases such as the hemoglobinopathies can be transmitted to the allograft recipient; thus, donor health is an important consideration in donor selection and determination of donor eligibility.

Evaluation of Hematopoietic Stem Cell Donor Suitability and Eligibility

The immediate precollection evaluation of a patient or donor is intended to address the risks of the collection procedure to the donor

Choice of Hematopoietic Stem Cell Product for Transplantation

Virtually all patients undergoing autologous hematopoietic stem cell (HSC) transplantation will have peripheral blood stem cells (PBSCs) as the source of HSC, based on the following advantages: ease of collection, greater quantities of HSCs (resulting in faster hematologic recovery and shorter and less costly hospital stays), and potentially lower risks for tumor cell contamination of the graft.

The allogeneic donor has a wider range of options, including marrow, PBSCs, or umbilical cord blood (UCB) products from human leukocyte antigen-compatible or partially compatible related or unrelated donors. The transplant recipient may request a source of cells, but the donor has the right to decide about the method of donation. PBSC products have the greatest quantity of HSCs and will result in faster hematologic recovery compared with marrow or UCB transplants. In some reports, PBSC transplantation resulted in a survival advantage. However, PBSC transplantation is also associated with a higher risk for difficult-to-control chronic graft-versus-host disease (GVHD) and may not be appropriate for use in patients who would not benefit from a robust graft-versus-leukemia effect, such as those treated for nonmalignant disease. UCB has the advantage of being immediately available, reducing the time to transplantation. Targeted collection of UCB products from ethnic populations not well represented in the various donor registries will facilitate treatment of ethnic minority patients. The relative immature immunity of the cord blood donors allows the use of human leukocyte antigen-mismatched products without an undue increase in GVHD risk. Infusion of two cord blood units may achieve a greater graft-versus-tumor effect (this concept has not been proven), even though one unit will be rejected. The much smaller quantity of HSCs in the cord blood product results in slower hematologic recovery, and the adult patient, in particular, may be at greater risk for posttransplant infection because of the relative immature immune system of the donor.

(“donor suitability”) and the risks for transmission of disease from the donor to the recipient (“donor eligibility”). The same general health criteria apply to both bone marrow and PBSC donors. Patients undergoing autologous HSC collection and transplantation are not at risk for transmitting disease to themselves, and determination of donor eligibility is not medically required or economically justifiable, but these patients must be evaluated for their suitability for the collection procedures. All allogeneic and syngeneic HSC donors must be evaluated for donor eligibility, as well as suitability, using the same criteria currently applied to blood or other tissue donors, including a targeted history regarding behaviors exposing the donor to infection, recent or concurrent illnesses, and medication use.^{22–26} This evaluation of the allogeneic donor suitability and eligibility must be clearly documented in the donor medical record, with appropriate additional documentation of donor eligibility placed in the intended recipient’s medical record before initiation of the transplant conditioning regimen. Older donors have a greater probability of comorbid medical conditions, which will increase the risks of the collection procedures, and the risks to the allogeneic donor with underlying health problems must be fully considered before subjecting the donor to HSC collection. Published standards describe evaluation of the donor for the risk of the donation process, as well as the risk for transmission of disease to the recipient.^{22–24,26} Evaluation by appropriate consultants may be required before autologous or allogeneic donor approval is finalized. Procedures involving donors with acute infectious illnesses should be delayed, if at all possible, because of the risk for disease transmission. Genetic disorders, such as hemoglobinopathies, will be transmitted to the recipient as a direct consequence of stem cell engraftment. Cancer can be transmitted, as illustrated by the transmission of donor leukemia not detected during initial evaluation of the donor,²⁷ and donors previously treated for cancer should be evaluated for the probability of recurrent disease that could be transferred to the immunocompromised recipient.²⁸ Collection of PBSCs is generally an outpatient procedure conducted in the clinic setting. In contrast, marrow harvesting has the luxury of the intensive support capability of the operating room. PBSC collection, therefore, should never be viewed as a safer alternative to marrow harvesting for the donor with

Evaluation of the Allogeneic or Syngeneic Marrow or Peripheral Blood Stem Cell Donor

Hematopoietic stem cell (HSC) transplantation involves the infusion of a “blood product”, and allogeneic and syngeneic donors must be evaluated for risks for disease transmission as per the current criteria for blood or tissue donation (“donor eligibility”). Exemptions from criteria that specifically address the risk for disease transmission are permissible, if the risks of excluding an otherwise appropriate donor outweigh the risks for disease transmission to the transplant recipient, who may not have an alternate donor. Informed consent must be obtained for the evaluation and collection procedures. Informed consent also must be specifically obtained for the release of protected donor health information to the transplant recipient, allowing proper informed consent for the transplant to be obtained. Minors and donors not competent to provide consent must be represented by a third party not involved in the care of the recipient. Ideally, similar courtesy will be provided to the adult competent donor.

Donors must also be evaluated for health issues that would increase the risks resulting from the collection procedures (“donor suitability”). For marrow donors, this includes the risks of anesthesia and harvesting in the prone position; for PBSC donors, evaluation should include the risks of mobilization medications and apheresis, including the need for venous catheter placement.

The donor collection facility’s standard operating procedures for evaluation of HSC donors must meet the Foundation for the Accreditation of Cellular Therapy/Joint Accreditation Committee or AABB standards and United States Food and Drug Administration (or other regulatory agency) regulations, and include policies and procedures for the following:

- Education of donor, including education regarding procedures, risks and alternatives, and possible request for future donations;
- Medical history, including special attention to history of autoimmune disorders, arthritis, cardiac and vascular disease, and history of cancer;
- History of high-risk behaviors, such as recent tattoos, body piercing, sexual practices, and travel;
- Physical examination, including vein assessment (PBSC donors) and oral examination (marrow donors undergoing inhalational anesthesia);
- Laboratory studies, including verification human leukocyte antigen typing, ABO typing, complete blood count, chemistry panel, infectious disease panel, urinalysis, ECG, CXR;
- Consent for the collection procedures and the release of protected health information to the stem cell recipient;
- Documentation of both donor eligibility and suitability before initiation of the transplant conditioning regimen.

underlying health problems. Pediatric donors present different challenges, based on the smaller size and varying ages (and ability to cooperate) of the donors (see box on [Evaluation of the Allogeneic or Syngeneic Marrow or Peripheral Blood Stem Cell Donor](#)).

Use of a donor who does not meet eligibility criteria and who poses a risk for transmission of disease requires appropriate informed consent both from the donor (for disclosure of this confidential health information to the recipient and for counseling of the recipient) and from the recipient (for use of the stem cell product). The potential conflict of interest between protecting donor confidentiality and patient needs must be recognized by the personnel caring for each person, and preferably, the donor and patient should be represented by different physicians.²⁹

Determination of Suitability for Bone Marrow Donation

Anesthesia and blood loss present the greatest risks for serious complications to the bone marrow donor. Most marrow harvesting is performed under general anesthesia, which requires intubation for control of the airway for a surgical procedure being performed on a prone patient. Regional (spinal or epidural) anesthesia may not be effectively established, so patients and donors who express a preference for this form of anesthesia must be counseled about the potential

need for general anesthesia. The health assessment must include questioning about a history of joint disease of the cervical spine and mandible, and examination of the mouth if general anesthesia requiring intubation is chosen. Patients and donors with comorbid conditions, such as aortic stenosis sensitive to changes in blood volume and blood pressure, may require anesthesia consultation and plans for invasive monitoring during the surgical procedure. A history of marrow fibrosis, pelvic irradiation, or pelvic tumor involvement may exclude a patient from marrow harvesting, although unilateral harvesting from the posterior and iliac crests and aspiration of the sternum may achieve adequate quantities of cells for transplantation.

Determination of Suitability for Peripheral Blood Stem Cell Donation

The PBSC donor is exposed to the risks of cytokine (and chemokine) administration and the risks related to the apheresis procedure, including the risks of central venous catheter insertion and use. No long-term health consequences have been associated with G-CSF administration, and the specific toxicities with these agents are described later. G-CSF may lead to a flare of autoimmune disorders and may increase the risk for blood clots, particularly for donors who are sedentary or who may be traveling shortly after the donation procedures.³⁰ The PBSC donor must be assessed for venous access before the patient receives conditioning, and consent for use of a central venous catheter must be obtained if the venous access is deemed inadequate for the apheresis procedure.

Suitability and Eligibility for Umbilical Cord Blood Donation

Evaluation of the donor for UCB donation begins with a history of maternal and paternal illnesses and exposures to infectious diseases. Although linkage between the infant and the product is currently maintained, an update of infant health is not obtained at the time of transplantation, which may be several years after collection. Therefore, parental medical history includes specific questions addressing the risks for transmission of hereditary or acquired blood-borne diseases. A comprehensive genetic and family history should be obtained. Testing for infectious diseases is obtained from the mother at the time of collection to minimize loss of product through such testing.

Public UCB banks set criteria for the storage of units in order to avoid the collection and storage of UCB units that would not be acceptable for transplantation.³¹ Exclusion criteria for potential donors in one multicenter study, for example, included the following: multiple gestation; premature delivery; active chorioamnionitis or sepsis; mother being the recipient of an organ transplant; mother with history of cancer; mother with high-risk behaviors or previously diagnosed with HIV, hepatitis, or syphilis; and mother having an active venereal disease such as vaginal herpes simplex and delivering vaginally.

COLLECTION OF BONE MARROW FOR TRANSPLANTATION

Bone Marrow-Collection Techniques

Bone marrow is typically harvested from the posterior iliac crests using virtually the same techniques used to obtain diagnostic samples in the clinic. The primary differences between obtaining diagnostic specimens and cell quantities adequate for transplantation are the volume of blood and marrow removed, which requires attention to fluid and blood component replacement during the procedure, and the need for appropriate anesthesia. Bone marrow harvesting from healthy donors presents little risk for serious morbidity, permitting

the ethical recruitment of allogeneic and syngeneic donors, including pediatric bone marrow donors and donors not related to the recipient.^{22–25} Multiple aspirations are performed with collection of approximately 5 mL of marrow from each puncture site. If properly spaced, no more than two or three skin-puncture sites per side usually are required. Other harvest sites, such as the anterior iliac crests or sternum, can be used, but at increased risk for complications from accidental laceration or perforation of contiguous anatomic structures. For patients with a history of radiation or tumor involvement of one pelvic crest, adequate cells can be harvested from the anterior and posterior crests of the other side.

The prescription for marrow collection will define the desired quantity of nucleated cells per kg recipient weight to be collected. Ideally, this quantity of cells will be collected in a minimal total volume and procedure duration. Although transplant registries may require physicians to be experienced in marrow harvesting, defined as the number of procedures performed, few published studies report a correlation between such experience and harvest yields or donor complications.³² The nucleated cell yield (cells per volume aspirated) appears greater for needles with side aspiration ports.³³ Smaller quantities aspirated per “pull” also improves cell yield.³⁴ Warming of the donor may improve cell yield.³⁵ Quality-assurance management should review for each harvest team the nucleated cell yield per volume of marrow, total volume aspirated, use of blood replacement, and duration of anesthesia.

Marrow is collected in the day surgery suite using either general or regional anesthesia. With proper fluid and blood replacement, overnight hospitalization should not be required. Bone marrow harvesting necessitates placing the donor into the prone position, which has specific considerations to avoid complications directly resulting from this positioning.³⁶ Donors must be supported, at a minimum, by positioning on chest rolls. For the healthy donor, the risks for serious complications from either general or regional anesthesia are minimal, although a multivariate analysis of adverse events performed by the National Marrow Donor Program for unrelated donors reported a higher risk for serious adverse events for donors receiving regional anesthesia.^{37,38} Use of spinal or epidural anesthesia avoids the nausea that may occur with general anesthesia, especially for younger women, but hypotension from loss of vascular tone in the lower extremities often occurs as the volume of marrow is collected. General anesthesia is preferable for the donor with comorbid disorders such as cardiovascular or cerebral vascular disease because of the better control of donor airway and lower risk for hypotension during the harvest procedures. Local anesthesia is acceptable only if a very limited harvest is being performed, because local anesthesia does not achieve anesthesia of the marrow space and because large quantities of lidocaine, for example, are cardiotoxic.

Both heparin and acid-citrate-dextran-A (ACD-A) can be used for anticoagulation of bone marrow products. ACD-A decreases the accumulation of lactic acid and may be preferable, especially for products that will be transported or stored for longer periods before infusion or cryopreservation.³⁹

Toxicity of Bone Marrow Collection

Anesthesia complications present the major health risk to the donor; marrow aspiration is generally well tolerated, although postharvest discomfort is experienced to some extent by all donors.⁴⁰ Complications include hemorrhage and infections at skin-puncture sites. Severe hematomas and neuralgias rarely occur, and training regarding pelvic anatomy is required to decrease the risk for damage to vessels and nerves lying under or adjacent to the iliac crest harvest sites. Irritation of the sacral nerves may result from needle penetration through the pelvic bone or from blood tracking into the nerve roots, and requires several months of convalescence. Localized pain is common, may last for several days, and may require a brief period of opioid medication. In a survey of over 9000 donors for unrelated bone marrow transplantation, 82% reported collection site pain, with a median time to recovery of 3 weeks (see Figs. 95.1 and 95.2).³⁸ Pain associated with

Fig. 95.1 (A) Percentage of BM donors reporting pain at selected sites over time. Reports of pain and pain severity were collected at the indicated time points post-donation. Throat pain is largely restricted to donors receiving general anesthesia, whereas headache is more common in donors receiving regional anesthesia, for example, epidural. (B) Six most frequently reported body symptoms experienced by BM donors at the indicated time points post-donation. (C) Percentage of PBSC donors reporting bone pain over time. Reports of bone pain and severity of pain were collected at the indicated time points during mobilization, collection, and post-donation. Day 1 is the first day of filgrastim administration; day 5 is the first day of apheresis. Bone pain represents pain in at least one of the following sites: general bone pain, back, head, limb, joint, hip, and neck. The severity of bone pain is defined as the maximum grade among these pain sites. (D) Six most frequently reported body symptoms experienced by PBSC donors during mobilization and collection, and at the indicated time points post-donation. The percentages for day 1 to day 6 represent the frequencies of the highest grade of symptoms during mobilization and collection. (From *Biol Blood Marrow Transplant.* 14(9 Suppl):29–36, 2008, doi: 10.1016/j.bbmt.2008.05.018.)

the anesthesia procedures (throat pain, 33%; postanesthesia headache, 17%) was reported by a large proportion of the donors. Fatigue was reported by 59% of donors. Serious adverse effects were reported for 125 donors (1.35%), with 116 donors reporting serious complications considered to be a consequence of the collection procedures. Most of the serious complications ($n = 69$) were mechanical injury to tissue, bone, or nerve; and a smaller number ($n = 45$) were related to anesthesia. Infection and grand mal seizure were reported for one donor each. A retrospective survey of donor events reported by the European Group for Blood and Marrow Transplantation described almost 28,000 bone marrow donors, with one death from pulmonary embolism.⁴¹ An additional 12 donors experienced severe adverse events, including four cardiac arrests (three during anesthesia), two episodes of severe hypertension, one pulmonary embolism from heparin-induced thrombocytopenia, one episode of pulmonary edema, one donor with a subdural hematoma, and three events not otherwise specified. This retrospective survey did not include all donors and may have underreported adverse events. This report,

furthermore, did not report the experiences of related and unrelated donors separately. The adverse events reported by unrelated donor registries will underestimate the risks faced by donors for related recipients, who may undergo collection despite comorbid illnesses that would preclude participation in an unrelated donor registry.^{26,42} Most donors are able to return to routine activities 1 to 2 days after harvesting. The total recovery time for the 67 donors reporting serious mechanical injury was a median of 10 months (range: 1–96 months).³⁷ Toxicity was more likely to occur for less experienced harvest teams,³² and harvest teams must address training and maintenance of harvest skills in their quality-assurance plans. Any team associated with a second severe mechanical injury should specifically be evaluated, in light of the very low probability of these events.

The usual volume harvested from healthy donors is approximately 10–15 mL of marrow per kilogram of recipient bodyweight to achieve the desired nucleated cell and CD34⁺ cell doses. This results in a blood loss of 800–1000 mL for donors providing marrow for an average-sized adult recipient. The quantity of marrow harvested from

Fig. 95.2 Kaplan-Meier plots of time to recovery from stem cell donation (first donations performed from November 2001 through March 2006). (From *Biol Blood Marrow Transplant.* 14[9 Suppl]:29–36, 2008, doi: 10.1016/j.bbmt.2008.05.018.)

autologous patients may be greater, reflecting previous chemotherapy given to these patients causing decreased marrow cellularity. Donors for pediatric recipients will lose proportionately less blood. Most patients and donors receive blood transfusions to alleviate symptoms of volume depletion. With proper preharvest autologous blood storage, use of homologous blood for healthy first-time allogeneic donors should be extremely rare. For a blood loss of less than 10 mL/kg of donor weight, salt solutions are acceptable for volume replacement. Colloid solutions, such as hydroxyethyl starch, can be used to avoid homologous blood transfusion for blood losses between 10 and 20 mL/kg donor weight. Blood transfusion will be required for larger blood losses (>20 mL/kg) or for patients with comorbid illnesses. Homologous blood transfusions must be irradiated to prevent transfusion-associated GVHD in the transplant recipient caused by “passenger lymphocytes” from the third-party blood donor. Donors undergoing a second harvest shortly after the first harvest are more likely to require homologous blood.²⁴ Oral iron supplements should be considered for healthy donors, particularly for female donors or donors from whom a proportionately large blood volume is to be harvested.

COLLECTION OF UMBILICAL CORD BLOOD STEM CELLS FOR TRANSPLANTATION

Cord Blood Collection Techniques

Advantages of this source of HSCs include the ability of public cord blood banks to target collections from ethnic-minority populations not well represented in the various unrelated donor registries and the relative immaturity of the donor immune system allowing transplantation of HLA-mismatched units without overwhelming GVHD. The primary obstacle to the widespread use of cord blood cells is the limited quantity of HSCs collected, and one public UCB bank predicted that from less than 5% to less than 38% (depending on the cell dose criterion for transplantation) of the units stored in that bank would be acceptable for transplantation of an 80-kg adult patient.⁴³ The speed and success of engraftment are predicted by the total nucleated cell dose and, more important, by the quantity of CD34⁺ cells or infused colony-forming units (CFUs).⁴⁴

UCB is collected from the placental vein after delivery of the infant and transection of the cord, either before delivery of the placenta by the obstetrician or by laboratory personnel after delivery of the placenta.⁴³ Published reports conflict regarding the volume of UCB collected and the likelihood of obtaining a product inadequate

for storage with either in utero or ex utero collection techniques. The timing of cord clamping after delivery of the infant is associated with the volume of cord blood collected, and greater volumes are collected with earlier clamping. Greater cell quantities were found for infants with greater birth weight, but no difference was found based on gender or gestational age. Ethnic background appears to predict the cell quantities, with smaller quantities of cells collected from ethnic minorities compared with whites.⁴⁵ UCB is usually collected by cannulation of the umbilical cord veins with aspiration of the blood into a collection bag. Collection of cord blood into open containers results in an unacceptable rate of bacterial contamination. Perfusion of the placenta with salt solutions may increase the cell number collected, but this technique has not been widely adopted. Many cord blood banks reduce the volume of the product by red cell and plasma depletion to minimize storage space and to reduce possible infusion-related toxicities from mature blood cells contained in unfractionated cord blood units.⁴⁶ Bacterial contamination of UCB products is of concern, especially in the collection of products for related donor transplantation by obstetricians with limited or no experience in HSC collection and processing.⁴⁷ The identification and evaluation of the donor and the collection techniques used should be viewed as the first steps in a manufacturing process with adequately validated procedures, personnel training, quality control, and performance improvement oversight.

COLLECTION OF PERIPHERAL BLOOD STEM CELLS FOR TRANSPLANTATION

Background

The presence of HSCs in the peripheral circulation was suggested by animal studies as early as 1951.⁴⁸ Although the nature of the survival agent was not recognized at that time, parabiosis experiments demonstrated that some factor in the blood of a healthy animal was able to rescue another animal from the effects of lethal irradiation. Subsequently, a number of animal models demonstrated the presence of HSCs in the peripheral blood and the successful use of these cells to rescue animals from the marrow-lethal effects of radiation. The concentration of HSCs in the peripheral blood is normally very low, requiring the processing of large quantities of blood to collect the quantity of HSCs equivalent to what could be collected in a bone marrow harvest. For this reason, PBSC transplantation was initially used by a few transplant programs that explored this source of HSCs for patients who otherwise were ineligible for marrow harvesting, collecting cells during steady-state hematopoiesis or during the transient increase in circulating HSCs that occurred during recovery from marrow hypoplasia-producing chemotherapy.^{49–53} These early reports noted that engraftment could be achieved sooner after infusion of PBSC components compared with marrow cell transplantation. However, because of the occasionally limited quantity of HSCs that was collected from the peripheral blood, the kinetics of engraftment for some patients was considerably slower. The effective mobilization of HSCs achieved by cytokine or chemokine administration,^{54–56} and the reliability of same-day flow cytometric analysis in assessing the quality of the collection, are the direct bases for the rapid and widespread adoption of PBSCs as a source of HSCs for transplantation (see box on [Mobilization and Collection of Peripheral Blood Stem Cell for Autologous Transplantation](#)).

Mobilization of Hematopoietic Stem Cells Into Peripheral Blood

The self-renewal and differentiation of HSCs is controlled by the surrounding microenvironment of the stem cell niche(s) in which the HSC reside.⁵⁷ These niches are composed of a complex three-dimensional architecture of a variety of cell types including sinusoidal endothelial cells, sympathetic nerve fibers, cells of the osteoblastic

Mobilization and Collection of Peripheral Blood Stem Cells for Autologous PBSC Transplantation

Five important considerations when prescribing a mobilization regimen for collection of peripheral blood stem cells (PBSCs) for autologous transplantation are as follows: (1) A regimen of chemotherapy followed by granulocyte colony-stimulating factor (G-CSF) results in higher numbers of circulating CD34⁺ cells than will be found with G-CSF alone. (2) The choice of chemotherapy (or cytokine alone mobilization) should be appropriate to the disease and stage of disease for the patient. (3) Each cycle of prior chemotherapy and any previous treatment with radiotherapy will decrease the response to mobilization therapy. (4) Tumor infiltration of the marrow will increase the probability of circulating tumor cells and will decrease the response to mobilization therapy. (5) Some patients will benefit from tandem cycles of dose-intense therapy, and the prescription should target adequate quantities of CD34⁺ cells for these patients. With these considerations in mind, elective collection of PBSCs either before extensive treatment or after a limited number of cycles of debulking chemotherapy should be considered. Additional cycles of chemotherapy can be given after PBSC collection is completed, for those patients who require further tumor reduction before proceeding to transplantation. The timing of apheresis after chemotherapy and G-CSF mobilization is best guided by measurement of the level of peripheral blood CD34⁺ cells. Daily or every-other-day quantification of these cells can be initiated after the white blood cell count reaches 1000/ μ L. Patients with poor mobilization of CD34⁺ cells should be considered for large-volume apheresis or addition of a chemokine such as plerixafor to reduce the costs associated with daily doses of G-CSF, laboratory testing, apheresis procedures, and cryopreservation. Patients who fail to mobilize may have successful collections if given a short drug “holiday” before undergoing mobilization with high-dose G-CSF with plerixafor.

lineage, macrophages, and mesenchymal stem cells that are responsible for controlling the balance between HSC quiescence, self-renewal, and differentiation. A number of pathways with mutually recognized cellular adhesion molecules and their respective ligands responsible for the spontaneous migration of HSCs from the stem cell niche, as well as the multistep process of homing back into the niche, have been identified.⁵⁸ The mechanisms by which granulocyte colony-stimulating factor (G-CSF) and other cytokines promote mobilization of HSCs are being elucidated and appear to be an indirect effect (HSCs do not express receptors for G-CSF) on the CXCR4-chemokine receptor 4 (CXCR4)/stromal cell-derived factor-1 (SDF-1) axis mediated by monocytes and the sympathetic nervous system.⁵⁷ The mechanisms of mobilization by chemotherapy and CXCR4 antagonists such as plerixafor are also being determined, and the elucidation of the mechanisms of mobilization and homing may result in more effective harvesting and transplantation techniques.⁵⁹

Cytokine Mobilization

The ability of recombinant hematopoietic cytokines to increase the level of myeloid progenitor cells in the blood, as well as mature blood cells, was reported in 1988 by different groups for both G-CSF and granulocyte-macrophage colony-stimulating factor (GM-CSF).^{60,61} Subsequently, a number of different investigators reported the collection of PBSCs from patients using a variety of mobilization regimens, including cytokines alone, cytokine combinations, and combinations of chemotherapy with cytokines. Various other recombinant human hematopoietic cytokines, including erythropoietin and fusion molecules, increase the quantity of CD34⁺ cells in the peripheral blood but have not been developed for clinical transplantation.

Granulocyte Colony-Stimulating Factors Including Biosimilars

G-CSF is the cytokine most commonly used because of its efficacy compared with other cytokines and its relatively benign toxicity

profile. Recombinant methionyl human G-CSF (filgrastim) and recombinant human G-CSF (lenograstim) were the two forms of this cytokine initially available for clinical use.⁶² There are slight differences between these two similar cytokines in their ability to mobilize PBSCs. Watts and colleagues⁶³ studied 20 healthy volunteers and found that peak levels of colony-forming unit-granulocyte-macrophages (CFU-GMs) in the peripheral blood were 28% higher after treatment with the glycosylated molecule (lenograstim), attributed to the higher specific activity of this form. De Arriba and colleagues⁶⁴ treated 30 women with breast cancer in a randomized study of these two drugs, using dosages containing bioequivalent units of activity and found no difference in mobilization of CD34⁺ cells. The two forms have otherwise similar biologic activity and are not further distinguished in this discussion.

Regulatory agencies including the United States Food and Drug Administration (US FDA), the European Medicines Agency, and others established regulatory pathways leading to approval of biologic medicines that are highly similar to an already-approved biologic product (“biosimilar”).^{65,66} In the US, The Biologics Price Competition and Innovation Act of 2009 created an abbreviated licensure pathway for biological products shown to be “biosimilar” to or “interchangeable” with an FDA-licensed biologic product, known as the “reference product.” This abbreviated licensure pathway permits reliance on existing scientific knowledge about the safety and effectiveness of the reference product, and enables a biosimilar biologic product to be licensed based on less than a full complement of product-specific preclinical and clinical data usually required before marketing of a new drug. The biosimilar must show it has no clinically meaningful differences in terms of safety and effectiveness from the reference product. Only minor differences in clinically inactive components are allowable. Filgrastim-sndz is the first biosimilar drug approved by the US FDA, and is marketed with the same indication for use as filgrastim. Tbo-filgrastim, however, was licensed under a different mechanism, and does not have US FDA approval for use in PBPC collection. The use of a biosimilar G-CSF in mobilization of PBPCs must be extrapolated from laboratory data such as mobilization of CD34⁺ cells, and it is conceivable, although considered very unlikely, that differences in the mobilization of stem and other cells, as well as in toxicity to the donor, may occur.^{67,68} Clinical experience describing similar mobilization results are now being reported for these drugs.⁶⁹

Mobilization of Hematopoietic Stem Cells Using Granulocyte Colony-Stimulating Factor

G-CSF is the most potent cytokine currently available for mobilization of HSCs. In a randomized study of healthy volunteers comparing G-CSF, GM-CSF, and the combination of both, Lane and colleagues⁷⁰ reported an average 0.99% CD34⁺ cells in the peripheral blood of healthy donors treated with 10 μ g/kg per day of G-CSF compared with 0.25% for donors treated with the same dose of GM-CSF. The quantity of CD34⁺ cells in the peripheral blood before treatment averaged 1.6/ μ L. After GM-CSF treatment, the level increased to 3/ μ L, but with G-CSF, the level increased to 61/ μ L. Each group underwent one leukapheresis on the 5th day of treatment, and the collections from donors treated with G-CSF averaged 119×10^6 CD34⁺ cells compared with 12.6×10^6 for the donors treated with GM-CSF.

The appearance of CD34⁺ cells during administration of G-CSF follows a distinct time course, with the maximal level of CD34⁺ cells occurring on day 5 after daily G-CSF administration.⁷¹ Smaller numbers of CD34⁺ are present on days 4 and 6, and the level falls rapidly on subsequent days despite a continual rise in white blood cell (WBC) count.

The number of CD34⁺ cells collected after G-CSF treatment is proportional to the number of these cells in the peripheral blood before initiation of the cytokine.¹⁸ Although doses as low as 5 mcg/kg/day have been used, there is a dose response to G-CSF, with higher average levels of CD34⁺ cells achieved with 10 mcg/kg/day compared

with 5 mcg/kg/day.⁷² With appropriate dosing of allogeneic donors, adequate numbers of CD34⁺ cells can be collected in one procedure for transplantation of most patients. A similar dose response is observed in autologous patients and may extend to doses as high as 40 mcg/kg/day.⁷² An advantage to twice-daily dosing of G-CSF has been suggested but not confirmed. Anderlini and colleagues⁷³ compared administration of 6 mcg/kg given twice daily with 12 mcg/kg given once daily and found no differences in CD34⁺ cells per liter of blood processed during the apheresis procedure or the total yield of CD34⁺ cells per kilogram collected. In contrast, a second trial enrolling primarily pediatric patients noted better results with the twice-daily schedule.⁷⁴ Patients, especially those previously treated with chemotherapy or radiotherapy, will generally have lower quantities of CD34⁺ cells mobilized.⁵⁹

Toxicity and Complications of Granulocyte Colony-Stimulating Factor

The toxicity of G-CSF has been most clearly defined in studies of allogeneic donors.^{30,75,76} The autologous patient will experience a similar toxicity profile, but with the added complications of the underlying malignancy and its treatment.

Almost all recipients of G-CSF will develop somatic complaints, of which skeletal pain is most prominent (see Fig. 95.1), but also including fatigue, insomnia, and nausea.^{30,37,38,41,75–77} The somatic complaints are generally tolerable, and few donors will require reduction in dose or discontinuation of the medicine. At present, there appear to be minimal, if any, long-term health risks for the donor. Few serious complications of the mobilization regimen and donation process have been reported.⁷⁷ G-CSF increases spleen size, with a rare patient or donor experiencing splenic rupture. G-CSF may induce a hypercoagulable state, which is of concern for donors (and patients) requiring central venous catheter placement or for those who may have other risk factors for the development of deep venous thrombosis (such as air travel immediately after the collection procedures). Patients with autoimmune disorders may experience a flare-up of their disease during administration of G-CSF, and a variety of case reports of ophthalmologic and other adverse events have been reported for healthy donors or patients treated with G-CSF.

Of concern is the possibility that cytokine administration will increase the risk for marrow dysplasia or malignancy. Although this is a theoretical concern in that these cytokines are known to stimulate growth of leukemia cells, no clinical evidence from large registry reviews of healthy donor experiences indicates that these agents will induce abnormalities in the hematopoietic stem cell.^{77,78}

G-CSF administration results in a number of changes in blood counts and chemistries in addition to the coagulation factor changes. Alanine aminotransferase, lactate dehydrogenase, and alkaline phosphatase levels increase, and the levels of blood urea nitrogen and bilirubin may decrease.⁷⁶ The elevation in alkaline phosphatase level is primarily of bone origin; γ -glutamyl transferase levels remain normal. These abnormalities of serum chemistries resolve within 2 weeks after discontinuation of the medication. G-CSF administration also will result in a decrease in platelet count, especially if the cytokine is administered over 5 to 10 days.⁷⁶ WBC counts fall rapidly after discontinuation of G-CSF. In approximately 10% of donors, the WBC count may fall to abnormal levels (but generally still remain above 1000/ μ L), reaching a nadir 10 to 14 days after discontinuation of the cytokine before stabilizing at normal levels.

Granulocyte-Macrophage Colony-Stimulating Factor

Much of the early experience with the use of hematopoietic cytokines for mobilization of HSCs involved GM-CSF and chemotherapy.^{61,79} GM-CSF is not as potent as G-CSF,^{70,79} although as with G-CSF, there is a dose response in mobilization of PBSCs with GM-CSF over a range from 0.3 to 30 mcg/kg/day, without a plateau.⁸⁰ In this dose-ranging study, however, the average increase in CFU-GM in the

blood at this highest dose level again was only 8.4-fold. In a randomized study comparing GM-CSF with G-CSF, or both drugs used in sequence after chemotherapy administration, patients had faster recovery of counts, required less supportive care including transfusions, and achieved greater collections of CD34⁺ cells if given one of the G-CSF-containing regimens.⁷⁹

Administration of GM-CSF results in somatic complaints and hepatic function abnormalities similar to those reported after G-CSF administration. In addition, 44% to 80% of patients experience fever, sometimes after each dose, as well as generalized or local skin reactions. Doses greater than 20 mcg/kg/day are poorly tolerated because of fluid retention, pleural and pericardial inflammation, and venous thrombosis. A “first-dose reaction”, characterized by hypoxia and hypotension occurring within 3 hours of administration, has been described for some recipients, especially after intravenous administration.

Other Hematopoietic Cytokines

Recognition of the mobilization potential of G-CSF led many investigators to study other hematopoietic cytokines, including erythropoietin, monocyte-colony-stimulating factor, interleukin (IL)-3, PIXY 321 (a fusion molecule), and stem cell factor (SCF) for their capacity to mobilize HSCs into the peripheral blood. Used as single agents, these cytokines resulted in only an approximately 5- to 10-fold increase in circulating CFU-GM or CD34⁺ cells.

Chemotherapy Plus Cytokine Mobilization

The number of HSCs in the peripheral blood is moderately increased during the early hematologic recovery phase after marrow hypoplasia-producing chemotherapy. Chemotherapy plus cytokine generally mobilizes greater numbers of PBSCs than either agent alone. This finding was confirmed in a randomized study comparing cyclophosphamide followed by G-CSF versus G-CSF alone, in which higher numbers of CD34 cells were found for the patients treated with the chemotherapy-based regimen.⁸¹ However, no differences in the degree of tumor cell contamination of PBSC components, speed of hematologic recovery after transplantation, or survival probability were found. A wide variety of different chemotherapy regimens has been used successfully for mobilization of HSCs into the blood, with cyclophosphamide- or ifosfamide-based regimens being most commonly used. The primary consideration is that the choice of chemotherapy used for mobilization must also meet the treatment needs of the patient. Demir and colleagues⁸² studied the effect of different chemotherapy regimens for mobilization of HSCs for patients with breast cancer. Four regimens were used, all involving cyclophosphamide (CY), but including etoposide with or without cisplatin, or paclitaxel. All patients also received G-CSF. The median quantity of CD34⁺ cells collected on the first day of apheresis after cyclophosphamide mobilization was 0.9×10^6 per kilogram of patient weight. The addition of etoposide and then of etoposide and cisplatin increased the first-day yield to 8.1×10^6 and 3.5×10^6 CD34⁺ cells/kg, respectively, in separate cohorts of patients. The median number of CD34⁺ cells harvested on the first day of apheresis after cyclophosphamide plus paclitaxel was 11.1×10^6 /kg, and more than 50% of the women mobilized with this last regimen achieved the target dose of CD34⁺ cells in one apheresis procedure. Of the 100 women studied, 94 achieved the target dose of greater than 5×10^6 CD34⁺ cells/kg. Only four patients failed to reach a lower but acceptable dose of 2.5×10^6 CD34⁺ cells/kg.

Chemokines

Chemokines (chemoattractant cytokines) are a family of approximately 40 related small proteins that influence leukocyte (and malignant cell) migration and function.⁸³ Chemokines with varying

effects on different WBC populations have been identified, as have a number of chemokine receptors. The roles of chemokines and chemokine receptors in the trafficking of HSCs into and from the bone marrow compartment are under active investigation.⁸⁴

In a preclinical study, administration to both mice and rhesus monkeys of a modified CXC chemokine growth-related oncogene- β after 4 days of G-CSF resulted in a fivefold increase in the number of circulating stem and progenitor cells compared with G-CSF alone, with also a much shorter time course of release, measured in hours.⁸⁵ Furthermore, more rapid recovery of hematopoietic function was observed for animals given similar quantities of cells collected after administration of the chemokine and cytokine combination. IL-8, a related ligand for the CXCR2, mobilizes stem cells within 15 to 30 minutes of injection into mice,⁸⁶ which appears to involve increased matrix metalloproteinase-9 activity detectable immediately before the appearance of HSCs in the peripheral circulation. Murine studies demonstrate a mobilizing effect of the chemokine SDF-1 and its receptor CXCR4 that can be blocked by neutralizing antibodies to either.⁸⁶ The bicyclam molecule plerixafor disrupts SDF-1/CXCR4 binding and has been shown to result in mobilization of HSC in murine, canine, and nonhuman transplant models.

Similar signaling pathways are used for mobilization and homing of normal and malignant hematopoietic cells.⁸⁷ Although PBSC products collected after G-CSF mobilization generally contain fewer detectable tumor cells than does bone marrow harvested from the same patient, the effects of chemokine treatment on the degree of PBSC contamination and on disease relapse after autologous transplantation remain to be elucidated. For example, acute myelogenous leukemia cells express CXCR4 in varying levels and homing of primary human acute myeloid leukemia cells into nonobese diabetic/severe combined immunodeficiency mice is CXCR4 dependent, similar to normal human stem cells. Similar studies of chemokine control on tumor cell growth, migration, and metastasis are being reported from a number of laboratories. There are now reports of a possibly increased risk of posttransplant myelodysplasia or acute leukemia after transplantation using plerixafor-mobilized cells,⁸⁸ although others have reported that poor mobilizers (who are more likely to receive this chemokine) have a higher risk of posttransplant myelodysplasia,⁸⁹ complicating determination of causation of this complication of transplantation.

Plerixafor

Plerixafor (AMD3100) is a small-molecule inhibitor of CXCR4. Clinical studies of HSC mobilization using plerixafor with or without G-CSF priming are being reported in both healthy donors and patients undergoing autologous or allogeneic HSC transplantation. In a study involving normal volunteers, a single dose of plerixafor was equal in mobilization of CD34⁺ cells to administration of a standard 5-day course of G-CSF.⁹⁰ However, a single dose of plerixafor given on day 5 of a daily course of G-CSF administration resulted in a further 3.8-fold increase in circulating CD34⁺ cells (as well as B and T cells, which may be important in allogeneic transplantation). Randomized phase III studies conducted in patients undergoing autologous PBSC transplantation in the treatment of multiple myeloma or non-Hodgkin lymphoma demonstrated a clear increase in CD34⁺ cells collected by the addition of plerixafor to filgrastim.^{91,92} Plerixafor was also effective in remobilization attempts for patients who failed initial collection goals.⁹³ Plerixafor clearance is proportional to the degree of renal function in patients with renal failure.⁹⁴ Minor gastrointestinal symptoms appear to be the most common toxicities of this medication.

Strategies for the Patient Who Is Difficult to Mobilize

Most patients achieve the targeted dose of CD34⁺ cells after processing 20 to 30 L of blood in one to three apheresis procedures. However, approximately 5% to as many as 30% of patients in various series

have inadequate collections because only small numbers of HSCs are present in the peripheral blood despite the administration of hematopoietic cytokines. Of note, the number of days of apheresis also predicts the kinetics of neutrophil engraftment independent of the CD34⁺ cell dose infused, indicating an undefined measurement of graft quality, probably a reflection of the various quantities of CD34⁺ cell subsets and CD34⁺ stem cells, as well as the characteristics of the stem cell niche.⁹⁵ Patient-specific factors predictive of poor mobilization include older age, marrow disease, prior radiotherapy, and prior chemotherapy.⁹⁹ Approximately 50% of patients who fail to achieve the targeted dose of CD34⁺ cells will achieve this goal on a second attempt. High-dose (15 mg/kg twice daily) G-CSF after a 2- to 4-week drug holiday to allow marrow recovery is one strategy. Combination cytokine therapy is also of potential value in this situation, and the combination of SCF with G-CSF may be effective for patients who reside in countries where SCF is available. The addition of GM-CSF to G-CSF is not of proven value. The addition of plerixafor will often be effective when used in combination with G-CSF for collection of PBSCs from patients who failed a prior mobilization attempt.⁹³ Treatment with the use of cyclophosphamide- or ifosfamide-based mobilizing chemotherapy plus a cytokine regimen also will be effective, but will be associated with increased toxicity.⁹⁶ Bone marrow collection is very unlikely to achieve an acceptable product in that the poor mobilization of PBSCs predicts for a poor marrow harvest. Patients who fail initial collection attempts will frequently fail subsequent attempts, and transplantation of these patients with a lower dose of CD34⁺ cells (as low as 1×10^6 CD34⁺ cells/kg) may be an option.

It is, therefore, strongly preferable to avoid collection failure. Consideration should be given to the prophylactic collection of PBSCs early in the course of treatment for patients who later may be candidates for autologous HSC transplantation but who are advised to receive multiple courses of therapy or therapy involving alkylating agents or radiation therapy. HSCs can be collected and cryopreserved before extensive therapy while the patient has good marrow function and stored for years without obvious progressive loss of engraftment potential.

Timing of Apheresis

A major problem with chemotherapy-based mobilization regimens is the difficulty in determining the optimal time to commence HSC collection. Apheresis devices can collect only those CD34⁺ cells actually being released into and circulating in the peripheral blood. It is possible to estimate the quantity of CD34⁺ cells that will be collected during apheresis by multiplying the quantity of CD34⁺ cells in the blood by the total volume of blood processed during the apheresis procedure and by the efficiency of the apheresis device in collecting these cells. If the device has an efficiency of 50% and the patient undergoes a 10-L exchange, approximately 5×10^7 CD34⁺ cells will be collected for a peripheral blood level of 10 CD34⁺ cells/ μ L and 5×10^8 CD34⁺ cells for a blood level of CD34⁺ cells that is 10-fold higher. Although many protocols call for initiation of apheresis after chemotherapy mobilization when the WBC count has recovered to greater than 1000/ μ L, there is a poor, if any, correlation between the peripheral blood white cell or mononuclear cell counts and the CD34⁺ cells in the peripheral blood. Characteristics that suggest a higher CD34⁺ cell level are a rapidly rising WBC count, shift in differential to immature myeloid cells, circulating nucleated red cells, and platelet transfusion independence. However, it is much more cost effective to obtain an actual measurement of CD34⁺ cells in the blood and to time the apheresis collection when these cells are present in adequate numbers. Fig. 95.3 shows such a relationship for patients with lower concentrations of CD34⁺ cells in the peripheral blood and illustrates the very poor collections obtained when the peripheral blood CD34⁺ count is less than 10/ μ L. Although there is considerable error in the enumeration of CD34⁺ cells at levels less than 5/ μ L, this error is not clinically relevant because even a doubling of the CD34⁺ cells in this low range still results in a very poor apheresis yield.

Fig. 95.3 RELATIONSHIP BETWEEN QUANTITY OF CD34⁺ CELLS IN THE PERIPHERAL BLOOD AND NUMBER COLLECTED BY APHERESIS USING APHERESIS AND FLOW CYTOMETRIC TECHNIQUES. Data shown are limited to peripheral blood CD34⁺ cell numbers <50.0/μL ($n = 157$, $r = 0.82$, $p < .001$).

The level of CD34⁺ cells in the peripheral blood at which to start apheresis is a clinical decision. Although levels in the range of 50–100/μL or greater will reduce the number of apheresis procedures necessary to achieve a target goal of CD34⁺ cells, each day's delay in initiating apheresis incurs the costs of additional cytokine administration and blood testing. In some patients who previously have undergone extensive treatment and who may show a slowly rising WBC count, multiple apheresis procedures may be necessary to achieve the target goal. No patient should undergo apheresis if the peripheral blood CD34⁺ cell count is less than 5/μL (see Fig. 95.3). For patients with CD34⁺ cell counts in the range of 10–20/μL, it is possible to process more blood per day using large-volume leukapheresis (LVL) techniques, thereby reducing the numbers of days the patients are required to return to the apheresis unit. Most patients mobilized with chemotherapy have a rising CD34⁺ cell count in the peripheral blood, so starting apheresis the day after the patient has achieved a desirable CD34⁺ level generally is feasible.⁹⁷

The timing of apheresis after G-CSF mobilization differs from the timing after chemotherapy and cytokine mobilization. For both patients and healthy donors, the peak concentration of CD34⁺ cells occurs on day 5 of G-CSF administration (after 4 daily doses).⁷¹ Lower levels are present on day 4, and the concentration continues to fall after day 6, even if cytokine administration is continued and despite a possible continued rise in WBC count. Thus, PBSC collection should be initiated on day 4 or 5 of G-CSF administration. The kinetics of CD34⁺ cells in the peripheral blood for patients and donors mobilized with G-CSF alone are so reliable that monitoring of peripheral blood levels is not necessary unless there is concern that the patient has failed to mobilize cells and it is practical to obtain the cell count rapidly enough to initiate apheresis on the same day.

Timing of Apheresis Using Plerixafor

Plerixafor administration results in a rapid mobilization of HSCs into the peripheral blood, with peak CD34⁺ cell and CFU-GM concentrations occurring about 6 to 10 hours but with a wide range of activity extending to over 24 hours after administration of a dose of 240 mcg/kg.^{98–100} The initial phase III studies demonstrating the efficacy of this agent in patients failing to mobilize adequate cells with G-CSF alone required administration of plerixafor about 10 hours before apheresis, and then daily administration of plerixafor on the same schedule until completion of collections. The broad duration of activity may allow alternate timing schedules and, conceivably, two apheresis procedures after one dose of plerixafor (particularly for patients with renal impairment⁹⁴). Although rigorous clinical studies

Physician Prescription for Apheresis and Peripheral Blood Stem Cell Processing

The attending physician should be aware of apheresis and laboratory procedures in order to maximize the value of peripheral blood stem cell (PBSC) products. The choices of venous access, anticoagulant(s), blood volume processed, target dose of CD34⁺ cells, and cryopreservation volumes can be individualized. Apheresis unit staff may ask for guidance regarding pain medications, concurrent medications, and blood transfusions (although it is advisable to avoid transfusion during the apheresis procedure because of citrate or other reactions, and because changes in the hematocrit may affect the efficiency of the collection). Adequate numbers of CD34⁺ cells can be collected for more than one cycle of chemotherapy. It is important to communicate with the cryopreservation facility if PBSC components will be used to support more than one cycle of chemotherapy or if dimethyl sulfoxide toxicity is of concern, in order to facilitate appropriate packaging of each product. Current cytometric techniques for quantification of CD34⁺ cells require at least 1 hour of processing, so it may not be practical to prescribe the number of CD34⁺ cells to be frozen in each bag. However, it is possible to divide the component into the number of bags equaling the number of anticipated infusions so that equal numbers of CD34⁺ cells will be available for each.

addressing alternate timing schedules have not been performed, small studies have demonstrated the ability to collect PBSCs with alternate schedules.^{101,102} In a study of 11 patients who failed two previous attempts to collect PBSCs using G-CSF alone, Lefrere et al¹⁰² found an early rise in circulating CD34⁺ cells, as early as 3 hours, with a fall in circulating CD34⁺ cells occurring after 8–12 hours.

Collection of PBSCs by Apheresis

A number of apheresis devices are available for separating HSCs from the peripheral blood. The devices may be classified as continuous flow (e.g., Fenwal CS3000, COBE Spectra, Spectra Optia, Fenwal Amicus) or discontinuous flow (e.g., Haemonetics family of equipment). Discontinuous-flow devices have the advantage of requiring only a single venous access. Continuous-flow devices require two access lines for aspiration and return of blood, but they process much larger volumes of blood in a shorter period of time. All apheresis devices collect HSCs. Continuous-flow devices are more efficient in the collection of PBSCs and are, accordingly, preferred over discontinuous-flow devices (see box on [Physician Prescription for Apheresis and Peripheral Blood Stem Cell Processing](#)). The ideal apheresis device will have: a high efficiency of CD34⁺ cell collection with minimal contamination of the product by mature blood cells such as granulocytes, which complicate subsequent processing and can increase infusion toxicity; rapid blood processing with minimal anticoagulant use reducing toxicity to the donor; and minimal depletion of platelets. The various apheresis devices, in general, have similar efficacies in collecting CD34⁺ cells from the peripheral blood, but may vary in processing time, and in final product volume and mature blood cell contamination.¹⁰³

Apheresis Technology

Apheresis technology is widely used for collection of platelets and other blood products from healthy donors and is considered to be without major risk to the donor. The important safety considerations for PBSC collection are the same as for platelet collection and include the venous access to be used for the procedure, the extracorporeal volume of blood during the procedure, and the solutions administered to the donor. Of note, however, PBSC collection for autologous transplantation involves patients with underlying medical conditions who may require considerable nursing care during the procedure. In a prospective evaluation of 2408 healthy unrelated volunteer donors, apheresis-associated adverse events were reported by 20% of female

donors ($n = 964$) and 7% of male donors ($n = 1444$) on the first day of apheresis, falling to 10% and 4%, respectively, on the second day of collection (if performed).⁷⁷ Most (51%) of reported adverse events were related to citrate infusion. A smaller proportion of donors (22%) reported problems with venous access. Rare (1–6% of events) adverse events included hypertension or hypotension, allergic reactions, fatigue, and syncope. The placement of a central venous catheter was required by 17% of female donors and 4% of male donors. Also, larger-volume and repetitive exchanges will result in platelet depletion.⁷⁶ The platelet count may reach its nadir several days after completion of the apheresis collections and discontinuation of G-CSF, and donors should be counseled in this regard.

Important caveats are that the donors in this analysis from the unrelated donor registry met strictly defined health criteria and were between 18 and 69 years of age. A higher probability of adverse events may be expected in patients and in donors of older (or younger) age. For example, in an older retrospective publication, Goldberg and colleagues¹⁰⁴ studied the complications occurring during 554 PBSC collections from 75 consecutive patients. Patient diagnoses and the mobilization treatment regimens were varied. All but one patient had subclavian or jugular venous system catheters placed for apheresis. A median of nine collections per patient were performed using a discontinuous-flow apheresis device. The most common problems were related to the venous catheters: 50% of patients developed at least one occlusion. Hypocalcemia occurred in 14.6% of patients and hypotension in 13.3%. Sixteen percent of patients experienced infectious complications during the PBSC collection period.

Staffing of the apheresis unit should be appropriate for the medical condition of the patients undergoing apheresis. Staffing must include nurses familiar with the care of the oncologic patient who may be recovering from marrow hypoplasia complicated by neutropenic fever requiring multiple medications and the care of a central venous catheter. Collection of PBSCs by apheresis in the outpatient setting should be performed only after careful review of the medical support requirements for the individual patient or donor, and it should never be assumed to be a safer alternative for the donor or patient with a serious comorbid illness than marrow harvesting conducted in the intensive care setting of the operating room.

Venous Access

Adequate venous access is required for optimal apheresis technique. Continuous-flow apheresis devices require two-lumen access with a stable blood flow capacity generally greater than 20 mL/min. Single-lumen access may be used with discontinuous-flow apheresis devices, although at a much slower rate of blood processing. The great majority ($\approx 95\%$) of adult male allogeneic PBSC donors have adequate arm veins for the procedure to be conducted “vein to vein,” with female donors more likely to require alternate venous access.⁷⁷ Some donors, especially those with small veins and undergoing several daily procedures, may require placement of a temporary venous catheter. Venous access for the patient undergoing collection for autologous PBSC transplantation is much more heterogeneous. Vein-to-vein procedures can be performed, even on several consecutive days, with proper phlebotomy technique and postcollection care of the phlebotomy site. Most patients received previous chemotherapy or are proceeding directly to transplantation, conditions for which tunneled access is commonly placed. Ideally, this venous access should be appropriate both for the apheresis procedures and the subsequent transplant. Length, lumen size, and wall stiffness all affect the blood flow that can be achieved through a catheter. For this reason, the commonly used dual-lumen Hickman or Broviac catheters are usually unsuitable for apheresis, as are all subcutaneously placed ports. Most triple-lumen catheters are inadequate because of the small lumen size. If such access is already in place, consideration can be given to replacement with a shorter, stiffer tunneled catheter or to placement of a temporary percutaneous dialysis/apheresis catheter. The catheters designed for dialysis and apheresis have adequate wall thickness to

prevent collapse during aspiration of blood, as well as a tip design that decreases local recirculation of blood and the resulting decrease in apheresis efficiency. Catheters of 10 F or larger size are appropriate for adult patients. Pediatric patients, whose blood flow rates are considerably slower, may use catheter sizes of 5–7 F.¹⁰⁵

Anticoagulation for PBSC Collection

Anticoagulants are added to the blood during apheresis to prevent clotting of the extracorporeal circuit and clumping of cells in the component. Citrate anticoagulants have a proven record of safety in the apheresis of healthy platelet donors. The major drawback is the risk for a symptomatic decrease in the level of ionized calcium (“citrate toxicity”), especially during processing of large volumes of blood. Citrate ions chelate calcium ions (and other divalent cations such as magnesium), making them unavailable for Ca^{2+} -dependent metabolic reactions. ACD-A contains 10.67 g of citrate per 500-mL volume in the form of trisodium citrate and citric acid. Citrate is diffused throughout the extravascular space, and this diffusion is the first defense against citrate toxicity. The body size and difference in muscle mass between men and women results in an increased risk for citrate toxicity for women in particular and smaller donors in general. Metabolism by liver, kidney, and muscle also reduces the concentration of citrate. Metabolism of citrate becomes an important clinical consideration during processing of larger blood volumes or at higher rates of blood flow. The initial signs of citrate toxicity include circumoral or acral paresthesias and may progress to nausea, vomiting, loss of consciousness, tetany, and seizures. Because pediatric patients may not be able to relate the initial symptoms of the condition, citrate toxicity should be considered as the cause of any change of behavior, such as crying, during the apheresis procedure. Citrate toxicity is prevented by limiting the quantity of citrate infused either by decreasing the blood flow rate through the apheresis device or changing the blood-to-citrate ratio. The processing of blood from patients experiencing the initial symptoms of citrate toxicity should be temporarily halted until the symptoms abate and then resumed at a slower rate. The benefit of oral calcium supplements for these patients is not proven and may cause abdominal discomfort. Heparin can be used as a replacement for some or all of the citrate, although additional citrate should be added to the component bag to prevent clumping of platelets. Some centers that use citrate anticoagulants also administer intermittent or continuous infusions of calcium gluconate during the procedure, especially if large volumes of blood are being processed. However, excessive calcium replacement can induce cardiac dysfunction.

Large-Volume Leukapheresis

The apheresis device has a uniform and fairly reproducible efficiency of collection. Thus, for a consistent quantity of blood processed through the machine, the quantity of $\text{CD}34^+$ cells collected is directly related to the number present in the peripheral blood. Greater quantities of $\text{CD}34^+$ cells can be collected by increasing the number of these cells in the peripheral circulation or by increasing the volume of blood processed in each procedure (LVL). For patients with lower $\text{CD}34^+$ cell levels, multiple apheresis procedures will be required to achieve the target dose of $\text{CD}34^+$ cells needed for transplantation. An alternate approach is to process the same total quantity of blood but in fewer, longer procedures. LVL is not standardly defined, but in general usage it refers to processing of more than two or three times the patient's blood volume. Typically, the quantity of blood processed is six or more times the patient's blood volume, often 25–36 L of blood. The advantage of LVL is that it reduces the number of days of cytokine administration and apheresis, with associated reduced costs of laboratory processing and testing. The apheresis techniques are the same as those used for processing of smaller volumes of blood, although blood flow rates may be increased to reduce the time required. The risks of LVL are the increased time required and the

^aShown are numbers of CD34⁺ cells in the peripheral blood or apheresis component for five patients with acute myelogenous leukemia or multiple myeloma undergoing large-volume leukapheresis after granulocyte colony-stimulating factor (G-CSF) or chemotherapy plus G-CSF mobilization treatment. Blood volumes processed were six times the calculated blood volume of the patient. Peripheral blood stem cell collection was performed on the COBE Spectra. The total number of CD34⁺ cells in the blood (third column) was calculated from the level of CD34⁺ cells in the blood and the estimated blood volume of the patient. The total number of CD34⁺ cells released (fifth column) was calculated from the total number in the apheresis component and the number in the peripheral blood after collection minus the total number in the peripheral blood at the start of the collection procedure. All CD34⁺ cell quantities (except blood levels reported per μ L) are $\times 10^6$. Full data are given in Rowley SD, Yu J, Heimfeld S, et al: Trafficking of CD34⁺ cells into the peripheral circulation during collection of peripheral blood stem cells by apheresis. *Bone Marrow Transplant* 28:649, 2001.

higher risk for citrate (or other anticoagulant) toxicity. Patients will also incur a proportional drop in platelet counts and may become profoundly thrombocytopenic.

Most reports of LVL describe the collection of more CD34⁺ cells than are calculated to be present in the peripheral blood at the initiation of the apheresis procedure. This results from the ongoing release of cells from the marrow replacing those cells removed by apheresis (or returning to the marrow space).¹⁰⁶ Apheresis of CD34⁺ cells is a three-compartment system consisting of the extracorporeal circuit of the apheresis device (including the collection bag), the peripheral blood, and the marrow. It is not obvious that the apheresis technique itself “mobilizes” CD34⁺ cells. Apheresis-induced mobilization, if it occurs, may be related to a decrease in divalent cations resulting from the citrate anticoagulant, possibly affecting cell adhesion forces.

Studies at the Fred Hutchinson Cancer Research Center demonstrated a continuous release of CD34⁺ cells from the marrow (and, presumably, return to the marrow space).¹⁰⁶ Patients having higher levels of CD34⁺ cells in the peripheral blood appeared to have a greater number of these cells circulating between the marrow and peripheral blood compartments (Table 95.1). In this model the apheresis device merely serves as a siphon, removing these cells from the blood as they are released from the marrow. If this description of CD34⁺ cell kinetics is accurate, it may be possible to deplete these cells from the blood and marrow by prolonged processing, but probably only if limited numbers of them are present in the marrow compartment. Also, the model suggests that higher blood flow rates used to shorten the apheresis procedure may be counterproductive for patients with low CD34⁺ cell levels in the blood because of the slower rate of release of CD34⁺ cells in these patients.

Pediatric Donors and Patients

PBSCs can be collected from pediatric patients, including infants. The special challenges of the pediatric patient arise from the fixed extracorporeal blood volume of the apheresis device, the need for venous catheters for blood access, and the management of a patient who may be unwilling or unable to rest quietly for the period of apheresis. It is especially important in management of the pediatric patient that timing of apheresis be optimal to minimize the number of procedures required to achieve the desired quantity of PBSCs.

Given these considerations, a number of centers have reported successful collection of PBSCs from pediatric patients and donors.

Almost all pediatric patients undergo insertion of a venous catheter adequate for the flow rates expected, although older patients (>12 years) may tolerate vein-to-vein procedures. The whole blood flow rate for the pediatric patient is much reduced compared with that of adult patients, and catheters as small as 5 F may be adequate.

Appropriate management of fluid balance during the apheresis procedure is critical for the smaller patient. The volume of red blood cells contained in the extracorporeal circuit of the continuous-flow apheresis device could represent 30% to 50% of the red cell mass of a pediatric donor. Although discontinuous-flow devices are appealing because of the feasibility of performing apheresis with a single-lumen venous access, they may result in even higher extracorporeal volumes and should be avoided in the smallest patients. The obvious solution to this problem is to prime the apheresis device with ABO-compatible, irradiated red blood cells (leukocyte-depleted and cytomegalovirus-negative blood is also desirable) when the blood in the extracorporeal circuit is expected to exceed 15% of the patient's blood volume. Packed red blood cell units can be diluted with saline or albumin (to reduce the loss of plasma protein that may occur). The red cells remaining in the extracorporeal circuit at the completion of the run need not be returned (“rinse-back”), although if performed slowly with monitoring of vital signs, rinse-back may actually increase the hematocrit after the procedure and otherwise reduce the need for red cell transfusions for these patients. For the intermediate-size pediatric patient (weight 25–50 kg), the apheresis device can be primed with a 5% albumin solution. This step will reduce the albumin loss that otherwise would occur. However, clotting proteins and other proteins not contained in this solution may decrease with repetitive apheresis.

The pediatric patient may not exhibit or relate the prodromal symptoms associated with citrate toxicity. Continuous calcium gluconate infusion can be incorporated into the procedure, or heparin can be added to the citrate anticoagulant solution or used as the sole anticoagulant. Sedation of the pediatric patient is usually not necessary and hinders the ability to recognize the symptoms of citrate toxicity. (Some patients may require antihistamine premedication if the apheresis device is primed with red blood cells.) Centers routinely performing pediatric PBSC collection should design an environment conducive to the management of pediatric patients and develop support procedures that recognize the unique physical and cognitive features of pediatric patients.

The range in blood volumes for pediatric donors of differing ages is greater than the range for adult donors. Therefore, most centers set a goal for volume processed based on the individual's blood volume instead of a set volume (e.g., two blood volumes vs. 6 L of blood) for all patients. The pediatric patient may undergo LVL to achieve the target goal of HSCs with fewer procedures. Blood flow rates for pediatric patients are slower than for adults to minimize the risk for citrate reaction. As with adults, the timing of apheresis can be optimized by monitoring the quantity of CD34⁺ cells in the peripheral blood.

QUALITY CONTROL OF HSC PRODUCTS

Quantity of Bone Marrow Cells for Transplantation

Cell dose is normally used as a surrogate for the stem cell content of the marrow product because the definition of adequate HSC products predated the availability of flow cytometric analysis of HSC content, and nucleated cell counting is the only quality-control measure easily performed during the collection procedure. For autologous transplantation, cell doses of 1×10^8 nucleated cells/kg are adequate. Based on early reports that smaller quantities increased the risk for engraftment failure, most centers target 3×10^8 nucleated cells/kg of recipient weight for allogeneic transplantation. However, those early reports were of patients being treated for aplastic anemia, in which engraftment failure is a more common event. A review of unrelated

donor transplantation found that recipients of higher marrow cell doses experienced faster neutrophil and platelet engraftment, as well as better leukemia-free survival.¹⁰⁷ Pretreatment of the marrow donor with either GM-CSF or G-CSF may increase the number of myeloid progenitor cells harvested and decrease the period of posttransplant aplasia to that achievable by PBSC transplantation. CD34⁺ cell dose is now being correlated with transplant outcomes—with more rapid engraftment kinetics, possibly lower transplant-related mortality, and better overall survival, for example, in recipients of allogeneic bone marrow products containing higher quantities of CD34⁺ cells.¹⁰⁸ This assay should be a routine component of bone marrow product quality control.¹⁰⁸

Definition of Adequate PBSC Component(s)

The quantity of CD34⁺ cells in a PBSC component varies greatly and is dependent on the number in the peripheral blood at the time of apheresis, the volume of blood processed, and the efficiency of the apheresis device. Therefore, any definition of an adequate component cannot include a set number of CD34⁺ cells to be contained in any single apheresis component. Instead, one or more components will be collected to meet the appropriate dose of these cells for transplantation. The dose of CD34⁺ cells required for infusion depends on the intended treatment regimen. For marrow-ablative regimens, increasingly higher CD34⁺ doses results in greater likelihood of rapid engraftment (Figs. 95.4 and 95.5).¹⁰⁹ Lower doses of CD34⁺ cells appear satisfactory for nonablative regimens.

Patients who receive a dose of CD34⁺ cells above a certain threshold will engraft. At lower doses of CD34⁺ cells, considerable heterogeneity occurs in engraftment speed, especially for platelet engraftment. Why this heterogeneity exists is not known, but it may reflect a weakness in the correlation between CD34⁺ cells and the cells responsible for engraftment, a greater heterogeneity of CD34⁺ subsets collected, or perhaps simply a greater degree of error in the measurement of CD34⁺ cells at the lower cell concentrations. As the dose of CD34⁺ cells increases, the engraftment kinetics becomes both more rapid and more consistent for the population studied.¹⁰⁹

Subset analysis of CD34⁺ cells may improve the accuracy of predicting neutrophil and platelet engraftment kinetics but does not appear to predict engraftment failure enough to be of clinical utility. Pecora and colleagues¹¹⁰ reported that the quantity of CD34⁺CD33[−] cells infused was identified as an independent factor predictive of engraftment kinetics. Dercksen and colleagues¹¹¹ reported better correlation between the number of CD34⁺CD33[−] cells and time to granulocyte engraftment, and between the number of CD34⁺CD41⁺

cells and time to platelet engraftment than found with the overall number of CD34⁺ cells. Coexpression of adhesion molecules is also predictive of hematopoietic recovery, with the same pathways important for both mobilization and homing of HSCs.¹¹² Given the limited range in recovery times when adequate numbers of CD34⁺ cells are collected and infused, however, this additional information is currently of limited clinical value.

CD34⁺ cell dose is also predictive of outcome of allogeneic PBSC (and marrow) transplantation.^{108,113} Higher CD34⁺ cell doses result in better neutrophil and platelet engraftments after either related or unrelated donor transplantation and may correlate with better survival after bone marrow transplantation, but may also be associated with the development of more chronic GVHD.

Tumor Cell Contamination

The probability that tumor cell contamination of HSC product could contribute to relapse was demonstrated by Brenner and colleagues¹¹⁴ in studies involving the autologous transplantation of genetically marked marrow cells, as well as in individual case reports describing the transmission of malignancy to allogeneic recipients from donors with occult disease at time of harvesting.^{27,28} Sensitive immunocyto-staining techniques, clonal assays, flow cytometric analysis, and polymerase chain reaction amplification of malignant genetic material detect tumor cells in the autologous PBSC components of many patients with a variety of malignancies.¹¹⁵ In general, the incidence of contamination (number of patients with positive components) and the level of contamination (number of tumor cells per number of normal cells) is much less for PBSCs than for marrow products.

The presence of tumor cells at the time of collection or persisting after ex vivo processing may correlate with the extent of systemic disease or the chemotherapy sensitivity of disease at the time of cell collection. Whether patients transplanted with autologous PBSCs have a lower relapse rate compared with patients receiving bone marrow is not well defined, and appropriate phase III studies of this question will be difficult to design and enroll with patients in light of the other well-defined advantages of PBSC transplantation. In a retrospective study, Sharp and colleagues¹¹⁶ demonstrated similar probabilities of relapse-free survival in recipients of PBSCs or marrow components if the components were free of lymphoma cells. In that study, patients with marrow involvement by lymphoma were assigned to transplantation with PBSCs. The authors concluded that PBSC transplantation is a sensible approach to the patient with overt marrow involvement. However, Brugger and colleagues¹¹⁷ demonstrated that patients with breast cancer involvement of the marrow

at the time of chemotherapy mobilization were likely to mobilize tumor cells into the blood. The most disturbing finding of this study is that the tumor cells were detected in the peripheral blood at the same time as CD34⁺ cells.¹¹⁷ Similarly, Pecora and colleagues¹¹⁸ found a relationship between the ability to detect tumors in PBSC components and in bone marrow samples, but they also found a higher incidence of positive PBSC components for patients who required greater numbers of apheresis procedures to achieve the target dose of CD34⁺ cells. Investigators at The Johns Hopkins Oncology Center found no difference in the incidence of tumor contamination of PBSC components between patients treated with chemotherapy and cytokines and those treated with cytokines alone.¹¹⁹ Ex vivo purging of tumor cells from PBPC products has not been shown to reduce the risk for relapse after autologous transplantation, either because the techniques are not adequate in depleting minimal residual disease or because patients relapse primarily from endogenous disease surviving the pretransplant conditioning regimen. Patients with marrow involvement may benefit from several cycles of debulking (in vivo purging) chemotherapy before collection of HSCs, with the caveat that extensive chemotherapy will also decrease the subsequent yield of PBSCs. Tumor cells in the HSC inoculum likely will not benefit the patient, but until further data demonstrating a deleterious effect on transplant outcomes are available, it is advisable that reports of tumor contamination in the collections for individual patients be interpreted with caution.

Microbial Contamination of Hematopoietic Stem Cell Components

Bacterial culture is an essential quality-control component in HSC collection and transplantation used to identify errors and breakdowns in manufacturing technique. Skin flora are the bacteria usually isolated, and infusion of culture-positive HSC products is generally without clinical sequelae, although serious infections have occurred after infusion of HSC products contaminated during processing.⁴⁷ Culture-positive products need not be automatically destroyed. Any decision regarding the disposition of a culture-positive HSC product must be made by the patient's transplant physician after considering the type of contamination, the anticipated risks from use of the component, and the ability to replace the culture-positive product(s) in a timely manner.

The incidence of culture-positive PBSC components is considerably less than that for marrow. The actual incidence of contamination for all HSC products is likely several times higher than reported, however, because most laboratories will culture only a very small volume of product (≈1 mL). In a retrospective review of 2935 HSC products processed and transplanted at one center, positive microbial products were reported for 1.3% of bone marrow products, 0.7% of PBSC products, and 2.0% of UCB products.⁴⁷ Coagulase-negative *Staphylococcus* and *Bacillus* species accounted for 23 of the 38 positive cultures, but *Escherichia coli*, *Klebsiella pneumoniae*, and *Pseudomonas cepacia* were cultured from one product each. The recipient of the *Pseudomonas*-contaminated product subsequently died of complications of *Pseudomonas* sepsis, but no adverse sequelae could be documented for any of the other 34 recipients of culture-positive products. The highest rate of contamination occurred in the UCB products collected for related donor transplantation (5 out of 18, 27.8%), likely a reflection of the collection techniques in place at the time, and illustrating the need for strict quality control in the collection and processing of HSC products.

Quantitation of CD34⁺ Cells

Quantification of CD34 antigen-positive cells by flow cytometry has become the standard of care for management of the PBSC donor because it provides a rapid and clinically relevant assessment of HSC content in the peripheral blood or in the PBSC product. This antigen is found on HSCs (including a variety of subpopulations) and limited

populations of other blood cells,¹²⁰ and can be identified using a variety of commercially available antibodies. If antibodies directly conjugated with dyes are used, the technique requires only about 1 hour of preparation time. Cell viability using propidium iodide or 7-aminoactinomycin D exclusion can simultaneously be determined if the cells are analyzed while still fresh, or the cells can be fixed after staining for analysis at a later date. Other antibodies can be added for analysis of CD34 subsets if desired (and if the flow cytometer has proper detectors to detect the different emission wavelengths of the fluorochromes used). A strong correlation exists between the numbers of CD34⁺ cells and CFU-GM in the sample, but with ratios of about 5 : 1 to 20 : 1.¹²¹ Thus, CD34 analysis will provide data similar to that obtainable with cell cultures, except that the latter demonstrates the functional viability of the progenitor cells. Mobilized PBPC products contain a heterogeneous mixture of cells including CD34⁺ cells belonging to different cell subsets. Subset analysis of CD34⁺ cells will provide additional information regarding early and sustained engraftment after autologous PBPC transplantation but does not appear to be clinically useful for the patient who easily meets the PBSC collection goal.

The major difficulty with analysis of CD34⁺ cells is the low frequency of these cells. Clinical decisions to initiate apheresis are being made for CD34⁺ cell levels as low as 10/μL. This may represent a cell frequency that is 0.01% or less of the nucleated cells in the specimen. This enumeration is possible because of multidimensional measurements obtained by flow cytometry. Most cytometers can measure at least five characteristics of each cell, including size, granularity, and the presence of up to three different fluorochromes. Thus, the cells of interest can be separated in five-dimensional space, achieving discrimination of cells as rare as 1 : 10,000. The difficulties arise from developing an adequate technique that makes optimal use of the cytometer to measure these rare cells. Sources of errors include (A) sampling of the HSC product, (B) cell counting, (C) cytometer calibration and operation, (D) choice of antibody and fluorochrome, (E) lysis technique, and (F) gating strategy. Moreover, cytometry provides a proportion of cells that must be multiplied by the cell count to obtain an absolute number. The steps involved in preparing a specimen for cytometry may alter the proportion of cells in the sample, and this error will be translated into an error in the absolute number. Clinically, this imprecision may explain some of the range in engraftment kinetics observed for patients receiving low doses of CD34⁺ cells.

INVESTIGATIONAL NEW DRUG–ENABLING PROCESSES FOR CELL-BASED THERAPIES

Robert Lindblad, Traci Heath Mondoro, Deborah Wood, and Gillian Armstrong

The use of donated human cells as more than replacement therapy has become a reality over the course of the last several years. While basic and clinical scientists are developing many new and promising strategies to improve immune reconstitution and transplant outcome at the manufacturing and individual patient level, they are dependent on many others to implement these new therapies on a larger scale. Ultimately, implementation of procedures that were successful in the laboratory can be expensive and difficult to scale up to a process that will produce the required dosage while maintaining the consistent cellular product quality needed for clinical trials. To cope with these issues, many institutions have established specialized cell-processing centers; however, a specialized cell-processing laboratory and specially trained laboratory staff do not resolve all the problems associated with scaling a new procedure for a clinical trial. In some cases, equivalent reagents and processes suitable for use in large-scale clinical trials are not available.

In addition to the technical challenges of producing clinical grade cells in larger quantities, all of this work involving more than minimally manipulated cell therapy products must be performed under the Investigational New Drug (IND) process through the US Food and Drug Administration (FDA). The use of any cell product that is more than minimally manipulated and is for a nonhomologous indication in humans requires an IND, and even if the cellular therapy has been approved, a new IND may be needed if the agent is being tested in new populations or a situation where the risks to the patient are unknown (Table 96.1). An IND-enabling pre-clinical program is geared toward generating and collecting critical safety/toxicology/pharmacology data required to allow first-in-human studies. Appropriately designed pre-clinical studies are essential to the successful development and characterization of clinical scale manufacturing processes that will enable the filing of a well-supported IND with the FDA for a clinical trial. After IND filing, the FDA will review the procedures in place for the procurement, storage, and processing of the cells, as well as the proposed clinical trial design. A clinical study that is not likely to yield interpretable results is considered an unethical study because it places participants at risk without the prospect of either direct or generalizable benefit.

As the field of cellular therapy moved beyond transfusion of blood components and bone marrow transplantation, it became apparent that the processing and preparation of the cellular product was becoming a science unto itself. The isolation and identification of the desired cell population could take months, and the optimization of this process could take years. This did not include the development and validation of potency assays. All of this work is expensive, labor intensive, and requires staff qualified to perform at the highest technical level. Even though these tasks are vital to the production process, they are not hypothesis driven, so this type of work does not meet the requirements for National Institutes of Health (NIH) research project grants. One of the review criteria for NIH grant applications and contract proposals is innovation. Work required to develop and validate scale-up procedures and potency assays is not considered innovative and therefore is not eligible for discovery research that is typically funded through NIH grants. Many investigators perform this translational work by piecing

together funding from institutional or philanthropic sources. The National Heart, Lung, and Blood Institute (NHLBI) will accept grant applications for cell therapy studies that include manufacturing and translational studies. The National Institute of Biomedical Imaging and Bioengineering (NIBIB) funds hypothesis-driven research related to technologies, and some investigators have been able to utilize services provided by NIH Clinical and Translational Sciences Awards (CTSA) programs. Regardless of the source of funding, this chapter will provide general information about requirements during the IND-enabling phase of the development of a cellular therapy before it is tested for safety in a clinical trial. Critical elements involved in the stages of cell therapy product development are outlined in Fig. 96.1.

OVERVIEW OF THE CELL THERAPY PRODUCT

Novel cell-based therapy offers great potential for treating a number of currently untreatable disorders and diseases including immune reconstitution, tissue repair and regeneration, and metabolic support. Cell-based therapies can be derived from a variety of human autologous, allogeneic, or xenogeneic tissue sources such as blood, bone marrow, adipose, umbilical cord blood, fetal, embryonic stem cell lines, and induced pluripotent cells. Cellular engineering techniques such as selection, depletion, expansion, and genetic modification can be applied to alter or modify a cell to achieve a desired therapeutic effect. With these novel cell therapies, however, come development, manufacturing, characterization, and testing challenges in consistently generating a safe and effective cell therapy product.

Challenges for Cell Therapy Product and Manufacturing Development

Current good manufacturing practices (cGMPs) govern manufacturing processes to ensure consistent manufacture of safe, pure, and potent products.¹ Current good tissue practices (cGTPs) govern the methods used in, and the facilities used for, the manufacture of human cells, tissues, and cellular and tissue-based products (HCT/Ps). cGTPs focus on the prevention of the introduction, transmission, and spread of communicable diseases or other adverse events while preserving product function and integrity.²

Biological Variability

Living biological products present unique challenges. With cell-based therapy there is inherent patient-to-patient biological variability and cellular heterogeneity. Cell therapy products are derived from tissue sources that contain multiple cell types. In addition to known “active components,” there are known and unknown cell subpopulations that may be considered “contaminants” or “inactive components,” or could be critical to the biologic function of the product. Viability alone is a poor marker of cell function. Evolving characterization and

TABLE 96.1 Regulation of Human Cells, Tissues, and Cellular and Tissue-Based Products

HCT/Ps Regulated Under 351 of the PHS Act	HCT/Ps Regulated Under 361 of the PHS Act
Require IND submission and premarket approval; do not meet the definition of exempt products described for 361 products; 21 CFR 1271	No IND required/no premarket approval requirement
More than minimally manipulated	- Minimally manipulated, and - For homologous use, and - Not a combination product, AND either - has no cellular or systemic effect or - if it is active on a cellular or systemic basis is used in an autologous setting, in an allogeneic setting in first- or second-degree blood relatives, or is for reproductive use
Not intended for homologous use	
Associated with a device or scaffold ^a	
Cellular or systemic effect or dependent of metabolic activity of the cells for its primary function	

^aCell therapies that also have a device or scaffold associated with them can be regulated by the Center for Devices and Radiological Health (CDRH) as a consultant to the Center for Biologics Evaluation and Research (CBER) or as the lead center if the scaffold is the primary mode of action.

rigorous process control are therefore critical to counter the intrinsic heterogeneity and variability of cell therapy products.³

Characterization

Cell therapy products are difficult to fully characterize. Critical decisions need to be made in the product-development stage and the establishment of a desired characterization profile should occur early in the process to drive development. Successful product development demonstrates that a cell therapy product can be consistently manufactured which is safe, pure, potent, effective, and stable. Of

these five elements, developing a potency assay for cell therapy products is most challenging. Potency measures the product's relevant biological function and therefore is a critical aspect of both safety and efficacy. Potency requires understanding a mechanism of action that is relevant to the use of the product in humans. Biological products are inherently complex, variable, and often heterogeneous, with complex and/or poorly defined mechanisms of action(s). Despite complex cell-engineering processes, the final product may contain both therapeutic and nontherapeutic cells; however, it can be difficult to ascertain if the combination of "active" and "inactive" components contribute to biological function. Because cells and cell lines are genetically diverse, they may behave differently during manufacturing than they did under experimental conditions. Cell-characterization testing, particularly with respect to potency, will evolve and change significantly during pre-clinical testing and clinical product development.⁴

Raw Materials

Many types of raw materials are used in cell therapy manufacturing. Such materials include culture media, sera, growth factors, cytokines, and "feeder cells," which are used to support cell growth. They may be simple or complex and may remain in the final therapeutic product as active substances, excipients, or as impurities, and, as such, their levels should be measured, controlled, and justified. They may also be used in the manufacturing process as ancillary products. A qualification program for raw materials that includes microbial testing (sterility, pyrogenicity [endotoxin], mycoplasma, and other adventitious agents) needs to be implemented to ensure the consistency and quality of raw materials and be designed to address identification and selection of the material, suitability of materials for use in manufacturing, characterization of materials, justification for use of animal-derived materials (i.e., fetal bovine serum), and quality assurance (QA) for all materials.⁵

Adventitious Agents

Adventitious agents (e.g., viruses, endotoxin mycoplasma, bacteria, parasites, fungi) may originate from the source (e.g., infected animals, tissues), during cell culture manipulation (e.g., repeated passages and manipulation in the laboratory), or by using contaminated biological reagents. Unidentified diseases may exist in the use of xenogeneic cells. The range of infectious agents that produce little or no effect in animals may have severe consequences in humans. With xenogeneic materials rigorous qualification of source animals and primary cell substrates is critical. Also, complex cell engineering procedures may extend over months, and can result in increased risk of contamination and other adverse effects. A risk-based assessment of the quality control (QC) aspects of the manufacturing process is

necessary as poor controls of production processes can lead to the introduction of adventitious agents or other contaminants, or to inadvertent changes in the safety, potency, purity, or stability of the biological product that may not be detectable in final product testing, which is a keystone of the final product release.⁶

Aseptic Processing

As living functional cells are the product, terminal sterilization is not an option, therefore aseptic processing is required, with the use of closed manufacturing systems to the extent possible. This is considered a critical aspect of the manufacturing process and should be defined and validated as such, particularly as the risk of delivering a contaminated product is increased not only because of the inability to sterilize the product, but also because the timelines involved with cell products and product administration may occur before final sterility testing has been completed. The nature of the starting material and processes that involve open or closed manipulations determine the level of a controlled environment to be implemented.

Target Cell Population

Cells of therapeutic interest are often found in small numbers. Therefore an important first step of cell processing can be the initial isolation or enrichment of a cell population of interest from the tissue source. Several commercial fully automated closed systems are already in use and include the CliniMACS Prodigy system (Miltenyi Biotec), the Sepax 2 system (Biosafe SA), and the Elutra system (Terumo BCT). Cell-culturing processes can be specific to a given cell type; for example, cells such as T cells can be grown in nonadherent suspension culture where large-scale bioreactors, such as bag-based and traditional stirred-tank vessels, are used. This culturing system requires a small surface area and can produce high cell yield. There is a growing interest in *ex vivo* expansion of adherent cells for a variety of clinical applications. Mesenchymal stromal cells are grown adherently on tissue culture-treated surfaces but require a large surface area to be produced on a large scale. Miltenyi Biotec culture bags offer a closed-system process along with the CLINICell (MABio). Multilayered flasks have been developed (CellCube and CellSTACK, Corning) to address surface area. Bioreactors (G-Rex, Wilson Wolf Manufacturing and WAVE, GE Healthcare Life Sciences) and microcarrier-based culturing systems (SoloHill Engineering) are designed to support cell growth at a variety of scales.⁷

Autologous Versus Allogeneic Products

Given their unique donor specificity, autologous products are attractive because of their decreased risk of immunologic reactions, bioincompatibility, and communicable disease transmission. However, they are inherently more limited and more variable owing to individual patient characteristics and/or disease state. Use of allogeneic donors is associated with greater risk than autologous donation because of the risk of infectious disease transmission from the donor to the recipient, overall risk of an immune response, and donor-to-donor variability. However, allogeneic cells have the potential to treat hundreds of patients from a single manufactured lot of cells and can be an “off-the-shelf” product.

Methods used in the production of cell products for clinical therapies depend on the nature of the final product and their targeted population. Autologous products are patient-specific and are manufactured using a “scaled out” approach. Cells are manufactured in small-volume batches and each patient constitutes their own “lot” of product. Allogeneic product manufacturing can use a scaled-up approach with a bulk manufacturing strategy to produce larger-volume batches to treat multiple patients.

In summary, cell therapy products are being used in a variety of therapeutic indications and their development for and use in other indications is progressing into the clinic. However, the clinical administration of living biologics carries elements of risk. Rigid control processes to minimize risk need to be implemented. Characterization, although a predictor of efficacy, is not a predictor of safety or quality. As full characterization is unlikely, it is imperative that manufacturing and aseptic processes be designed and validated to produce a safe, reliable product. If manufacturing methods change, as is often the case, essentially a new product is created, and recharacterization and repeat testing will be required to assess the impact of those changes on the product.

THE REGULATION OF CELL THERAPY PRODUCTS

The Center for Biologics Evaluation and Research (CBER) currently regulates cell therapy products considered as HCT/Ps under two sections of the Public Health Service (PHS) Act.^{8,9} Section 361 includes products that require no IND be filed prior to the initiation of clinical studies and are consistent with products defined in 21 CFR 1271.10,¹⁰ i.e., minimally manipulated, homologous use, not a combination product, and either has no cellular or systemic effect, or, if it is active on a cellular or systemic basis, is used in an autologous setting, in an allogeneic setting in first- or second-degree blood relatives, or is for reproductive use. Section 351 of the PHS Act^{10,11} includes products that require clinical data be collected under an IND application, and do not meet the definition of exempt products described above for Section 361 products. Cell therapies that also have a device or scaffold associated with them can be regulated by the Center for Devices and Radiological Health (CDRH) as a consultant to CBER or as the lead center if the scaffold is the primary mode of action. Table 96.1 summarizes regulation of HCT/Ps as Section 351 and 361 products.

THE INVESTIGATIONAL NEW DRUG PROCESS

Presented below is a summary of the basic procedures to file an IND with the FDA. The regulatory pathway to conduct a clinical trial using a cell therapy product will involve an IND if the product does not meet the major criteria defining minimally manipulated products.

IND Sponsor/Investigator

The *Sponsor* of an IND trial is the individual or organization that takes legal responsibility for and initiates the clinical investigation. This may be an individual, an academic institution, the government (the NIH), or a pharmaceutical company. In contrast, the *Investigator* is the individual who actually conducts the clinical trial and under whose direction the investigational product is administered. In many small cell-therapy clinical trials, the sponsor may in fact also be the investigator, so that the trial is conducted under a single individual who is designated as a *Sponsor/Investigator*.¹²

Requesting a Meeting

Product regulatory development almost always begins with meetings between the sponsor and the FDA. Even with the availability of various Guidance Documents, sponsors are rarely in a position to submit a successful IND application with a cellular therapeutic product without direct FDA interactions in order to agree on submission details. The agency has designated meeting types to create a consistent level of support for products under development. A meeting request is submitted to the FDA stating the type of meeting requested with draft questions and suggested dates for the meeting.

Type A meetings are used to discuss products stalled in the development pathway and products that have been placed on clinical hold after a clinical trial is already underway. Type B meetings (the most common) include several specified time points in the development of a product. These include a pre-IND, end of phase I, end of phase II/pre-phase III, pre-biological license application (BLA), product license application (PLA), establishment license application (ELA), and new drug application (NDA) meetings. Type C meetings are any other meetings not covered under type A or B.^{13,14} Under the performance goals set for the FDA, type A meetings should occur within 30 calendar days from receiving the request, type B meetings within 60 days, and type C meetings within 75 days.

Background information, sufficient to allow the FDA to answer the questions posed, should be submitted to the agency with the type A meeting request and 30 days prior to the scheduled meeting for type B and C meetings.¹⁴

Pre-IND Meeting

For cell therapy products the most critical meeting is the pre-IND meeting. The content of a pre-IND package that the sponsor sends to the FDA 30 days prior to the meeting will be driven by the questions the investigator wants to pose to the FDA, but generally includes a synopsis of the proposed clinical protocol, pre-clinical information (pharmacology and toxicology), any existing clinical information, a manufacturing section presenting proposed manufacturing methods and specifications, and copies of pertinent references. A list of questions that the sponsor would like the FDA to address and focus the discussion is critical to the success of the meeting. The FDA will specifically address these questions and provide a formal response prior to the meeting, which becomes part of the meeting minutes, allowing the meeting to be further focused on outstanding issues. Questions should include issues related to the pre-clinical testing data, chemistry, manufacturing, and controls (CMC) information, and the clinical protocol (safety assessments, inclusion/exclusion criteria).

The sponsor, the principal investigator, the individual responsible for the pre-clinical work, and the cell manufacturer should attend the pre-IND meeting. The FDA will be represented by reviewers to match these areas. After the pre-IND meeting, FDA reviewers in general make themselves available for further discussion and clarification, or can review a new manufacturing technique or a pre-clinical study to ensure that the sponsor and the FDA are in agreement regarding the next steps. This is a collaborative process with the goal of moving the process into the clinical arena as quickly and as safely as possible. Engaging the FDA early on in the IND submission process is recommended to facilitate the overall success of the IND. Within CBER, pre-pre IND meetings are available that are nonbinding, informal scientific discussions between CBER reviewers (pharmacology/toxicology) and the sponsor to initiate dialogue at an early stage in the process to facilitate design of expensive pre-clinical studies and allow data to be collected and presented at a type B, pre-IND meeting. This structure reflects the willingness of the CBER to engage the cell therapy community early in the development process and helps avoid delays because of lack of communication.

IND Submission

The submission of the IND will follow the pre-IND meeting and must fully address the issues raised at the pre-IND meeting in order to move forward. Once the IND is submitted, the FDA has 30 days to respond. The clinical study may proceed unless the FDA reviewers provide comments, or place the IND on hold within that 30-day time limit. Typically the FDA will have comments and will contact the IND sponsor prior to the 30-day deadline, requesting clarifications or updates to key documents. The IND submission will be

organized in a similar fashion to the pre-IND package noted earlier. Several key sections in the IND are the clinical protocol with appropriate eligibility, endpoints, stopping rules and dosing justification, the CMC section, and the pre-clinical section.¹²

Chemistry, Manufacturing, and Control Section

Unlike chemical manufacturers that may produce a single large lot of drug to treat multiple individuals, cell therapies can be a single lot to treat a single individual or a small number of patients. The CMC section of a cellular therapy IND is crucial to the success of an IND submission.¹⁵ From the regulations in 21 CFR 312.23,¹⁶ sufficient information is required to assure the proper identification, safety, quality, and purity of the cell product. The *drug substance* is the starting material(s) including the procurement, process description, and test methods used to determine identity, strength, quality, and purity. The *drug product* is the end product, and its composition, manufacturing methods and packaging, and stability data should be included. Setting appropriate specifications with acceptable criteria for the drug product is crucial. Components used in the manufacturing of the IND—active, inactive compendial, and noncompendial excipients—should be listed. If available, Certificates of Analysis for reagents not FDA approved should be submitted. The IND/GMP Sliding Scale was developed with the recognition that manufacturing under cGMP is a challenge for early-stage cell therapy research. Perceived deviations from standard cGMP can be acceptable with scientific justification and an alternative approach proposed. The FDA will not direct the development of the product but will respond to the data-driven suggestions put forward by the sponsor in an IND application.

The format of the information that is included in the CMC section of an IND is described in CFR 312.23.¹⁶ Typical problems encountered with submission of CMC sections include:

- Poor organization and key elements missing from the submission
- Incomplete descriptions of materials and reagents used in the manufacturing process
- Insufficient facility information
- Insufficient details regarding release criteria and tests employed
- Insufficient standard operating procedures (SOPs)

Pharmacology/Toxicology Section

The pharmacology/toxicology section must support the planned clinical trial. Pharmacology information should describe the pharmacologic effects and mechanism of action in the animal model and provide information on the absorption, distribution, metabolism, and excretion of the product. In cellular therapies much of this information is not readily measurable, but cell survival posttransplantation, cell migration, and tissue integration can be explored in pre-clinical studies, and therefore an attempt to organize the pre-clinical data to address these areas should be made. If this information is not known, it should be stated. Toxicology studies, however, are critical to the initiation of clinical trials in humans.

Pre-clinical animal studies in general will be conducted in two species under good laboratory practices (GLP) conditions including a developed protocol and complete data record keeping. An adequate number of animals, typically of both sexes, and adequate sampling time points for pharmacokinetic analysis are required. The appropriate studies include a proof-of-concept demonstration in a relevant animal model of the disease/injury and healthy animal toxicology studies. One study must include the same route of administration, the same cell manufacturing technique, and the same product as will be proposed in the clinical study. Deviations from this ideal should be clearly explained and justified scientifically. The pre-pre IND meeting is the time to come to an agreement with the FDA regarding the acceptable animal models in which to conduct these studies prior to embarking on time-consuming, expensive pathways that do

not adequately answer the questions to advance the development process.

Cross-Referencing

The FDA permits one IND to cross-reference information that is already on file at the agency; for example, in another IND or a drug master file. Written authorization must be obtained from the sponsor of the submission that is being cross-referenced and be included in the new IND. Specific details including the submission and volume number, the heading, and page numbers should be provided to identify what material is being cross-referenced. This allows FDA reviewers to quickly locate the referenced materials, facilitating the review process.

An IND Hold

Once the IND is filed, the FDA has 30 days to respond with comments prior to the IND automatically becoming active. If there are safety concerns, the FDA applies a clinical hold to stop the clinical investigation from proceeding until identified issues are adequately addressed.¹⁷ For new INDs, this represents a failure of the pre-IND process. If the sponsor in the pre-IND meeting presents sufficient detail and asks appropriate questions, then potential hold issues will be addressed prior to the IND submission. The FDA will put a clinical trial on hold for predefined reasons that include:

- Exposure to unreasonable risk for significant illness or injury
- Clinical investigators are not qualified
- The investigator brochure is misleading, erroneous or incomplete (multicenter studies)
- The IND does not contain sufficient information to assess risk
- Gender exclusion for a condition that occurs in both men and women

In practice, a clinical hold on cell therapy INDs is applied for several reasons, which include:

- The clinical trial does not provide adequate safety protection, which includes appropriate dosing, based on the preliminary clinical or pre-clinical data, appropriate dose escalation, and appropriate stopping rules for the trial
- The pre-clinical data do not support the clinical trial based on product manufacturing or route of delivery
- The manufacturing section has inadequate characterization of the product, inadequate controls over manufacturing and insufficient details

These issues should all be addressed in the pre-IND process.

IND Maintenance

When an IND becomes active, future communication with the FDA outside of specific meeting requests occur through the submission of IND amendments. Each submission is sequentially numbered and adds to the overall content of the IND. Amendments are submitted to the IND on a rolling basis and include protocol revisions, expedited safety reports, changes to the manufacturing technique or to the facility, key personnel changes, and any other significant changes to the clinical or manufacturing portions of the IND. Additionally, each IND sponsor is required to submit an annual report, summarizing the clinical study conducted over the past year. In some cases, the FDA may require more frequent progress reports. Each annual progress report is an opportunity to submit other details regarding the INDs that were not submitted during the year. The annual report is due within 60 days of the anniversary date of the IND becoming active.

WHEN IS A CELL THERAPY PRODUCT READY TO BE TESTED IN A CLINICAL TRIAL?

The ultimate test of the cellular therapy is its performance in human trials. This is the last step of an incredibly complex journey. The cell population has been identified along with a manufacturing method and assays to characterize the consistency and key properties of the product. The manufactured product has been tested in animal models for both proof-of-concept data including the route of administration, dosing schemes, and toxicology. The best way to make the transition from animals to humans smoothly is, if possible, to continue working with the same cell-processing facility and staff that have been preparing the product throughout the pre-clinical study stage. Good communication among the investigator, the cell-processing staff, and the FDA is key for the success of the clinical trial. When this occurs, it is then easier to solve inevitable operational difficulties, attribute adverse events, and solve recruitment problems that may occur during the course of the trial.

Trial Design Considerations

Initial clinical studies are safety based, typically at a single center, and expose a small number of patients to the new therapy while carefully monitoring for adverse effects and collecting preliminary efficacy data. As development continues, clinical trial design can be broken down into two broad areas: scientific and operational. The scientific area includes the clinical questions to be answered and the statistical methods used to answer them. The investigator and the cell-processing staff should meet early with statistical staff to determine how to phrase the clinical questions such that they can be answered with appropriate clinical endpoints. If a surrogate endpoint is proposed, this should be discussed with FDA staff to ensure it is acceptable from a regulatory standpoint. The method of endpoint measurement must be determined. Is there an existing validated assay to measure the endpoint? Is the assay commercially available and is it FDA approved for clinical use, or is it a “research-based” assay? The statisticians will calculate the appropriate sample size that is required to answer the questions with sufficient statistical power. Once the sample size is derived, the investigators must determine if the trial can be conducted at one center or if a multicenter study is needed.

Operational Issues

These are addressed using experience gained from prior clinical trials, or may need to be solved through pilot studies or “dry runs” by the manufacturing and clinical staff, including the use of any device needed to deliver the cell therapy product. The first operational details to be worked out are those involving the timing of manufacture and the delivery to the patient. If the trial must be conducted at multiple sites, will there be a central manufacturing site or will processing staff need to be trained at each recruitment site?

Shipping and Administration of Cellular Products

Shipping is considered an extension of storage conditions. Selecting the right vendor is essential to shipping a stable product. The shipping containers purchased must be validated by the laboratory prior to their use. Transport documentation is a cGMP requirement for traceability of donor to final product purposes [1271.290(e)].¹⁸ The US Department of Transportation has guidance on classifying biological materials in accordance with 49 CFR 171.¹⁹

Depending on the type of product, certain postshipment release testing may be indicated prior to product use in the clinic. This requires cell therapy expertise at the receiving site or significant training. Shipping-validation procedures can be conducted to determine

which tests are required for certain products. Establishing postshipment acceptance criteria is critical for the use of many cell therapy products.²⁰ Practice runs are recommended for shipment of the product, especially if the timing of the administration is crucial. For example, if a product is to be administered during a surgical procedure, it will be important to know the product viability if there are delays in shipment or postshipment testing, or during the surgical procedure.

In addition to a product meeting the appropriate release criteria, the product administration process needs to be monitored. Patient baseline and postadministration evaluations are conducted, adverse events are documented, and any deviations from the product administration procedures/processes are recorded. Such documentation can allow the cell-processing laboratory to evaluate common elements across different products as well as observe any product-specific trending.

Quality Control/Quality Assurance

A parallel process to the manufacturing process and pre-clinical studies is QC and QA. QA begins before the manufacture of the cellular therapeutic begins. It is based on the manufacturing process and confirms that each step from raw material procurement to product release can be performed in a consistent and regulation-compliant manner. QC is product based and confirms whether or not the final cell therapy product satisfies the preestablished specifications for final release. Managers and third-party auditors are responsible for QA through the development of process documentation, establishing SOPs, conducting audits, and training. Inspectors and area supervisors perform QC by performing and receiving inspection reports at all points throughout the manufacturing process.

Data and Adverse Event Monitoring

In addition to the QC/QA of the cellular therapeutic, there is also the QC of data collection. Case report forms must be tailored to the study and need to be linked to the source data collected during the manufacture and delivery of the cells, and throughout the clinical trial. The forms should be tested for ease of completion so that data coming in from the clinical sites will be easy to collect and interpret. Data coordinators and/or research nurses should be given rigorous training on the completion of these forms and should know how long each form takes to complete so they will be able to give a reasonable estimate of how many subjects they can follow within a given time period.²¹

Single-center trials are often monitored by an institutional safety monitoring committee (SMC), whereas multicenter trials typically

have a centralized independent data safety monitoring board (DSMB) that is often convened by the sponsor (NIH or a pharmaceutical company). A monitoring plan must be developed for the collection and reporting of adverse events to the SMC/DSMB and the FDA. This is another step where good communication is essential. The trial investigator and the cell-processing facility must meet regularly to discuss any adverse events and events that occur during product administration to determine if they are attributable to the cellular product or the subject's underlying disease. The FDA and the SMC/DSMB must be informed of these events to determine if a prespecified stopping boundary has been crossed.

CONCLUSIONS

The development of novel cellular therapeutics is a long and complex process requiring an IND. There are many translational steps to be completed before exposure to humans is feasible. These steps range from practical issues such as the shipment of cells to the complicated issues of setting acceptable product specifications and conducting pre-clinical studies in animal models to predict product safety profile. Investigators need to develop good working relationships with the cell-processing facility staff and statistical staff in order to conduct a technical and scientifically robust clinical trial. The key to a successful IND is early and frequent communication with the FDA.

GRAFT ENGINEERING AND CELL PROCESSING

Adrian P. Gee

Hematopoietic stem cell transplantation (HSCT) originated using bone marrow (BM) cells from allogeneic donors. Sources of cells have subsequently increased to include autologous marrow, growth factor-mobilized peripheral blood, umbilical cord blood, and placenta. In this chapter, the *ex vivo* processing of these cells and other cells used in the context of HSCT is reviewed. Processing may range from simple depletion of ABO-incompatible red blood cells (RBCs) or plasma, to more complex procedures designed to engineer the graft components to enhance engraftment, prevent graft-versus-host disease (GVHD), or to introduce genetic modifications into the cells. Facilities performing these procedures are often involved in other types of cellular therapies. These include provision of cells for adjuvant therapies in the post-HSCT setting and to support clinical trials in regenerative medicine. The dramatic growth in these new applications has attracted the interest of regulatory agencies, which have worked hard to develop an appropriate strategy to address a complex new area of medicine. An understanding of the regulations is therefore essential because they are based on the type of cellular therapy product.

REGULATORY ISSUES WITH CELL PROCESSING

Regulation of a fast-moving field, such as cellular therapies, has posed a challenge to the United States Food and Drug Administration (FDA) and other national regulatory authorities. However, in the past few years, a risk-based structure has emerged in the United States of America that has clarified the strategy. In brief, manufacturers of cellular therapy products need to determine whether they fall under Investigational New Drug (IND) regulations, which require manufacturing of the product under good manufacturing practices (GMP); whether they fall under Part 1271 of Title 21 of the Code of Federal Regulations (21CFR) Human Cells, Tissues, and Cellular and Tissue-Based Products (HCT/Ps), which require manufacturing of the product under good tissue practices (GTP); or whether they are exempt from both of these regulations.

GTP regulations, which came into effect in May 2005, were established nominally to prevent the introduction, transmission, and spread of communicable diseases by HCT/Ps. This was based on the presumption that most posttransplant infections and admissions to intensive care units were attributable to administration of contaminated products. The validity of this assumption is open to question. GTP regulations provide a framework for screening, performing *ex vivo* processing, storing, and distributing HCT/Ps, and provide the FDA with an overview of current activities by requiring an annual registration of collection and processing facilities. The Part 1271 regulations effectively filled a gap in the law that left unregulated HCT/Ps that were minimally manipulated (e.g., were not cultured *ex vivo*, genetically modified, or activated *ex vivo*), were intended for homologous use, or were not combined with another article (e.g., a matrix or scaffold) for administration. Minimally manipulated HCT/Ps should not exert a systemic effect and should not be dependent on the metabolic activity of living cells for their function. If this were not the case, then the cells should be for autologous use only, for use in a first- or second-degree blood relative, or for reproductive use. Cellular products that fall into this classification are referred to as *Type 361 products*. The Part 1271 regulations do not apply to vascularized organs for transplantation; whole blood or blood components;

and, important for this discussion, minimally manipulated BM for homologous use and not combined with another article. This therefore means that traditional HSCTs do not fall under FDA regulations, and that these procedures are currently considered practice of medicine.

With the exceptions noted, most other cellular therapy and HSCT products fall under IND regulations and are referred to as *Type 351 products*. These are cells that have been cultured *ex vivo* and transduced or activated *ex vivo*, and therefore are more than minimally manipulated. The facility processing these cells is required to operate under GMP. These regulations were originally developed for the pharmaceutical industry to ensure that drugs are manufactured under a controlled and auditable process that ensures their safety, purity, and potency. The FDA has indicated that the application of GMP to cellular therapy products follows a continuum, such that products that are manufactured for a phase I/II clinical trial under an IND are not expected to be prepared under full GMP. As the trial proceeds the expectation is that the application of GMP will become more rigorous, such that a phase III product would be extensively characterized and manufactured using a fully validated process.

Implementation of Part 1271 regulations has had an impact on the “routine” laboratory that prepares cells primarily for HSCT. Laboratories that use cells other than BM must now register annually with the FDA; ensure that donors meet eligibility requirements (or document why noneligible donors are used); and manufacture, store, and distribute the cells under GTP. If a laboratory has previous experience manufacturing products under GMP conditions, it already will be familiar with most of the features of GTP. In general, these cover personnel, procedures, facilities, environmental control and monitoring, equipment, supplies and reagents, recovery, processing and process controls, process changes, process validation, labeling controls, storage, receipt, predistribution shipment and distribution, records, tracking, and complaints. Implementation of the components of GMP and/or GTP operations is a time-consuming process that requires development, implementation, and maintenance of numerous components and generates a considerable volume of documentation. Professional societies, such as the Foundation for the Accreditation of Cellular Therapy (FACT) and AABB (formerly the American Association of Blood Banks), have developed standards and an accreditation process that takes into account GTP/GMP regulations and provides a framework around which compliance can be built (see [Professional Standards](#) section).

An exception from the products described earlier is cord blood. In the United States, cord blood is a licensed product and facilities that prepare and bank cord blood are required to obtain a Biologics License. This allows the manufacturer to introduce, or deliver for introduction, a biologic product into interstate commerce (21 CFR 601.2).

Central to both GMP and GTP regulations is the establishment and maintenance of a quality program. This must ensure that the appropriate regulations are being followed on an ongoing basis; that mechanisms are in place for detecting, reviewing, and remediating errors and deviations from regulations, policies, and procedures; and that an audit program will be developed, implemented, and maintained. Activities performed by the quality program must be documented, and the program should be staffed by individuals who are not involved in hands-on manufacturing of the products.

Holders of INDs must provide the agency with an annual report on the protocol and include a listing of the products administered and those that have been prepared but not used. In addition, cell-processing facilities should be prepared to assist the IND sponsor by providing information on products that have been associated with severe adverse reactions in the recipients, and whether these were attributable to product quality. For Type 361 products, the facility must report, as Biological Product Deviations, any contaminated products that have been administered to a patient.

PROFESSIONAL STANDARDS

The two major accrediting organizations in the United States for cellular therapies are FACT and AABB. Whereas FACT offers accreditation of collection, processing, and clinical use of cellular therapy products, the AABB focuses on collection and laboratory processing. Both organizations inspect based on standards that are published every 18 months to 3 years. In the case of FACT, the standards are published in collaboration with the Joint Committee on Accreditation in Europe. FACT also publishes separate standards in collaboration with NetCord that cover cord blood banking. Both organizations have worked to harmonize their standards with American, Canadian, Australasian, and European regulatory agencies; therefore, accreditation by either organization is of great assistance on the pathway to regulatory compliance. A number of other professional organizations accredit particular aspects of operations within the cell-processing facility. These include the College of American Pathologists, which accredits general laboratories, and hematology and flow cytometry facilities; the American Society for Histocompatibility and Immunogenetics; and the European Federation for Immunogenetics, which accredits histocompatibility-testing laboratories. Some organizations, such as the College of American Pathologists and StemCell Technologies, also provide proficiency testing services for laboratory staff.

MANIPULATION OF HEMATOPOIETIC STEM CELL TRANSPLANTATION PRODUCTS

Manipulation of a product for hematopoietic rescue is intended to remove a component that is unwanted or may cause adverse effects or to enrich a desired population, such as CD34⁺ cells. As discussed previously, the degree of manipulation may determine the regulations under which the product is manufactured and handled. The FDA defines minimal manipulation as processing that does not alter the relevant biologic characteristics of the cells or tissues. This includes procedures such as RBC and plasma depletion, and cell selection using an approved device. By contrast, more than minimal manipulation would include activities such as culture *ex vivo*, genetic modification, and *ex vivo* activation.

Routine Minimal Manipulation for Volume Reduction or ABO Incompatibility

The most widely used form of manipulation in the hematopoietic progenitor cell (HPC)-processing facility is probably removal of erythrocytes and/or plasma to overcome incompatibility between donor and recipient (Table 97.1). This process is performed largely using techniques that were developed by the blood banking industry.

Plasma depletion to remove donor antibodies that may react with recipient cells is achieved by centrifugation of the graft, usually in a transfer pack, at approximately 2000 g for 10 minutes at ambient temperature. The pack then is placed in a plasma expresser, which compresses the product bag so that plasma can be forced out and into a separate collection bag. Plasma depletion can also be used to reduce the volume of ABO-compatible grafts when the donor is large and the recipient small.

TABLE 97.1

Processing Performed to Address ABO Incompatibilities Between Hematopoietic Stem Cell Donors and Recipients

Recipient ABO Type	Donor ABO Type	Type of Processing
ABO identical	ABO identical	No special processing required
A or B	AB	RBC depletion
O	A/B/AB	RBC depletion
A	B	RBC + plasma depletion
B	A	RBC + plasma depletion
Antibody to RBCs	N/A	RBC depletion
A/B/AB	O	Plasma depletion
AB	A or B	Plasma depletion

N/A, Not applicable; RBC, red blood cell.

RBC depletion removes incompatible donor erythrocytes that would stimulate a reaction by the donor upon administration. Most facilities establish a maximum volume of incompatible RBCs that can be infused with HPCs; exceeding this limit can result in hemolysis and a transfusion reaction. Depletion of erythrocytes can be achieved most simply by centrifugation. The product is centrifuged at approximately 3000 g for approximately 10 minutes at ambient temperature, and the leukocyte-rich buffy coat is collected at the interface between the plasma layer and the RBCs.

RBC depletion can also be achieved by sedimenting erythrocytes using hydroxyethyl starch (hetastarch). This promotes RBC sedimentation by formation of erythrocyte rouleaux. The hematocrit of the product is first adjusted to approximately 25% by addition of normal saline, and 6% hetastarch (Hespan) is added at a volume:volume ratio of 1:6 to 1:7. Sedimentation can be performed under gravity or may be accelerated by centrifugation.

The most rigorous erythrocyte depletion is achieved by centrifugation of the collection on a Ficoll-Hypaque density gradient. This process enriches mononuclear cells at the interface between the gradient and the layered cells after centrifugation and depletes erythrocytes, platelets, and granulocytes. As a result of enrichment for mononuclear cells, the overall nucleated cell recovery is lower than with other techniques in which granulocytes are retained.

Automated devices are available for preparing buffy coats and density gradient-enriched cells. For larger volumes, the COBE 2991 Cell Processor from Terumo can be used. This requires a minimum volume of 150 mL RBCs for operation and may therefore not be suitable for pediatric processing. It is capable of preparing buffy coats and density-separated cell preparations using a functionally closed disposable set.

The COBE Spectra from Terumo is in common use to collect peripheral blood progenitor cells by apheresis. The device is also less widely used in the processing facility to enrich mononuclear cells from BM.

For smaller starting volumes, the Sepax device from Biosafe can be used (Fig. 97.1). It has found widespread application in cord blood banks for buffy coat preparation (with or without addition of hydroxyethyl starch) and has also been used for volume reduction of peripheral blood progenitor cell collections, density gradient separation of BM, and for cell washing. The device has a small footprint, uses functionally closed disposables, and provides a print-out of operations.

Xpress devices for cord blood and marrow processing are available from Thermogenesis. The AXP AutoXpress is designed for enriching mononuclear cells from cord blood that is transferred to the processing set, which is then placed into the AXP device. This fits into a centrifuge bucket, and during spinning the red and mononuclear cells are collected into separate bags and the plasma is retained in the processing set. The MarrowXpress performs a similar procedure on marrow harvests. Both devices provide closed sterile systems, and the

Fig. 97.1 THE BIOSAFE SEPAX DEVICE. Used for automated processing of hematopoietic cells. A newer version of this device provides additional good manufacturing practice features.

XpressTRAK software enables data tracking to assist with regulatory compliance.

Purging of Autologous Grafts

Autologous HPCs can be used for recipients lacking a human leukocyte antigen (HLA)-matched related or unrelated donor. It has been proposed that occult viable tumor cells collected with the graft and returned to the patient could act as a source for disease relapse. Gene-marking studies have supported this hypothesis. As a result, much effort has been exerted to develop methods for the *ex vivo* detection and removal of tumor cells from autologous grafts. Techniques have included incubation with chemotherapeutic drugs, such as 4-hydroperoxycyclophosphamide, photosensitizing agents, and antisense oligonucleotides. Alternatively, tumor-directed monoclonal antibodies (MAbs) can be used to identify the cells and effect their removal. The MAb-coated tumor cells can be eliminated by addition of serum complement, or by capturing them on a solid phase, such as a column matrix, a plastic sheet, or magnetic particles. These particles may be large (5 μm diameter) so they can be collected, with the attached tumor cells, in a standard magnetic field. The matrix material may be much smaller, such as nanoparticles or ferrofluids, which coat the cells. These are then collected on a metal matrix placed in a field generated by permanent magnets. Such systems are capable of depleting 4–6 logs of tumor cells from a graft. However, even at such high efficiencies, and given the limits of our ability to detect residual tumor cells, the clinical value of purging autologous grafts is debatable. There has also been a decline in interest in purging techniques because of the potential benefits of a graft-versus-tumor (GVT) effect detected in recipients of allogeneic grafts.

T-Cell Depletion of Allogeneic Products

T cells in HPC grafts have the potential to cause severe or lethal GVHD or potentially to exert a beneficial GVT effect (discussed in

Chapter 108). Considerable work has been done to determine whether these opposing effects are produced by distinct subpopulations of T lymphocytes. This would allow *ex vivo* manipulation of allogeneic grafts to remove differentially the GVHD-producing T cells while sparing those that mediate GVT responses. Various subpopulations of T cells have been identified as candidate effector subpopulations; however, there is no widespread consensus as to which subsets should be targeted.

Methods are available for eliminating T cells from grafts using approaches similar to those used for purging tumor cells. Early techniques included use of soybean agglutinin to aggregate the majority of nonprogenitor cells and rosetting of sheep erythrocytes with T cells to facilitate their removal. Although successful, these techniques are not “FDA friendly” and do not offer the specificity that likely is required to engineer T-cell subpopulations in allogeneic grafts. This is made possible by the use of MAbs directed toward the antigens that are currently used to identify T-lymphocyte subpopulations. The target population then can be removed with high efficiency using immunomagnetic separation, as described previously for purging autologous grafts. The challenge remains to identify the appropriate target T-cell populations and to source clinical grade MAbs for these procedures. A number of potential target antigens have been identified and separation techniques implemented. They range from pan-T-cell depletions using antibodies to CD3 and CD2, to depletions of helper and cytotoxic T cells using MAbs against CD4 and CD8, to stimulation and removal of alloreactive populations by targeting activation antigens.

Efforts have recently focused on depletion of $\alpha\beta$ -positive T cells from the graft. This spares the donor-derived alloreactive natural killer (NK) and $\gamma\delta$ T cells, which may provide a tumor-directed response. Promising early clinical results have been obtained using this approach. An alternative approach is to administer regulatory T cells (Tregs) posttransplant to prevent and treat GVHD. A first-in-man clinical study was performed using *in vitro*-expanded Tregs from partially HLA-matched third party umbilical cord blood units that were administered to 23 patients receiving double-cord blood transplants. Results were compared with 108 historical controls. No Treg acute toxicities were seen, and there was a reduced incidence of grades II–IV acute GVHD, but since this was a phase I study it was not designed to demonstrate efficacy. Later studies support the finding that donor Treg infusions can prevent GVHD after allogeneic transplantation. Evidence that Tregs can be used to treat GVHD is still under evaluation.

Methods that eliminate or physically remove either T cells or tumor cells from grafts are referred to as *negative selection techniques*. They are affected by variables such as target antigen expression, sensitivity of detection technologies for quantitating separation efficiency, and other technical hurdles. These may be difficult to control in order to achieve the ideal composition of the graft and the target level of residual T cells, or T-cell subsets, remains to be established. A dose of 10^5 T cells/kg is generally regarded as the goal to minimize the risk of GVHD while facilitating engraftment. There are also no approved devices for negative selection, so these types of procedures must be performed under an IND.

For many years, the goal was to replace negative selection with a procedure in which HPC populations could be specifically enriched by positive selection. This would effectively deplete T cells or tumor cells from allogeneic and autologous grafts, respectively. The problem was the lack of a method for identifying the target HPCs until the CD34 antigen was identified on a small population of progenitor cells, including the pluripotent cells required for hematopoietic transplantation. The subsequent availability of MAbs directed against this antigen made possible the development of techniques for enrichment of these cells. Immobilization of the antibodies on a matrix (e.g., plastic sheets) and cellulose and magnetic particles was used as the primary approach, and a number of devices were commercially developed. The first to achieve FDA approval for use with apheresis products was the Baxter Isolex 300i, which uses Dynal 5- μm magnetic beads as the separation modality and releases

Fig. 97.2 MILTENYI CLINIMACS CELL SEPARATOR AND PRODIGY CELL PROCESSOR. The Prodigy (right side) is a self-contained cell separation and processing device. CliniMACS is a cell separation system using magnetic nanoparticles conjugated with monoclonal antibody to the target antigen. Investigators should determine the status of regulatory approval of these devices before clinical use. (Copyright 2015 Miltenyi Biotec GmbH. All rights reserved.)

CD34⁺ cells from the beads using a competitive binding peptide. This device was recently withdrawn from the market for this application and is currently under evaluation for use in regenerative medicine protocols.

An alternative is the CliniMACS system (Miltenyi Biotec; Fig. 97.2), which currently has regulatory approval in Europe but still requires an IND for use in the United States for other than one specific indication. This uses anti-CD34 nanoparticles to effect separation. The labeling with and removal of unbound CD34 reagent is performed manually. The CD34 reagent-treated cells are then processed on the device, where they are retained on a column located in a high-gradient magnetic field. Nonlabeled cells flow through the column and are collected in the negative fraction. The labeled cells are recovered from the column after several automated separation and washing cycles by removing the magnetic field. The nanoparticles remain on the CD34⁺ cells; however, they are biocompatible and may be infused into the recipient. The device normally achieves purities in excess of 90% with yields of approximately 60%. This results in passive depletion of 4–6 logs of T cells. The device may be used with a variety of MAbs directed against antigens expressed by various types (T, B, and NK cells), potentially allowing it to be used as a platform for multiple types of graft engineering. Recently, Miltenyi Biotec has introduced a new device (the Prodigy; see Fig. 97.2), which can automatically perform many of the steps requiring manual intervention on the CliniMACS. Additional features provide the potential ability to fully automate the preparation of a variety of cellular therapy products in a functionally closed system. The regulatory status of these devices should be discussed with the FDA before clinical use.

Positive selection techniques may, however, passively deplete from the graft certain cells that could be of potential benefit to the recipient. These include some stromal elements, GVT-mediating T cells, and other populations that may facilitate engraftment. As our understanding of the identity of these populations improves, it may be possible to recover them from the normally discarded negative fraction and add them back to the CD34⁺ cells, or to administer them in the posttransplant period as donor leukocyte infusions (see later discussion).

TABLE 97.2

Methods Used for T-Cell Depletion of Hematopoietic Grafts

Destruction in Situ	Physical Separation
Monoclonal antibody-based	Monoclonal antibody-based
Antibody + complement	Immunomagnetic separation
Immunotoxins (e.g., ricin)	Negative selection (T-cell removal)
Panning and immunoaffinity columns	Positive selection (CD34 selection) CliniMACS device
Cytotoxic drugs (e.g., 4-HC)	Rosetting with sheep erythrocytes
Photopheresis	Lectins (e.g., soybean agglutinin) Centrifugal elutriation
4-HC, 4-Hydroperoxycyclophosphamide.	

Table 97.2 lists various methods of direct T-lymphocyte depletion and indirect depletion by HPC enrichment.

EVALUATION OF MANIPULATED GRAFTS

Most allograft engineering has focused on T-lymphocyte depletion and has emphasized quantitative versus qualitative removal. The majority of allografts are infused immediately after preparation rather than after cryopreservation and storage. This restricts the types of assays that can be used to evaluate graft composition to those that have a rapid turnaround, and the implications of infusing large numbers of T lymphocytes can be severe or lethal. Therefore, it is important to have available methods that can rapidly enumerate the numbers of T lymphocytes within the graft. Although early methods used detection of E-rosette-forming cells or manual immunofluorescence after staining with pan-T-lymphocyte-directed MAbs, most laboratories currently rely on flow cytometry. This technology is widely used in routine clinical laboratories; however, some precautions must be taken when it is used for T-depleted allografts.

Flow Cytometry

Accurate enumeration of very small numbers of target cells by cytometry requires rare event analysis. In this technique, large numbers of events must be accumulated and carefully analyzed if reliable data are to be obtained. This approach has been widely adopted for counting CD34⁺ cells in unfractionated grafts but is often neglected when enumerating T lymphocytes in depleted grafts. The choice of MAb for detection of the T-lymphocyte population also is critical when a MAb-mediated depletion technology is used. The same MAb should not be used for both depletion and analysis because cells that became coated with the antibody during the depletion phase, but were not effectively removed, will be blocked from detection. However, they can be detected by adding an antiimmunoglobulin antibody conjugated to a fluorochrome different from the one conjugated to the T-lymphocyte-directed MAb. The most sensitive detection is achieved by using panels of non-cross-blocking anti-T-lymphocyte antibodies directed against a variety of epitopes.

It is important to include a viability stain in the analysis panel. Although this is less crucial when T-lymphocyte depletion is achieved by physical removal of target cells, it is extremely important when *in situ* elimination methods are used. In these cases, the depleted allograft may contain dead or dying T lymphocytes that will be detected by flow cytometry but may not contribute to postinfusion events. Suitable viability stains include propidium iodide and 7-aminoactinomycin. Analysis of cell viability after *ex vivo* depletion is not straightforward. Cell death may not be expressed immediately but develops in the hours or days after processing and infusion. Under such circumstances, the analysis of apoptotic cells by a combination of Annexin-V staining with 7-aminoactinomycin may provide a more accurate estimate of cell damage. This approach can be used in combination with simultaneous staining for T-cell surface markers to provide additional information. In some cases, incubating the cells for a period before analysis is advisable (e.g., in the case of depletion by immunotoxins, cells require time to divide to manifest the toxic

effects). Stimulation of cells with interleukin-2 (IL-2) and *ex vivo* culture also has been used to detect functional residual T lymphocytes. In some cases, this method has shown a correlation between the numbers of T lymphocytes in the cultured sample and the development of clinical GVHD in the graft recipient.

Tetramer Analysis

Enumeration of T cells bearing receptors for specific antigens can be achieved using tetramer analysis (Fig. 97.3). In this procedure, soluble versions of heavy chain of major histocompatibility complex molecules are synthesized and adopt the appropriate conformation when a synthetic peptide representing the epitope is recognized by the T-cell receptor and β 2-microglobulin is added. The carboxyl-terminus of the MHC molecule is biotinylated, and four of these peptide/MHC-biotin complexes assemble into a tetramer when streptavidin is added. The streptavidin is tagged with a fluorochrome; therefore, T cells reactive with the chosen peptide-MHC complex become fluorescently stained and can be detected by flow cytometry.

Functional Assays

Flow cytometry detects residual cells by their ability to bind MAbs. Routine flow does not provide information on the functional capacity of these cells, which may be important when assessing the graft for its potential to mediate GVHD or GVT. For this purpose, a number of assays have been developed. These are not suitable for use as release tests because of their turnaround time, but they can provide retrospective information that may correlate with clinical outcome. They include limiting dilution analysis, in which a range of dilutions of the graft are plated out and assessed for the ability of T cells to form colonies in response to the addition of stimulants, such as phytohemagglutinin and IL-2. Based on the proportion of colony-forming

TABLE 97.3 Immunotherapeutic Cells Frequently Used in HSCT Recipients

Cell Type	Clinical Use
T regulatory cells	Prevention/treatment GVHD
Mesenchymal stromal cells	Immunosuppressive effect (GVHD) Regenerative applications
NK cells, TIL cells, LAK cells, NKT	Anticancer response
CAR-T cells	Anticancer response
Dendritic cells	Anticancer vaccines Antigen-presenting cells

CAR, Chimeric antigen receptor; GVHD, graft-versus-host disease; LAK, lymphokine activated; NK, natural killer; NKT, natural killer T cells; TIL, tumor-infiltrating lymphocyte.

cells at the various dilutions, it is possible to determine by Poisson distribution the number of T cells present in the original graft.

Another approach is use of an enzyme-linked immunosorbent spot (ELISpot) assay in which cells are stimulated to produce an analyte that is characteristic of their normal function. The cells are plated onto a surface that has been coated with an antibody directed against that analyte and incubated for a fixed period. The secreted analyte binds to this antibody, and the cells and any other unbound material are washed away. The surface is incubated with a biotinylated antibody directed against the analyte and washed and incubated with alkaline phosphatase linked to streptavidin. After washing, the plate is incubated with a substrate solution. A blue-black precipitate will appear at sites where the analyte was produced, with each spot representing an analyte-secreting cell. The spots can be enumerated manually or by using an ELISpot reader.

CELLULAR THERAPY PRODUCTS

A number of cellular therapy products (Table 97.3), including some that have been genetically modified, are being evaluated in clinical trials to determine their value in preventing or treating GVHD, and for potential antitumor responses (see Chapter 108). These have examined the safety and efficacy of different cell populations, including, but not limited to, nonmanipulated leukocyte infusions from HPC donors, cytokine-induced T cells, lymphokine-activated killer cells, tumor-infiltrating lymphocytes (TILs), T-regulatory cells, antigen-specific T cells (see Chapter 100), mesenchymal cells (see Chapter 99), dendritic cells (DCs) (see Chapter 23), and NK cells (see Chapter 101). Detailed accounts of the scientific basis for such studies as well as results of clinical trials are given in Chapters 100 and 101. This section focuses on processing and product evaluation issues.

Cells that have been more than minimally manipulated must be prepared under GMP conditions. This requires that manufacturing be performed by trained staff following formal standard operating procedures. These procedures will have been submitted to the FDA in the chemistry, manufacturing, and control (CMC) section of the IND application and will specify how the product is prepared, the reagents and materials that will be used, and the criteria for the release of the product for clinical use. Release criteria are test specifications that are designed to ensure that the product is sterile and pure, and they may include assays for functionality. The specific tests for sterility and purity that have been approved by the FDA are described in 21CFR 610.12, and a number of guidances have been issued by the FDA on the use and validation of alternative techniques.

In the normal release mechanism for a cellular therapy product, the quality unit reviews the production records and issues a certificate of analysis (Fig. 97.4). This document details the testing that was performed together with test method, the testing laboratory, the

specification required by the FDA, and the actual results obtained. Routine testing required for most cellular therapy products consists of aerobic, anaerobic, and fungal sterility; endotoxin levels (by Limulus amoebocyte method, e.g., Endosafe from Charles River); mycoplasma for ex vivo expanded cells (assayed by the culture method or by a validated polymerase chain reaction based method); identity and purity (by flow cytometry and, in some cases, HLA typing); and, for products in later stages of evaluation, functionality (e.g., cytotoxic activity toward target cells or secretion of specific bioactive products). Products that have been transduced with a retroviral vector will also require testing for replication-competent virus. Use of non-FDA-approved test methods should be cleared with the FDA at the IND application stage. Regulatory agencies also like to see some form of stability testing program that evaluates the stability of the cellular product over time in storage in the frozen state and when thawed for administration.

Phase I studies are designed to evaluate the safety of the product and should include assessment of reactions to infusion, risks for contamination during preparation, and delayed effects after administration. Clinical efficacy is evaluated during phase II/III. At this time, progress should be made toward the development of an in vitro assay for potency that correlates with clinical efficacy. This can be problematic because most in vitro assays currently used are unreliable as predictors of the clinical value of the product, and some form of surrogate marker has been substituted.

Donor Leukocyte Infusions

The ability of infusions of donor leukocytes (DLI) to mediate anti-tumor responses was originally described in patients with chronic myeloid leukemia in hematologic relapse after allogeneic stem cell transplantation, but lymphomas and Hodgkin disease also are sensitive to the effects of DLI. Remission rates of up to 80% have been reported in chronic myeloid leukemia patients who relapse after transplant. Up to 90% responses have been described in patients with Epstein-Barr virus (EBV)-associated lymphoproliferative disease. Moderate success has been achieved with use of DLI after relapse in other malignancies such as acute myeloid leukemia (15%–40%), low-grade lymphomas ($\leq 60\%$), and metastatic multiple myeloma (40%–60%). Fewer than 5% of patients with relapsed acute lymphoblastic leukemia respond to DLI alone. Although the etiology is unclear, the reason could be lack of antigenic expression, downregulation of T-cell recognition molecules, or tumor burden at the time of treatment.

The regulatory situation for DLI is complicated and is probably in transition. At present, nonmanipulated DLI are classified as Type 361 products and fall under Part 1271 of 21CFR. It is possible that they will be reclassified as Type 351 products requiring an IND application. Currently, formal release criteria are not required; however, the normal practice is to evaluate T-cell content by flow cytometry and to test for sterility. This may be done by a gram stain (used for immediate release) accompanied by culture-based methods. These provide results after the product has been infused. Formal procedures should be in place to inform the recipient's physician if a positive test result is subsequently received. The contaminant should be speciated and antibiotic sensitivities obtained and communicated to the physician. DLI that have been manipulated ex vivo in any way (e.g., by targeting them to specific antigens or by transduction with a suicide gene, as described later) will be classified as Type 351 products requiring an IND. These products will require formal release testing as described previously for other cellular therapy products.

Nonspecifically Activated Autologous T Cells

T cells can be expanded ex vivo through polyclonal activation using phytohemagglutinin, anti-CD3 antibody, or a combination of anti-CD3 and anti-CD28 antibodies. Several groups have evaluated

whether such expanded T cells have antitumor activity. Faster recovery of lymphocyte counts with improved outcome after autologous transplant observed in non-Hodgkin and Hodgkin lymphoma led to a phase I study evaluating the infusion of autologous CD3/CD28-activated cells after a CD34-selected stem cell transplantation.

Cells prepared for these types of studies are Type 351 products because they are cultured ex vivo and may have undergone some form of activation. Manufacturing must be carried out under GMP, and the clinical studies must be performed under an IND. The IND application must describe in the CMC the procedure for

manufacturing the cells and the criteria that will be used to determine whether they can be released for clinical use. Many manufacturing procedures use reagents and materials that are not approved for human use, and the application should include information about these materials and what testing will be performed before they can be used for manufacturing the clinical product. Justification should be provided for the use of nonapproved media and supplements and any potentially undesirable ancillary products, such as antibiotics. Evidence should be provided on the efficacy of their removal before administration of the product.

The release criteria for autologous T-cell products are similar to those described for generic Type 351 products. They include tests for sterility, endotoxin, mycoplasma, and identity and purity (i.e., by flow cytometry); some test of potency is recommended, but is not usually required for phase I studies. A draft of the certificate of analysis, which will be used for release, should be included in the IND submission.

Tumor-Infiltrating Lymphocytes

TILs are cells harvested from tumor sites and are expanded ex vivo with IL-2. As the cells are being expanded, increased tumor specificity is achieved by pulsing the cells with tumor-specific peptides or transducing them with a retrovirus encoding a tumor-specific T-cell receptor. A major limitation is that patients must have preexisting lymphocytes that can both respond to tumor and be expanded ex vivo. Transfer of these cells has led to tumor regression in 50% of lymphodepleted patients with metastatic melanoma.

A number of methods have been developed for isolation of TILs from tumors. They include mechanical disruption, enzymatic treatment, differential centrifugation approaches, and positive immunomagnetic selection. The method of choice depends on the type of tissue from which the cells are to be extracted and the availability of reagents, such as MAbs, to enrich the T-cell population of interest. As with T-cell depletion of allogeneic grafts, the predominant effector TIL cell population is not fully characterized, and the availability of this information should facilitate the design of more effective separation techniques. A number of approved enzymes and centrifugation media are available, and several companies have suitable MAbs that have been prepared under GMP conditions but have not been submitted for FDA approval.

The extracted cells are expanded ex vivo, usually starting in semio-pen systems such as cluster plates. The initial populations may be tested in a cytotoxicity assay in an attempt to identify the effector population, which can then be selected for expansion. The expansion phase usually progresses through a number of types of cultures as cell numbers increase. These may progress from plates to T flasks and gas-permeable bags to hollow fiber and culture bag bioreactors. The culture medium contains IL-2 as the primary cytokine, although other agents alone and in combination may be used to promote outgrowth of specific cell subpopulations.

Some investigators have used irradiated tumor cells to restimulate TILs during culture; others have performed selective separations to enrich the effector cells during expansion. Highly characterized tissue culture media, such as the serum-free lymphocyte medium AIM V (Thermo Fisher Scientific), have been used for expansion. The goal is to use the simplest medium with the fewest additives that will support growth of functional cells. When possible, the media should be free of animal serum and proteins to simplify the regulatory issues. However, the FDA is aware that complex media and serum combinations may be required to support growth of some cell types and is willing to consider them, particularly if the cells can be washed into an approved excipient for administration.

Initiation of a phase I study using TILs or TIL subpopulations will not require complete characterization of the effector cell population, but some preliminary information should be available that allows quantification of the putative effectors for dosing purposes. In most cases, flow cytometric analysis will be used, and the target antigens may be pan-T-cell markers or specific combinations of T

subset markers. When other constituents of the product may adversely affect the activity of effector cells, it may be necessary to set an upper limit for contamination by these cells in the clinical product. Most facilities perform some type of functional assay as a part of the release process, which in the case of TILs may be cytokine release or cytotoxic activity toward tumor cells of the appropriate histologic type.

Allodepleted Cells

The major drawback of DLI is the significant risk of GVHD, which is the most important source of treatment-related mortality. Given that the frequency of tumor or viral antigen-specific T cells in most cases is considerably lower than that of alloreactive T cells, it is necessary to expand antigen-specific T cells ex vivo not only to enhance antitumor activity, but also to try to separate GVHD from GVT effect. An alternative method for separating GVHD from GVT effect is to selectively deplete alloreactive donor T cells ex vivo. Selective allodepletion is performed by removing donor T cells that express activation markers after coculture with nonleukemic recipient cells. Activation markers investigated include CD25 and CD69 and the increased sensitivity of activated T cells to photosensitizing dyes. A number of phase I/II studies using immunotoxin directed against CD25 have demonstrated the feasibility of this approach, with accelerated reconstitution of virus-specific and total T-cell numbers and low rates of severe GVHD. Relapse rates remained high in this study, which probably reflects the high-risk nature of the patient population.

Potential recipients of allodepleted cells often receive a CD34-selected HPC graft. As a part of the CD34 selection process, a negatively selected population of cells that includes T cells becomes available. However, this fraction usually is not used as the source of cells for allodepletion. These cells usually have been obtained from donors who received granulocyte-macrophage colony-stimulating factor for mobilization of peripheral blood progenitor cells, and during processing for CD34 selection they were exposed to anti-CD34 MAbs. Therefore, it is preferable to obtain cells for allodepletion from a peripheral blood draw of the donor before administration of growth factor for mobilization. The T-cell-enriched fraction is usually obtained by centrifugation on a Ficoll-Hypaque density cushion. The cells are washed and coincubated with irradiated recipient mononuclear cells, which act as stimulators. A convenient source for stimulator cells is obtained by generation of a cell line from the donor by infection of his or her peripheral blood mononuclear cells with a laboratory strain of EBV. The coincubation step produces stimulation of alloreactive donor T cells with resulting expression of activation markers, which can then be targeted to remove the alloreactive population. Methods for elimination include cytotoxic drugs (e.g., methotrexate), anti-CD25 MAbs conjugated to the toxin ricin, and immunomagnetic selection. All of the regulatory issues associated with the manufacturing and release of Type 351 products apply to allodepleted T-cell products. Release criteria include routine assays for sterility and purity. HLA typing may be included as a confirmation that the cells in the product are of donor origin. Functional assays may include demonstration that the allodepleted cells fail to proliferate when cultured in a primary mixed lymphocyte reaction (MLR). If a suicide gene has been introduced (see next section), testing will include demonstration that it can be efficiently activated.

Suicide Gene-Transduced Lymphocytes

Although treatment with DLI has led to remission in patients with disease after HSC transplantation, unmanipulated cells also contain alloreactive T cells and can induce GVHD. The incidence of GVHD ranges from 55% to 90% and is associated with a treatment-related mortality rate of about 20%. Approaches that maintain the GVT effect while decreasing the incidence of GVHD have been evaluated and include transduction of donor T cells with a "suicide gene."

Genes can be introduced into DLI or alloreactive-depleted cells to express the herpes simplex virus-1 thymidine kinase (HSV-tk). If GVHD develops, Ganciclovir is administered to the recipient, resulting in suicide of the transduced donor leukocytes.

Alternative suicide genes based on the dimerization of Fas or Caspase-9 in the apoptotic pathway have been developed to circumvent the problem of immunogenicity of HSV-tk. The inducible Caspase construct also encodes a selection marker, such as CD19, that can be used to enrich the transduced population. In the event that GVHD develops after administration of the Caspase-transduced cells, the suicide activation drug can be administered to the recipient to eradicate the transduced T cells by dimerization of Caspase 9 and activation of the apoptosis pathway.

Antigen-Specific Cytotoxic T Lymphocytes

Two major prerequisites for generating antigen-specific cytotoxic T lymphocytes (CTLs) are the identification of appropriate viral (in the case of EBV-associated lymphomas) or tumor target antigens and the availability of suitable antigen-presenting cells (APCs). After being identified, CTL lines can be generated by coculturing T cells with APCs that express the target antigen. The lines are then expanded by restimulation with the antigen of choice and the addition of cytokines such as IL-2.

To generate antigen-specific CTLs, it is necessary to have a good source of APCs and a source of antigen to present to T cells. A variety of APCs have been evaluated, including fibroblasts, monocytes, and DCs, using different sources of antigen, including virus lysate or lysate of antigen-positive cells, peptides, or transduction of the APC, such as lymphoblastoid cells (LCLs) and DCs with an immunodominant antigen. Use of lysates as the antigen source can be problematic because they are likely to be variable and difficult to standardize. Alternatively, many processing laboratories may not be experienced in handling virus and virus-infected cells.

LCLs prepared using laboratory strains of EBV make excellent APCs for use in manufacturing EBV-specific T cells. They present EBV antigens efficiently, and they express high levels of costimulatory molecules. The normal procedure for generating the LCL is coinubation with EBV derived from the tamarin B95-8 cell line. This line has undergone extensive testing and has been approved for use as a source of “clinical” EBV. The resulting LCLs are cultured in media containing acyclovir to eliminate any residual EBV. The LCLs are used to repeatedly stimulate T cells (as a mononuclear cell fraction of peripheral blood leukocytes), resulting in a population that is directed toward the immunodominant EBV antigens. These CTLs can be frozen while release testing is performed. They are delivered frozen to the bedside, where they are thawed and administered intravenously. Release testing consists of the routine tests described earlier for Type 351 products. For allogeneic CTLs, functionality is usually assessed by cytotoxicity assays, which must demonstrate less than 10% killing of autologous blasts.

One limitation of this approach is that expansion of virus-specific T cells to achieve adequate dose levels is extremely time consuming. All of these procedures require several weeks to generate APCs. More recently accelerated methods of production have been developed. These include the use of direct T-cell stimulation using mixtures of peptides for overlapping regions of the target antigen(s) (PepMix, JPT) and the use of disposable bioreactors that provide improved gas exchange, thereby markedly improving rates of T-cell expansion.

An alternative strategy is to manufacture and bank third-party allogeneic EBV-specific CTLs with a range of HLA types so that an “off-the-shelf” product is available. Clinical responses have been described for patients who received partially matched allogeneic CTLs. The generation of banks of CTLs requires careful donor screening and HLA typing to allow at least partial matching with the intended recipient.

The use of T cells transduced to express chimeric antigen receptors directed against tumor antigens has produced very promising results in early-phase clinical trials in CD19⁺ leukemias. The chimeric

antigen receptor often incorporates other moieties that are designed to dampen inhibitory signals from the cancer or to amplify a beneficial immune response. Manufacture of these cells requires preparation of an appropriate construct and delivery system (viral or nonviral vector) that is used to modify the expanded T-cell population. Release testing is similar to that required for other gene-modified cellular therapeutics (see Fig. 97.4).

Natural Killer Cells

NK cells are effectors from the innate immune system that also mediate antiviral and antitumor immunity. Studies have shown that haploidentical NK cells infused after lymphodepleting chemotherapy can have antitumor effects. Most facilities use a simple positive selection with clinical scale immunomagnetic methods involving CD56 selection or CD3 depletion for such products. These procedures must be done under an IND because of lack of commercially available devices and reagents for this indication. Recent evidence has suggested that cryopreserved NK cells have impaired functionality on recipients, in contrast to cells that are infused fresh. This poses an additional challenge to the manufacturer, who must coordinate testing and possible shipment of the fresh product. It is not clear whether the same finding may apply to other cell therapy products.

When preparing an IND application for NK cell enrichment, care should be taken to ensure that the MAbs used for the selection or depletion are of the highest quality available. A certificate of analysis for these reagents should be submitted with the IND application, and the agency will probably require detailed information on their manufacturing (i.e., to ensure that the process includes robust procedures for virus inactivation or removal). The same type of information may be required for any ancillary reagents (e.g., buffers and protein sources used to supplement buffers). Preclinical data demonstrating that the enrichment technique is effective should be provided and accompanied by data from clinical scale validation enrichments, providing evidence that the NK cells can be separated with acceptable viability, purity, and yield for the proposed study. The CMC section of the IND application should include information on the methods used to store, label, and administer the cells. Engineered APCs, such as the K562-mb15-41BBL cell line, if used to stimulate NK cells, should initially have been grown and tested as a Master Cell Bank, from which a Working Cell Bank is generated and tested for routine use.

Dendritic Cells

DCs are powerful APCs that can be used in vitro or in vivo to elicit immune response to the antigen they are presenting. A number of studies have evaluated tumor antigen-primed DCs for treatment of hematologic malignancies and solid tumors. Antigen-primed DCs are used to target T cells in vitro toward specific antigens. These cells then can be used therapeutically to eliminate viruses or tumor cells bearing that antigen. DCs can be derived from BM or cord blood and mobilized, and resting peripheral blood obtained from normal donors and patients. The normal procedure consists of enriching monocytes from the source material, which has been accomplished by plastic adherence or CD14-based immunomagnetic selection (or by depletion of CD19⁺ B cells and CD2⁺ T cells). An alternative approach is use of elutriation to collect an enriched monocyte fraction from the donor. A purpose-built elutriation system for collection of monocytes is available (the Elutra, Terumo BCT). This method has also been used successfully to enrich monocytes from cryopreserved mobilized apheresis collections.

The monocyte fraction can be cultured in polystyrene tissue culture flasks or gas-permeable bags in culture medium containing IL-4 and granulocyte-macrophage colony-stimulating factor to induce DC differentiation. This is followed by culture in medium containing proinflammatory mediators to accelerate maturation. A

number of supplements have been used during this phase, including CD40 ligand or poly(I:C), interferon- α , tumor necrosis factor- α , IL-6, IL-1 α , and prostaglandin E₂. Some protocols add proinflammatory mediators at the initiation of the cultures rather than after induction of differentiation. One issue for manufacturers is finding clinical or GMP-grade cytokines and growth factors. Some sources now are available, and many manufacturers assist investigators by providing information on test procedures and stability information. Attempts have been made to expand DCs in serum-free medium with varying degrees of success; improved growth and maturation have generally been obtained in the presence of human AB or autologous serum. Of note, minor changes in composition of the culture medium and even in the type of vessel used for culture have been reported to affect the yield, phenotype, and functional activity of the resulting DCs. Cultured DCs have been effectively transfected using native tumor DNA or lentiviral or adenoviral vectors. The cells can be cryopreserved for later administration or use.

Assessment of DC product usually involves immunophenotyping (CD1a⁺, CD80⁺, CD83⁺) and some type of functional assay (ability to generate an allogeneic T-cell response or response to a recall antigen as measured by proliferation assay) in addition to the standard release assays.

Mesenchymal Stromal Cells

Mesenchymal stromal cells (MSCs) are cells with multilineage potential that have shown efficacy in promoting engraftment and suppressing GVHD. They are also widely used in regenerative medicine applications, where their mode of action is not well understood. In vitro MSCs are capable of differentiating into bone, cartilage, cardiac and skeletal muscle, neuronal cells, adipose and connective tissue, and tendons. The cells are not inherently immunogenic and do not appear to be recognized by allogeneic T cells or NK cells. They express very low levels of MHC class II and intermediate levels of class I antigens. They appear to be able to suppress T-cell proliferation and function of both memory T and naive T cells in vitro, as well as inhibit the development of monocyte-derived DCs in vitro.

A number of technical variables affect MSC culture and expansion ex vivo. They include culture medium, passaging density, serum type and concentration, population selection, culture vessel, and use of growth factors. To reduce some of this variability and decrease the cost of preclinical testing, the FDA often encourages investigators to adopt a manufacturing process that is in current clinical trials. The following is a basic procedure. MSCs are usually isolated from BM collected from the iliac crest. The cells are diluted, and the mononuclear fraction is isolated using a Ficoll-Hypaque density cushion (GE Healthcare Life Sciences). This fraction is plated into culture flasks to enrich for adherent cells. The nonadherent population is removed after approximately 7 days of incubation. The adherent cells are washed and detached by incubation with trypsin/ethylenediaminetetraacetic acid (alternatively, TrypZean [Sigma-Aldrich], a recombinant form of trypsin, can be substituted) and then cultured and passaged at weekly intervals. In a study designed to optimize culture conditions, the best results were obtained when cells were cultured in low-glucose Dulbecco's modified Eagle medium-based media containing 10% fetal bovine serum (human platelet lysate is now frequently substituted) and GlutaMAX (Thermo Fisher) instead of L-glutamine. The cells also proliferated better when plated at low cell densities (5000–10,000 cells/cm²) in Falcon flasks. Use of basic fibroblast growth factor as a growth supplement was found to be effective; however, it caused HLA-DR induction and upregulated HLA class I expression. This did not affect the immunosuppressive capabilities of the cells. An increase in osteogenic and adipogenic potential was noted, but neurogenesis and engraftment support for CD34⁺ cells were slightly suppressed. A number of media specifically designed for culture of MSCs are commercially available (e.g., PRIME-XV from Irvine Scientific, STEMPRO MSC SFM, a serum-free formulation from Invitrogen, and MesenCult, a basal culture medium from StemCell Technologies). Various investigators have

reported success growing MSCs in serum-free media or using platelet lysate, autologous serum, or human AB serum as alternatives to fetal bovine serum. The traditional method for producing MSCs in tissue culture flasks is laborious and involves many open procedures that could result in product contamination. An alternative method is to use a functionally closed, hollow-fiber bioreactor, such as the Quantum from Terumo. In this system whole marrow is loaded into the reactor and the adherent cells attach to the fibers. Nonadherent cells are flushed from the fibers, which are perfused with the culture medium. Growth is monitored by glucose consumption and/or lactate production, and the flow rate of medium is increased based on these readings. The cells are removed from the fibers by routine enzymatic treatment.

Mesenchymal stromal cells can be characterized by their expression of CD105, CD73, and CD90 and their lack of expression of CD45, CD34, CD14 or CD11b, CD79a or CD19, and HLA-DR. They must be plastic adherent under standard culture conditions and must be capable of differentiating into osteoblasts, adipocytes, and chondroblasts in vitro. Differentiation assays involve growing MSCs under conditions that promote differentiation along the specific pathway. For neurogenic differentiation, the medium contains linoleic acid, platelet-derived growth factor, and epidermal growth factor. Neural cells are identified by immunostaining with antibodies against tubulin BIII, synaptophysin, galactocerebroside, neurofilament M, and neuronal nuclei. To assess adipogenic potential, the medium contains dexamethasone, isobutylmethylxanthine, and indomethacin. The lipid droplets in the generated adipocytes are visualized by staining with Sudan Black IV. Osteogenic differentiation is measured by culturing the cells in medium containing dexamethasone, β -glycerophosphate, and L-ascorbic acid 2-phosphate. Calcium accumulation and alkaline phosphatase activity in the resulting cells is visualized by alkaline phosphatase/Von Kossa staining, and the osteogenic differentiation is measured as the percentage of mineralized area in the total cultured area.

The ability of MSCs to suppress an MLR is used as an indication of their immunosuppressive activity. A traditional MLR assay is used; however, in the test wells, the MLR is performed on a layer of MSCs seeded the day before. The response is traditionally measured by uptake of tritiated thymidine. Numerous animal assays for MSCs are available but are predominantly used in preclinical studies and are not useful as release assays. Release criteria consist of the usual assays for sterility, endotoxin, and mycoplasma, with immunophenotyping for the MSC population. Depending on the intended use of the MSC, the release process may require an assay showing potential for differentiation into a specific lineage or ability to suppress an immune response such as an MLR assay.

Genetically Modified Cell Therapy Products

Many cell therapy approaches involve genetic modification of either APCs or effector cells (see earlier discussion). This therapy requires a source of vector that has been manufactured to meet regulatory requirements. Viral vector specifications changed markedly after the death of a gene therapy patient in Philadelphia, and they continue to evolve. Manufacturers must maintain close contact with the FDA to ensure that their products meet current specifications. Manufacturing and testing of viral vectors is extremely expensive, and use of genetically modified products requires additional monitoring of recipients. Use of vectors to transduce or transfect cellular therapy products ex vivo usually requires additional testing of the product, which may include detection of replication-competent virus and checking the functionality of the introduced vector (by detecting expression of the gene product).

Gene-Modified Tumor Vaccines

Tumor vaccines as an approach to inducing or stimulating immunity have been evaluated. Various techniques have been tested, including

the use of DCs pulsed with a tumor-associated antigen preparation and the use of the entire tumor cells as an immunogen, either unmodified or transduced with immunostimulatory genes, aimed at eliciting a broad-based, robust immune response.

From the manufacturing perspective, the autologous product is much more of a challenge because a stable tumor cell line must be isolated from each patient. This can be an extremely difficult process. Many isolated lines do not expand well in culture, or they change phenotype over time. In some patients, the line cannot be generated; other patients progress clinically before the vaccine is available and are excluded from the study. As a result, the autologous approach has a relatively high “failure rate”. The allogeneic cell line approach is technically easier because a line is selected before the study and can be used as the generic immunogen. This line must be tested extensively for infectious agents and should pass the FDA testing criteria for Master and Working Cell Banks. Currently, testing of this type costs \$100,000–200,000 for each line. Scientifically, the drawback is that the selected line may not adequately express the antigen or range of antigens present on each patient’s tumor. In addition, the choice of immunostimulatory molecules that are expressed or enhanced by transduction of the cell line may not be those that would most effectively evoke an immune response. These products are relatively expensive to produce, involving not only the costs of testing the tumor cell line, but also the expense of manufacturing and testing the vectors used for transduction. However, these are one-time costs because the same vaccine is used for all patients in the study.

Release testing involves testing for sterility, endotoxin, and mycoplasma, with immunophenotyping of the cells and some form of test demonstrating that the line has been effectively transduced (e.g., flow cytometry for CD40 ligand and IL-2 production in the examples described earlier). Because the product will be stored cryopreserved over the course of the study and thawed for administration to each patient, the requirement for an ongoing stability study should be anticipated.

FUTURE DIRECTIONS

The science and practice of hematopoietic transplantation has expanded dramatically over the past 10 years and has stimulated entirely new areas of medicine. New sources of stem cells have been discovered that have expanded the availability of grafts and provided new insights into stem cell biology. An improved understanding of the immunology of transplantation and immune responses to malignancies has led to more sophisticated methods to manipulate the hematopoietic graft and the immune system in the recipient to produce more favorable outcomes. The ability to target T cells to residual disease by genetic modification of the cells to express chimeric antigen receptors has produced promising results that have reinvigorated prospects for effective immunotherapy of cancer.

In parallel, the regulatory situation has become clearer and we are starting to see widespread development of commercial reagents and devices that facilitate easier compliance when manufacturing cell products.

These advances in knowledge coupled to development in technology promise a bright future for engineering specific cell populations to provide targeted therapies.

PRINCIPLES OF CELL-BASED GENETIC THERAPIES

David A. Williams

The use of gene transfer to treat human diseases has now been demonstrated to be efficacious in a limited number of instances. Proof-of-principle successes in several monogenic diseases—both hematologic and nonhematologic—have been published and widely publicized in the past decade. The previous occurrence of serious adverse events in some trials related to insertional mutagenesis has stimulated rapid development of safer vector systems. This chapter discusses the basic biology of vector systems applicable to blood diseases, the details of the application of gene therapy to blood diseases using specific trials as examples of this technology, and the modifications in vector systems driven by clinical experience that predict future trials. The chapter also discusses the evolving field of somatic cell reprogramming and genome editing that may impact clinical applications in the future.

HEMATOLOGIC DISEASES, CELLULAR TARGETS, AND THE BASIS FOR GENETIC THERAPIES

Gene therapy is defined as the introduction of new genetic material into the cells of an organism for therapeutic purposes. Broadly speaking, two types of gene therapy can be envisioned. The introduction of genetic material into germ cells such that the new DNA can be expected to be passed into the gene pool. This is termed *germline gene therapy* and is currently banned in the United States and around the world. The potential for newer methods of genome engineering to be utilized in clinical applications (discussed later) has led to more recent calls for extending this restriction. In contrast, introduction of new genetic material into specialized cells of the body with no risk of the new genetic material being passed onto subsequent generations is termed *somatic gene therapy*. The ultimate goal of gene therapy is to correct the targeted genetic disease by *replacement* of the defective gene in situ. Such gene replacement could be envisioned via a process termed *homologous recombination*. Homologous recombination in mammalian cells is widely practiced in laboratories but up to now has been relatively inefficient, although newer technology may overcome some of the previous limitations to efficient genome editing. Advantages of this approach would include a reduction in the risk of inadvertent disruption or dysregulation of expression of a critical gene sequence and regulated (appropriate level and distribution) expression of the normal (replaced) gene. However, the frequency of homologous recombination (in contrast to random chromosomal integration) in mammalian cells and primary tissues makes therapeutic use of homologous recombination somewhat impractical at this point. Methods to effect homologous recombination have improved in the past 5 years and may make this goal attainable in the future.

The requirements for successful application of our current gene transfer technology for treatment of human diseases include knowledge of the abnormal gene sequence responsible for the disease phenotype and the availability of the corresponding normal gene sequence that can be packaged into current vector backbones for efficient recombinant virus production. In addition, the cells responsible for the disease phenotype must be identified and accessible for genetic manipulation. Finally, a means of introducing and expressing the correct gene sequence in cells such that the disease phenotype can be reversed is needed. Although effectively accomplished nearly three decades ago in murine studies, this latter requirement encompassing both in vivo administration of DNA sequences and ex vivo cell

manipulation has been the most difficult to consistently meet in human applications using current gene transfer technology.

Since the early development of virus vectors, blood-forming cells have been used as one optimal target for ex vivo gene transfer studies. For this purpose, hematopoietic stem and progenitor cells (HPSCs) are isolated, manipulated in the laboratory, and administered back to the patient. The advantages of these cells as targets of gene transfer are multiple. First, all blood cells are derived from a common progenitor cell, the hematopoietic stem cell (HSC), which is both long lived in vivo and capable of significant self-renewal. The latter capacity and the pluripotency of HSCs is exploited to amplify the genetically manipulated cells into large cell numbers of multiple blood lineages derived from the genetically altered cells in vivo. There is a long and successful experience in obtaining these stem cells from the bone marrow (BM) and peripheral and umbilical cord blood. There is extensive experience in the use of HSCs in the clinical setting for transplantation, and there is experience in purification of these cells and limited knowledge of the requirements for ex vivo manipulation of the cells. In addition, the experience of HSC transplantation (HSCT) has defined a variety of genetic diseases in which the phenotype can be altered by the successful engraftment of normal allogeneic donor cells. Finally, the blood system is involved as a major dose-limiting organ in cancer therapies and both a target and an effector organ in immune reactions, providing a large group of diseases that could theoretically be approached using gene transfer technology. As noted earlier, there are already a large number of monogenic diseases of the blood extensively characterized, with more being defined at the molecular level on a regular basis as whole-exome and whole-genome sequencing is being applied to rare disease phenotypes. In addition to HSC targets, another application of gene transfer technology exploits the experience in adoptive T-cell immunotherapy. In this application, T cells (and less well developed to this point, other immune effector cells) are modified ex vivo in an attempt to enhance potency and specificity. This application of gene transfer technology will not be reviewed here.

The field of gene therapy is rapidly evolving. Successes of “proof-of-principle” small trials have demonstrated the utility of gene transfer approach in a sizable number of patients but in a limited number of diseases. The technology itself is quickly evolving in response to new understanding of viruses, the regulation of gene expression, and gene editing. The application of gene transfer technology to HSC gene therapy has been made possible by exploitation of viruses that have evolved the capacity to efficiently and precisely insert viral genomes into cellular chromosomes of infected cells. The field has taken more than 30 years to evolve to its current state of clinical application. Although this might be viewed as a slow pace, in reality, this time frame parallels the development of many other novel therapies. This developmental phase also reflects the complexities of the biologic systems involved and the caution required in moving forward in the face of serious adverse events seen in early safety trials. It is indeed an exciting time with respect to the clinical application of gene transfer technology in human diseases.

VECTOR SYSTEMS

The initial impetus to develop gene transfer for human studies derived from the exploitation of oncoretroviruses, mainly murine

γ -retroviruses, as vectors for gene delivery in the early 1980s. However, since these early studies, a multitude of virus vectors have been developed. All vector systems exploit the virus life cycle to increase the frequency and fidelity of gene transfer. Although many vector systems have been developed, retrovirus and lentivirus vectors have become the most used platforms for human gene therapy trials involving HSCs, and this review will focus primarily on these vector systems and the closely related foamy virus and avian virus vectors (reviewed by Touw and Erkeland¹). As noted, the majority of trials registered with the Recombinant DNA Advisory Committee of the National Institutes of Health use retroviruses, with nonintegrating adenovirus vectors, adeno-associated virus, and nonvirus (liposomes and plasmids) systems making up the second- and third-largest groups. The latter are primarily focused on immune stimulation trials in cancer and have limited relevance to the use of HPSCs for the treatment of genetic blood diseases.

Retrovirus Vectors

The use of γ -retroviruses as gene transfer vectors takes advantage of the normal virus life cycle. The virus, a membrane-bound particle enclosing a dimer of genomic RNA, Gag, and reverse-transcriptase proteins, interacts with specific cell surface receptors on the target cell. After entry into the cytoplasm, the virus is uncoated, and the genomic messenger (m)RNA is reverse transcribed into DNA. Subsequent polymerase activity yields a double-stranded (DS) DNA provirus molecule. For γ -retroviruses, transport into the nucleus depends on the loss of the nuclear membrane, which accompanies cell division (see later discussion). Integration of the DS provirus in the chromosome is semi-random. The occurrence of insertional activation of oncogenes in several human trials and the subsequent scrutiny of insertion sites in HSC-derived progeny in both murine and human cells using deep sequencing methods have provided a more detailed understanding of the subtle but biologically relevant preferences for insertions of these vectors (see later discussion). After being integrated, the provirus can give rise to mRNA, leading to encoded protein products. Full-length (genomic) mRNA can also be used as the genomic nucleic acid in newly formed virus particles, which are budded nonlytically from the cell surface after assembly in the cytoplasm of the infected cell. The use of retroviruses for gene delivery depends on the capacity to replace viral genes with other heterologous gene sequences and to provide necessary viral proteins in trans in specialized cell lines, called *packaging cells*. The advanced generation of packaging cells appears to be capable of generating pure stocks of recombinant virus without contaminating wild-type helper virus, an important safety consideration. Indeed, to date in human trials, there have been no reports of inadvertent generation of infectious virus. Thus, the infection with replication-incompetent (i.e., helper-free) retrovirus vectors would be predicted to yield integration into the targeted cell population but no further spread of virus in the body of the treated patient. The proteins provided in trans for γ -retroviruses are generally Gag, reverse transcriptase, and envelope proteins, the latter defining the host range of infection. In summary, the advantages of retrovirus vectors include the high efficiency of stable transfer of intact DNA sequences, the broad range of host cells susceptible to infection by retroviruses, and the ability to generate helper-free recombinant virus via stable packaging cell lines.

Despite these advantages, the application of retrovirus vectors for treatment of human blood diseases in early trials was disappointing. In multiple studies, transduction of long-lived and transplantable HSCs has been extremely low. In most studies, the frequency of circulating marked blood cells was too low to effect phenotypic correction of any disease, usually less than 0.1%. The biologic parameters contributing to the poor results in human trials are varied. The major impediments appear to include the low levels of viral receptors on the surface of human HSCs, reducing the efficiency of interaction of virus particles with these target cells, and the quiescent nature of the majority of HSCs, which hinders the transport of the

provirus into the nucleus and thus reduces integration frequency. Practical issues, including the difficulty in obtaining high-titer virus in large-scale preparations required for human trials, have also been noted.

These difficulties have led to various strategies and the development of entirely new vector systems, which seek to improve gene transfer methods in human HSCs. These strategies include attempts to increase virus–cell interactions or methods to enhance the chances of successful DNA integration. Different viral envelopes were used to pseudotype recombinant particles to more efficiently target CD34 cells. The use of various cell surface markers, such as CD34, to purify the target cell population can also increase the multiplicity of infection at a given virus titer and has been used in clinical transplantation protocols. Thus, the development of antibody-based enrichment of the CD34⁺ HPSC compartment from human hematopoietic tissues using magnetic column purification provides a rapid, clinically applicable method to further enhance retroviral transduction by increasing the vector-to-target cell ratio. Methods to increase physical interactions between vector particles and target cells include colocalization on fibronectin and centrifugation methods. Where polycations such as polybrene had previously been used to enhance transduction frequencies by negating electrostatic charge repulsion between target cells and viral particles, the characterization of the recombinant CH296 fibronectin fragment (Retronectin) as a matrix upon which one could colocalize HSCs and viral particles was a significant advance in the quest to improve CD34⁺ transduction frequencies. Other efforts to increase the chances of DNA integration have focused on attempts to increase the number of HSCs that are undergoing cell division (primarily the use of cytokines that effect stem cell proliferation). The development of improved in vitro growth media formulations incorporating novel cytokine cocktails achieved the dual aim of promoting HSC division, which is required for transduction with γ -retroviral vectors while minimizing stem cell loss via apoptosis or differentiation. Finally, the use of new virus systems that do not require nuclear membrane disruption (and, therefore, cell division) for entry of the provirus DNA into the nucleus, including primarily lentivirus vectors but potentially also vectors based on foamy viruses, appears to be the most significant development in the field in the past decade. These newer vector systems will be discussed later.

In addition to advancing stem cell transduction methodology, additional work has focused on developing retroviral vectors that would express transgene cassettes at levels that would be high enough to elicit a therapeutic benefit and be resistant to gene silencing. Advances in vector design such as the optimization of long-terminal repeat (LTR) enhancer and promoter elements and viral leader sequences resulted in recombinant vectors that were able to mediate high-level transgene expression in both primitive and mature hematopoietic cells. As discussed in detail later, although these powerful promoter and enhancer elements provided robust expression of transgenes, they also appear to be capable of long-range activation of endogenous regulatory sequences as a form of insertional mutagenesis, which can have significant deleterious effects. Taken together, these technologic advances served as the platform for the first successful gene therapy trial in humans.

The use of pharmacologic in vivo selection in combination with gene transfer, both in the setting of cancer trials and in genetic diseases, remains a potentially important method to enhance the reconstitution of human recipients with gene-modified blood cells, but it has not yet gained widespread usage. General considerations include the need for a particular drug to effect damage to BM stem or progenitor cells. A gene or genes encoding resistance to this agent would need to be identified and resistance in vivo to the agent would need to be demonstrated after overexpression of this gene in BM cells. For applications in cancer therapies, dose intensification of drugs used within chemotherapeutic regimens should improve antitumor efficacy. Work is ongoing to use transgenic expression of O⁶-methylguanine methyltransferase (MGMT), which generates resistance to bis-chloroethylnitrosourea, temazolamide, and 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea and cytidine deaminase, which generates resistance to cytosine arabinoside, gemcitabine, decitabine, and

azacytidine for applications in cancer. For noncancer applications (for coselection of a nonselectable therapeutic gene in a genetic disease application), the mutagenic potential of the chemotherapy agent must be considered as a risk in relation to the overall benefit of the gene therapy procedure. Several chemoresistance genes and chemotherapy drug combinations are currently under investigation for this application, and encouraging preclinical studies have led to a limited number of early-phase human studies in cancer patients. In a recently reported human trial in which *MGMT* gene transfer was utilized, patients receiving temozolamide for treatment of brain tumors tolerated significantly more chemotherapy compared with historical controls, with transient increases in gene-modified cells in the peripheral blood in a few patients.²

Lentivirus Vectors

One of the key advances in the gene therapy field in the past decade has been the development of recombinant vectors based on lentiviruses, including human immunodeficiency virus (HIV). These vectors were originally developed after the observation that targets of HIV included more differentiated cells, such as macrophages, that are often also postmitotic, suggesting this group of retroviruses has evolved a method of circumventing the block in infection of γ -retroviruses seen in nondividing cells. Investigators demonstrated lentivirus vectors derived from HIV were capable of infecting nondividing neurons after direct injection into the brain. Subsequently, Naldini and colleagues showed efficient infection of growth-arrested cells. As with γ -retroviruses, lentivirus vectors use key viral gene products in trans to generate replication-defective infectious particles carrying the transgene of interest. To date, most lentivirus vectors use vesicular stomatitis virus as envelope sequence, which provides a very broad range of target cells susceptible to lentivirus vector transduction. In the case of lentivirus vectors, viral Gag and Pol, as well as Tat and Rev protein expression are required in trans for efficient virus production along with the envelope proteins. These proteins are usually supplied from separate plasmids, and recombinant lentivirus production is today generally created using “four-plasmid” systems encompassing all the necessary viral proteins on three plasmids and the transfer vector sequences on the fourth plasmid. In addition to *gag* and *pol*, the transfer vector contains all the virus regulatory sequences required in cis for packaging an infectious particle, including the *psi* packaging sequence, integrase, and reverse transcriptase. Thus, generation of high-titer recombinant virus is more complicated than γ -retroviruses and remains a significant issue for large-scale, clinical grade production for use in human trials.

To reduce the chances of generation of replication-competent retroviruses (RCRs), a major safety concern with HIV, most of the nonessential viral sequences have been removed from currently utilized vectors. This included *vif*, *vpr*, *vpr*, and *nef* genes, and subsequently *tat*, an important regulator of viral transcription. Recombinant vectors generated without these sequences were demonstrated to efficiently infect a variety of cells. RCR testing is based on sensitive assays to detect Gag protein by p24 immunoassays or polymerase chain reaction. In addition, lentivirus vectors have traditionally been produced using the “self-inactivating design” (SIN) for added safety because of reduced risk of recombination with and subsequent mobilization of endogenous HIV viruses. The transfer vector thus contains a deletion of the 5' LTR U3 region and is devoid of viral enhancer and promoter sequences. During reverse transcription, the 5' LTR is replicated, and the integrated provirus is thus devoid of both 5' and 3' U3 regions. In SIN constructs, the transgene of interest is thus expressed from an internal promoter that can be chosen with varying strengths. This added safety feature ultimately has also proven important to reduce the risk of insertional mutagenesis (see later), by which integration near cellular genes are inadvertently activated by the LTR enhancer sequences of vectors.

Lentivirus vectors were originally developed for use in a wide range of tissues in which cells are largely nondividing. Early work focused on brain, retinal cells, liver, pancreatic islets, airway

epithelium, and muscle. However, it was subsequently appreciated that the requirement of stimulating HSCs into division with various cytokines to effect efficient transduction with γ -retrovirus vectors may have negative effects on engraftment, or that a large fraction of HSCs remain quiescent and therefore resistant to transduction during clinical transduction protocols. After several groups reported successful transduction of primitive HSC populations in protocols in which these cells remained resistant to transduction by γ -retroviruses, the adaption of lentivirus vectors has now included several recent human trials, and initial results are encouraging. In a trial for childhood cerebral adrenoleukodystrophy (CCALD),³ long-term “marking” in the myeloid compartment appears to be 10% to 20%, a level that is about 100-fold higher than the marking in the myeloid compartment seen in previous trials in immunodeficiency conditions that used γ -retrovirus vectors. In addition to the safety advantage of SIN vector design used in all lentivirus vectors, there is an additional theoretical advantage of the preference of lentiviruses for integration away from transcription start sites (TSS) of genes in contrast to γ -retroviruses. However, the recent experience with a lentivirus vector used in a single patient with thalassemia,⁴ in which abnormal splicing resulted in clonal expansion in the erythroid compartment, suggests that insertion within genes including intronic and noncoding regions of genes may also have potential adverse effects on endogenous sequences. These trials are described in more detail later. Thus, the long-term safety of lentiviruses in human trials remains to be determined, and important aspects of insertional mutagenesis are described in more detail later.

Foamy Virus Vectors

Foamy viruses possess several features that have been exploited to yield vectors for the purpose of transducing HSCs. Foamy viruses are members of the spumaretroviruses family. They have been shown to be endemic retroviruses in a wide range of animals but are not found in humans. These vectors are the largest of the retroviruses (≈ 14 kb) and thus yield vectors with a capacity to efficiently package large amounts of genetic sequences. The virus has a DNA genome that is reversed transcribed within the virion particle, forming a stable pre-integration complex within the transduced cell. As with γ -retrovirus vectors, the virus packaging signals have been successfully exploited to allow production of high-titer, replication-free vector stocks. Based on accidental exposure of a limited number of animal care workers, it has been reported that infection of humans with wild-type foamy virus has no pathologic effects. Foamy virus vectors have been used to successfully transduce mouse and human hematopoietic cells. Proof-of-principle work by Hickstein's group has demonstrated correction of canine leukocyte adhesion deficiency using a foamy virus vector expressing CD18 after transduction and infusion of CD34⁺ cells after submyeloablative conditioning. No human trials have been opened to date using this vector system, but several are planned for the future.

Alpharetroviruses

Retrovirus vectors derived from Rous sarcoma virus, which is a member of the alpharetrovirus family, have been described. Although these vectors maintain genomic integration as part of the viral life cycle, they have attracted recent attention because of their propensity to integrate in a relatively neutral fashion with respect to promoter regions and TSS of genes. In large animal studies, alpharetrovirus-transduced HSC-derived progeny demonstrated integrations that were not clustered in gene-rich CpG or TSS regions of the genome. The development of a self-inactivating alpharetrovirus with a split-packaging design by Schambach and colleagues⁵ has provided proof-of-principle with respect to the capacity to generate high-titer, replication-free vector stocks from stable producer cell lines that use internal promoters to express transgenes in a potentially safer fashion than γ -retrovirus vectors. Such vectors have been demonstrated to

efficiently infect murine and human hematopoietic cells, including T lymphocytes, at low multiplicity of infection.⁵

EXPERIENCE IN HEMATOLOGIC CLINICAL TRIALS TO DATE

X-Linked Severe Combined Immunodeficiency

Severe combined immunodeficiency (SCID) comprises a number of rare monogenic diseases, with common features including a block in T-cell differentiation and impaired B-cell and natural killer (NK) cell immunity. Studies of pattern of inheritance, immune function, and genotypes have led to the identification of at least 11 distinct SCID conditions. The most common variant of SCID results from the deficiency in expression or function of the common cytokine receptor γ chain, which is shared by the receptors for interleukin (IL)-2, IL-4, IL-7, IL-9, IL-15, and IL-21. This condition is inherited in a sex-linked fashion (X-linked SCID or SCID-X1) and accounts for 40% to 50% of all SCID cases. SCID-X1 is characterized by abnormal development or function of T, B, and NK cells, although B cells are usually present in humans (so-called *T-minus, B-plus SCID*). Survival depends on the reconstitution of T-cell development and function by allogeneic BM transplantation (BMT). If a genotypically matched family donor is available, HSCT confers greater than 80% chance of long-term survival. The absence of T and NK cells in the patient allows for the engraftment of donor cells without preparative chemotherapy conditioning; thus, this is the treatment of choice with minimal toxicity. When a genotypically matched family member is not available, haploidentical donors (e.g., a parent) or closely matched unrelated donors are used, with varying preference center to center, and a survival rate of 64% to 78% has been reported. These inferior outcomes may be attributed to the increased risk of graft rejection or graft-versus-host disease (GVHD), as well as the effects of T-cell depletion, immune suppression causing slower immune reconstitution, or conditioning with increased risk of infection. Haploidentical transplants rigorously depleted of T cells, similar to genotypically related transplant, are performed in some institutions without preparative chemotherapy conditioning; however, B-cell reconstitution is poor, and the majority of patients require intravenous immunoglobulin (IVIG) replacement for life. Interestingly, spontaneous partial correction of severe T-cell immunodeficiencies, including SCID, has previously been reported, suggesting a selective advantage of wild-type T cells over defective T cells.

Three independent gene therapy trials aimed at correcting the immunologic defect of SCID-X1 patients who lack a genotypically matched BM donor have been reported.⁶ In the initially reported trials, a total of 20 patients have been treated.^{7,8} Despite minor technical differences in the two protocols, the basic design of both gene therapy trials is quite similar: the complete coding region of the human γ -chain was cloned into a “first-generation” γ -retroviral vector regulated by the murine leukemia virus (MLV) LTR sequences, which was used to infect BM-derived CD34⁺ cells in vitro. The transduction occurred in the presence of early acting cytokines (stem cell factor, thrombopoietin, IL-3, and FMS-like tyrosine kinase 3 ligand) and the CH296 human fragment of fibronectin described earlier. Cells were subsequently infused without prior conditioning or cytoreductive treatment. Minor differences between the two protocols included the uses of a threefold higher concentration of IL-3 and 4% fetal cell serum in the French trial. Additionally, the French investigators used the amphotropic envelope pseudotype compared with the use of gibbon ape leukemia virus envelope in the British trial. Results in both trials have been extremely encouraging.

In the French trial, 10 children younger than the age of 1 year were enrolled between 1999 and 2002. Nine out of 10 infants developed normal numbers of T and NK cells, with good immune function. In seven of the nine patients who developed T cells, T-cell counts reached normal levels within 3 months and have remained normal at the time of the last published follow-up. Protective levels

of antibodies, including antibody production after immunization, were achieved, and the prophylactic administration of IVIG was discontinued. At almost more than 10 years after gene therapy, these patients continued to retain a functional immune system, enabling them to live normally.

However, serious adverse events related to gene therapy have been reported in four patients in the French trial, occurring 31 to 68 months after gene therapy, and in one patient in the British trial. In these patients, untoward effects of viral integration into the genome resulted in T-cell leukemia, leading to the death of one of the four affected patients. Much research has subsequently been directed at elucidating the mechanism responsible for these adverse events. Retroviral integration in the proximity of proto-oncogenes, particularly the LIM domain only 2 (*LMO2*) promoter, was involved in leukemogenesis in three French patients and one British patient. An integration of the unaltered γ -chain-encoding viral vector on chromosome 11q13, near the first exon of the *LMO2* gene, led to the unregulated transcription of *LMO2*, giving rise to a T-cell acute lymphoblastic leukemia (T-ALL)-like lymphoproliferation in the initial two patients. In the patient in the British trial, the integration of the vector 35 kb upstream of the *LMO2* locus cooperated with secondary genetic aberrations, including a gain-of-function mutation of *NOTCH1*, a deletion at the *CDKN2A* tumor-suppressor gene locus, and a translocation of the T-cell receptor β region, to give rise to T-ALL. *LMO2* is a master regulator of human hematopoiesis that is involved in stem cell growth and is not normally expressed in T cells. However, *LMO2* activation has been implicated in some cases of human T-cell leukemia. In addition, *LMO2* transgenic mice have been shown to develop T-ALL within 10 months. It is increasingly clear that retroviral vectors may “turn on” cellular proto-oncogenes adjacent to their integration site in the genome. The strong promoter or enhancer activity of the retroviral LTR element shows particular propensity to the upregulation of genes neighboring the integration site. Multiple studies now indicate that γ -retroviral vectors, such as the vectors used in the two SCID-X1 trials, preferentially integrate into the 5' end of genes near the TSS. In addition, γ -retroviral vectors have been shown to integrate in or near a number of proto-oncogenes that are actively expressed in human CD34⁺ cells. When human CD34⁺ cells were transduced with retroviral vectors ex vivo, 21% of retroviral integrations occurred at recurrent insertion sites (“hot spots”), which were highly enriched for proto-oncogenes and growth-controlling genes. A series of papers investigating the vector integration sites in both SCID-X1 trials and a trial treating adenosine deaminase (ADA) deficiency, the ADA-SCID trial (see later), observed a greater-than-random frequency of vector integrations near the TSS of genes that are active in HSCs. Interestingly, in the SCID-X1 trial, a skewing of vector integration site distribution in vivo was noted. Compared with retroviral integration sites (RIS) recovered from transduced CD34⁺ cells, RIS recovered from T cells in vivo 9 to 30 months after transplantation showed an overrepresentation of RIS within or near genes encoding proteins with kinase activity, transferase activity, or proteins involved in phosphorous metabolism. This skewing of RIS in vivo suggests a selection of T cells as a result of viral integration in certain growth- and survival-promoting genes. A more recent trial in X-SCID utilizing a SIN γ -retrovirus design reports early follow-up on nine patients,⁶ although the trial is still accruing patients (NCT01129544). The virus design is noteworthy in that it is more directly comparable to a lentivirus, since the viral enhancer elements are deleted and expression of the IL-2 γ -chain is from an “internally positioned” cellular promoter. The initial results reported efficacy similar to the previous SCID-X1 trials—no leukemias and integration analysis that appears safer than those seen in the previous two trials. In the eight evaluable patients treated in this trial, six demonstrated correction of T-cell reconstitution. One patient died prior to full engraftment of gene-modified cells of preexisting viral infection that did not resolve after gene therapy. The two failures correlated with lower vector copy number in the transduced product as a result of inadequate gene transfer. This study is particularly noteworthy as the only human study in which a γ -retrovirus vector deleted of enhancer elements has been utilized. It thus provides a

platform for more direct comparison with previous γ -retrovirus and lentivirus trials with respect to safety and efficacy.

Strikingly, in contrast to five cases of insertional mutagenesis in the two SCID-X1 trials, no adverse events have been reported in the 10 patients treated in the ADA-SCID trial, despite a similar RIS pattern observed in this patient group. There have been no leukemias reported in more than 40 patients treated worldwide (including in London, Los Angeles, and at the NIH) and most of these have benefited from gene therapy. The observation of the difference in leukemia in these trials has led to the proposal of a “disease effect” contributing to oncogenesis of γ -chain gene therapy. Woods and colleagues demonstrated lentiviral transduction of $\gamma_c^{-/-}$ mice with vectors containing the human common γ -chain ($c\gamma$) or an inert control gene at very high viral doses.^{8a} They observed the induction of T-cell malignancies in one-third of the animals receiving $c\gamma$ -transduced cells but not in the control groups. The merit of this very limited study was subsequently challenged, primarily on the basis of a viral dose much higher than that used in clinical scenarios and incomplete data on the pathogenesis of the malignancies, particularly as they relate to the downstream activation level of a key signaling target of the common γ -chain, Janus kinase 3, in the tumors. In addition, the lentiviral vector used in this study incorporated a hybrid promoter or enhancer element that is extremely powerful and likely to possess a greater transactivating potential than promoter or enhancer elements that would be considered for clinical gene therapy use. More recent occurrence of leukemia in another trial for Wiskott-Aldrich syndrome (WAS; see later) using the same vector backbone further challenges the presence of SCID-X1 disease or transgene effects in these leukemias.

In summary, thus far, 5 out of 20 patients treated with gene therapy for SCID-X1 have encountered a life-threatening severe adverse event, thought to be triggered by retroviral activation of LMO2 in 4 patients. Four patients were salvaged with chemotherapy, and one patient succumbed to the disease after an unsuccessful allogeneic BMT. At this point, the use of MLV-based retroviral vectors with LTR promoter enhancer elements intact is viewed as contraindicated in this disease by most investigators in the field. The continued development of safety-enhanced vectors and the validation of these vectors in clinically relevant systems have emerged as a major priority in the field, and, as noted above, an international trial has recently been reported using a γ -retrovirus that is deleted of LTR enhancer elements. Transgene expression is mediated by a weak cellular promoter in this vector. Data suggest that early efficacy is maintained despite lower expression of the $c\gamma$ -chain and that the deletion of the γ -retrovirus enhancer is a key to improved safety.⁶

Adenosine Deaminase Deficiency

ADA is a housekeeping enzyme of the purine metabolic pathway that is expressed in all tissues of the body. Deficiency of this enzyme leads to a buildup of toxic metabolites with detrimental systemic effects, including neurodevelopmental deficiencies, sensorineuronal deafness, and skeletal abnormalities. Importantly, ADA deficiency causes abnormal T-, B-, and NK-cell development, resulting in the SCID phenotype. As is the case with the more common SCID-X1, untreated patients generally succumb to severe opportunistic infections in the first year of life. Treatment strategies used to manage affected patients include allogeneic HSCT, enzyme-replacement therapy, and, more recently, gene therapy. Allogeneic HSCT from a human leukocyte antigen-matched family donor offers good immunologic and biochemical correction with 73% survival. However, outcomes after mismatched and haploidentical transplants are less impressive. Likewise, the exogenous replacement of ADA, administered in a polyethylene glycol (PEG) conjugate by intramuscular injection on a weekly or twice-weekly schedule, results in systemic detoxification and immune reconstitution. In the long term, however, about half of the patients receiving PEG-ADA replacement continue to require IVIG infusions, and some patients show a decline in T-cell numbers over time.

A number of gene therapy trials for ADA deficiency were initiated in the early 1990s, targeting retroviral gene transfer into various cell types, including peripheral blood lymphocytes, umbilical cord blood, BM, and CD34⁺ selected stem cells. These early studies failed to produce clear efficacy. By contrast, more recent studies introduced key modifications to the gene therapy protocol, including the use of a reduced-intensity myelosuppressive conditioning regimen and the withdrawal of concurrent PEG-ADA replacement. The Milan-based group of Aiuti and colleagues have reported on their initial experience with 10 children.¹¹ Patients were conditioned with 4 mg/kg of busulfan before the infusion of transduced cells. The mean age at the time of gene therapy was 2.2 years. All children on this trial are healthy and thriving, with the longest published follow-up time now more than 64 months. Gene therapy has resulted in a substantial increase of lymphocyte counts and normalization of T-cell function. A recent update on this trial,⁹ published in abstract form, reports that 18 patients have been treated and are alive and, of these, 15 do not require replacement enzyme treatment.

Similarly, four patients have been treated in London.¹⁰ One patient that has been reported in detail had been treated with PEG-ADA for 3 years but showed a gradual decline in T-cell numbers despite effective metabolic correction. Because a matched BM donor was not available, the patient was enrolled on the ADA-SCID gene therapy trial. PEG-ADA replacement was stopped 1 month before gene therapy, and the patient was conditioned with a single dose of 140 mg/m² of melphalan before infusion of the transduced BM CD34⁺ cells. At the time of the last published follow-up, the patient was 2 years from gene therapy, clinically well, and off prophylactic antibiotic therapy.^{10a} An increase in T-cell numbers and normalization of the proliferative response have been noted. Importantly, no adverse events have occurred thus far in the patients treated for ADA-SCID at these two centers.

Aiuti and colleagues recently published a comprehensive genome-wide analysis of RIS of five patients treated in Milan. This paper analyzed the RIS patterns in CD34⁺ cells before infusion as well as RIS in vivo up to 47 months after gene therapy. As anticipated, a nonrandom proviral integration pattern, favoring TSS and gene-dense regions, was observed in the pretransplant cells. RIS observed in vivo in T cells were additionally enriched for TSS, suggesting the occurrence of in vivo selection. More recently, Aiuti and colleagues¹¹ have demonstrated that cellular genes in the proximity of the proviral integration site are subject to moderate dysregulation in gene modified T-cell clones isolated from patients. However, in contrast to the SCID-X1 trial, no in vivo skewing toward RIS in genes affecting survival, cell cycling, signal transduction, or proliferation were observed, making a clonal dominance effect appear less likely. Interestingly, only one RIS was detected at the *MDS-EVII* locus and became undetectable at later time points. This is in contrast to the clonal dominance of *MDS-EVII* integration sites observed in the X-linked Chronic Granulomatous Disease trial (see later). Additionally, an overrepresentation of RIS was noted in the proximity of the *CCND2* and *LMO2* genes, with a total of 5 out of 523 RIS recovered in vivo. Notably, the *CCND2* insertions were detected only in the first 2 years of follow-up and not subsequently. *LMO2* insertions were also overrepresented in the pretransplant CD34⁺ samples, highlighting the fact that the *LMO2* gene is a hotspot for retroviral integration in human CD34⁺ cells. The lack of in vivo expansion of clones carrying *LMO2* RIS indicates that this integration site may not be sufficient to mediate clonal dominance and leukemic transformation. Rather, additional cooperating mutations or insertions are required for malignant transformation. The lack of malignant transformation in two ADA-SCID trials may point to the role of the genetic background or the role of the therapeutic transgene introduced into human CD34⁺ cells. However, the patient cohort remains relatively small, and follow-up is still short term. As noted previously, over 40 patients have now been treated worldwide, with no leukemias reported in any trial in this disease to date.¹² An ongoing new multicenter trial utilizes a lentivirus platform (NCT01279720). Overall, the genotoxicity profile in the ADA-SCID trials has been sufficiently favorable to continue to recommend this experimental

therapy to patients and families lacking a perfectly matched sibling donor. Indeed, this vector and treatment portfolio has been licensed in 2011 to a major pharmaceutical company for clinical development.

Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) is an inherited disorder of phagocyte dysfunction characterized by often life-threatening invasive fungal and bacterial infections and by granuloma formation in vital organs. CGD results from a mutation in one of four subunits of the reduced form of nicotinamide adenine dinucleotide phosphate oxidase of phagocytes. The inability to form microbiocidal oxygen species renders the phagocytes unable to fight invasive infections. Almost 70% of CGD cases result from defects in the X-linked gene encoding gp91^{phox} (X-CGD). With conventional therapy, including lifelong antimicrobial prophylaxis and interferon- γ therapy, the yearly mortality rate of X-CGD remains at 5%. HSCT is curative for patients with a perfectly matched sibling donor but remains risky in patients with active infections. Unrelated donor transplantations are not routinely recommended. Thus, the development of a gene therapy approach that uses autologous HSC provides an important therapeutic advance for this patient group. In previous clinical gene therapy trials conducted without myeloreductive conditioning, the engraftment level of gene-modified cells remained low.

In 2002, the German group of Grez and colleagues in Frankfurt, Germany, initiated a gene therapy trial of X-CGD.^{12a} The initial patients received a mild immunosuppressive preparative regimen and failed to engraft significant numbers of gene-modified cells. However, 2 years later, low-dose busulfan—modeled on the successful gene therapy trial for ADA-SCID—was incorporated into the preparative regimen, and additional patients were treated. This group of patients has been followed with unprecedented sophistication by the prospective monitoring of integration sites that marks each hematopoietic cell before transplantation and then allows the tracking of these cells in vivo. The initial two patients treated were 26 and 25 years old. Both patients carried the diagnosis of X-CGD and had failed to clear invasive infections, including a *Staphylococcus aureus* liver abscess and pulmonary aspergillosis with medical treatment. Thus, autologous peripheral blood CD34⁺ cells were mobilized with granulocyte colony-stimulating factor and collected. Gene transfer was performed using a γ -retroviral vector SF71gp91^{phox}. This vector, containing the spleen focus-forming virus LTR elements (in contrast to the Moloney MLV LTR in the two SCID trials) was chosen for its ability to achieve high expression levels in transduced HSCs. The in vitro transduction rates in the two patients were 45% and 39.5%, respectively, with a proviral copy number of 2.6 and 1.5 per transduced cell. Proviral integration occurred preferentially in gene-coding regions (47–52%) and was highly skewed toward the 5-kb sequence surrounding TSS. Moreover, the clonal distribution pattern was not stable over time. Rather, starting 5 months after therapy, a less diverse integration pattern emerged, indicating the appearance of dominant clones.

Clinically, following a period of cytopenia after conditioning and cell infusion, the initial engraftment rates detected in the peripheral blood were 12% to 13%. Significant improvement in the previously refractory infections was noted 50 to 60 days after therapy. Surprisingly, a gradual increase in the number of gene-corrected cells up to 50% to 60% of all peripheral blood cells was observed, starting around day 150 after transplant. This coincided with increased oxidase activity and occurred in the absence of altered blood counts. These events were accompanied by a selective outgrowth of progenitors carrying vector insertions that activated one of three oncogenes: *PRDM16*, *SETBP1*, and most notably *MDS-EV11*. Although all three genes are well-known cancer-associated genes, most clonal outgrowths were exhausted after a few months with the exception of *MDS-EV11*, which increased to 67% to 90% in both patients approximately 1 year after cell infusion. Of note, the dominant *MDS-EV11* clones initially did not transgress the boundaries of the normal myeloid pool because these cells remained cytokine dependent

in vitro and failed to engraft in immunocompromised mice, suggesting their benign nature. Thus, the expansion of gp91^{phox+} cells, although clearly providing therapeutic benefit during the initial phase, was viewed with mixed feelings by the investigators and the general gene therapy community.

More recent follow-up on these two study patients has been provided.^{13,14} Indeed, although gene marking remained high in both patients, downregulation of gene expression was noted as a result of CpG methylation in the viral LTR promoter. As a consequence, gp91^{phox} expression was suppressed, but the capacity of the LTR-encoded enhancer to transactivate nearby genes remained intact. One patient died 2.5 years after therapy of severe sepsis. The second patient developed monosomy 7 and myelodysplastic syndrome (MDS) and died after an unsuccessful unrelated donor BMT.¹³ Of note, the *EV11* locus has previously been identified as a common target of retroviral oncogenesis. *EV11*, which is not detected in normal hematopoietic cells, has been associated with myeloid leukemia and MDS. The constitutive overexpression of *Ev11* in mouse BM cells has been shown to induce MDS in mice and data from the CGD trial suggest that dysregulated expression is associated with genomic instability, presumably contributing to the acquisition of additional somatic mutations. Despite these molecular events, the infusion of gene-corrected CD34⁺ cells was highly effective with regard to clearing refractory pyogenic infections, raising the possibility of using gene therapy to bridge patients with refractory pyogenic infections into eligibility for allogeneic HSCT. A multiinstitutional international trial has recently opened in which the GP91^{phox} gene is expressed in a lentivirus backbone via a chimeric myeloid internal promoter (NCT01855685).

Wiskott-Aldrich Syndrome

WAS is an X-linked immunodeficiency caused by inactivating mutations in the WAS protein (WASP). WASP plays a regulatory role in cell signaling and cytoskeletal reorganization in hematopoietic cells. The disease is fatal and is characterized by severe combined immunodeficiency, thrombocytopenia, elevated frequency of tumor formation, eczema, and other autoimmune manifestations. The only currently available curative therapy for WAS is BM transplant, but as with the other primary immunodeficiencies, the availability of suitably matched donors is limiting. A clinical trial for the genetic correction of WAS via retroviral delivery of the WASP cDNA into autologous CD34⁺ cells was recently reported.¹⁵ A combination of a relatively high cell dose (7–8 $\times 10^6$ CD34⁺/kg body weight) and good transduction efficiency led to gene marking across both myeloid and lymphoid lineages. A marked clinical benefit from gene therapy has been reported in one of the patients.¹⁵ Of particular note is the fact that the architecture of the vector backbone used in this trial is similar to that used in both the CGD and the SCID trials described earlier. That is, the γ -retroviral vector has an intact LTR that contains the enhancer and promoter from the spleen focus-forming virus.¹⁶ Recent reports describe T-cell leukemia from insertional mutagenesis in 7 of the 10 patients in this trial.¹⁷ Thus, a common molecular etiology in this trial strongly suggests that the initial vector design (intact strong viral LTRs containing enhancer elements that can transactivate promoters over long distances) are unsafe. In addition, the occurrence of T-cell leukemia in a disease other than SCID weakens the argument that the leukemias in X-SCID was related either to the transgene or some unknown disease-specific characteristic. In any regard, use of the “first-generation” MLV backbone in human trials may now be ended. More recently, several new clinical trials have opened that utilize a SIN lentivirus vector for treatment of WAS (NCT02333760, NCT01410825, and NCT01347346). These trials utilize the same vector backbone. In a total of 10 patients studied, 9 were reported alive and showed clinical benefit with reduced autoimmunity, including improvement in eczema and reduced platelet transfusion dependence with no serious bleeding. One patient died from preexisting viral infection that did not resolve after gene therapy. In one study it was noted that the degree of myeloid engraftment and platelet

reconstitution in this disease treatment correlated with the dosage of gene-corrected cells.

Childhood Cerebral X-Linked Adrenoleukodystrophy

Childhood cerebral X-linked CCALD is a fatal neurodegenerative disease that results from progressive neural demyelination within the brain. The defective gene that is responsible for the phenotype, adenosine triphosphate-binding cassette D1 (*ABCD1*), encodes a transmembrane transport protein that is responsible for the shuttling of fatty acids into peroxisomes, where they are subsequently degraded. ALD is characterized by an accumulation of very long-chain fatty acids, although the exact pathophysiology of the disease is unknown. Cerebral demyelination is associated with inflammation evident on gadolinium magnetic resonance imaging studies. Most patients progress from no symptoms to a vegetative state and death within 8 years of diagnosis. Allogeneic BM transplant has been found to be therapeutic for cerebral demyelination, presumably because of the infiltration of donor-derived microglia cells into the brain. However, because of the very rapidly progressive nature of the demyelination and the time required to generate mature microglia from transplanted HSCs, BM transplant is most effective when administered as soon after the development of demyelination evident by imaging methods as possible. In cases in which CCALD is successfully treated with HSCT, continued progression of the disease occurs for 18 months to 2 years before disease arrest. Myelin inflammation resolves, but lost neurologic function is not regained in successfully treated patients. Because of the time constraints imposed upon finding a suitable human leukocyte antigen-matched donor and the occurrence of GVHD, the genetic correction of autologous BM CD34⁺ cells is an attractive experimental therapeutic option.

A phase I gene therapy trial using a recombinant HIV-1-based lentiviral vector to deliver the *ABCD1* cDNA into CD34⁺ cells has been reported from Paris.³ In the three patients who have been enrolled to date, a transduction efficiency of 30% to 50% in CD34⁺ cells was achieved, with mean vector copy numbers of 0.6 to 0.7 per cell. Patients were preconditioned with cyclophosphamide and busulfan, and between 9% and 23% multilineage gene-marked chimerism has been reported in a follow-up period that extends up to 16 months. In the two patients who had been followed for 16 months after transplant, HSC gene therapy resulted in arrests of neurologic functional loss and resolution of central nervous system inflammation that are similar to those achieved with allogeneic transplant. This trial is particularly noteworthy in that it is the first trial to report reconstitution of BM cells that have been transduced with a recombinant lentiviral vector. Molecular characterization of lentiviral integration sites in engrafting cells indicated that reconstitution was polyclonal, but detailed analysis of genomic loci targeted by this vector has yet to be reported. A multisite, biotechnology-sponsored phase II/III registration trial is currently accruing patients in several countries using a similar lentivirus vector in this disease (NCT01896102).

β -Thalassemia

Patients treated in a clinical trial that used a lentiviral vector for the correction of β -thalassemia have recently been reported⁴ and subsequent updates are in abstract form.^{18,19} Two patients treated have become transfusion independent and a third patient has shown increasing levels of gene-modified red blood cells expressing transgenic hemoglobin. Thalassemias result from mutations that attenuate the expression of either the α - or β -globin chains that compromise hemoglobin synthesis and thus cause ineffective erythropoiesis. Because adult hemoglobin consists of a tetramer of two α - and two β -chains, inherited mutations at the β -globin locus cause a mismatch in the ratio of these two chains, thus preventing the correct assembly of the hemoglobin molecule. Clinically, this may result in transfusion-dependent anemia, which in turn can promote the serious side effect of iron overload. In general, disease severity correlates with the degree

to which inactivation mutations inhibit β -globin expression. However, other genetic loci can modulate the disease phenotype, for example, by inducing adult expression of the fetal γ -globin gene, which can be efficiently incorporated into functional hemoglobin in place of the β -globin chain. In particular, Orkin's group has recently demonstrated that the transcription factor BCL11A plays a major role in switching γ -globin off and β -globin expression on during the transition from fetal to adult life.^{19a} Gene therapy of β -thalassemia is complicated by the requirement for an exact stoichiometry of α - and β -globin chains to facilitate efficient assembly of hemoglobin. Thus, an effective gene therapy vector must be able to facilitate high level expression of β -globin in the range of that mediated by the normal endogenous gene in an erythroid-specific context. Lineage-specific expression of the β -globin chain is particularly important in the context of genetic modification of HSC to prevent high-level expression of β -globin in nonerythroid hematopoietic lineages.

The lentiviral vector used in the trial mentioned earlier comprises a SIN configuration with elements from the β -globin locus control region driving expression of the β -globin cDNA that has been mutated to enhance β -globin chain stability. Additionally, the vector's expression cassette is flanked by chromatin insulator elements that function to both prevent silencing of the transgene expression cassette by inhibitory chromatin structure surrounding the integration site and to prevent the vector-encoded enhancer from modulating expression of endogenous genes near to the insertion site. An interim report on the findings of the clinical trial describes that, in 2007, a single patient with severe transfusion-dependent β -thalassemia major received CD34⁺ cells transduced with the lentiviral vector described earlier.⁴ There was a clear demonstration of clinical efficacy because the patient has been transfusion independent for 15 months. Of note, posttransplant molecular analysis revealed a clonal skewing of peripheral blood cells. The clone, which harbors a proviral integration within the high-mobility group A2 proteins (*HMG A2*) gene locus, is reported to be stable. Insertion of the provirus into this locus resulted in the production of a 3' truncated mRNA resulting from the introduction of a cryptic splice acceptor, present in the vector insulator element, into intron 3 of the gene. This truncated mRNA, comprising exons 1–3, was expressed at elevated levels because of a loss of negative posttranscriptional regulation by Let-7 miRNAs because the miRNA target sequence in exon 5 was lost. *HMG A2* has been found to be mutated in chromosomal translocations, primarily in benign tumors and less often in malignant tumors. Although the clinical implications of this clonal outgrowth are unclear, this event clearly demonstrates that lentiviral vectors can contribute to insertional mutagenesis, albeit in this case via modulation of posttranscriptional regulation of gene expression. Indeed, the propensity to insert in coding sequences may lead to an abundance of abnormal mRNA splicing variants.

Several additional trials are planned using a similar approach to express either a sickle-resistant mutated β -globin protein or to increase expression of protective fetal hemoglobin, or to reverse the so-called *fetal to adult globin switch* based on recent data showing "cure" of humanized sickle mice by genetic deletion of *BCL11A* expressing short hairpin RNA against this transcription factor or by gene-edited deletion of the *BCL11A* gene in HSCs.²⁰ These trials represent important extensions of the technology from very rare diseases to a disease with a much larger patient population.

INSERTIONAL MUTAGENESIS

From an early stage in the development of retroviral vectors for gene therapy applications, there has been a concern that recombinant vectors could elicit cellular transformation by altering expression of either cellular proto-oncogenes or tumor suppressor genes that are proximal to the genomic integration site. This phenomenon, referred to as *insertional mutagenesis*, was characterized as a property of wild-type γ -retroviruses. Having greatly reduced the likelihood that retroviral gene therapy vectors could generate replication-competent virus, the risk of a recombinant vector being able to transform a cell via

insertional mutagenesis was initially perceived by many investigators to be very low. The lack of efficacy in preclinical models using human hematopoietic stem and progenitor (CD34⁺) cells also shifted emphasis away from the risks of insertional mutagenesis. However, soon after the publication detailing the efficacy of the Paris-based SCID-X1 trial, work emerged from the group of Baum and colleagues that would reestablish the importance of insertional mutagenesis as a significant risk factor in the retroviral-mediated genetic correction of hematopoietic cells and that ultimately predicted the appearance of leukemia in the SCID, CGD, and WAS gene therapy trials described earlier. Baum demonstrated for the first time that a replication-incompetent retroviral vector backbone designed for gene therapy applications could cause cellular transformation via insertional mutagenesis in the context of a transplant model of transduced murine HSCs. In this and a subsequent study, it was found that a single retroviral insertion in the vicinity of the ecotropic viral integration site 1 (*Evi1*) gene or the related PR domain-containing 16 (*PRDM16*) gene resulted in their overexpression, likely because of the influence of the LTR viral enhancer element, and was sufficient to initiate a cascade of events resulting in leukemic transformation *in vivo*. Furthermore, a high copy number infection of murine BM with recombinant retroviral vectors was able to facilitate combinatorial hits, which caused leukemogenesis. The pattern of cellular genes that combine to promote cellular transformation demonstrated a significant overlap with those that are deregulated in experiments that used RCR vectors to provoke the development of leukemia. Although murine HSCs likely represent a more readily transformed target than their human counterparts, these studies formally established the mutagenic potential of recombinant retroviral vectors intended for gene therapy applications.

Baum's group then made the seminal observation that at low copy numbers, retroviral-transduced murine HSCs are selectively expanded during transplant dependent upon proviral insertion sites. These nonmalignant dominant clones are enriched for proviral integration sites in the locale of genes encoding signal transduction molecules and growth-promoting genes. Analysis of mRNA expression levels in these clones revealed that the proviral insertion did indeed alter transcriptional regulation of genes proximal to the integration site and led to the hypothesis that this was a powerful method to identify proengraftment genes through positive selection. These observations were found to have direct translational relevance in the gene therapy trial for CGD where the nonmalignant expansion of dominant retroviral transduced clones in two patients was found to correlate with insertional upregulation of growth-promoting genes. Subsequent experience with γ -retroviruses used in the clinical trial for WAS confirmed that insertional leukemogenesis in the SCID-X1 trial was not a disease-specific side effect. Multiple children in the WAS trial have developed T-cell leukemia.¹⁷ Thus far, leukemias associated with replication-incompetent retrovirus vectors are associated with insertional activation of known proto-oncogenes by viral promoter and enhancer sequences (reviewed by Kohn et al²¹).

Wild-type and recombinant retroviral vectors (including α , γ , spuma, and lenti) integrate into the host genome in a semi-random manner and demonstrate insertion site biases that are dependent on the accessibility of the insertion site in the target cell and variations in the viral integrase enzyme that depend on retroviral genus. γ -retroviruses such as MLV have been shown to exert a clear preference for integration in the region immediately surrounding the TSS of actively transcribed genes. Although lentiviral vectors also demonstrate a preference to integrate within the loci of actively transcribed genes, their integration profile favors sites that are downstream of the TSS within the body of the primary transcript.

Using viral chimeras, it has been shown that incorporation of MLV integrase into an HIV-1-based vector alters the integration pattern of the lentivirus to more closely resemble that associated with a γ -retroviral vector. It is possible that this phenomenon results from the binding of the MLV integrase with cell type-specific transcription factors, resulting in the recruitment of the preintegration complex to the promoter and enhancer region of actively transcribed genes. This work clearly demonstrates that γ -retroviral and lentiviral vectors have

developed distinct mechanisms of integrase-dependent integration that may have an impact on the mutagenic potential of recombinant retroviral vectors. If one considers the possibility of integrating vectors upregulating oncogene expression via either read-through transcription or enhancer effects on the endogenous promoter, then γ -retroviral vectors could be considered as potentially more mutagenic than lentiviral vectors in this context because of their preference for integration near the TSS. Conversely, preferential integration within the body of the primary transcript may result in lentiviral vectors having a higher probability of interrupting, for example, tumor suppressor gene expression, or as noted earlier in the treatment of one patient with thalassemia in altering normal gene splicing. Progress has been made in the development of model systems to functionally evaluate the relative mutagenic potential of different vector systems. However, the model systems developed to date have a clear preference to detect mutagenesis mediated via upregulation of oncogene transcription. It is not clear whether this is a reflection of tumor suppressor gene inactivation being inconsequential as a mechanism of insertional mutagenesis or is a result of bias within the model system. Clearly, the preliminary results from the β -thalassemia trial described earlier demonstrate that lentiviral vectors may mediate insertional mutagenesis via alternate mechanisms.

As noted earlier, other related retroviral vector systems have also been shown to have an integration pattern that is distinct from γ -retroviral vectors, and as such may represent a safer vector configuration. Recombinant foamy virus vectors do not preferentially integrate within genes, and their integration pattern does not significantly correlate with actively transcribed genes. Likewise, avian sarcoma leukosis (α -retrovirus) vectors do not favor gene-rich regions or TSS as preferred integration sites. However, these novel vectors systems have not been as well characterized as γ -retroviral or lentiviral vectors with regards to safety and efficacy, and have not yet been translated to clinical use in the near future.

RECENT MODIFICATIONS OF VECTOR SYSTEMS BASED ON CLINICAL EXPERIENCE

New Cell Targets in Genetic Engineering

Despite recent advances in improving *ex vivo* manipulation of HSCs for the purpose of gene transfer, an ongoing limitation of this technology is the loss of engraftment potential of manipulated cells. This is dramatically emphasized in genetic diseases such as Fanconi anemia, in which the disease process itself leads to a marked reduction in HSC targets and, in addition, in HSCs, which appear to have increased susceptibility to *in vitro* stress. An exciting area of recent research advances that may in the future address this issue and also allow prescreening at the molecular level of insertions to determine safety is the use of embryonic stem (ES) or induced pluripotent stem (iPS; next paragraph) cells. These cells offer exciting possibilities for studying mechanisms of pluripotency; establishing models for disease-specific investigations; and enabling future applications in genetic and cellular therapies, including tissue engineering for regenerative medicine. ES cells can be propagated and expanded *in vitro*, making them amenable to manipulations, including the genetic correction of molecular defects. ES cells can be differentiated into a number of cells resembling mature cell types *in vitro*. In theory, cell therapy using donor cells of the same genetic constitution as the recipient may avoid the issues related to the immune barrier of allogeneic transplantation. One of the key ethical and practical barriers to applying ES cell research to human diseases is the need for obtaining human oocytes or embryos for the *in vitro* generation of ES cell lines.

A key recent finding with potential applications in cell and gene therapy has been the observation that many somatic tissues can be "reprogrammed" into pluripotent stem cells with characteristics of ES cells, termed *iPS cells*, and direct reprogramming of differentiated somatic cells by gene transfer of a small number of defined transcription factors has been shown to yield cells that are indistinguishable

from inner cell mass-derived ES cells. Takahashi et al reasoned that forcing the expression of ES cell-specific genes, particularly transcription factors in somatic cells, might induce (reprogram) somatic cells to take on the properties of ES cells, much like factors present in oocytes can reprogram somatic nuclei in mammals.^{21a} By systematic screening experiments, four factors, including some known to be involved in the process of self-renewal (Oct3/4, Sox2), and others associated with transformation and maintenance of ES cell pluripotency (c-Myc, Klf 4), were identified as sufficient to achieve reprogramming. The resultant cells, termed *iPS cells*, exhibited key features of ES cells, including the fulfillment of stringent pluripotency requirements. This work was subsequently confirmed and expanded upon by other groups describing the application of this technology to human cells. Proof-of-concept for the utility of iPS cells in regenerative medicine of inherited blood disorders was recently provided when iPS cells were generated from tail tip fibroblasts in a humanized sickle cell anemia mouse model. The genetic sickle hemoglobin defect of the iPS cells was corrected in vitro via homologous recombination. Using established protocols for the differentiation of hematopoietic progenitors from ES cells, hematopoietic cells capable of reconstituting lethally irradiated recipient mice were generated.

Transplantation of these cells into irradiated recipients resulted in robust engraftment and amelioration of the sickle cell phenotype in transplant recipients. Reprogramming of a panel of disease-specific human iPS cells, including patients with blood diseases, has been demonstrated. Human iPS cell lines shared defining features with human ES cells, including morphology, proliferation, feeder dependence, surface markers, gene expression, promoter and telomerase activities, in vivo differentiation, and teratoma formation. In analogy to the murine system, the reprogramming viruses are strongly silenced in human iPS cells, indicating that the maintenance of pluripotency does not depend on continuous transgene expression. Enforced transgene expression appears to initiate a sequence of stochastic events over several days that eventually induces a small fraction of cells (0.001–0.5% of cells) to acquire a stable pluripotent state. During direct reprogramming, gradual changes lead to a stable epigenetic state that is indistinguishable from inner cell mass-derived ES cells. For example, the Dnmt3a and Dnmt3b methyltransferases become activated and silence the viral transgenes as endogenous pluripotency factors are transcriptionally reactivated. Human iPS cell lines thus represent a novel stem cell population that can be studied with regard to normal and pathologic tissue formation in vitro, enabling disease investigation, drug development, and a platform for producing autologous cell therapies that avoid immune rejection. Moreover, the creation of iPS cells allows the correction of genetic defects and exhaustive molecular characterization at the clonal level before tissue reconstruction. While genetic transduction with exogenous genes, particularly oncogenes such as *c-MYC* and *KLF4*, and the use of integrating retroviral delivery systems are clear handicaps of this technology with regard to future clinical translation, newer methods have utilized nonintegrating vectors and even mRNA transduction to generate iPS. However, to date, robust reconstitution of murine hematopoiesis has not been consistently demonstrated, and there are no successful reports of in vivo reconstitution of human hematopoiesis in model systems. These all represent significant barriers to the translation of this powerful technology into human therapies.

One utility of targeting iPS cells for genetic therapies is that these cells can be cloned and expanded, allowing analysis of vector insertion sites before clinical use. In addition, reprogramming has now been accomplished, albeit at lower efficiencies using both nonintegrating vectors and protein transduction. Reprogramming has also now been accomplished with the expression of fewer transcription factors, most notably without c-Myc. Several laboratories have demonstrated that targeting specific loci is associated with limited or no adverse effects on expression of neighboring genes (reviewed by Sadelain et al²²). For example, targeting of the *AAVS1* locus located on chromosome 19 has been well characterized. This locus encodes the *PPP1R1C* gene that is ubiquitously expressed. Insertion at this site appears to provide a “safe harbor” with respect to genotoxicity and allows stable and long-term expression of transgenes in human embryonic stem cells.

Finally, Naldini and colleagues have demonstrated that targeted insertion into two genomic sites (*IL2RG* and *CCR5*) using zinc-finger technology leads to no detectable alteration in the expression of nearby genes and sustained expression of the transgene cargo.²³ The frequency of directed site-specific integration in primary fibroblasts was as high as 10%.²³ In addition, elegant work by Sadelain and colleagues has demonstrated the feasibility of screening large numbers of iPS-derived clones for both integration in operationally defined safe harbors and for clinically relevant transgene expression using vectors that express globin genes.²⁴ Thus, this approach offers exciting future applications in treating a variety of human diseases.

Site-Directed Homologous Recombination to Correct Gene Mutations

A long-standing but unrealized goal of genetic therapy has been homologous recombination to affect replacement of abnormal disease-causing gene mutations. Although human ES cells theoretically provide an ideal target for such correction, gene targeting in these cells has proven difficult. Zinc-finger nuclease (ZFN)-mediated DS breaks allow high-efficiency site-specific homologous recombination and has been used to target a number of genes in human cells. ZFNs are generated by fusing the FokI nuclease domain to a DNA recognition domain composed of engineered C₂H₂ zinc finger motifs that specify the genomic DNA binding site for the chimeric protein. Compared with standard homologous recombination vectors, one advantage of ZFN is the relatively short stretch of homology needed (500 bp vs. 10–12 kb) to mediate genomic targeting. Binding of two fusion proteins to cognate DNA allows dimerization of the nuclease, leading to generation of a DS DNA break. When donor DNA with homology to sequence flanking the DS break is present, repair occurs with incorporation of the incoming DNA sequence. This system has been successfully used to target genes in multiple species and has recently been demonstrated in both human ES cells and iPS cells to effectively target both expressed and nonexpressed genes with a frequency of 1% to 20% and has been termed *genome editing*. Because the development of a DNA DS break is a prerequisite to ZFN-mediated gene editing and such breaks induce both p53 and HDR, this approach, although attractive, could also have significant “off-target” effects. In addition, as efficiency improves, direct targeting in HSCs is possible and a trial is currently under development to utilize ZFN-mediated deletion of *BCL11A*, which repressed fetal hemoglobin expression for the treatment of β -thalassemia.²⁵

Other systems that seek to target specific genetic loci have also been described and are at different levels of development. As with ZFN nucleases, these approaches use cellular DNA repair mechanisms to introduce exogenous DNA sequences into the chromosome. Thus, methods to increase the efficiency of targeting by introducing DNA DS breaks as well as several other methods have exploited endonucleases that target rare DNA sequences to establish these DS breaks. Alternative methods in development include meganucleases and transcription activator-like effector nucleases.²⁶ Even more recently, bacterial immunity-related clustered regularly interspaced short palindromic repeats have shown higher efficiencies of genome editing by expressing the Cas9 protein and guide RNAs to target the mammalian genome at specific locations. Challenges of all of these approaches include efficiency of targeting in primary cells and potential off-target effects on the genome, and will likely also depend on technological advances that allow ex vivo HSC cloning and large-scale expansion. At present, the use of ES or iPS cells is clearly amenable to this approach, but as noted earlier, use of these cells to derive transplantable HSCs is a major impediment to clinical utilization.

FUTURE DIRECTIONS

The use of gene transfer to treat human diseases has now been successful in several diseases. Compared with allogeneic BMT, ex vivo gene therapy using autologous cells obviates the need to search for

an appropriate donor, eliminates the risk of GVHD, and in some cases reduces the intensity of preparative regimen required before transplant, which also reduces toxicity. Thus, in some diseases, this therapeutic approach can now be considered an alternative to standard therapy. Insertional mutagenesis, which has resulted in serious adverse events in several trials, has stimulated rapid development of putative safer vector systems that are being tested in human trials but remains a challenge. Rapid progress in molecular technology, such as high-throughput sequencing and the development of new sources of expandable stem cell sources, offers significant potential for ongoing development of gene transfer in regenerative biology for a wide range of human conditions.

MESENCHYMAL STROMAL CELLS

Jacques Galipeau

Alexander Friedenstein first described, in 1974, fibroblast-like colony-forming units (CFU-F) isolated from the bone marrow (BM) by plastic adherence in tissue culture plates that could support hematopoiesis *in vitro*.¹ The culture-expanded progeny derived from CFU-F could proliferate robustly and differentiate into mesenchymal lineages. In 1991, Arnold Caplan from Case Western Reserve University introduced the term *mesenchymal stem cells* (hereafter MSCs) to name this unique cell population, referring to their mesenchymal plasticity and potential use in bone repair.² He and others then proceeded to demonstrate that these cells could differentiate into several mesenchymal lineages, such as bone, cartilage, muscle, and fat, and serve as progenitor cells for nonhematopoietic tissues.³ The intrinsic mesenchymal plasticity deployed by culture-expanded MSCs informed the notion that they could be used in regenerative medicine for the treatment of congenital mesenchymal disorders such as *osteogenesis imperfecta* (OI). Based on the ability of MSCs to migrate to the bone and differentiate into osteoblasts, Edwin Horwitz et al hypothesized that the infusion of whole BM containing mesenchymal progenitors could attenuate if not cure OI. In 1999 the first clinical study was conducted on three infants with severe deforming OI⁴ infused with unmanipulated BM graft from human leukocyte antigen (HLA)-identical or single antigen-mismatched siblings following a myeloablative regimen. All patients presented hematopoietic engraftment, and new bone formation could be seen in bone biopsies performed 3 months after implantation. Total body bone mineralization and growth were increased, while fracture incidence was reduced in the first 6 months following BM transplantation. Encouraged by these results, this group conducted a second clinical trial published in 2002, in which OI infants were not only given BM transplant, but were also infused with *in vitro* expanded allogeneic MSCs.⁵ Of the six infants treated, five presented MSC engraftment in BM—albeit at a very low frequency—accompanied by a net increase in growth. However, only one child had a substantial increase in total body mineralization. Since no changes were observed in the only patient in whom injected MSCs did not engraft, the beneficial effects seen in the other infants can presumably be attributed to the infused MSCs and their paracrine effect. Contemporaneous to the OI studies, a first-in-human clinical use of culture-expanded autologous marrow MSCs by Hillard Lazarus was conducted in 1995 as adoptive cell therapy for support of hematopoiesis in the setting of autologous peripheral blood stem cell transplantation (SCT).⁶ In addition to their trophic effects on hematopoiesis, intravenous transfusion of MSCs were later shown to deploy robust immune suppressive properties in a nonhuman primate model of skin allotransplantation, which augured a 2004 case report from the Karolinska Institute by Katarina LeBlanc describing the anecdotal yet substantial effect of haploidentical MSCs on steroid-resistant grade IV acute graft-versus-host disease (GVHD) in a 9-year-old boy (Fig. 99.1).⁷ This report was followed by a series of phase II studies of allogeneic MSCs in prevention and treatment of acute, steroid-refractory GVHD.⁸ However, a phase III clinical trial of an industrial random donor MSC product in steroid-resistant acute GVHD reported in 2009 that it failed to meet its primary endpoint of durable GVHD remission.⁹ Notwithstanding, culture-expanded MSC-like cells derived from marrow, adipose tissue, or umbilical cord are under intense clinical study for ailments falling roughly into three categories: adjunct to hematopoietic stem cell (HSC) transplantation, autoimmune and inflammatory disease, and tissue repair. See box titled “[Considerations](#)

in [Development of MSC-like Cells as a Cellular Pharmaceutical for GVHD](#)”.

ENDOGENOUS MESENCHYMAL STEM CELLS

The estimated frequency of CFU-F progenitors relative to total nucleated cells in marrow is approximately 1:100,000 to 1:240,000. Despite their relative rarity, endogenous marrow MSCs are active components of the BM hematopoietic niche.¹⁰ They are mainly localized in the endosteum of the bone where they give rise to pericytes, myofibroblasts, osteocytes, and endothelial cells, as well as all functional elements of the BM stroma supporting HSCs and progenitor cells development. MSCs have also been identified *in vivo* as perivascular cells expressing the STRO1, CD146 and 3G5 antigens. Despite a close relationship between these two cell types in terms of surface phenotype and qualitative *in vitro* assays, MSCs in general lack the contractility of pericytes and may show marked differences in gene expression. In addition, some have described a neuroectodermal origin of MSCs through either Sox1⁺ neuroepithelial cells or Nestin⁺ precursors. MSCs also express fibronectin, laminin, collagen, and proteoglycans, which are part of the extracellular matrix of the BM stroma. Importantly, MSCs directly interact with hematopoietic cells via an array of surface markers and cytokines, which regulate different aspects of HSC development: quiescence, proliferation, and differentiation. Cell-cell contact between MSCs and hematopoietic cells is mediated by several adhesion molecules such as intercellular adhesion molecule (ICAM)-1, ICAM-2, ICAM-3, vascular cell adhesion molecule (VCAM)-1, leukocyte function-associated antigen (LFA)-3, CD44, and CD72. Among factors secreted, MSCs were shown to express hematopoietic growth factors such as bone morphologic protein 4 (BMP4), Flt-3, leukemia inhibitory factor (LIF), oncostatin M (OSM), stem cell factor (SCF), stromal cell-derived factor-1 (SDF-1), and transforming growth factor- β (TGF- β), and interleukins such as interleukin (IL)-1, IL-6, IL-7, IL-8, IL-11, IL-14, and IL-15. CFU-F-forming cells from BM can be obtained through the prospective isolation of CD45⁺ MSCs with anti-STRO1, anti-CD271, or anti-CD146 antibodies, or selection for nestin-expressing cells. Nevertheless, not enough data concerning purified MSCs are available to assume that endogenous MSC progenitors possess the same immune regulatory properties of *ex vivo* expanded culture-adapted MSCs.¹¹ Therefore, almost the entire amount of data concerning the immunological properties of MSCs refers to adherent expanded, culture-adapted MSCs.

BONE MARROW MESENCHYMAL STEM CELL MANUFACTURE AND PHENOTYPE

The manufacture of MSCs in large numbers requires collection and processing of marrow followed by *ex vivo* culture expansion in serum-containing growth media. Typical processing protocols involve Ficoll enrichment of mononuclear cells from liquid BM aspirates and subsequent plating of unfractionated nucleated cells onto plastic tissue culture plates maintained within humidified incubators set at 37°C and 5% CO₂. Within a week or so, plastic adherent CFU-F arise, and subsequent passaging depletes nonadherent myelolymphoid cells and gives rise to a homogenous polyclonal population of

Fig. 99.1 CLINICAL COURSE AND IMMUNOSUPPRESSION OF THE FIRST GRAFT VERSUS-HOST DISEASE PATIENT TO BE TREATED WITH MESENCHYMAL STEM CELLS. Pharmacologic immune suppression is indicated (top); arrows indicate the time of MSC infusions. ASCT, Allogeneic stem cell transplantation; MSC, mesenchymal stem cell; PUVA, psoralen and ultraviolet light A. (With permission from Le Blanc K, Rasmussen I, Sundberg B, et al: *Treatment of severe acute graft-versus-host disease with third party haploidentical mesenchymal stem cells*. Lancet 363:1439, 2004.)

plate-adherent MSCs with a doubling time of roughly 24–72 hours. Serial passaging allows for continued expansion for up to more than 50 cell doublings. Under microscopic observation, human MSCs appear morphologically heterogeneous and contain fast-replicating spindle- or round-shaped cells and slow-replicating large cells. The International Society of Cellular Therapy (ISCT) arrived at the conclusion that although the cell culture may contain stem cells, most culture-expanded progeny do not meet the criteria attributed to stem cells (self-renewal and mesenchymal pluripotency). Therefore they proposed the name multipotent *mesenchymal stromal cells*, since MSCs are consistently found to be part of the stroma independent of the tissue from which they arise.¹² Indeed, cell populations with multipotent mesenchymal plasticity and self-renewing potential are found in various tissue such as adipose tissue, umbilical cord blood (CB), and placenta, to name a few. As the field of MSC research matured, different isolation methods, tissue origins and characterization criteria were developed. In order to standardize the elements defining MSCs, the ISCT proposed a list of criteria published in 2006.¹² It was proposed that first, MSC populations must be plastic adherent; second, although many isolation methods based on surface cell markers have been established, the only markers recognized for MSCs are CD105⁺, CD73⁺, CD90⁺, and negative hematopoietic cell markers CD45, CD34, CD14 or CD11b, CD79a or CD19, and human leukocyte antigen, antigen D related (HLA-DR); third, cells should be shown to differentiate into osteoblasts, adipocytes, and chondroblasts in vitro (Fig. 99.2); and finally, the origin of the cells should always be clearly stated, such as “bone marrow–derived” or “adipose-derived MSC.” Subsequent guidance from the ISCT¹³ and the International Federation for Adipose Therapeutics and Science (IFATS)¹⁴ regarding phenotypic characteristics of adipose-derived MSCs and cytokine-activated cells provides an evolving understanding of phenotype and function (Table 99.1). See box titled “MSC Phenotype: Does Form Predict Function?”.

IMMUNE PROFILE OF MESENCHYMAL STEM CELLS

MSCs are typically identified by their coexpression of CD73, CD90, and CD105. Although these markers provide identity to MSCs, the

Blood 109:4245, 2007.)

role of these molecules in MSCs has not been established. However, CD73, an ectoenzyme that catalyzes the dephosphorylation of adenosine monophosphates into adenosine, is known to suppress adaptive immune responses. MSCs constitutively express major histocompatibility complex (MHC) class I molecules and are able to present MHC class I-restricted epitopes from transfected tumor antigens or virally introduced antigens to CD8⁺ T lymphocytes. It has been demonstrated that human MSCs are capable of cross-presentation of soluble antigens and effective antigenic presentation to naive CD8⁺ T cells. Expression of CD80, CD86, CD28, ICOSL, and 41BBL co-stimulatory molecules are not observed on MSCs; however, they express low levels of CD54/ICAM-1 or CD106/VCAM-1, both of which could play a role in T-cell co-stimulation. MSCs have been shown to produce basal levels of biologically active chemokines, cytokines, and inflammatory mediators, in particular CXC-chemokine ligand 12 (CXCL-12)/SDF-1, IL-6, prostaglandin E₂ (PGE₂), and TGF- β . CXCL-12 is a small chemotactic cytokine that is often found in inflammatory sites and is an important

chemoattractant for a variety of cells, in particular hematopoietic stem/progenitor cells. It supports the function of MSCs in HSC niches and tissue regeneration. The role of CXCL-12 in the immune properties of MSC has not been fully investigated; however, while this cytokine has been described to mediate attraction and proliferation of lymphocytes, it may also favor the establishment of immune tolerance in vivo. IL-6 is a well-characterized cytokine that functions in inflammation, lymphocyte proliferation, and B-cell maturation. Compared with primary blood macrophages, basal production of IL-6 and PGE₂ is substantial in MSCs. For instance, primary unstimulated human macrophages produce less than 1 ng/48 h/10⁶ cells of IL-6, while human MSCs produce 5–30 ng/48 h/10⁶ cells of IL-6, and production of PGE₂ and IL-6 by MSCs is increased upon exposure to inflammatory products, such as tumor necrosis factor- α (TNF- α) or Toll-like receptor (TLR) ligands. Accordingly, inhibition of IL-6 produced by MSCs results in enhanced suppression of proliferation of activated lymphocytes in vitro. IL-6 was shown to be responsible for neutrophil protection from apoptosis in cultures with

low numbers of human MSCs and has been suggested to play a role in the blocking of monocyte differentiation into DCs. MSC-derived TGF- β was shown to play a role in the inhibition of natural killer (NK) cells *in vitro* and is the dominant cytokine that drives the polarization of FoxP3⁺ CD4⁺ T cells to FoxP3⁺ regulatory T (Treg) cells. Accordingly, production of TGF- β by MSCs favors the induction of Treg cells *in vivo*. PGE₂ is a metabolic product of arachidonic acid conversion by the enzyme COX-1 and COX-2. MSCs constitutively express COX-2 and secrete low levels of PGE₂. Expression of COX-2 and secretion of PGE₂ are considerably increased when encountering an inflammatory signal such as interferon (IFN)- γ , TNF- α , or lipopolysaccharide (LPS). In addition to its role in the inflammatory reaction, PGE₂ is described as an important pathway in T-cell immunosuppression mediated by MSCs. Human MSCs have also been shown to express an array of other potential immune suppressive effectors, including LIF, HLA-G, TNF- α -stimulated gene/protein 6 (TSG-6), as well as soluble and cell surface-associated galectins, in particular galectin-1, galectin-3, and galectin-8. Expression of several molecules known to play an important role in fetomaternal tolerance such as indoleamine dioxygenase (IDO) occurs in human MSCs and these appear to be central in the suppressor functionality of human culture-expanded MSCs. Exposure of MSCs to IFN- γ increases the expression of these factors that mediate inhibitory action on T, B, and NK cell activities. MSCs can also affect differentiation of monocytes to IL-10-producing M2 macrophages and dendritic cells, as well as their maturation, migration, and functions.¹⁵

MESENCHYMAL STROMAL CELL IMMUNE PLASTICITY IN RESPONSE TO INFLAMMATORY CUES

In a resting state, cultured MSCs display immune homeostatic features biased toward suppression and are further highly responsive to environmental inflammatory cues.¹⁶ *In vivo* experiments in rodents and nonhuman primates have demonstrated that although a large portion of MSCs are trapped in the lung following systemic intravenous administration, infused MSCs can migrate to several organs such as the liver, spleen, BM, and kidneys. Their migratory potential is associated with the expression of VCAM-1, which allows them to interact with endothelial cells. In addition, MSCs can express chemokine receptors (CCR1, CCR7, CCR9, CXCR4, CXCR5, and CXCR6) that promote their migration to specific sites, such as the BM via SDF-1, or to inflamed tissue via other CC and CXC chemokines. MSCs express multiple receptors for inflammatory signals, such as receptors for chemokines, type I and II IFNs, IL-1, and TNF- α , as well as TLRs that bind to pathogen-associated conserved motifs. These mediators are produced by fully activated immune cells and upregulate the expression of immunosuppressive factors by MSCs, which in turn dampens the immune and/or inflammatory response. IFN- γ is a well-studied immunomodulatory cytokine that robustly modulates the immunobiology of MSCs, and the *in vivo* suppressive properties of MSCs are likely dependent on activation by IFN- γ secreted by activated lymphoid effector cells. The importance of IFN- γ for augmentation of the veto properties of MSCs has been demonstrated in multiple key seminal observations: anti-IFN- γ receptor antibodies abrogate the suppressive properties of MSCs; IFN- γ receptor knock out of MSCs does not inhibit T cells¹⁷; and, IFN- γ licensing is crucial for MSCs to suppress T-cell effector functions. Accordingly, *in vivo* experiments in murine GVHD models demonstrated that MSCs were not effective at controlling GVHD if mice were transplanted with T cells defective for IFN- γ production, and MSCs pretreated with IFN- γ were more potent than nontreated MSCs at inhibiting GVHD. The downstream effects of IFN- γ activation on MSCs are protean. IFN- γ -primed MSCs robustly upregulate markers such as MHC I and II molecules, immune modulatory molecules (CD200, CD274/PD-L1/B7-H1), cytokine/chemokine receptors (CXCR3, CXCR4, CXCR5, CCR7, CD119/IFN- γ receptor), adhesion molecules (CD54, CD106), DNAM ligands (CD112, CD155), NKG2D ligands (macrophage

inflammatory complex [MIC] A/B, UL binding protein 1, 2, 3), and Notch receptors (Jagged-1). Intriguingly, human MSCs do not upregulate co-stimulatory molecules (CD80, CD86) in response to IFN- γ , and immune modulators such as TGF- β can markedly blunt MHC class II upregulation in response to inflammatory stimuli. IFN- γ -inducible IDO expression plays a major role in the immunosuppressive properties of MSCs and defines an important component of MSC immune plasticity. IDO catabolizes conversion of tryptophan to kynurenine, which is an inhibitor of T-cell proliferation. Blocking IDO catabolic activity with 1-methyl tryptophan abolishes the suppressive activity of MSCs on T-cell proliferation *in vitro*. Another tryptophan-degrading enzyme, tryptophan 2,3 dioxygenase (TDO), has a homeostatic housekeeping role predominantly in the liver, and unlike IDO it does not respond to immunoactive signals. Human MSCs were shown to express TDO in the resting stage and IFN- γ stimulation does not upregulate its expression. This suggests the leading role of IFN- γ -inducible IDO in modulating the tryptophan catabolic pathway and subsequent immunosuppression by MSCs. Upregulation of IDO by IFN- γ can be augmented synergistically by other cytokines such as TNF- α , which are poor inducers of IDO by themselves alone. TLR activators such as LPS and polyI:C have been shown to upregulate IDO through autocrine IFN- β signaling loop independent of IFN- γ . Interestingly, MSCs with defective IFN- γ receptor 1 can still suppress T-cell proliferation. This suggests that other immunosuppressive mechanisms are operative in synergy with IFN- γ -induced effects on MSCs to regulate T-cell proliferation, such as: HLA-G5, PGE2, galectins, insulin-like growth factor (IGF)-binding proteins, and TSG-6. The breadth and effectiveness of an ongoing immune response are determined by both T-cell proliferation and their effector function, as defined by cytokine secretion and degranulation, respectively. Thus, IDO expression by MSCs targets the proliferative response of T cells while PDL1/PDL2-PD-1 interaction likely regulates memory T-cell function.

Whereas it is known that most somatic cells express one or two TLRs, the exact expression profile of TLRs in MSCs is controversial. Protein expression of TLR1, TLR2, TLR3, TLR4, TLR5, TLR6, TLR7, and TLR9 has been reported in human and mouse MSCs; however, in humans only TLR3 and TLR4 were expressed at levels comparable to blood mononuclear cells. The response to TLR ligands in MSCs appears quite different compared with macrophages. When activated, both cell types secrete chemokines, PGE₂, and IL-6; however, only macrophages produce IL-10, TNF- α , and, following IFN- γ priming, IL-12. In addition, factors secreted by TLR-activated MSCs, in particular PGE₂, act *in vitro* and *in vivo* on surrounding macrophages, resulting in increased production of IL-10. It has been shown that MSCs can reduce mortality in a mouse model of peritonitis associated with septicemia and release of bacterial toxins in the circulation.¹⁸ In this study, MSCs injected in the systemic circulation of septic mice localized in the lung, where they were found surrounded by macrophages. These macrophages were shown to produce increased levels of the antiinflammatory cytokine IL-10 both *in vivo* and *ex vivo* in response to bacterial LPS compared with untreated septic mice. *In vitro* assays suggested that the suppressive effect of MSCs on the macrophage inflammatory response to LPS was dependent on the expression of the LPS receptor TLR4 by both cell types. Results suggested that LPS or TNF- α -mediated activation of MSCs upregulated the expression of cyclooxygenase 2 and PGE2 by MSCs, which in turn bind to the EP2 and EP4 receptors on macrophages, stimulating the production of IL-10.

A fundamental discrepancy between the immune cell physiology of MSCs from different species is the relative importance of nitric oxide (NO) and IDO in murine and human MSCs.¹⁹ After inflammatory priming, human MSCs express extremely high levels of IDO and low levels of inducible nitric oxide synthase (iNOS), which is opposite to that seen with mouse MSCs. The *in vitro* functional relevance of IDO bioactivity in human MSCs can be readily shown by use of the specific inhibitor L-1 methyltryptophan (L-1MT), which completely abolishes the inhibition of T-cell proliferation, whereas mouse MSCs are unaffected by L-1MT. Inhibition of NO

production in mouse MSCs abolishes their ability to suppress T-cell proliferation, a phenomenon not observed in human MSCs. In addition to IDO, other human-specific tolerance molecules such as HLA-G are upregulated by IFN- γ in human MSCs but not in the murine system. These important differences between the mechanisms of priming and action of immunosuppression by mouse versus human MSCs highlight some of the limitations of *in vivo* studies assessing the immunosuppressive mechanism of action properties of murine MSCs in animal models of disease.

MESENCHYMAL STROMAL CELL IMMUNE PRIVILEGE: A CONTROVERSIAL ISSUE

Based on the extensive results demonstrating the immunosuppressive effect of MSCs *in vitro*, it was suggested that MSCs could use their immunosuppressive mechanisms to evade the immune system and therefore be used as an immune-privileged “off the shelf” allogeneic donor product for clinical applications. Several studies have suggested that allogeneic MSCs are ignored by the immune system and/or are weakly immunogenic. For instance, the persistence of fetal MSCs in the bone marrow of the mothers was reported decades after pregnancies. Baboons that received allogeneic MSCs injected at high doses (5×10^6 MSCs/kg), first intravenously and then intramuscularly developed alloantigen-specific antibodies but had reduced alloantigen-induced PBMC proliferation compared with naive controls, and persistence of donor MSCs could be observed 4 weeks later. In contrast, other studies have suggested that MSCs can be fully recognized by the immune system and/or support immune cell activation in an antigen-independent fashion, challenging the notion of immune privilege.²⁰ In mice and pigs, allogeneic MSCs injected subcutaneously induced both alloantigen-specific T- and B-cell responses. In a rat model of transplantation, allogeneic heart transplants were rejected earlier if recipients were previously sensitized to donor MSCs. In human MSCs, detailed analyses showed that in certain experimental conditions MSCs can support *in vitro* allogeneic T-cell proliferation, LPS- or antigen-induced IgG secretion by spleen B cells, or suppress neutrophil apoptosis. These events could be initiated through direct antigenic recognition of MSCs and soluble factors produced by MSCs, in particular IL-6. Paradoxically, IFN- γ stimulation of MSCs enables them to acquire antigen-presenting cell-like features. Human and mouse MSCs activated by IFN- γ upregulate MHC class I molecule expression and MHC class I-mediated antigen presentation of endogenously expressed viral proteins to cytotoxic T lymphocyte lines. Expression of MHC class II molecules and antigenic presentation to CD4⁺ T cells was observed to be induced by IFN- γ , and depended *in vitro* on IFN- γ concentration. Antigenic presentation by mouse or human MSCs to CD8⁺ or CD4⁺ T lymphocytes induced IFN- γ and IL-2 production by T lymphocytes and T lymphocyte proliferation. Antigen processing was not affected by sole treatment with TNF- α , or TLR3 or TLR4 ligands. In addition, MSCs can present extracellular soluble proteins to CD8⁺ T cells through their MHC class I molecules. This function, a hallmark of professional antigen-presenting cells, is known as *cross-presentation* and is critical for the mounting of a T-cell immune response targeted at extracellular pathogens or tumor antigens. Although MSCs do not express the classical B7 co-stimulatory molecules CD80 and CD86, they express other surface molecules (ICAM and LFA-3) and cytokines (IL-6 and IL-7), which can deliver co-stimulatory signals necessary for T-cell activation.

MESENCHYMAL STROMAL CELLS FOR THE PREVENTION AND TREATMENT OF STEROID-REFRACTORY ACUTE GRAFT-VERSUS HOST DISEASE

Based upon their dual role in supporting hematopoiesis and modulating immunity, MSCs have been studied as a companion transfusion product for HSC transplantation (SCT), and can be categorized into

two broad categories: prevention and treatment of GVHD, and adjuvant to HSC engraftment. Much has been done since the first described successful treatment of a 9-year-old boy suffering from acute steroid-resistant GVHD with MSCs. Several phase I/II clinical and multiinstitutional trials have been published with encouraging results in adult or pediatric patients. In most studies, MSCs were infused intravenously at a dose of $1\text{--}8 \times 10^6$ MSCs/kg in subjects with GVHD. The intravenous route allowed the injection of several doses of MSCs, and the number of MSC infusions was often increased in patients with partial responses. MSCs were from HLA-identical siblings or HLA-matched or -mismatched donors; however, the response rate to MSC infusion was not related to the degree of HLA matching. The largest academic, multicenter phase II experimental study was described in 2008, in which 55 adult and pediatric patients with steroid-resistant acute GVHD were treated with steroids and MSC infusions. Thirty patients had a complete response, 53% of whom were alive 2 years later. Although similar results were obtained in other studies, some failed to reach a positive outcome. An industry-sponsored phase III randomized, placebo-controlled clinical trial for steroid-refractory acute GVHD in adults and children was completed in 2009 and the results presented in February 2010 at the BMT Tandem Meetings. Six infusions of industrial MSCs (Prochymal, Osiris Therapeutics) were administered at a dose of 2×10^6 MSCs/kg twice a week for 3–4 consecutive weeks, in addition to standard glucocorticoid therapy. The results that have been released to date demonstrate that in adults there was no statistical difference between MSCs and placebo on the overall response rate (35% vs. 30%; $n = 244$). Nevertheless, in a post-hoc analysis MSCs improved liver GVHD (day 100 response rates of 76% vs. 47%) or gastrointestinal GVHD (day 100 response rates of 82% vs. 68%). In pediatric patients, Prochymal showed a trend of improvement in durable CR rates (64% vs. 43%; $n = 28$), allowing for conditional approval of by Canadian and New Zealand authorities for use in children.²¹

Although numerous clinical studies using MSCs for the treatment of GVHD have been conducted, the mechanisms by which MSCs mediate their immunosuppressive effect against GVHD in humans is still unknown. It was described that acute GVHD is accompanied by a burst in cytokine production by activated donor immune cells, including IFN- γ and TNF- α . In a mouse model of GVHD using MSCs from iNOS-knock out mice, it was demonstrated that NO produced by MSCs in response to the presence of high levels of IFN- γ was principally responsible for the immunosuppressive effect observed. It was also shown that IFN- γ stimulation of MSCs is the key element promoting the immunosuppressive effect of MSCs. The latter study suggested that the effectiveness of MSC infusions to treat mice undergoing allogeneic BM transplant varied with the phase of the disease and the level of circulating IFN- γ . Co-transplantation of MSCs with HSCs did not prevent the appearance of GVHD, whereas MSC infusion 20 days post-HSC transplantation (when levels of IFN- γ are high) or implantation of prestimulated MSCs with IFN- γ resulted in enhanced survival. Additional studies hinted that the timing of MSC administration relative to HSC transplant may dramatically influence the outcome of both the graft-versus-leukemia (GVL) response and GVHD. Ning et al. reported results from a clinical trial in which patients with hematological malignancy underwent haploidentical peripheral blood stem cell (PBSC) transplantation in combination with MSCs or not, where they observed a reduction of GVHD in MSC-injected patients but also a 60% tumor relapse compared with a 20% relapse in the non-MSC group.²²

MESENCHYMAL STROMAL CELLS TO PROMOTE HEMATOPOIETIC STEM CELL ENGRAFTMENT IN PRECLINICAL MODELS OF STEM CELL TRANSPLANTATION

Engraftment of HSCs is a considerable barrier to successful transplant, particularly in allogeneic SCT for nonmalignant diseases. Graft

failure is predominantly immune mediated, where recipient T cells play a dominant role in rejecting donor hematopoietic cells. The risk of graft failure therefore increases with the degree of human leukocyte antigen mismatch, the intensity of pretransplant conditioning, and ex vivo graft T-cell depletion. The majority of preclinical murine studies examining the use of human MSCs have utilized immune-defective nonobese diabetic (NOD)/severe combined immunodeficiency (SCID) mice that have received sublethal doses of radiation prior to human HSC transplantation. MSCs isolated from human fetal lung, fetal BM, adult BM, and placenta enhance engraftment of single human CD34⁺ CB, although results were not statistically significant using placental MSCs. Both placental and BM MSCs enhance double-CB engraftment in the NOD/SCID mouse model. Third-party human BM MSCs also increase the engraftment of double CB compared with single CB. Both human placental and BM MSCs also significantly decrease single-cord dominance in this model. In an effort to identify MSC subsets that may show enhanced ability to support HSC engraftment, MSCs expressing markers that enrich for CFU-F activity such as the low-affinity nerve growth factor receptor (LNGFR, CD271) and STRO-1 have been examined. The infusion of selected human CD271⁺ marrow-derived MSCs has been compared with the infusion of standard MSCs for engraftment of human CD133⁺ peripheral blood cells into NOD/SCID mice. In this study, CD271⁺ MSCs displayed full MSC CFU-F activity (with none in the CD271⁻ fraction) and demonstrated one- to threefold higher proliferation compared with standard MSCs. While both MSC subsets increased engraftment, CD271⁺ MSCs resulted in greater CD45⁺ donor cell engraftment. Similarly, both STRO-1⁺ and STRO-1⁻ MSCs have been shown to increase BM, peripheral blood, and spleen engraftment of human CB cells in this model, although STRO-1⁻ MSCs are superior in this effect. The MSC donor source may also impact the effect of MSCs on engraftment. In murine models, syngeneic murine BM-derived MSCs significantly increase donor murine HSC engraftment, whereas donor-derived MSCs significantly decrease engraftment, and third-party MSCs have no effect.²³ In contrast, in a NOD/SCID model, autologous or allogeneic MSCs comparably increase myeloid engraftment of human CD45⁺ cells. This suggests that, at least in a murine model of SCT, MSCs are not immunologically inert, and that the donor source of MSCs can lead to profound differences in engraftment depending on the transplant model. MSCs had no effect in two canine models of SCT using different MSC and HSC donor sources. Third-party MSCs (either from primary culture or an immortalized clonal population) had no impact on the engraftment of canine haploidentical BM cells following total-body irradiation when compared with BM cells alone, with half of the animals rejecting grafts and half developing fatal acute GVHD. Donor-derived BM MSCs also had no impact on engraftment in a canine leukocyte antigen-identical transplant model using nonmyeloablative conditioning (1 Gray), a model in which costimulation (CTLA4) blockade or anti-CD154 has been successful. Failure of MSCs in these canine models may be attributed to numerous reasons, including the source of MSCs, intensity of conditioning, absence of posttransplant immunosuppression, and/or the dosing schedule of MSCs. Finally, MSCs have been studied in a nonhuman primate model of autologous CD34⁺ intra-BM transplant in which autologous BM MSCs increased the percentage of donor CFUs found in recipient BM, although the primates were not followed long term.

CLINICAL TRIALS OF MESENCHYMAL STROMAL CELLS TO PROMOTE HEMATOPOIETIC STEM CELL ENGRAFTMENT

A number of clinical trials have been published demonstrating the use of MSCs to promote allogeneic HSC engraftment. Several clinical trials have evaluated the use of MSCs following CB transplantation using third-party or haploidentical MSCs. Following infusion of haploidentical MSCs, pediatric patients with high-risk acute leukemia had engraftment and rates of GVHD comparable to historical

controls; all eight patients engrafted with a low rate of acute GVHD. A similar study utilized haploidentical MSCs in pediatric patients with hematologic malignancies and hemophagocytic lymphohistiocytosis. Compared with a historical control group, there were comparable rates of engraftment, although patients receiving MSCs had significantly less grade III–IV acute GVHD. Interestingly, no patients in either of these studies developed chronic GVHD. Finally, a study of adult patients with high-risk hematologic malignancies found comparable rates of CB engraftment in patients receiving donor-derived (mostly haploidentical) MSCs to that of a concurrent control group. All patients receiving MSCs had rapid donor engraftment with a low incidence of chronic GVHD and no grade III–IV acute GVHD.

In addition to being given early in SCT to support HSC engraftment, MSCs have been employed to promote ex vivo expansion of HSCs. In an elegant study by de Lima et al.,²⁴ adult patients with hematologic malignancies receiving double-CB transplant had the smaller CB expanded in ex vivo coculture with third-party MSCs, then infused on day 0 following receipt of the unmanipulated larger CB unit. Patients had significantly more rapid neutrophil and platelet engraftment and higher cumulative incidence of neutrophil and platelet engraftment when compared to a matched historical control group. The expanded cord predominated early post-SCT, while the unmanipulated cord predominated long term. The authors attribute this observation to coculture increasing progenitor cells committed to megakaryocyte and myeloid lineages, and depleting cells important in long-term repopulation. Interestingly, several other clinical trials in which MSCs were coinfused with allogeneic BM also demonstrated that, despite successful donor HSC engraftment, donor MSCs cannot be recovered from the marrow compartment posttransplant. This observation suggests that allogeneic MSCs do not meaningfully engraft into the host BM, but rather likely support the newly engrafted donor HSCs through the transient expression of hematopoietic cytokines and immune modulation.

SAFETY PROFILE OF ADOPTIVELY TRANSFERRED MESENCHYMAL STROMAL CELLS

Numerous studies on a variety of conditions have thus far documented safety following infusion of MSCs, and a recent metaanalysis of 36 studies (including 11 SCT studies) demonstrated no association with acute infusion toxicity, organ toxicity, malignancy, infection, or death, with a significant association only seen with transient fever.²⁵ The genomic stability of cultured adult stem cells and MSCs in particular is robust and not as significant a source of concern.²⁶ Based upon the immunosuppressive properties of MSCs, downstream effects on malignant cells and infections have been of particular concern in SCT patients. The study by Ning et al.²² is the only published study reporting an increase in relapse rates following MSC infusion, although the study did not report statistical analyses and did not preserve the randomization. The inverse relationship found between GVHD and relapse in this study, however, does fit with numerous other studies documenting the same effect (likely due to decreased GVL) and warrants continued long-term monitoring in patients receiving MSCs in the malignant setting. Increased rates of infectious complications have been reported in several small nonrandomized trials, but as previously stated no association was found in a recent meta-analysis.²⁵ Cytomegalovirus (CMV) viral loads and the rate of CMV disease were higher than expected in 31 patients receiving MSCs as treatment for GVHD or hemorrhagic cystitis. All cases of CMV disease, however, occurred in a GVHD-affected organ and most were described as mild.²⁷ Furthermore, this study was single arm without even a historical comparison group reported, so it is difficult to ascribe a causative effect. A cohort of pediatric patients receiving MSCs as treatment for steroid-refractory GVHD had comparable rates of CMV, Epstein-Barr virus, and adenovirus when compared to historical controls, although adenoviral infection resulted in decreased survival, particularly when it occurred following MSC infusion.

While an effect on adenovirus-specific T cells was found in vitro, no in vivo effect was found, and the authors note significantly higher rates of HLA-mismatched grafts in the MSC group. A retrospective analysis of 1021 patients transplanted at the Karolinska University Hospital found MSC infusion to be a significant predictor of post-transplant lymphoproliferative disease on multivariate analysis, a finding that has not been previously reported. As none of these studies were randomized trials, they serve as further reminders that long-term monitoring in patients receiving MSCs is necessary, particularly in future randomized trials.

REGULATORY OVERSIGHT OF MESENCHYMAL STROMAL CELLS DEVELOPMENT AND MARKETING APPROVAL

The clinical evidence-based development of HSC transplantation as a therapeutic modality has historically been performed as “practice of medicine”, akin to organ transplantation and transfusion medicine. In this particular setting, the cellular product is considered minimally manipulated and is therefore recognized as a 361 product by the US Food and Drug Administration (FDA). In contrast, any cellular product that requires some adulteration, nonhomologous use, or more-than-minimal manipulation is considered a 351 product and regulated by the FDA as a drug.²⁸ In order to evaluate these products on humans in the United States, the academic investigator or company will need to develop a manufacturing process and controls that meet the requirements of the FDA. The FDA’s requirements for manufacturing investigational cell therapy products include adherence to the following regulations: 21 CFR 210/211 Current Good Manufacturing Practice (cGMP), 21 CFR 600 and 610 Biological Products General and Biological Products Standards, and 21 CFR 1271 Human Cells, Tissues, and Cellular and Tissue-Based Products (HCT/PS). These regulations require the establishment of systems for the design, monitoring, and controls of the manufacturing process and facility. For an academic researcher or a startup company, establishing systems and facilities that are compliant with these regulations requires a considerable amount of resources and time. Consequently, manufacturing stands as a major hurdle to overcome for the clinical translation of cell therapy technologies—particularly for individuals, companies, or academic health centers with limited resources. MSC-like cells that have undergone ex vivo culture expansion fall under this regulatory oversight, and an FDA Center for Biologics Evaluation and Research (CBER) Investigational New Drug (IND) application is mandatorily required to engage in human clinical trials.²⁹ Clinical trials demonstrating an impact on clinical outcomes are required to eventually secure FDA marketing approval and Biologics License Application (BLA) for reimbursement and deployment. Herein lies a substantive distinction in traditional evidence-based clinical science and the pathway to widespread adoption of progress in clinical centers and the regulatory requirements imposed upon more-than-minimal manipulated cell products for the same end. Whereas any accredited clinical center can readily adopt practice of medicine cell therapy technologies without licensing requirements, the same is not true for adoption of more-than-minimally manipulated (e.g., 351) cell therapies. This regulation of cells as drugs favors a development model driven by industry where mass-produced universal product amenable to batch manufacture and release testing is compatible with a sustainable business model consistent with drug cell manufacture and deployment. In contrast, personalized cell medicine, as exemplified by autologous PBSC transplantation, is typically provided as a medical service within accredited medical centers. Providing such services within medical centers with the additional encumbrance of BLA requirement is a challenge for which no clear pathway has been defined. Although industrial models based on manufacture of personalized cell therapies have been feasible, the business sustainability of such has been a challenge, as exemplified by the bankruptcy of Dendreon Corporation (WA, USA), which obtained the first ever FDA marketing approval for an industrial manufactured autologous cell-based vaccine pharmaceutical. The added requirements for regulatory science and innovative reimbursement models in traditional

medical center service-based care delivery will likely have a substantial impact on deployment of MSC-based technologies. See box titled “Cryobiology and Fitness of Thawed MSC Cellular Pharmaceuticals.”

FUTURE DIRECTIONS

The number of clinical trials examining the use of MSCs for treatment of acute, steroid-resistant GVHD and other immune ailments is growing exponentially. Subtle differences in donor source, culture methods, and expansion levels make head-to-head comparisons of the different MSC products challenging when interrogating their utility. The European experience in exploiting random donor MSCs to treat GVHD is wide in its breadth and robustness. Although solely phase II studies, as an aggregate their cumulative experience and the very meaningful differences in MSC cell preparation when compared to their industrial counterpart, in particular the use of early passage cells, point toward key remedies that may be buttressed by mechanistic interrogation. Virtually all human clinical trials carried out to date involve the use of culture-expanded MSCs maintained in their default setting. Preclinical animal data strongly support the notion that the use of augmented MSCs prior to infusion, either by the use of cytokine activation, genetic engineering, or reprogramming robustly, enhances their pharmaceutical potency.³⁰ Therein lies the path for MSC v2.0. In closing, understanding this mechanism and how it relates to clinical utility remains the only rational path to the successful development of MSCs to their full clinical potential.

Considerations in Development of MSC-like Cells as a Cellular Pharmaceutical for GVHD.

The use of allogeneic mesenchymal stromal cells (MSCs) for the treatment of steroid-resistant graft-versus-host disease (GVHD) builds upon encouraging phase II clinical trial data published by European academic collaborative groups in the past few years. However, a large multicenter phase III clinical trial (NCT00366145) conducted in the USA examining the use of an industrial marrow-derived MSC product (Prochymal) reported in 2009 that it failed to meet its primary clinical endpoint of achieving a significant increase of complete response of steroid-resistant GVHD lasting at least 28 days. This pivotal phase III study does not support the use of Prochymal in this clinical indication and has not gained FDA marketing approval. The field of MSC cell therapy is faced with a paradox regarding the clinical utility of MSCs for GVHD, with opposite clinical outcomes when testing industrial and locally sourced MSCs. MSC cell biology informs us that there may well be meaningful distinctions between the functionality of industrial MSCs and those manufactured by academic centers. Most typically, a polyclonal pool of culture-expanded random donor MSCs is manufactured, and here lies a major difference: academic centers seldom manufacture more than 5–10 MSC doses from a single volunteer donor, whereas up to 10,000 doses are manufactured per donor for Prochymal lots. From a cell biology perspective, genetic reprogramming will inexorably occur when progenitor cells are continuously culture expanded to achieve large lots of qualified pharmaceutical. Although MSC cultures are polyclonal at onset, expansion pressure leads to clonal impoverishment with time. Culture-expanded human MSCs have been shown to undergo telomere shortening and other alterations of phenotype, which may play a role in modifying their regenerative and immunosuppressive properties or triggering an immune response, limiting their survival and function in vivo. Among these acquired alterations is the gradual entry into senescence of MSCs as they approach replicative exhaustion. Although senescent MSCs have a virtually indistinguishable marker phenotype from nonsenescent MSCs, their functional properties, immune in particular, may be significantly altered. Clinical data from the Karolinska Institute suggest that late-passage MSCs are less effective than comparable early-passage MSCs with regard to survival outcomes in GVHD patients. The MSC manufacture protocols utilized by academic collaborative groups would predictably minimize meaningful epigenetic reprogramming of MSCs when compared to industrialized expansion scale, and therein lies a plausible shortcoming to industrial-scale culture expansion of MSCs and their effectiveness in human trials.

Cryobiology and Fitness of Thawed MSC Cellular Pharmaceuticals

Mesenchymal stromal cells (MSCs) from either a marrow or adipose source, autologous, or of random donor origin are being investigated in a large number of clinical trials as a cellular pharmaceutical for treatment of immune disorders such as Crohn disease, systemic lupus erythematosus, multiple sclerosis, graft-versus-host disease, and others. Most typically, a polyclonal pool of ex vivo culture-expanded cells is cryopreserved and banked for later use. Human subjects subsequently receive an intravenous transfusion of thawed MSCs that were retrieved directly from cryostorage no more than a few hours beforehand. It is assumed that viable, immediate post-thaw MSCs deploy the same biochemical, homing, and immunomodulatory features as their pre-freeze counterparts. This assumption may be erroneous and may provide, in part, an explanation for the discrepancy between preclinical animal models of MSC effectiveness and negative outcomes of prospective randomized clinical trials. In contrast to what is done in human trials, virtually all published preclinical work in mice reports the effect of live, metabolically fit MSCs. It has been shown that MSCs deploy a heat shock response immediately post-thaw, as well as trigger an instant blood-mediated inflammatory reaction (IBMIR). These acquired MSC physiologic anomalies are associated with a profound alteration of their in vivo distribution and fate post-intravenous transfusion, markedly blunts their ability to exert immunomodulatory effects, and renders them susceptible to complement-mediated lysis. This fundamental discrepancy in the handling of MSCs at time of adoptive transfer to animal models and human subjects provides an explanation for the apparent paradox of MSC utility for mice but not in men. A fundamental truism applicable to most cell-based therapies may be that metabolically fit, undamaged cells are distinct than a thawed product as a cellular pharmaceutical.

MSC Phenotype: Does Form Predict Function?

Mesenchymal stromal cells (MSCs) are a cellular product that is ex vivo culture expanded using established, clinically applicable methods. According to the International Society of Cell Therapy guidelines, MSCs must be plastic adherent when maintained in standard culture conditions, express major histocompatibility complex class I molecules as well as surface CD105, CD90, CD73, and CD44; lack expression of hematopoietic markers CD45, CD34, CD11b, and CD19; and retain the ability to differentiate to osteoblasts, adipocytes, and chondroblasts in vitro (Table 99.1). Although useful in confirming identity, these markers have virtually no utility in predicting function or immunosuppressive potency. Indeed, these markers are remarkably uniform in their expression among different individual donors, and the assumption is that marrow MSCs are equipotent independent of donor fitness, age, or biology. This assumption may be flawed, especially when interrogating the immune plasticity of MSCs derived from otherwise indistinguishable donor source. It is now well established that cytokine licensing of human MSCs with interferon- γ (IFN- γ) markedly potentiates their immunosuppressive properties in vitro, and murine data support the theory that in vivo IFN- γ responsiveness is mandatory for their suppression function. Utilizing IFN- γ -induced IDO upregulation as a surrogate marker of suppressor function, it has been shown that there are substantial differences in the magnitude of IDO responsiveness arising from IFN- γ activation of otherwise indistinguishable MSC preparations from normal human donors and that the magnitude of IDO response among individual donors correlates with MSC veto function. This observation strongly suggests that IFN- γ responsiveness is not uniform among human subjects and that MSCs derived from low IDO inducers may be substantially less potent than cells derived from high inducers. Clinical studies exploiting mass-produced MSCs on an industrial scale where thousands of doses derived from a few donors are used to treat a multiplicity of subjects, which may lead to an unfavorable potency bias. For example, if many patients receive MSCs derived from a normal volunteer who happens to be a low IFN- γ responder, the outcome may be not as good as if patients had received cells from a high IFN- γ responder donor. Mechanistically-defined MSC potency profiling may provide scientific rationale for selection of volunteer donors whose MSC deploys the greatest veto function and avoid the pitfalls of less potent MSC products in subjects participating in pivotal clinical trials.

T-CELL THERAPY OF HEMATOLOGIC DISEASES

Gianpietro Dotti and Malcolm K. Brenner

INTRODUCTION

Conventional modalities for treating cancer remain unsatisfactory. Despite the introduction of small molecules that target specific molecular lesions or pathways within the cancer cells, cure rates for many common tumors remain low, while adverse events are still distressingly high. Cancer immunotherapy represents a promising extension of highly targeted cancer therapy with a favorable toxicity profile and excellent pharmacoeconomics. Until recently, most attention has been on the development of conventional monoclonal antibodies that target specific tumor-expressed antigens. Over the past few years, the focus of monoclonal antibody therapy has shifted to agents that recruit innate or adaptive immune responses against the tumor, either by blocking immune regulation by tumors or by simultaneously engaging tumor cells and effector lymphocytes (bispecific antibodies).^{1,2} More recently, however, strikingly beneficial results with direct (adoptive) transfer of immune system cells are now being reported.³ Although to date, these have primarily been obtained in patients with leukemia, lymphoma, melanoma, or neuroblastoma, methodologies are being developed to allow us to extend the tumor range.

Many human tumors express tumor-specific antigens (TSAs) or tumor-associated antigens (TAAs) that can be recognized by the host immune system and induce antitumor cell-mediated and humoral immune responses. Although these responses may be transient and are not always associated with clinical responses, they provide evidence for the existence of tumor-directed immunity in humans that may also have antitumor activity. Several barriers block the development of more effective antitumor immunity in people with cancer. First, many human tumors express few major histocompatibility complex (MHC) molecules or have poor processing of their potential tumor antigens. Even when TAA/TSA are processed and presented, most tumors lack the costimulatory molecules necessary to implement a long-lived and effective immune response. In addition to these passive defenses against immunity, many tumors can “edit” the immune system to their advantage, secreting cytokines such as TGF β or by expressing molecules such as programmed death-ligand 1 (PD-L1) that act as inhibitory or check point signals to cytotoxic effector T-cell growth, function and survival, or that favor expansion of Th2/regulatory T cells rather than effector T cells. Finally, intensive chemotherapy and radiotherapy can themselves severely reduce immune function by destroying antigen presenting cells and dividing T lymphocytes.

As our understanding of the molecular basis of tumor immune escape has increased, it has been possible to derive countermeasures that may allow us to induce more potent antitumor immune responses, and that will soon allow us to extend effective therapies to a broad range of common tumors.

TYPES OF CELLULAR IMMUNOTHERAPY

Cellular immunotherapy may be *active*, using cell-based vaccines derived from tumor cells themselves or antigen-presenting cells expressing TAA/TSA from proteins or peptides, or *passive*, by direct adoptive transfer of viable immune cells. The former approach relies on the intact afferent and efferent immune system of the host responding to the stimulus with an effective antitumor response,

while the latter is the cellular equivalent of antibody serotherapy, in which the transferred immune cells are expected to attack the tumor cells directly, albeit with a phase of in vivo expansion, and to subsequently establish a pool of memory cells to provide long-term protection against resurgent disease. Several cell subsets are currently being studied in adoptive transfer protocols, including activated T lymphocytes (ATL), tumor infiltrating T lymphocytes, antigen-specific cytotoxic T lymphocytes (CTL), natural killer (NK) cells, $\gamma\delta$ T cells and natural killer T (NKT) cells. In this chapter, we discuss adoptive transfer of ATL and CTL.

Adoptive Cell Therapy With T Lymphocytes

In principle, lymphocytes have the ability to traffic through multiple tissue planes and to be self-renewing. These assets, coupled with their ability to destroy tumor or viral infected target cells through a range of mechanisms makes them an appealing resource for adoptive transfer, and a multiplicity of clinical studies using this approach have now been described. Adoptive lymphocyte therapies may use allogeneic or autologous cells, which may be of tightly defined specificity (e.g., T-cell clones) or broad phenotype and activity (e.g., tumor infiltrating lymphocytes). As we have learned more about the molecular basis of immune recognition and immune regulation, it has become possible to genetically modify the infused lymphocytes to alter their specificity or behavior. In this section, we describe examples of each type of T-cell adoptive transfer and discuss the relative merits and limitations of each.

Donor Lymphocyte Infusion

It has long been apparent that the curative effects of allogeneic hematopoietic stem cell transplants (HSCT) for many hematologic malignancies can be attributed to a graft-versus-leukemia (GVL) effect largely mediated by the incoming T cells within the donor graft. Thus, patients with chronic graft-versus-host disease (GVHD) were well recognized as having a lower probability of relapse than individuals without this unpleasant complication. Similarly, recipients of syngeneic grafts have the lowest rate of GVHD and the highest risk of relapse. In 1990, Kolb and colleagues took advantage of this observation and deliberately infused donor lymphocytes in an attempt to eliminate recurrent disease in patients with chronic myeloid leukemia (CML). Their positive results have been confirmed in multiple studies worldwide, and remission can be induced in more than 50% of CML patients who relapse after transplantation by stopping immunosuppressive treatment or infusing donor lymphocytes. Unfortunately, donor lymphocyte infusion (DLI) is much less effective at treating other types of relapsed leukemias after transplantation, with a 29% remission rate for acute myeloid leukemia and only 5% for acute lymphoblastic leukemia (ALL). It is not clear why these differences occur, since all these leukemias present the minor histocompatibility antigens (mHags) that are likely the targets of this GVL effect, although many mHags have yet to be defined. DLI therapy may also produce severe adverse effects, since the frequency of broadly alloreactive effector cells is usually much higher than the frequency of lymphocytes targeted exclusively to the relapsed malignancy. As a consequence, patients receiving DLI often develop GVHD. This

complication of DLI usually increases in frequency and severity if donor and recipient are unrelated or human leukocyte antigen (HLA) haploidentical. Strategies aimed at retaining the benefits of GVL whilst preventing GVHD have included the depletion of alloreactive T cells in the donor lymphocyte product and the incorporation of suicide genes into the infused donor T cells so that they may be killed if the GVHD activity exceeds the benefits from GVL.^{4,5} Recently, the manipulation of the stem cell graft to deplete only the $\alpha\beta$ T-cell receptor (TCR)+ T lymphocytes whilst retaining the $\gamma\delta$ TCR+ T-cell compartment may reduce GVHD without compromising stem cell engraftment and retain some protection against opportunistic infections.⁶ Ultimately, investigators may wish to identify tumor-restricted target antigens on the malignant cells and infuse antigen specific T cells directed to them. It has proved feasible to prepare donor-derived T lymphocytes specific for mHags and to show both the feasibility and potential efficacy of the approach, although scalability remains challenging.⁷

Infusion of Activated T Lymphocytes

When T cells are polyclonally stimulated, for example by simultaneously cross-linking their CD3 and CD28 receptors by CD3/CD28 monoclonal antibodies on beads, then the cells proliferate. They also secrete tumoricidal cytokines such as TNF α and can mediate MHC-unrestricted cytotoxicity towards a range of tumor target cells. Efforts have been made to harness these effects by producing large numbers of CD3/CD28-activated T cells for cancer patients and infusing them. Although infusion of CD3/CD28-ATL after autologous stem cell transplant may improve patients T-cell reconstitution, as yet there is no evidence to suggest improved antitumor activity.⁸ ATL that are additionally primed with interferon gamma (IFN- γ) and interleukin (IL)-2 (so called cytokine-induced killer cells or CIK) may have superior clinical potential for hematologic malignancies and early phase clinical trials may be showing clinical benefits.⁹

Adoptive Immunotherapy With Virus-Specific Cytotoxic T Lymphocytes

Viral infections are one of the most common causes of morbidity and mortality after allogeneic HSCT, and are more prevalent as the degree of antigen mismatching between donor and recipient is increased. Cord blood transplantation in particular, is associated with often-intractable virus infections that are becoming recognized as a major limitation of the approach. The most common problematic viral infections after allogeneic HSCT are reactivated herpes viruses, including cytomegalovirus (CMV) which typically causes pneumonitis and hepatitis and the gamma herpes virus Epstein-Barr Virus (EBV), which may cause a rapidly fatal lymphoproliferative disease (LPD). In children and recipients of cord blood transplants, adenoviral disease is also common. Adoptive transfer of virus-specific T cells (VSTs) appears to effectively prevent and treat these infections after transplant. Infusion of even small numbers of specific cells (10^6 or less) may be sufficient for benefit, since the lymphodepletion of the immediate posttransplant period is associated with the release of homeostatic cytokines such as IL-7 and IL-15 which augment the expansion of virus specific T cells when they encounter their antigen.

The feasibility of adoptive transfer of VSTs after HSCT has greatly increased over the past decade because of the simplification of the procedures required to isolate or expand these cells *ex vivo*. The pioneering approach developed at Fred Hutchinson Cancer Research Center and St. Jude Children's Research Hospital aimed at generating *ex vivo* CMV-specific CD8+ T-cell clones and polyclonal EBV-VSTs were effective in controlling CMV and EBV-reactivation after allogeneic HSCT, respectively. However, the broad application of these therapeutic approaches was significantly limited by the laborious process required to generate VSTs with sufficient specificity and in sufficient number for adoptive transfer. The recent introduction of long-peptide libraries (pepmixes) as a source of viral antigens, allowed

significant reduction of the time necessary for the generation of clinical grade VSTs (<10 days), without compromising their specificity or increasing the risk of GVHD.¹⁰ Another important change has been the creation of banks in which VSTs from donors with common HLA polymorphisms can be manufactured in advance and stored for immediate administration to partially HLA matched transplant recipients with active virus infections. Crawford and colleagues previously demonstrated that such a "third party" bank of polyclonal EBV-VSTs could be safely infused based on the best available HLA match and had a high success rate in patients who developed EBV-lymphoproliferation after solid organ transplantation (SOT). In a phase-II multicenter trial, 33 patients with EBV-LPD had an overall response rate of 64% at 5 weeks and 52% at 6 months. These impressive results in SOT recipients led us to develop a similar multicenter study to evaluate whether "best matched" VSTs may have similar activity against EBV, CMV, and adenovirus after allogeneic HSCT. We observed a circa 75% response rate to all three viruses, comparable to the reported response rates obtained by infusing VSTs generated from the stem cell donor.¹¹ This approach may be suited for further scale up and broader application. An alternative approach is to eliminate *ex vivo* expansion of VSTs by selecting such cells directly from leukapheresis products. This can be accomplished by using HLA-multimers to bind the relevant cells, or by overnight exposure to viral peptides to stimulate γ -IFN production followed by bead selection of γ -IFN+ cells. These selected VSTs are then infused into the recipients without any *ex vivo* expansion, and their use is being explored for the prevention and treatment of CMV and other viral infections after HSCT.

Adoptive Immunotherapy of Virus-Associated Malignancies

The encouraging results of adoptive immunotherapy with EBV-VSTs in the immunocompromised host led us to extend this strategy to other EBV-associated tumors (lymphoma and nasopharyngeal cancer) that develop in the immunocompetent patient. Unlike EBV-LPD, which expresses the highly immunogenic viral latency antigens EBNA1, EBNA2, and EBNA3, these other EBV tumors express a limited number of poorly processed (EBNA1) or weakly stimulatory (latent membrane protein [LMP]1 and LMP2) EBV-derived antigens. We have therefore used VSTs specific for these EBV antigens, beginning with the cells directed to LMP2. Initially, the VSTs were generated from patients with Hodgkin lymphoma or non-Hodgkin lymphoma by using dendritic cells that are engineered to overexpress LMP2. The infusion of polyclonal LMP2-specific T cells containing both CD4+ and CD8+ T cells increased LMP2-specific T-cell responses, and lead to sustained complete tumor regression in 56% of patients with relapsed/resistant EBV+ lymphoma.¹² Complete responses have also been obtained in EBV-associated nasopharyngeal carcinoma (NPC), a tumor which originates from the epithelial cells of the nasopharynx, and a promising increase in overall survival has been obtained in phase II studies. Like EBV-associated lymphomas, NPC express the same restricted set of weakly immunogenic viral antigens including EBNA1, LMP1, and LMP2. As for the VSTs infused after allogeneic HSCT, simplification of manufacture has been accomplished by using peptide libraries as a source of viral antigens. VSTs so generated retain their specificity and may have increased longevity *in vivo* based on their less differentiated phenotype. The development of this simplified therapeutic strategy has allowed the implementation of larger scale commercialization.

Infection with human papilloma virus (HPV; particularly serotypes 16 and 18) has been associated with orogenital epithelial cancers. T lymphocytes directed to the persisting viral antigens (such as E5 and E6) may be effective treatment for these tumors, and a recent study using T cells genetically manipulated to express an anti-HPV E6 TCR induced sustained tumor regression in two patients with advanced metastatic cervical cancer (Hinrichs et al, unpublished data). A number of groups are now exploring the value of the approach.

Fig. 100.1 GENETIC MODIFICATIONS OF T LYMPHOCYTES FOR ADOPTIVE T-CELL THERAPY. *TCR*, T-cell receptor.

Adoptive Immunotherapy of Virus Independent Malignancies

The majority of human malignancies are not evidently associated with viral infection and thus alternative antigens must be targeted by T cells to achieve antitumor responses. Many different types of tumor-associated or TSAs have been described and several attempts have been implemented to target these antigens, either by stimulating T cells in vivo through vaccination with the antigens, or ex vivo through isolation of specific CTLs. Unfortunately, multiple, physiologic and pathologic factors significantly limit the success of these approaches. Physiologically, the great majority of T cells with high affinity for self-antigens have been deleted during T-cell development. Thus, in cancer patients, T cells specific for self-antigens that can potentially recognize tumor cells have suboptimal affinity for the target antigen and are also frequently functionally anergic because of the highly immunosuppressive tumor environment (Fig. 100.1). Indeed, recent evidence suggests that effective antitumor responses in patients infused with ex vivo expanded tumor infiltrating lymphocytes are preferentially directed against neoantigens from mutated genes in tumor cells rather than to the unmutated self-antigens, even if these are more highly expressed on the tumor cells than by normal tissues.¹³ The importance of such neoantigens is supported by recent clinical studies using monoclonal antibodies to molecules such as PD-1, PD-L1, or cytotoxic T lymphocyte antigen 4 (CTLA-4), which block T-cell inhibitory pathways. In these studies, clinical responses are preferentially observed in patients affected by highly mutated tumors.¹⁴ For all these reasons, the production of effector T cells with the ability to target solid tumors effectively, while resisting their immune evasion strategies will likely require extensive engineering of the effector cells, by genetic modification or other means.

GENETIC MODIFICATION OF T CELLS

Early clinical studies using genetic modification only attempted to “mark” the T-cell infused to follow their fate in the peripheral blood or other tissues. More recently, efforts have been devoted

to “redirecting” the antigen-specificity of T lymphocytes and thus providing them with robust antitumor activity. To overcome the low affinity of tumor-specific CTLs detected in vivo, investigators have cloned T-cell receptor α and β chains ($\alpha\beta$ TCR) of high affinity.¹⁵ Alternatively, tumor-specificity has been generated by the construction of chimeric antigen receptors (CARs)¹⁶ which are most commonly composed of the binding domains of a monoclonal antibody and the ζ signaling domain of the CD3 $\alpha\beta$ TCR as well as components of costimulatory molecules to ensure signaling and T-cell activation once the CAR has been engaged (see Fig. 100.1). Finally, interest in genetic modification of T cells has also arisen as a means of incorporating countermeasures to the multiplicity of immune evasion strategies used by potentially immunogenic tumor cells or to enhance the “survival” of T cells in vivo (see Fig. 100.1). Because T lymphocytes can be long-lived cells and may proliferate extensively in vivo, most gene transfer studies have used integrating vectors such as gamma-retroviral vectors, lentiviral vectors or transposon/transposase integrating plasmids to ensure long-term expression of the therapeutic transgene.¹⁶

Artificial $\alpha\beta$ T-Cell Receptors

The large-scale culture of T lymphocytes to enrich the scanty precursors specific for weak TAAs is often unsuccessful and always tedious. This process can be bypassed by introducing additional T-cell receptor genes with predetermined specificity and high affinity for the weak tumor antigen into a polyclonal population of T cells. Technical improvements in retroviral transduction mean that >30% of polyclonal T lymphocytes can now be induced to express a transgenic TCR with high affinity for TAAs including MART-1, melanoma antigen (MAGE)-3, MDM2, WT1, NY-ISO, survivin, and for mHags such as HA1 and infectious agents such as human immunodeficiency virus (HIV)-1 and EBV.^{17,18}

Polyclonal T cells expressing transgenic MART-1 specific $\alpha\beta$ TCRs have been infused in patients with metastatic melanoma after lymphodepleting chemoradiotherapy.¹⁵ Up to 30% of these patients had objective regression of metastatic disease. Similar results have been obtained in patients with metastatic synovial cell sarcomas and

melanoma who were given T cells expressing an NY-ESO-1 specific $\alpha\beta$ TCR.¹⁷ Although most of these patients had no severe adverse events, toxicity was observed in normal tissues containing melanocytes such as skin and uvea in melanoma patients infused with MART-1 T cells.¹⁵ Colitis was also reported in patients with metastatic colon carcinoma who received T cells expressing a TCR directed to the carcinoembryonic antigen that is also expressed at low level in normal epithelia cells of the gut.¹⁹ Thus T cells with high-affinity transgenic TCR may produce “on target” but “off organ” toxicities to normal tissues that physiologically express the target antigen at low level. The first TCR gene therapy trial for patients with acute leukemia targeting WT1 is currently recruiting patients.

The major problem of TCR gene transfer in polyclonal T lymphocytes harboring their own native $\alpha\beta$ TCR was hypothesized to be the “cross-pairing” between transgenic α or β receptor chains and the reciprocal endogenous TCR α - and β -chains, that could create loss of function or—and potentially worse—gain of function receptors that may produce autoimmune disease, an adverse effect clearly demonstrable in mouse models.²⁰ These events have not been reported in clinical trials so far, but unfortunately other unexpected toxicities have been observed. Patients with myeloma or melanoma were given T cells modified to express a TCR specific for MAGE-A3 that had been synthetically affinity-enhanced. Two of the recipients rapidly developed lethal cardiotoxicity caused by an unanticipated cross-reactivity of the transgenic TCR against peptide epitopes derived from Titin, which were expressed only by cardiac myocytes.²¹ In a second study, the infusion of T cells expressing a transgenic high affinity MAGE-A3 TCR caused lethal neurotoxicity possibly caused by the simultaneous cross-reactivity of a MAGE-A12-derived peptide expressed in human brain.²² These results strongly indicate that T cells engineered with high-affinity TCR can be effective, but can also reveal unexpected and lethal cross-reactivity with other peptide epitopes that would not be recognized by TCR with more physiologic binding affinity.^{18,21} While such unanticipated toxicities may be avoided by ever more extensive preclinical evaluation, reliance on “superaffinity” TCR may be intrinsically hazardous.

Chimeric Antigen Receptors

The cytotoxic activity of T cells through their native or transgenic TCR is MHC-restricted so that multiple distinct transgenic $\alpha\beta$ TCR would be required to recognize tumor antigens associated with the multiple MHC polymorphisms in a human population, precluding a “universal” receptor. In addition, tumor cells can downregulate MHC molecules and avoid immune recognition by conventional TCRs. In an attempt to overcome this limitation, MHC unrestricted CARs have been generated.¹⁶ CARs are most commonly prepared by joining the light and heavy chain variable regions of a monoclonal antibody expressed as a single-chain Fv (scFv) molecule to the cytoplasmic signaling domains derived from CD3 ζ cytoplasmic and intracytoplasmic endodomains derived from costimulatory molecules such as CD28, 4-1BB and OX40.¹⁶ Thus when CARs are expressed by polyclonal T lymphocytes or VSTs, they can combine the antigen specificity of an antibody with the cytotoxic properties of T cells, together with the costimulatory signals provided by professional antigen presenting cells that allow survival and proliferation of activated T lymphocytes. Since CARs bind to target antigens in an HLA-unrestricted manner, they are resistant to many of the tumor immune evasion mechanisms, such as downregulation of HLA class I molecules or failure to process or present proteins, used by tumor cells to escape immune attack. Adoptive transfer of polyclonal activated T cells expressing a second generation CD19-specific CAR caused impressive clinical responses in patients with ALL and lymphomas with >75% complete response rates in relapsed/refractory ALL patients in several phase I clinical trials (Table 100.1). The small size and significant heterogeneity of these studies precludes definitive conclusions, but the data suggest that adoptive transfer of CAR-T cells is more effective in patients with B-ALL than in other B-cell malignancies. The effects also seem greatest when lymphopenia is

induced before infusion of the CAR-T cells. It is not yet known how the composition of the CAR affects the outcome, but patients can achieve remission regardless the type of CAR costimulation (CD28 or 4-1BB) used, although only 4-1BB costimulation appears to be associated with prolonged CAR-T-cell engraftment. Because the CD19 target molecule is also expressed by normal B cells, the eradication of B-cell leukemia is also associated with B-cell aplasia, which was sustained during the period of robust CAR-T-cell engraftment. CD19-specific CAR-T cells have been successfully used in both autologous and allogeneic (after HSCT) settings.

Despite their remarkable success, administration of CD19-CAR-T cells is also associated with potentially lethal acute toxicity caused by a profound perturbation of the immune system, often termed the systemic inflammatory response syndrome, which is manifest by hyperpyrexia, hypotension, and respiratory distress with high levels of circulating proinflammatory cytokines. Although investigators can usually control this unwanted outcome, larger scale clinical studies will be essential to assess the feasibility of safely introducing the approach into more generalized clinical practice.

CAR-T-cell therapies for other hematologic malignancies such as myeloid leukemia and multiple myeloma are also in preclinical stages or in phase I clinical trials. While targeting several candidate antigens such as B-cell maturation antigen (BCMA) or CS1 could be effective in controlling the proliferation of the malignant plasma cells of multiple myeloma without causing “on target” toxicities, the selection of antigens that can selectively control myeloblasts without causing myelosuppression remains more challenging.¹⁶ Recent clinical experience using CD33-specific CAR-T-cells in a single patient with acute myeloid leukemia suggests that the only potential clinical application of CARs targeting shared myeloid antigen is the induction of remission in preparation for hematopoietic stem cell transplantation.²⁶

Optimizing T-Cell Trafficking and Overcoming Tumor Immune Evasion

The expression of transgenic TCRs or CARs in T lymphocytes confers potent cytotoxic activity and potential long-term persistence to these cells. However, other functional T-cell properties may need to be addressed to maximize their antitumor effects. Table 100.2 and Fig. 100.1 summarize some of the T-cell modifications that may optimize the antitumor activity of T lymphocytes. For example, CD19-specific CAR-T cells may be more effective for the treatment of ALL than of lymphoma in part because they more efficiently eliminate tumor cells from the circulation and bone marrow than the lymph nodes. Many lymphomas are characterized by a particular chemokine milieu to which engineered T cells can be adapted. For example, Hodgkin lymphomas may produce high levels of TARC, and T cells coexpressing a CAR specific for the Hodgkin disease-associated CD30 antigen and a transgenic chemokine receptor CCR4 have significantly enhanced traffic to the tumor and consequently better antitumor activity in animal models.¹⁶ Even when tumor-specific T cells efficiently reach the tumor-environment, other tumor-associated factors may hamper T-cell survival and function. For example, many tumors, including hematologic malignancies, and their tumor-associated stroma produce transforming growth factor (TGF)- β , which favors the development of immune tolerance and T-cell anergy, inducing T effector cell growth arrest with induction of regulatory T cells. Transfection of a dominant negative form of TGF- β RII (dnTGF- β RII) confers resistance to the antiproliferative effects of TGF- β and improves the persistence of T cells and antitumor effects in preclinical models,¹⁶ and such approach is currently being studied in patients with EBV-associated lymphomas.

Achievement of sustained clinical responses upon T-cell transfer is strongly dependent on in vivo T-cell expansion and persistence, which in turn requires the infused T cells to contain a population with a stemness/memory signature and the availability of cytokines that sustain T-cell replication and survival. We do not yet know the optimal means by which stem/memory T cells can be preserved before adoptive transfer.^{27,28} Nonetheless it is clear that infusion of

–, none; ALL, acute lymphoblastic leukemia; Allo-HSCT, allogeneic hematopoietic stem cell transplantation; BEN, bendamustine; cCR, continued complete response (i.e., patient had no evidence of disease before and after infusion); CLL, chronic lymphocytic leukemia; CR, complete response; CTX, cyclophosphamide; DLBCL, diffuse large B-cell lymphoma; DLI, donor lymphocyte infusion; FL, follicular lymphoma; Flu, fludarabine; NA, not applicable since patients in CR underwent allogeneic stem cell transplant; NE, not evaluable; NHL, non-Hodgkin lymphoma; NR, no response; PR, partial response; PTS, pentostatin; SD, stable disease; SMZL, splenic marginal zone lymphoma.

tumor-specific T cells in a lymphodepleted host benefits T-cell expansion, likely because the infused T cells can exploit the favorable homeostatic cytokine milieu (including production of IL-7 and IL-15) and the transient depletion of regulatory T cells. Exogenous cytokines, such as recombinant IL-2 can also be infused, but may cause significant toxicity and concomitant expansion of regulatory T cells. Recombinant IL-15 infusions were anticipated to be more effective and better tolerated than IL-2, but toxicity remains problematic.²⁹ Thus investigators have developed T-cell engineering strategies that make tumor-directed T cells which produce their own cytokines or express receptors for specific cytokines.¹⁶ While these approaches are effective in preclinical models, we do not know if they can replace or augment the use of lymphodepleting agents before adoptive transfer.

The molecular pathways responsible for the regulation and contraction of the T-cell immune response (immune check-points) have become a major focus of effective immunotherapies, and as described earlier (“Adoptive Immunotherapy of Virus Independent Malignancies”) monoclonal antibodies that interrupt pathways such as the CD28/CTLA-4 and the PD-1/PD-L1 axes have emerged as potent new agents for the treatment of cancer, inducing sustained clinical responses in tumors likely mediated by the functional release of suppressed tumor-specific T cells recognizing neoantigens.^{14,30} Many investigators therefore believe that the adoptive transfer of tumor-specific T cells generated ex vivo will synergize with infusion of checkpoint antibodies, and this is an active area of clinical research.

T Lymphocytes and Transfer of Safety Genes

A major problem of any successful cell therapy is that adverse events produced by the infused cells may persist and worsen if the cells survive and proliferate. A classic example is the GVHD that occurs when allogeneic donor T cells are transferred with the hematopoietic graft. It is also clear, however, that even nonalloreactive T cells may cause serious and even lethal toxicities, particularly if they are genetically modified to target highly expressed self-antigens present both on tumors and normal tissues (see “Adoptive Immunotherapy of Virus Independent Malignancies” and “Chimeric Antigen Receptors” mentioned earlier).

Similarly, efforts to enhance the survival and expansion of T cells may lead to uncontrolled expansion of the manipulated T cells, an event that may even occur as a result of retroviral genotoxicity alone. While malignant transformation has so far only been observed in clinical studies of hematopoietic stem cells transduced by murine oncoretroviral vectors, there is understandable concern that it can potentially occur after the transfer of gene-modified T cells. For all these reasons, therefore, there has been increasing interest in the incorporation of safety switches or suicide genes in any T cell that is adoptively transferred to humans.

Safety or suicide genes have been best studied in the recipients of DLI in patients with hematologic malignancies relapsed after allogeneic HSC transplantation to prevent the occurrence of GVHD. Adequate doses of donor T cells can only be safely given if there is some means by which unwanted alloreactivity can be abrogated in

TABLE 100.2 Causes of Immunosuppression in Cancer Patients

Immunosuppression Induced by Tumors
Release of chemokine by tumor cells that attract immunosuppressive T lymphocytes
Antigen-specific CD4 ⁺ /CD8 ⁺ T-cell tolerance
Defective proximal TCR signaling (decreased expressions of CD3 δ chain, p56 ^{lck} , p59 ^{lyn} tyrosine kinases)
Impairment of antigen-processing machinery (TAP, LMP2, LMP7) or downregulation of MHC molecules and costimulatory molecules
Activation of negative costimulatory signals (CTLA-4, PD-1, B7-H4, BTLA)
Tumor-derived immunosuppressive cytokines (TGF- β , IL-10, VEGF, PGE ₂)
Expression of immunomodulatory or proapoptotic molecules by tumor (tryptophan-depleting enzyme IDO, galectin-1, FasL, TRAIL)
Recruitment and expansion of immunosuppressive cell populations (regulatory T cells, myeloid/plasmacytoid dendritic cells)
Immunosuppression Induced by Therapy
Neutropenia, depletion and functional impairment of monocytes
Hypogammaglobulinemia (decreased levels of IgA and IgM)
Defective T cell-mediated immune response
BTLA, B- and T-lymphocyte attenuator; CTLA, cytotoxic T lymphocyte antigen; FasL, Fas-Fas ligand; Ig, immunoglobulin; IL, interleukin; LMP7, latent membrane protein 7; MHC, major histocompatibility complex; PD-1, programmed death-1; PGE ₂ , prostaglandin E ₂ ; TAP, transporter associated with antigen processing; TCR, T-cell receptor; TGF- β , transforming growth factor- β ; TRAIL, tumor necrosis factor-related apoptosis-inducing ligand; VEGF, vascular endothelial growth factor.

vivo. Over the past 10 years, efforts have been made to achieve this aim by genetically modifying T cells through the introduction of suicide genes, of which the herpes simplex thymidine kinase (HSVtk) is the most popular and advanced in term of clinical development, as it is currently being tested in a phase III clinical trial.⁴ HSVtk phosphorylates specific nucleoside analogues, including gancyclovir (GCV), to nucleoside monophosphates. These compounds block effective DNA synthesis and kill dividing cells. In several clinical trials, this gene has been transferred to donor T lymphocytes, which have then been given to the allogeneic stem cell transplant recipient to prevent or treat relapse.

The approach has had some success. HSVtk gene modified-T cells persist in the circulation in most of the patients, and are removed after the administration of GCV, often with an improvement in GVHD.⁴ However, several problems remain. HSVtk is a viral protein and in some patients, a cell-mediated immune response against HSVtk is detected, causing undesired premature elimination of transgenic cells. Other drawbacks of HSVtk include the unintended elimination of gene-modified cells when GCV is used for treatment of CMV reactivation, GCV resistance that may occur from truncated HSVtk generated from cryptic splice donor and acceptor sites, and slow elimination of transgenic cells as HSVtk requires DNA synthesis to be active; such delayed activity may be undesirable if T cells are acutely toxic.

Investigators attempted to overcome some of these limitations by developing new suicide genes based on human molecules that are potentially less immunogenic. In particular, suicide genes based on chimeric molecules derived from human proteins that are involved in the apoptotic pathway and modified to be activated by a small molecule have been generated (inducible Fas and inducible Caspase9). Two clinical studies have used the *iCaspase9* (*iC9*) gene which consists of the sequence of the human FK506-binding protein with an F36V mutation, connected to human caspase-9 deleted for its endogenous activation and caspase-activating recruitment domain. FKBP12-F36V binds with high affinity an otherwise bioinert small molecule

dimerizing agent (AP1903). In the presence of the drug, the *iCasp9* promolecule dimerizes and activates the intrinsic apoptotic pathway leading to cell death. The study infused donor-derived *iCaspase9*-T cells after haploidentical stem cell transplant and if patients developed GVHD, administered a single dose of the dimerizing drug. There was rapid destruction of >95% of the cells with prompt resolution of GVHD and faster immune reconstitution that allowed robust protection against opportunistic infection.⁵ These promising results prompted the design of multicenter studies to reach the Food and Drug Administration approval and commercialization.

FUTURE APPLICATIONS AND IMPLEMENTATION OF CELL THERAPIES FOR CANCER

With the approval of the first cell therapeutics for cancer (ProVenge; Dendreon), and the publication of increasing numbers of reports of complete tumor responses after cellular immunotherapy, there is increasing hope that this methodology will finally take its place in cancer therapeutics. T-cell therapies with engineered T cells for B-cell lymphoid malignancies are currently a clinical reality, but much remains to be done to ensure the effectiveness and safety of these therapies. Equally important, and as illustrated by the fate of the Dendreon cancer vaccine, much remains to be learned about development of a sustainable economic model for their affordable and broad clinical application. Nonetheless the integration of cellular therapies with other biologic agents and small molecules continues to offer the prospect of truly transformative therapies for the treatment of hematologic and other malignancies.

NATURAL KILLER CELL–BASED THERAPIES

Sarah Cooley, Michael R. Verneris, and Jeffrey S. Miller

INTRODUCTION

The antitumor effect of allogeneic hematopoietic cell transplantation (allo-HCT) is mediated through both high-dose chemotherapy and immune reactions. Although relapse rates remain high, reduced intensity regimens do provide protection from relapse, demonstrating that allogeneic immune cells can eradicate leukemia and lymphoma. Exactly which cell populations contribute to the graft-versus-leukemia effect is not entirely established, and may vary among individuals and diseases. Immune cell populations can be mechanistically divided into two broad categories; the innate (natural killer [NK] cells and antigen presenting cells [APC]) and adaptive (T cell and B cells) arms of the immune system. It is commonly believed that mature innate immune cells are able to perform their biologic functions without prior activation, while in contrast adaptive immune cells require antigen presentation, activation, and expansion before they can act. These paradigms are changing. It is becoming increasingly clear that human cytomegalovirus (CMV) induces profound changes in the NK-cell repertoire promoting NK-cell populations that are capable of immunologic memory. These populations have been termed “adaptive NK cells.” Likewise, under certain conditions, T cells can mediate major histocompatibility complex (MHC)-unrestricted killing, typically considered a quality of the innate system. Importantly, cells from all components of the immune system are regulated in concert to achieve a balance between immune response and tolerance. Because the antitumor efficacy of conventional cytotoxic agents is limited by off target toxicity and resistance, targeted immune cell–based therapies provide an attractive alternative. Progress in cytokine biology and improvements in techniques to separate, expand, and target cells through immune engagers or chimeric antigen receptors (CARs) have transformed the concept of NK cell–based therapy. This chapter examines characteristics of NK cells and discusses how they may be manipulated to treat malignancy and combat infection, both in HCT and non-HCT settings.

NATURAL KILLER CELL BIOLOGY

NK cells were first described functionally in 1975 for their ability to lyse virally infected cells and tumor targets without prior sensitization. NK cells comprise 10% to 15% of the peripheral blood (PB) lymphocyte pool in normal humans, but they are also found in the bone marrow, spleen, liver, lymph nodes, lungs, and pregnant uterus (Fig. 101.1). Defined by the expression of CD56 or NKp46 and by the lack of a CD3/T-cell receptor complex, they develop from marrow-derived progenitors via distinct developmental stages in secondary lymphoid tissue.¹ Mature NK cells can be functionally distinguished by CD56 density. The CD56^{dim} subset exhibits natural cytotoxicity (killing of class I–negative targets) and displays Fc receptors (CD16) that facilitate the recognition of immunoglobulin-coated targets, a process called antibody-dependent cellular cytotoxicity (ADCC). CD56^{dim} cells also produce cytokines in response to the above stimuli. In contrast, CD56^{bright} NK cells are more proliferative and are less cytotoxic. CD56^{bright} cells respond to monocyte-derived cytokines (interleukin [IL]-12, IL-15, and IL-18) to rapidly produce large amounts of interferon gamma (IFN- γ). NK cells also proliferate and become activated in response to IL-2, IL-15,

and IL-21. IL-15 is of particular importance for NK cell development and homeostasis. Trans presentation of IL-15 by IL-15R α on APCs appears to be the physiologic source of cytokine leading to NK activation.² These cytokines enhance the expression of CD56 on activated cells, producing a population that should not be confused with steady-state CD56^{bright} cells, which have different functional properties.

Natural Killer Cell Functions

NK cells provide a link between the innate and adaptive immune systems³ and play an important role in immune surveillance, pregnancy outcomes, and response to infections (see Fig. 101.1). NK cell function can be divided into several separate activities that include interaction with APCs, activation, expansion, homing to malignant or virally infected targets, direct cell–cell killing, and cytokine production. These responses may differ based on the stimulus and the NK cell subset studied. Activated NK cells produce cytokines and chemokines, including IFN- γ , tumor necrosis factor, granulocyte macrophage colony-stimulating factor, and transforming growth factor beta. NK cells also express β 2 integrins such as leukocyte function–associated antigen-1 (LFA-1) and CD2, which bind to molecules such as intracellular adhesion molecule-1 and LFA-3 on APCs and other cells. If the balance of activating and inhibitor receptor signaling favors activation (see later), target-cell apoptosis occurs via membrane bound death receptors (Fas ligand [FasL] and tumor necrosis factor-related apoptosis inducing ligand [TRAIL]) or by releasing cytotoxic molecules (perforin and granzyme) into a small area between the NK cell and the target cells (called the immune synapse). These activated NK cells then produce cytokines. It is believed that the activating signal threshold required for IFN- γ production is higher than that needed for CD107a degranulation or cytotoxicity after target cell exposure. It is not known whether cytokine production or direct cell killing is physiologically most important for a therapeutic NK cell response, and it is likely that both are required for efficacy.

Natural Killer Cell Receptors

Unlike T cells or B cells that express a single, unique, rearranged antigen receptor, NK cells express a variety of different receptors that trigger either inhibition or activation. Many of the inhibitory receptors are MHC class I–specific, such that engagement of self results in a *reduction* in NK cell function. Thus recognition of MHC class I, which is ubiquitously expressed by healthy tissues, leads to NK cell tolerance. In contrast, the loss of MHC class I, which occurs during the process of viral infection and malignant transformation, leads to the *lack* of engagement of these inhibitory receptors and, in turn, permits activation of the NK cell via other receptor–ligand interactions. The activating receptors often recognize ligands that are induced by cell stress, such as MHC I–related chain A and B, the unique long (UL) 16-binding proteins (ULBPs), nectin-2, and CD48.⁴ The net balance of activating and inhibitory signals determines the NK cell response to a target, favoring elimination of infected, transformed, or stressed cells.

Fig. 101.1 ROLES OF NATURAL KILLER CELLS IN CANCER AND HEALTH. The expanding roles of NK cells in both health and cancer are depicted. NK cells play a critical role in initiation of immune responses by interacting with dendritic cells (DCs), resulting in reciprocal activation of both cell types (i.e., NK cells activate DCs and vice versa). NK-induced DC activation likely also results in the initiation of adaptive immune responses by inducing DCs to present antigens to T cells. Activated NK cells can go on to destroy malignant tissues including leukemia. In the setting of allogeneic transplantation, NK cells can eradicate recipient stem cells, thereby facilitating allogeneic stem-cell engraftment. Emerging data shows that a subpopulation of NK cells or similar cells (known as innate lymphoid cells) produce IL-22 and interact with lymph node stroma to mediate mucosal immunity and may accelerate immune responses after transplantation. A unique population of uterine NK cells is responsible for the maintenance of pregnancy. Still other roles for NK cells include the surveillance for and response to infectious organisms including hepatitis C virus, cytomegalovirus, and human immunodeficiency virus. *AML*, Acute myeloid leukemia; *CMV*, cytomegalovirus; *DC*, dendritic cell; *HCV*, hepatitis C virus; *HIV*, human immunodeficiency virus; *ILC*, innate lymphoid cell; *NK*, natural killer.

Killer Immunoglobulin-Like Receptors

The killer immunoglobulin-like receptor (*KIR*) gene cluster, located on chromosome 19q13.4, encodes 15 different molecules in the immunoglobulin (Ig) superfamily. *KIR* genes contain either two or three extracellular domains (2D or 3D), a transmembrane region, and

an intracellular domain that is either long (containing inhibitory motifs) or short (containing docking sites for activating molecules). In addition, there are two pseudogenes (*KIR2DP1* and *KIR3DP1*). Individuals carry two *KIR* haplotypes, which can be defined as A or B, based on their *KIR* gene content. All haplotypes include three framework genes bounded by *KIR3DL3* at the centromeric (Cen)

end, *KIR3DL2* at the telomeric end and *KIR2DL4* in the middle. The A KIR haplotype contains a fixed content of genes that also includes the inhibitory receptors *KIR2DL1*, *KIR2DL3*, and *KIR3DL1* along with a single activating receptor (*KIR2DS4*). In contrast, B KIR haplotypes contain a variable number of activating (*KIR2DS1*, *KIR2DS2*, *KIR2DS3*, *KIR2DS5*, *KIR3DS1*) and inhibitory (*KIR2DL5A/B*, *KIR2DL2*) genes. *KIR2DL2/3* and *KIR3DL1/S1* are genes whose alleles determine whether they define KIR A (*KIR2DL2* and *3DL1*) or KIR B (*KIR2DL3* or *KIR3DS1*) haplotypes.

Inhibitory KIR recognizes self-class I human leukocyte antigen (HLA) molecules on potential target cells. This interaction suppresses the NK cell effector responses. Inhibitory KIR recognizes polymorphisms of HLA-C and B in a biallelic manner (i.e., C1 versus C2 and Bw4 versus Bw6). *KIR2DL1*, *KIR2DL2/KIR2DL3* and *KIR3DL1* bind HLA class I C2, C1, and Bw4 alleles, respectively. These inhibitory receptor–ligand interactions are complex, as the mere expression of the receptors does not predict the cellular response. Rather, the affinity of a given KIR seems to depend on allelic polymorphisms both of KIR and its MHC class I ligand. In addition, the receptor–ligand binding rules are not absolute, as *KIR2DL2* can bind both HLA-C1 and HLA-C2 alleles. KIR also binds to HLA-A alleles (A3 and A11) that contain the Bw4 epitope, and *KIR3DL2* binds some HLA-A alleles in the context of certain peptides. Our understanding of the KIR system is further complicated by the fact that the natural ligands for activating KIR remain largely unknown. Although some bind MHC molecules at low affinity, it is not known whether MHC proteins function as the natural ligands in vivo. Although *KIR2DS1* has been shown to bind HLA-C2, *KIR2DS2* does not bind HLA-C1 but recently has been shown to recognize threonine 80 of HLA-A11, which can be modified by peptide.⁵

Additional Natural Killer Cell Receptors

Several other families of activating and inhibitory receptors influence NK cell function, some of which bind HLA molecules. The NKG2 family of C-type lectin receptors that heterodimerize with CD94 may be either inhibitory (NKG2A) or activating (NKG2C), and can recognize nonclassical HLA-E. NKG2D does not heterodimerize with CD94 and recognizes stress-induced molecules such as MHC class I polypeptide-related sequence A/B (MICA and MICB) or viral-derived proteins like the CMV-related UL binding proteins (ULBP1–6). Additional receptors include the natural cytotoxicity receptors NKp30, NKp46, and NKp44, DNAM-1, and Nectin-2 (CD122), 2B4, Ig-like receptors, and leukocyte-associated immunoglobulin-like receptor-1. These activating receptors are believed to play a role in communication between NK cells and dendritic cells as well as determining whether an NK cell can recognize a target.

Natural Killer Cell Education—The Acquisition of Function, Self-Tolerance, and Alloreactivity

A mechanistic explanation for the phenomenon of “hybrid resistance” and “missing self” is derived from the characterization of NK cell inhibitory receptors that recognize self-MHC class I. In both instances, because they fail to engage inhibitory receptors, target cells lacking self-MHC class I expression are sensitive to NK-mediated killing. Thus NK cells detect either allogeneic cells or disease-associated downregulation/loss of MHC class I on virally infected or tumor cells.⁶ The process of inhibitory receptor signaling that leads to the acquisition of cytotoxicity and cytokine production has been referred to as “NK cell education” or “NK licensing.”^{7,8} NK cells lacking both KIR and NKG2A are hyporesponsive and cannot be educated until inhibitory receptors are expressed. Relevant to the field of allo-HCT, NK cell education may not be fixed. For instance, adoptive transfer of hypofunctional NK cells from $\beta 2$ -microglobulin knockout mice (that lack MHC class I) into wild-type mice leads to their education

and gain of function. Conversely, adoptive transfer of fully functional NK cells from wild-type mice into $\beta 2$ -microglobulin knockout hosts results in NK hyporesponsiveness.^{9,10} Collectively, these data support the model of NK cell education as a dynamic, inherently plastic process where low level, tonic inhibitory signals are required to maintain cytotoxic capacity. It has also been demonstrated that the cumulative strength of inhibitory receptor signaling correlates with functional thresholds. This model, aptly compared to a “rheostat,” permits self-tolerance in the normal state and allows for enhanced sensitivity to damage to healthy cells through class I downregulation.¹¹ Importantly, it must be emphasized that not all acquisition of NK cell function is through NK cell education. NK cells can overcome rules of NK cell education in the presence of high concentrations of cytokines, in settings such as in vitro activation where exogenous cytokines are applied or during inflammatory conditions where high levels of cytokines are present. In the mouse, the importance of inflammation-induced cytokine production leading to enhanced NK function is clearly demonstrated by the ability of NK cells from $\beta 2$ -microglobulin knockout mice, which are hyporesponsive in vitro, to clear murine CMV. In summary, NK education determines the function of NK cells at steady state, but other factors may overcome or even dominate, especially when cytokines are administered to patients or used to stimulate NK cells that are adoptively transferred.

Natural Killer Cell Recognition of Tumors

Although the antitumor efficacy of NK cells has been most evident for myeloid malignancies, a wide variety of solid tumors including breast, ovarian, hepatocellular, colon, neuroblastoma, Ewing sarcoma, rhabdomyosarcoma, and melanoma can be sensitive to NK cell lysis. The relative resistance of some tumors may be caused by a higher expression of class I HLA, which inversely correlates with the susceptibility of primary pre-B cell acute lymphoblastic leukemia (ALL) blasts to NK cell lysis.¹² Successful destruction of a target requires coengagement of NK cell receptors by both inhibitory and activating signals. Accordingly, activating receptors such as NKG2D play an important role in immune surveillance and killing of acute myeloid leukemia (AML) stem cells. Other tumor ligands that correlate with responsiveness to NK cell-mediated killing include DNAM-1 on myelodysplastic syndrome blasts, CD137 ligand on AML targets, and B7-H3, which protects neuroblastoma from NK lysis. When considering therapeutic uses of NK cells and interventions such as the use of anti-KIR or anti-NKG2A antibodies to promote tumor lysis, it is important to remember that many NK cells circulating in steady-state peripheral blood variably express KIR and NKG2A. Therefore maximum killing of targets such as leukemia blasts may require blockade of multiple inhibitory receptor interactions.

Innate Lymphoid Cells

Until recently, NK cells were the only known lymphocyte population that could be considered “innate lymphoid cells.” However, more recently, it has been appreciated that there are a variety of different innate lymphoid cell (ILC) populations, known as ILC1, ILC2, and ILC3 cells. Similar to the T-cell paradigm, ILCs have been categorized by key transcription factor expression, which drives unique cytokine production in response to activation.¹³ More specifically, ILC1 cells (including NK cells) are characterized by T-bet expression and produce IFN- γ in response to the monocyte-derived cytokines IL-12 and IL-18. ILC2 cells express GATA-3 and produce IL-5 and IL-13 following stimulation with IL-25 and IL-33, and ILC3 cells express the transcription factor ROR- γ t and produce IL-22 in response to IL-1 and IL-23 stimulation. The physiologic role for these cells, both in health and pathology is still emerging, but recent studies suggest that ILC1 cells play a role in anticancer responses and ILC2 and ILC3 cells may assist in response to pulmonary and intestinal pathogens

and may also have a role in preventing graft-versus-host disease (GVHD).

CLINICAL APPLICATIONS OF NATURAL KILLER CELLS

Determination of Donor Natural Killer Cell Alloreactivity

It is widely accepted that the ability of NK cells to contribute to protection from relapse and infection requires that they be functionally competent and present in sufficient numbers. As described earlier, NK cells are alloreactive against targets that lack self-HLA ligands for the inhibitory receptors that contributed to their education or licensing. Recent studies have suggested that the diversity of the NK cell repertoire is massive (6000–30,000 phenotypically distinct individual clones in an individual),¹⁴ allowing NK cell education to occur through multiple receptor–ligand interactions. Several models have been developed to predict NK cell alloreactivity, but the aforementioned diversity suggests that the *in vivo* response is more complicated than the existing models. Donor and recipient HLA typing can be used to determine KIR–ligand mismatch or incompatibility, as defined by the Perugia group,¹⁵ which predicts that donor-derived NK cells will be alloreactive in the graft-versus-host direction when recipients lack C2, C1, or Bw4 alleles that are present in the donor. Alternatively, in the KIR–ligand absence model, alloreactive potential is based entirely on the number of KIR ligands (HLA molecules) a recipient lacks. The receptor–ligand model of alloreactivity requires knowledge of the inhibitory KIR expression in the donor (based on assessment of the donor KIR genotype or phenotype). Because *KIR* genes have multiple alleles with variable levels of expression and functional activity, alloreactivity may be best determined by evaluating the donor KIR genotype with functional assessments of their KIR phenotype.

The Role of Natural Killer Cells in Hematopoietic Cell Transplantation

NK cells are the first lymphocyte population to reconstitute after HCT. Engrafted alloreactive NK cells may mediate: (1) decreased rates of GVHD by targeting of host APC; (2) improved engraftment by secretion of stem cell trophic cytokines and elimination of host immune barriers; (3) targeting minimal residual leukemia and reduce relapse; and (4) decreased infectious complications. An early report published by the Perugia Group in 2002 demonstrated a beneficial effect of alloreactive NK cells and showed that donor KIR–ligand mismatched NK cells in the GVHD direction play a key role in achieving durable remission after CD34+ selected (T-cell deplete) haploidentical transplantation for AML, but not ALL. KIR–ligand mismatched donors were associated with improved engraftment, decreased relapse, and decreased GVHD.¹⁵ However, in a long-term follow up of 112 patients, only decreased relapse in patients transplanted while in complete remission and improved disease-free survival were maintained. Subsequent analyses of the role of KIR–ligand mismatching and KIR–ligand absence in different settings have produced mixed results. In umbilical cord blood (UCB) transplantation, the effect of KIR–ligand mismatching on outcomes appears to depend on either the intensity of the preparative regimen or the drugs used (i.e., ATG or not).^{16,17} In a 2009 study of 169 children treated with autologous HCT for neuroblastoma, KIR–ligand absence was strongly associated with improved survival and decreased risk of disease progression.¹⁸ Inconsistent effects of KIR–ligand mismatch and KIR–ligand absence strategies are likely caused by differences in the stem cell source, conditioning, degree of T-cell depletion, and post-HCT immunosuppression used, all of which can affect NK cell development, education, and function. Despite this confusion, NK cell effects continue to emerge, implicating them as having a key role in protecting against relapse in myeloid malignancies. Similar promise

has been demonstrated in pediatric, but not adult ALL, suggesting that unique interactions between NK cells and targets might account for these differences.

Natural Killer Cell Function After Hematopoietic Cell Transplantation

Despite their high numbers early after HCT, engrafting NK cells are not fully functional. This has been demonstrated by several investigators.^{19,20} Foley et al studied simultaneous NK cell functions in response to target cell exposure.²¹ They reported that degranulation stimulated by class I–negative targets recovered early after transplant, suggesting that NK cells could be educated through either NKG2A or KIR. NK cells from double umbilical cord grafts exhibited CD107a hyperfunction compared to adult unrelated donors, which may explain the enhanced relapse protection seen in this setting. In marked contrast, IFN- γ production was severely diminished for at least 6 months post-HCT, especially in settings of T-cell depleted grafts (even without posttransplant immune suppression) or grafts containing naive T cells (UCB), suggesting that NK cells require T cells for optimal education. This defect could be rapidly reversed by short-term exposure to IL-15. In addition, and in contrast to CD107a degranulation, IFN- γ production could only be educated through self-KIR (NK cells expressing KIR that encounter their cognate ligand [MHC class I] in the recipient), suggesting a hierarchy of thresholds for different NK effector functions. Lastly, different conditioning regimens may have varied effects on the tempo of NK and T-cell reconstitution after transplantation and may therefore affect function and impact on clinical outcomes.

Donor Selection Based on Killer Immunoglobulin-Like Receptor Genotype

Another approach to capitalize on the beneficial effects of NK cells after HCT is to consider the full KIR genotype of potential donors. In a study of 448 patients undergoing myeloablative HLA-matched or -mismatched unrelated donor (URD) HCT for AML, the 3-year overall survival was significantly higher after transplantation from a KIR B/x genotype donor (containing at least 1 B haplotype), irrespective of recipient KIR genotype, with a 30% improvement in relative risk of relapse-free survival.²² A subsequent analysis of 1409 URD transplant recipients confirmed these findings and refined the beneficial effect of *KIR B* genes to AML patients. Similar effects were not seen in ALL. In addition, this later study showed that the most benefit from donor KIR B genotype was localized to genes present in the centromeric part of the *KIR* locus. The greatest protection from relapse and best disease-free survival, in both HLA matched and mismatched transplants, was associated with donors homozygous for this region. Donors could be stratified by KIR into those with Best (Cen-B homozygous present in 11% of the population), Better (≥ 2 B defining domains as seen in 20% of the population), or Neutral donor KIR genotypes. A publicly available calculator to determine this stratification is available online (http://www.ebi.ac.uk/ipd/kir/donor_b_content.html). KIR genotyping as few as three of the best HLA matched donor candidates should substantially increase the frequency of URD transplants from donors with favorable *KIR* gene content (from 31% to 79%) AML.²³ New studies suggest that the benefit of Better/Best donors is further enhanced in HLA-C1 but not HLA-C2 recipients, which may inhibit KIR2DS1⁺ NK cells by downtuning NK cell educations in the context of HLA-C2.^{24,25} Several prospective trials using different graft sources designed to select donors for relapse protection are underway. The benefit of donor KIR B/x has been verified in other studies, and all *KIR B* genes contribute the clinical benefit. The B-haplotype *KIR* genes *2DL5A*, *2DS1*, and *3DS1* were associated with an AML-specific fourfold reduction in relapse in a study of 246 T-cell depleted HLA-matched sibling transplants, and KIR B haplotypes were associated with improved survival and reduced TRM in association with less CMV

reactivation in otherwise similar patients. In conclusion, in addition to HLA matching, donor selection for *KIR* genes is a promising strategy to improve outcome after HCT, but benefit may not be seen in all settings. While the benefits of NK cells can be realized in AML, the HLA-matched setting,²⁶ in the autologous setting,²⁷ and new studies in pediatric ALL,^{28,29} the benefit of a *KIR B/x* donor may be lessened when reduced intensity conditioning is used for transplantation by unknown mechanisms.

Making Natural Killer Cells Antigen Specific

Despite their ability to recognize malignant transformation or viral infection, NK cells are limited by their lack of antigen specificity. Bispecific or Trispecific killer engagers (termed BiKEs or TriKEs) have been developed to overcome this limitation. These novel drugs use the single chain antigen binding regions of antibodies (scFv) to redirect NK cells to targets. For instance, scFvs directed against CD16 on NK cells can be combined with an scFv against a tumor-associated antigen (i.e., CD33). They promote the formation of an immunologic synapse that is both antigen specific and leads to the engagement of other receptor/ligand pairs between NK cells and their targets. For example, CD16x33 BiKEs have been designed to target AML, and have the additional benefit of recognizing and killing CD33⁺ myeloid-derived suppressor cells.³⁰ The activation induced by BiKEs and TriKEs is potent enough to overcome inhibitory signaling through class I recognizing NK cell receptors. This platform is flexible and modular (for example, CD19 could be easily substituted for CD33), making it an exportable therapeutic approach without the need for gene therapy. The CD16x19x22 TriKE construct targets two tumor-associated antigens (CD19 and CD22) via CD16, or alternatively via the agonistic 41BB-ligand. An alternative approach being explored by some groups is the introduction of CARs into NK cells, but difficulties in lentiviral gene transduction may make other approaches such as the introduction of CARs into induced pluripotent stem cell (iPS)-derived NK cells or NK cell lines a more realistic approach because of their off-the-shelf renewal properties.

Control of Viral Infection

Perhaps the greatest advance in NK cell biology over the past 5 years derives from studies of the impact of murine CMV on NK cells. It had been recognized that murine CMV infection leads to expansion of a population of Ly49H⁺ NK cells that recognize the murine CMV protein M157. Following repeat challenges with CMV, these cells expand and attenuate CMV disease. Moreover, Ly49H⁺ cells can be adoptively transferred and protect mice from CMV-induced lethality. In 2004, Lopez-Botet and colleagues^{30a} found a unique population of NKG2C⁺ NK cells in CMV-seropositive but not CMV-seronegative humans. These cells were not induced by other herpes viruses such as herpes simplex virus or Epstein-Barr virus (EBV). NKG2C⁺ NK cells were also enriched *in vitro* when cultured with human CMV infected fibroblasts. Definitive data now shows that NKG2C⁺ and NKG2C⁺/CD57⁺ NK cells expand *in vivo* when immunosuppressed patients reactivate CMV after solid organ or hematopoietic cell transplantation.^{31,32} These NKG2C⁺ NK cells are long-lived and exhibit a high frequency of self-KIR expressing NK cells capable of enhanced target cell killing and IFN- γ production compared to NK cells lacking NKG2C. These findings suggest that NKG2C⁺ NK cells represent a unique NK cell population primed by human CMV. Although Ly49 recognizes murine CMV, it is not clear that NKG2C directly recognizes human CMV. The NKG2C⁺ population was also found to expand in victims of a hantavirus outbreak in Sweden and a chikungunya virus outbreak in Africa, suggesting that these NK cells may be involved in the response to multiple viral infections. However, both of these populations also had prior exposure to CMV, so at present it is unclear whether these viruses also induce NKG2C⁺ NK cells or whether they lead to concurrent CMV reactivation. It is interesting that NKG2C/CD94 and NKG2A/CD94 both recognize

HLA-E, often expressed on cancer cells. One simple explanation for how CMV influences NK cell function is by the conversion of HLA-E recognition on CMV-exposed NK cells from inhibition through NKG2A to activation through NKG2C as NK cells usually express one or the other receptor but not both. Recently, Lee et al³³ and Schlums et al³⁴ refined our understanding of subsets of NKG2C⁺ NK cells by precisely defining them by the additional loss of their adaptor or signaling proteins spleen tyrosine kinase, EAT-2 and Fc ϵ R γ . They refer to these CMV-induced, long-lived cells as “adaptive NK cells” drawing parallels between these cells and the T-cell arms of the (adaptive) immune system. In support of this, CMV induced a unique NK-cell methylation signature resembling CD8⁺ T cells that was distinctly different from conventional/canonic NK cells. In summary, data suggest that CMV exposure, latent CMV, and CMV reactivation has a profound effect on the NK cell repertoire with induction of adaptive NK cells. This is important in transplantation because 25% to 50% of seropositive patients will reactivate CMV. It has recently been discovered in the post-gancyclovir era that CMV reactivation protects against transplant relapse and prolongs disease-free survival^{35,36} suggesting that adaptive NK cells may play a role as antitumor effectors that merits further study. Recently, IL-12/IL-18 in addition to IL-15 has been shown to induce a population of primed NK cells that are long lived, and these cells are in clinical trials.³⁷ How these cells compare to CMV-induced adaptive NK cells is under study.

Adoptive Transfer of Natural Killer Cells

Although methods to exploit the beneficial effects of NK cells engrafting after allo-HCT are increasing, it should be recognized that NK cells are also well suited for adoptive cellular therapies. Many groups tested methods to induce autologous NK cell activity, such as treatment with prolonged, low-dose IL-2 subcutaneously, higher dose IL-2 intravenously, and infusions of ex vivo IL-2-activated NK cells. While these approaches induced *in vivo* NK cell expansion and function, they were shown by several investigational teams to have only limited clinical efficacy; therefore, the Minnesota Group pioneered the use of haploidentical NK cell infusions.^{37a} This approach was based on the likelihood that haploidentical NK cells, educated in the donor, would mediate stronger graft-versus-leukemia reactions because they are not exposed to immune suppressive mechanisms seen in cancer patients. It was further hypothesized that this would result in a higher frequency of alloreactive NK cells (NK cells with inhibitory receptors functionally educated through a different inhibitory receptor that will not be inhibited by class I expressed by the tumor). The safety and success of NK cell infusions was established in a trial using haplotype mismatched, related-donor NK cell products followed by subcutaneous IL-2 to induce *in vivo* NK survival and expansion.³⁸ Successful expansion was achieved only after a lymphodepleting regimen of high dose cyclophosphamide and fludarabine. Interestingly, complete remissions in AML correlated with *in vivo* NK expansion and higher proportions of circulating (and functional) NK cells. The importance of the high-dose chemotherapy regimen delivered before NK cell transfer cannot be overstated. Chemotherapy not only creates space for the NK cells to expand, but also results in a surge of endogenous IL-15 and IL-7 and transiently prevents recipient T cells from rejecting allogeneic NK cells. This platform allows *in vivo* expanded NK cells to partially overcome the rules of NK cell education and tolerance, potentially obviating the need to select specific alloreactive NK cell donors. This assumption requires formal clinical testing. Other modifications have shown that elimination of regulatory T cells with IL-2 diphtheria toxin fusion protein can enhance the clinical activity of NK cell infusions.³⁹ Adoptive transfer of haploidentical NK cells has been tested in other settings. In a pediatric cohort, recovery of functional donor-derived CD56⁺/CD16⁺ NK cells that lysed K562 targets mediated strong ADCC activity against neuroblastoma and leukemic blasts by day +14 after the infusion. The use of NK cell-based therapies to target minimal residual disease is being tested. This preemptive approach is

Fig. 101.2 MANIPULATIONS TO INCREASE THE EFFECTIVENESS OF ADOPTIVE NATURAL KILLER CELL THERAPIES. Current approaches to improve the effectiveness of adoptive transfer of NK cells involve a balance between factors from the NK cell product, the host, and the tumor target. The NK cell product can be derived from adult blood and can be autologous (although there is greater concern for “self” MHC inhibition through inhibitory receptors), allogeneic, derived from primitive progenitors, or even NK cell lines, all of which may be more amenable to gene therapy. The optimal product may be the one that gives rise to longer in vivo persistence and survival, which needs formal testing. Use of donor NK cells infused across allogeneic barriers involves variable degrees of purity, and clinical trials have been published using each of these manipulations. At a minimum, a T-cell depleted product is needed to prevent GVHD. Contaminating B cells have also been shown to contribute to complications such as EBV-induced lymphoproliferative disease and autoimmune hemolytic anemia as part of a passenger lymphocyte syndrome. It is still unclear whether NK cell products should be administered without activation (fresh or frozen), with IL-2 or IL-15, or using activation through other mechanisms (such as CMV reactivation or tumor cell lysates). Several investigators are exploring ex vivo expansion, a process that requires lymphoblastoid cell line or membrane bound IL-15 or IL-21 and 41BB-ligand transduced K562 feeders. The success of adoptive transfer is absolutely dependent on host factors that determine whether the recipient is permissive to adoptive transfer. Success depends on lymphodepletion allowing for transient removal of cytokines sinks to free up cytokines such as endogenous IL-15 as well as added myelodepletion that provides space for adoptively transferred cells. Immune barriers to adoptive transfer include an increase in regulatory T cells, especially when IL-2 is administered to the patient, and methods to blunt this inhibitory response may be effective if they do not dampen NK cell function. As NK cells and DC coactivate each other, use of DC vaccines or TLR-7 or TLR-9 agonists that work through DC may be synergistic. Lastly, there are a number of manipulations that involve the target itself to enhance sensitivity to NK cell adoptive transfer. These manipulations are intended to promote interactions between NK cells and their targets based on known biology to enhance activation interactions, decrease inhibition, or to prolong NK cell survival. It is anticipated that a combination of these variables will ultimately be needed for clinical efficacy, and these strategies may need to be tailored to different tumor types. *ADCC*, antibody-dependent cell-mediated cytotoxicity; *CMV*, cytomegalovirus; *DC*, dendritic cell; *EBV*, Epstein-Barr virus; *ES*, embryonic stem cells; *GVHD*, graft-versus-host disease; *HDAC-1*, histone deacetylase 1; *IL*, interleukin; *iPS*, induced pluripotent stem cells; *KIR*, killer immunoglobulin-like receptor; *MHC*, major histocompatibility complex; *NK*, natural killer; *TBI*, total body irradiation; *TLR*, toll-like receptor; *UCB*, umbilical cord blood.

being tested by use of NK cell donor lymphocyte infusions after haploidentical HCT in adults with AML. A published study in pediatric patients used NK cells as consolidation therapy to maintain remissions in a nontransplant setting. This platform is being adapted for testing in elderly AML patients. Additional studies to explore applications in multiple myeloma, lymphoma, and solid tumors are being developed.

FUTURE DIRECTIONS

Several promising strategies to exploit NK cell alloreactivity to treat cancer are in development. These include various approaches to develop in vivo or ex vivo expanded products, manipulations of the host immune system, and strategies to modify the tumor targets to enhance their sensitivity to NK cell–mediated killing (Fig. 101.2). Unlike T cells, haplotype mismatched or completely HLA-mismatched NK cells can be given without risk of GVHD, although a recent report cautions that conclusion when using highly expanded NK cells ex vivo using membrane bound IL-15 and 41BB-ligand K562 feeders, because some patients developed a syndrome that histologically and clinically was indistinguishable from GVHD.⁴⁰ Adoptive transfer is limited by the cell dose attained from a single leukopheresis and the current requirement for high dose lymphodepleting chemotherapy. In vivo expansion, while detectable, is transient and appears to require the use of exogenous cytokines such as IL-2, which is associated with induction of suppressive regulatory T cells. The use of IL-15 (or IL-15/IL-15R α complexes to trans present IL-15), the true homeostatic factor for NK cells, is now being tested in patients receiving adoptively transferred NK cells to treat their AML or posttransplant relapse. A major advantage of IL-15 is that unlike IL-2, it does not stimulate regulatory T cells. Various methods to enrich the NK cell fraction in haploidentical apheresis products are being tested, including depletion of T (CD3) and B (CD19) cells, or positive selection for CD56⁺ NK cells. Several investigators are also exploring ex vivo NK expansion using EBV-transformed or modified K562 feeder cells to increase the infused NK cell dose, potentially circumventing the need for in vivo expansion. The use of “off-the-shelf” NK cell lines, such as NK-92, may provide a large supply of highly cytotoxic NK cells that could be used for repeated infusions. Other approaches using NK cell products derived from UCB or placental progenitors, embryonic stem cells, or induced iPS cell sources are also being developed. UCB stem cell–derived ILC that produce IL-22 may enhance tissue integrity and improve immune reconstitution after HCT. Alternative forms of activation, such as combining NK cells with either toll-like receptor agonists and/or dendritic cell vaccines, are also being explored. Other possibilities are being aimed at sensitizing the target cells using chemotherapy (bortezomib or histone deacetylase inhibitors), or irradiation. Lastly, if cytokines such as IL-15 can safely and efficiently expand autologous NK cells in vivo, it may be possible to mimic an allogeneic approach by in vivo or ex vivo expansion of NK cells. Combining these with antibodies (anti-KIR and anti-NKG2A) that block inhibitory receptors or BiKEs that deliver potent activation signals that overcome inhibition through class I MHC receptors may be incredibly powerful.

CONCLUSION

The therapeutic use of NK cells is a promising strategy to treat cancer in both transplant and nontransplant settings. NK cells have the potential to induce graft-versus-tumor effects without inducing GVHD. To date, the majority of data supporting the antileukemic effect of NK cells has emerged from the allo-HCT literature. However, the complexities of allo-HCT, including variations in preparative regimens, stem cell sources, graft products, posttransplant immune suppression, and disease specific differences all complicate our understanding of the underlying biologic mechanisms. This limits the design of effective therapies exploiting NK cell alloreactivity. Investigators developing strategies using adoptive transfer of NK cells are

working to establish proof of concept and to develop exportable techniques. Development of platforms that support robust in vivo or ex vivo NK cell expansion and education, selection of NK donors based on their NK cell receptor genes, manipulation of tumor NK cell receptor ligand expression, and coordination of NK cell interactions with other immune cells are underway at many institutions. Ultimately, combination therapy using several strategies will likely prove most successful. In particular, cytokines such as IL-15, antibodies to block inhibitory receptors, methods to induce adaptive NK cells with properties of immune memory, and the use of BiKEs or TriKEs to make NK cells antigen-specific hold great promise.

IMMUNE CHECKPOINT BLOCKADE IN HEMATOLOGIC MALIGNANCIES

Reid Merryman and Philippe Armand

INTRODUCTION

The acquisition of a malignant phenotype by a cell is accompanied by many genetic and epigenetic changes. These changes result in the generation of distinct antigens (“tumor neoantigens”), which can be potentially recognized by T-cell receptors (TCRs) and targeted by a cell-mediated immune response. T-cell activation is a complex and carefully regulated process governed by stimulatory and inhibitory signals from antigen presenting cells (APCs) and other cells in the surrounding microenvironment. Many inhibitory and costimulatory receptors, termed “immune checkpoints,” have now been identified. Tumor cells are known to interfere with the normal operation of these pathways, providing a critical mechanism by which they can evade immune destruction. Our understanding of both the normal regulation of T-cell function and its dysregulation by malignant cells has accelerated greatly in recent years, allowing therapeutic intervention at the level of the immune synapse. The clinical development of immune checkpoint-blocking monoclonal antibodies (mAbs) now allows the therapeutic modulation of those pathways *in vivo* and the restoration of antitumor immune activity in patients. Already, antibodies for two targets—cytotoxic T lymphocyte-associated antigen 4 (CTLA-4) and the programmed cell death protein 1 (PD-1) pathway—have shown impressive efficacy in clinical trials. Several other targets are under investigation with promising preclinical and early clinical results (Fig. 102.1). Checkpoint blockade therapies (CBT) have been more extensively studied in solid malignancies, but a small number of early phase studies have generated exciting results in hematologic malignancies (HMs), particularly in Hodgkin lymphoma (HL). Given those early results, and the well-known susceptibility of many HMs to immunotherapy, illustrated by the success of allogeneic hematopoietic stem cell transplant (HSCT) across many HM subtypes, there is today a real hope that CBT could profoundly influence the treatment paradigms in HMs.

CYTOTOXIC T LYMPHOCYTE-ASSOCIATED ANTIGEN 4

CTLA-4, an inhibitory receptor expressed on T cells, was the first immune checkpoint receptor to be targeted for immunotherapy. Upon T-cell activation, CTLA-4 is generally upregulated, which results in the dampening of T-cell function through several mechanisms. First, CTLA-4 counteracts the costimulatory receptor CD28 by binding to their shared ligands CD80 and CD86 with greater affinity.¹ It triggers multiple inhibitory cell signaling pathways leading to T-cell anergy.^{2,3} Finally, it downregulates the function of T-helper cells and enhances the action of regulatory T cells (Tregs) through mechanisms that are not yet fully understood.¹ The multifactorial actions of CTLA-4 underpin its importance in maintaining immune tolerance, which is demonstrated by the immune hyperactivation phenotype of the lethal CTLA-4 knockout mouse.⁴

Given its fundamental role in immune tolerance, CTLA-4 was a natural target for testing the concept of immune checkpoint blockade; however, the prospect of blocking CTLA-4 in humans also raised the specter of significant autoimmune toxicity. In fact, clinical trials of CTLA-4 blockade using the mAb ipilimumab (Bristol-Myers Squibb, Princeton, NJ, USA) in patients with melanoma showed not only a

manageable safety profile but also an unprecedented overall survival benefit with significant rates of long-term survival.⁵ Beyond melanoma, ipilimumab has also shown therapeutic benefit in prostate, pancreatic, and nonsmall-cell lung cancer cancers.^{6–8} These results sparked interest in using CTLA-4 blockade in the treatment of HMs. In 2009, the first reported study, a phase 1 trial of ipilimumab in relapsed or refractory (R/R) non-Hodgkin lymphoma (NHL), demonstrated an 11% objective response rate (ORR). The response rate was less notable than the duration of the two clinical responses—a complete response (CR) in a patient with diffuse large B-cell lymphoma (DLBCL) lasting 31 months and a partial response (PR) in a patient with follicular lymphoma (FL) lasting 14 months.⁹ Such durable responses with single agent therapy spurred interest in CTLA-4 blockade specifically and CBT in general within HMs. There are ongoing trials of ipilimumab in myeloid and lymphoid malignancies (NCT01757639, NCT01896999, NCT01729806). In addition, ipilimumab has shown promise for the postallogeic transplant relapse setting, where it may augment the graft-versus-tumor (GVT) effect, as discussed later.

Importantly, early clinical results in HMs suggested that immune-related adverse events (irAEs) with ipilimumab are similar to those seen in solid malignancies. Continued observation and reporting will be necessary to ensure that rates of pneumonitis, colitis, dermatitis, endocrinopathies, and other immune side effects are generally manageable in HMs, as they appear to be in solid malignancies.

PROGRAMMED CELL DEATH PROTEIN 1

PD-1 is an inhibitory immune checkpoint receptor expressed on T cells and other lymphocytes. Like CTLA-4, PD-1 is upregulated upon T-cell activation. When bound to one of its two ligands (PD-L1 or PD-L2), it inhibits T-cell activation via phosphatase activity in a mechanism that appears to be distinct from that of CTLA-4.² In addition to CD8+ effector T cells, PD-1 is expressed on Tregs where it promotes their proliferation and downregulation of immune responses.¹⁰ PD-1 is expressed on tumor-infiltrating lymphocytes across many different types of tumors, and its ligands PD-L1 and PD-L2 are upregulated in many different tumors.^{10–12} In contrast to CTLA-4, which regulates early phases of T-cell activation, the PD-1 pathway appears to be most important during the effector phase of T-cell activation that occurs within the tumor microenvironment.¹⁰ It was therefore hoped that PD-1 blockade would provide a more targeted immune-enhancing approach at a later stage of T-cell activation and therefore result in lower rates of irAEs compared with CTLA-4 blockade.

Like CTLA-4, PD-1 blockade showed important therapeutic activity in melanoma, where phase III studies have shown benefit in heavily pretreated patients.¹³ Trials of PD-1 and PD-L1 blockade have also demonstrated benefit in nonsmall-cell lung cancer, RCC, and other solid malignancies.^{14–16} Multiple mAbs against PD-1 and PD-L1 have been developed and are in different stages of investigation. At this time, three PD-1 inhibitors—nivolumab (Bristol-Myers Squibb, Princeton, NJ, USA), pembrolizumab (Merck, Kenilworth, NJ, USA), and pidilizumab (CureTech, Yavne, Israel)—have been studied in published trials in HMs, with preliminary

Fig. 102.1 COSTIMULATORY AND INHIBITORY RECEPTORS. A partial list of stimulatory and inhibitory T-cell coreceptors currently in clinical development with their cognate ligands. *MHC*, Major histocompatibility complex; *TCR*, T-cell receptor.

results hinting at the potential therapeutic effectiveness of this approach.

Hodgkin Lymphoma

Among all HMs, there was particular interest in using PD-1 blockade in HL. HL is unique among lymphomas for its tissue architecture, which is composed of relatively rare Reed-Sternberg (RS) tumor cells surrounded by a much larger population of immune infiltrating cells that appear unable to generate an anti-RS cell activity. Genetic analyses of HL demonstrated frequent 9p24.1 amplification, driving increased expression of both PD-L1 and PD-L2, as well as increased activity of the Janus activated kinase/signal transducer and activator of transcription (JAK/STAT) pathway, which itself leads to increased expression of PD-L1.¹⁷ Epstein-Barr virus (EBV) infection, which occurs relatively commonly in HL, is also associated with increased PD-L1 expression.¹⁸ These mechanisms explain the high rates of PD-L1 and PD-L2 expression seen in HL and, additionally, suggest that this upregulation may be more fixed than in other tumors.

Based on these observations, patients with HL were included in independent expansion cohorts in two phase 1 trials examining PD-1 blockade with nivolumab (NCT01592370) and pembrolizumab (NCT01953692) within a mixed group of patients with R/R HMs. HL patients in both studies were heavily pretreated, with the majority having relapsed or progressed after brentuximab and autologous stem cell transplantation. Despite this, CR rates of 17% and 21% and ORRs of 87% and 65% were seen with nivolumab and pembrolizumab, respectively. The durability of responses with single-agent therapy have also been impressive with ongoing responses for greater than 1 year in many patients. Importantly, the mAbs in both trials showed an acceptable safety profile in HL with limited irAEs and no drug-related grade 4 or 5 toxicities.^{19,20} While these trials were small and merit confirmation, they have generated hope that PD-1 blockade could bring about a fundamental shift in the treatment of R/R HL. As more clinical data accumulate, PD-1 blockade will likely

move to earlier stages of treatment. Additional studies are planned and ongoing within HL.

Non-Hodgkin Lymphoma

While PD-1 blockade has shown the most promise in HL, clinical activity has also been seen in multiple types of NHL including FL, DLBCL, and T-cell lymphoma. Interest in CBT in NHL has been driven by the durable responses seen with ipilimumab,⁹ as well as by an early study of pidilizumab in patients with R/R HMs that demonstrated an isolated CR in a patient with FL.²¹ Based on these results, a phase II trial examined combination therapy with pidilizumab and rituximab in patients with rituximab-sensitive relapsed FL. Among 32 patients, the ORR was 66%, with a 52% CR rate.²² While it is difficult to assess the activity of this combination without a monotherapy control arm, these rates compare favorably with historic controls treated with rituximab alone. In addition, immunohistochemical analysis showed that PD-1 expression was significantly higher on T cells of responders, mechanistically supporting the role of PD-1 activity in the combination.²² Preliminary results from the previously mentioned phase 1 nivolumab trial (NCT01592370) also demonstrated activity in FL and DLBCL with OR rates of 40% and 36%, respectively.²³ The underlying biology of PD-1 blockade in these malignancies is less well understood. In general, FL is considered to be one of the more immune sensitive HMs based on occasionally witnessed spontaneous regressions and responsiveness to nonspecific immune activators like bacillus Calmette-Guérin and interleukin-2.²² Because of this, it is an attractive target for PD-1 blockade and immune checkpoint blockade in general. Within DLBCL, PD-L1 expression appears to be restricted to a subset of tumors, as discussed later, which could explain the activity seen with nivolumab. Larger phase II studies in FL and DLBCL are ongoing. Lastly, the phase 1 nivolumab trial also demonstrated a 17% ORR in a mixed population of T-cell NHLs.²³ The significance of these findings is not yet clear, but this represents an exciting new area of investigation for an otherwise difficult to treat, chemorefractory group of malignancies.

Multiple Myeloma

Multiple myeloma (MM) has been included in trials of PD-1 blockade based on preclinical data showing PD-L1 expression on MM cells and PD-1 upregulation on immune cells in the MM microenvironment.^{24,25} Despite these observations, early data obtained with PD-1 blockade has been disappointing. In the phase 1 nivolumab trial, no CRs or PRs were observed in 27 patients with MM; however, 18 of 27 (67%) had stable disease lasting several months.²³ CBT experience in solid tumors suggests that such stable disease may reflect antitumor activity and provide sustained periods of disease control; more investigation is needed in MM to determine if there is indeed a true clinical benefit from CBT. Based on these early results, PD-1 blockade is being investigated in early phase trials as part of combination therapy with lenalidomide, pomalidomide, and a novel Bruton tyrosine kinase inhibitor (NCT02077959, NCT02289222, NCT02362035).

Safety

In the limited experience with PD-1 blockade in HMs, the safety profile of the drugs appears to be comparable with the more extensive experience in solid malignancies. IrAEs with PD-1 therapy appear to be less common than with CTLA-4 blockade, specifically with lower rates of colitis and endocrinopathies. Within the phase 1 nivolumab, the largest trial published thus far in HM, the rate of pneumonitis was around 10%, which is only slightly higher than that seen in solid malignancies, despite high rates of prior treatment with potentially pneumotoxic regimens (including radiation therapy and brentuximab).²³ Additional studies are clearly needed, but these

results suggest that PD-1 blockade is generally tolerable for patients with HM.

CHECKPOINT BLOCKADE THERAPIES AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION

HSCT, using autologous or allogeneic grafts, is an important part of the treatment of many HMs, and may provide a fruitful setting for CBT. In the case of autologous HSCT, the minimal disease burden and presence of a remodeled immune system with a relative preponderance in the early post-HSCT period of immune cells that are targets of CBT, like natural killer (NK) cells and T-effector cells,²⁶ may allow the effective leveraging of CBT. PD-1 blockade has already been studied after autologous transplant in DLBCL. In an international phase 2 study, 72 patients with DLBCL received three doses of pidilizumab beginning 1–3 months after autologous stem cell transplant. Progression-free survival at 18 months after HSCT was 72%, higher than the 52% rate observed in a similar historic control cohort. Notably, the rate of progression-free survival among the higher risk group of patients with positron emission tomography (PET)-positive disease before transplant was 70%. In addition, among the 35 patients with measurable disease after transplant, the overall response rate after pidilizumab was 51% (CR, 34%). Importantly, pidilizumab was well tolerated without significant irAEs.²⁷ Together, these findings suggest that PD-1 blockade may have direct antitumor activity and important clinical activity in the postautologous transplant setting, warranting additional studies. Based on these promising early results, there are now several ongoing trials of PD-1 blockade after autologous transplant in HL, DLBCL, and MM (NCT02362997, NCT02181738, NCT02038933, and NCT02331368).

Allogeneic HSCT also represents an attractive, if challenging, field in which to deploy CBT. This form of transplantation is an important part of treatment for many HMs, as the attendant GVT effect may be salutary in patients who are not curable with conventional chemotherapy or autologous HSCT. Yet failure to develop an effective GVT occurs frequently, manifesting as posttransplant relapse, and the outcomes for those patients are usually dismal. The posttransplant setting is attractive for CBT because the treatment strategy is already based on immune manipulation. CBT was studied in this context in a phase 1 study of ipilimumab in patients with recurrent or progressive disease after allogeneic transplant. Remarkably, ipilimumab did not induce significant graft-versus-host disease (GVHD) and the rate of irAEs did not differ greatly from that seen outside of the transplant setting. In addition, objective responses were seen in three patients including two sustained CRs in patients with HL.²⁸ In a follow-up study investigating repeated dosing of ipilimumab in the posttransplant relapse setting, 6 of 27 patients have achieved formal responses including 4 CRs in acute myeloid leukemia and 2 PRs in patients with MM and HL. These responses are notable given that these patients had been highly pretreated including some who had received prior donor lymphocyte infusion after posttransplant relapse. They suggest an important potential role for CBT after allogeneic transplant. With repeated dosing, ipilimumab did result in increased irAEs, including two patients with grade 4 pneumonitis, three cases of GVHD, and one treatment-related death.²⁹ In most cases, however, AEs were manageable and did not prevent continued treatment with ipilimumab; however, safety of CBT in this setting will need to be carefully monitored.

LESSONS FROM CTLA-4 AND PD-1 BLOCKADE

Selection of Tumors and Patients

Unlike CTLA-4, the expression of PD-1 and its ligands varies widely across tumor types and patients. Differences in expression have been helpful in predicting the responses to PD-1 blockade in solid tumors, and those lessons may be instructive for the development of CBT in

HM and for targeting of other immune checkpoints. Initial studies in solid malignancies suggested that tumors with demonstrable PD-L1 expression on the tumor cell surface had higher response rates to PD-1 blockade^{30,31}; at first look, this pattern seems to also hold in HMs, as response rates have been highest in HL where PD-L1 expression is very frequent.³² However, in solid tumors, patients whose tumors did not demonstrate PD-L1 expression have also had meaningful responses, suggesting that PD-L1 expression should not yet be used to exclude patients from clinical trials.

Indeed, variation in tumor cell surface expression of PD-L1 is unlikely to entirely explain the apparent differences in clinical response to PD-1 blockade among HL, various NHLs, and MM. PD-L1 expression is a highly dynamic process that varies with time and environment and is likely poorly captured by isolated *in vitro* tumor biopsy analyses. Tumor-cell ligand expression also ignores the important role of immune cells in the tumor microenvironment whose expression of PD-1 and its ligands may affect response to therapy. While its role is less clearly delineated, PD-L2 may also be an important predictive marker for response to PD-1 blockade. PD-L2 amplification is uncommon in solid malignancies, but it is overexpressed in HL, primary mediastinal large B-cell lymphoma (PMBL), and some T-cell lymphomas.^{12,23} Lastly, the impressive response rates in HL also suggest that the *mechanism* of PD-L1 overexpression may be important; in the case of HL, constitutive overexpression of PD-L1/2 driven by EBV infection or genetic amplification events may result in a unique dependence on the PD-1 signaling pathway for survival, which could underlie HL's high vulnerability to PD-1 blockade. This phenomenon occurs in a few other HMs: there are virally-driven DLBCL and T-cell NHL subtypes, which appear to also show very frequent PD-L1 surface expression; and a specific NHL subtype, PMBL, which also harbors frequent 9p24.1 amplification and concomitant PD-L1 and PD-L2 expression.^{12,32} Those tumor subtypes are very attractive targets for PD-1 blockade, as is being explored in ongoing trials.

Treatment Setting

Clinical experience with CBT in HMs thus far has been limited to the R/R setting; however, treatment will likely move to earlier stages of diseases in the coming years, at least in HL. This transition has several important implications. Published trials have used CBT to augment the immune response of patients who have received numerous rounds of cytotoxic therapy. In newly diagnosed patients who have relatively normal immune function, responses may be significantly different. For this reason, earlier treatment with CBT may result in a more robust antitumor immune response. At the same time, it may also increase the incidence and severity of irAEs. Continued investigation is critical to determine how the setting of treatment will alter its efficacy and tolerability.

At this time, there is limited but exciting experience with CBT after HSCT. Yet if continued investigations confirm the early results, post-HSCT CBT may become an important part of transplantation, and may affect both the efficacy of HSCT and its place in the treatment course of patients with HMs.

Endpoint Definition

Early trials in CBT in solid malignancies showed that patients occasionally had evidence of progression before a response, longer times to CR than with traditional treatments, and long-term disease stability despite meeting traditional criteria for progressive disease.³⁰ As a result, new response criteria, the immune-related response criteria, were proposed for solid malignancies to account for different radiographic responses to therapy and to prevent early withdrawal of treatment from patients who might eventually show a response.³³ Hints of a similar pattern of delayed radiographic responses and disease stability have been seen in HMs. For example, 21% of patients had a delayed response (4 months or more after initiation of therapy)

in a trial of pidilizumab in FL.²² With the rapid growth of CBT trials in HM, there may soon be enough data to establish patterns of response by computed tomography (CT) and PET imaging, which can be used to revise response criteria for treatment with CBT.

FUTURE DIRECTIONS

Beyond CTLA-4 and PD-1

The interaction between T cells and tumor cells is complex, and our understanding of the inhibitory and costimulatory receptors that govern T-cell response is rapidly growing. With the success of CTLA-4 and PD-1 blockade, there is great interest in many of the other checkpoint receptors that regulate T-cell activation. For some of these receptors, mAbs have been developed and are in early stages of clinical development. Killer immunoglobulin-like receptor (KIR) is an inhibitory receptor found on NK cells. Similar to PD-1 and CTLA-4 on effector T cells, KIR is believed to facilitate evasion from NK cell-mediated immune destruction. Phase 1 trials of the Anti-KIR monoclonal antibody, lirilumab (Bristol-Myers Squibb, Princeton, NJ, USA), in MM and acute myeloid leukemia have demonstrated satisfactory tolerability and safety,^{34,35} and additional studies are underway (NCT 01248455, NCT01687387). Lymphocyte activation gene 3 (LAG-3), an inhibitory immune checkpoint receptor, is currently being targeted in a phase 1 trial in R/R HMs (NCT02061761). Another inhibitory receptor, CD27, is being targeted by the mAb varilumab (Celldex Therapeutics, Hampton, NJ, USA) in a phase 1 trial in HMs with a documented PR in a patient with HL (NCT01460134). Multiple costimulatory receptors have also been targeted and are in early trials. Urelumab (Bristol-Myers Squibb, Princeton, NJ, USA), an anti-CD137 monoclonal antibody, is under investigation in a phase I trial with rituximab in patients with R/R B-cell malignancies (NCT01775631). In addition, an anti-Ox40L mAb is currently being studied in combination with PD-1 or CTLA-4 blockade in HMs in a phase 1 trial (NCT02205333). As our understanding of immune checkpoint blockade expands, it is likely that additional targeted therapies will reach the clinic in the coming years.

Concepts in Combination Therapy

With early trials demonstrating safety and efficacy for CBT, checkpoint-blocking antibodies are being combined together and with other antitumor therapies including cytotoxic drugs, targeted therapies, radiation therapy, and other forms of immunotherapy. This approach may lead to responses across a broader group of HMs than is possible with single-agent therapy.

Cytotoxic and targeted therapies may have a synergistic effect with checkpoint-blocking antibodies by increasing tumor antigen presentation and thereby stimulating immune destruction. On the other hand, there is uncertainty regarding how cytotoxic and targeted therapies, many of which deplete lymphocyte populations, will affect CBT, as the latter depends on intact effector T-cell function for its antitumor effect. For this reason, the timing of combination therapy may be important to maximize benefits. Combination therapy in FL with pidilizumab and rituximab was well tolerated with suggestion of increased clinical efficacy,²² but experience with combination therapy in both solid and HMs is very limited. Again, ongoing trials in HMs may provide an early answer, as several trials are currently combining checkpoint-blocking antibodies with other agents including anti-CD19 and anti-CD20 in NHL (NCT02271945, NCT02220842), lenalidomide, and a novel Bruton tyrosine kinase inhibitor in MM (NCT02077959, NCT02362035), brentuximab in HL (NCT01896999), and dasatinib in chronic myeloid leukemia (NCT02011945).

Local radiation therapy likely also increases tumor antigen presentation through tumor cell destruction and may have less systemic immunosuppressive effects. A retrospective series in melanoma

reported an abscopal effect, whereby local radiation therapy in combination with CBT resulted in significant improvement in systemic disease control.³⁶ Combination therapy with local radiation therapy and ipilimumab in low-grade B-cell lymphomas is currently being investigated in a phase 1 trial (NCT02254772).

Another combination strategy is dual blockade with two immune checkpoint-blocking antibodies to further augment antitumor immune function. As discussed previously, T-cell activation is governed by numerous receptors and while CTLA-4 and PD-1 are critical actors, changes in expression of other checkpoint receptors may be sufficient to overcome single receptor blockade. The mechanism of immune evasion for patients failing CBT is not yet well understood, but could involve upregulation of alternative checkpoint receptors. Supporting this theory, a recent study in melanoma revealed that mice treated with CTLA-4 blockade and radiotherapy increased expression of PD-L1 in an apparent escape pathway from CTLA-4 blockade.³⁷ Additional knowledge of the pattern and frequency of these escape pathways will be useful in planning combination therapy.

Dual therapy with PD-1 and CTLA-4 blockade has shown tolerability and clinical benefit in a phase 1 study in melanoma.³⁸ Several phase 1 trials are underway in HMs including combination therapy with nivolumab and urelumab in NHL (NCT02253992) an anti-Ox40L mAb and a PD-L1 inhibitor in aggressive B-cell lymphomas (NCT02205333), and nivolumab plus ipilimumab or lirilumab in R/R HMs (NCT01592370). Results from those studies are eagerly anticipated to chart the future course of combination CBT.

Finally, CBT could be combined with other types of immunotherapies including tumor vaccines, oncolytic viral therapies, bispecific antibodies, and chimeric antigen receptor T cells. While there are very few results of this strategy at present, a murine study combining tumor vaccine and pidilizumab in MM,³⁹ and early results from a clinical trial in humans suggest that future efforts are worth pursuing.⁴⁰

CONCLUSION

Immune checkpoint blockade therapy targeting CTLA-4 and PD-1 has shown impressive results in early trials in several types of HMs. The dramatic response rates seen with PD-1 blockade in HL may not be easily replicated in other HMs. However, with judicious selection of tumor targets, of treatment setting, of combination partner(s), with appropriate endpoint assessment, and with diligently and collaboratively pursued correlative studies, there is hope that CBT-based therapy may in the near future, fundamentally alter the treatment paradigm for many HMs.

OVERVIEW AND CHOICE OF DONOR OF HEMATOPOIETIC STEM CELL TRANSPLANTATION

Helen E. Heslop

Since the first hematopoietic stem cell transplants (HSCTs) were performed more than 50 years ago, this modality has become a well-established therapeutic option for many hematologic malignancies as well as for bone marrow (BM) failure states, immune deficiencies, and inborn errors of metabolism (Table 103.1).^{1,2} The wider application of allogeneic transplantation has been possible because of increased knowledge of the genetic basis of histocompatibility and advances in molecular methodology to more accurately type donors and recipients. In addition, the development of large donor registries and cord blood banks has expanded access to transplant as well as increasing the likelihood that a recipient will find a well-matched donor.³

Over the last 20 years, there has also been identification of additional sources of stem cells so that BM, peripheral blood (PB), and umbilical cord blood (UCB) are all widely used in clinical practice to provide long-term hematopoietic reconstitution. The increasing use of reduced-intensity conditioning regimens has made transplant an option for older patients and patients with comorbidities. Finally, there have been improvements in graft-versus-host disease (GVHD) prophylaxis and supportive care during the period of hematopoietic and immune suppression after transplant. Allogeneic HSCT should therefore be considered for patients in whom this procedure is likely to result in superior long-term disease-free survival (DFS) compared with other therapeutic modalities. Potential candidates must also have a suitable source of hematopoietic stem cells (HSCs) available at an appropriate time in the course of the disease.

This chapter provides an overview of HSCT procedures, including conditioning regimens, selection of donor and HSC source, and common early and late posttransplant complications. These topics are discussed in depth in Chapters 104 to 109, and the disease specific indications are discussed in the relevant disease chapters (see Table 103.1 for details). Technical aspects of transplant, including HSC harvesting and cell processing, are discussed in Chapters 95 and 97.

ALLOGENEIC TRANSPLANTATION

Allogeneic transplant is a potential treatment for patients with relapsed or high-risk hematologic malignancy as well as for patients with inherited and acquired disorders of the hemopoietic and immune systems. The goal is to replace the recipient's hemopoietic and immune systems with normal HSCs from a closely matched donor whose hematopoietic stem and progenitor cells obtained from donor BM or other sources can home to the recipient's hematopoietic microenvironment and engraft. The major criteria for choosing an allogeneic donor is the degree of histocompatibility between the donor and recipient because the risks of both graft rejection and of GVHD increase with the degree of genetic disparity. The most important determinant of alloreactivity is matching at loci in the major histocompatibility complex (MHC) that includes human leukocyte antigens (HLA), encoded by class I (*HLA-A*, *HLA-B*, and *HLA-C*) and class II (*HLA-DR*, *HLA-DQ*, and *HLA-DP*) genes. HLA molecules were originally defined by serology, but molecular testing is now routine because gene sequencing has revealed multiple alleles for most serologically defined specificities (see Chapter 105).⁴

Other determinants include minor histocompatibility antigens, which are naturally processed peptides derived from normal cellular proteins that can stimulate an MHC-restricted response when different polymorphisms are present in donor and recipient. Natural killer (NK) cells may also contribute to alloreactivity, particularly in the setting of haploidentical transplantation (Chapter 101).⁵ There is also increasing evidence that genetic loci outside of the MHC may influence the risk of transplant complications such as infection or regimen-related mortality, and several groups have undertaken genome-wide association assays to define genetic variants that might predict these complications.⁶

Donor Choice

The choice of donor for an allogeneic HSCT depends on several factors, including donor choices, the urgency of the transplant, and the patient's disease status. The optimal donor is a matched sibling sharing HLA class I and HLA class II alleles, but because each child inherits one set of paternal and one set of maternal HLA antigens, the likelihood of any sibling matching is only 25%. For patients who lack such donors, other options include a closely matched unrelated or cord donor or a haploidentical family member. Development of high-resolution molecular tissue typing methods and establishment of large donor registries have facilitated transplants from closely HLA-matched unrelated donors. These volunteer donors are healthy individuals between 18 and 60 years of age who fulfill eligibility requirements similar to those applied to blood donors. With increasing registry size, the chance of finding a donor has increased, so that more than 70% of Caucasian patients can identify an HLA-A, B, C, and DRB1 allele-matched unrelated donor.⁷ The likelihood of finding a donor matching at these eight loci (or 10 loci if matching at DQB1 is also included) varies for different ethnic groups and is less for groups with more polymorphism of HLA antigens.³ The initial results of transplantation from unrelated donors were inferior to those seen after matched sibling transplantation because of increased incidences of graft rejection and of GVHD caused by the greater genetic disparity. Over the past decade, though, results have gradually improved in both single-center and multicenter registry studies, reflecting better donor–recipient matching and advances in GVHD prophylaxis and supportive care.⁷ A recent study has examined donor characteristics that predict outcome and found that after adjustment for patient disease and comorbidities when the donor was a 10/10 match, there was a significantly improved survival if the donor was young (aged 18–32 years).⁸ Indeed for every 10-year increment in donor age, there was a 5.5% increase in the hazard ratio for overall mortality.⁸ Overall donor age is the most important factor after donor–recipient HLA match when selecting an unrelated donor.

For a patient who lacks a matched sibling or 10/10 matched unrelated donor, the options are a mismatched unrelated donor, a haploidentical donor, or a cord, and each choice has benefits and disadvantages (Table 103.2).⁹ One limitation of unrelated donor transplant is the time required to identify and screen an unrelated donor, which can be up to 3–6 months. Cord units by contrast can be obtained within 1 week of identifying a suitable matched unit while almost everyone has a haploidentical donor who is usually

highly motivated and available for additional products. This source also has the potential for more graft-versus-tumor effects because of increased alloreactivity and the potential for a beneficial killer-cell immunoglobulin-like receptor mismatch. A haploidentical donor also has a lower “cost of goods” for procurement of the product. Several studies have compared outcomes of mismatched unrelated,

cord, and haploidentical donor transplants, but they do not show a definitive advantage for either source of HSCs.^{9,10} Most transplant units have therefore developed algorithms for donor selection based on local experience and patient characteristics such as size and disease.

Autologous Transplantation

In autologous transplantation the recipient's own HSCs are collected then reinfused after high-dose chemotherapy to produce hemopoietic reconstitution. This approach allows dose intensification in settings where there is a correlation between dose and tumor response rate and hematopoietic toxicity is a limiting factor for dose intensification. HSCs are harvested and cryopreserved and then reinfused after doses of chemotherapy and radiotherapy that would otherwise be lethal or require a prolonged period of recovery. In general, autologous transplant is well tolerated, and data from the Center for International Bone Marrow Transplant Research (CIBMTR) show that the 100-day mortality rate is less than 5%.⁸ The major cause of failure after autologous transplant is relapse of the primary disease. One longer-term concern is that recipients of autologous transplant have an increased risk of secondary therapy-related myeloid leukemia or myelodysplastic syndromes (t-MDS/acute myeloid leukemia [AML]) although this may also reflect effects of previous treatment. Indeed, a study that identified a pattern of altered gene expression in patients who developed t-MDS/AML after transplant for lymphoma found that the genetic programs associated with t-MDS/AML are perturbed pre transplant.¹¹

The most common indications for autologous transplant are currently myeloma, non-Hodgkin lymphoma, and Hodgkin lymphoma, in which it has been shown in randomized trials or concluded in evidence-based reviews that dose intensification and hemopoietic rescue result in improved DFS.^{12,13} Patients with newly diagnosed myeloma who are considered potential candidates for autologous transplant autologous stem cell transplantation are usually treated with two to four cycles of therapy that usually includes an immunomodulatory agent and a proteasome inhibitor before proceeding to autograft.¹⁴ High- or intermediate-dose melphalan is the most widely used conditioning regimen with patients who are younger than the age of 65 years and do not have significant comorbidities receiving high-dose regimens (200 mg/m²); older patients or those with comorbidities receive a reduced dose regimen (usually 140 mg/m²).¹⁴ The optimal postautograft therapy is under investigation. A multicenter randomized trial showed no advantage for performing nonmyeloablative allogeneic HSCT compared with tandem autologous HSCT for patients with standard-risk multiple myeloma,¹⁵ while lenalidomide maintenance therapy, initiated at day 100 after hematopoietic stem-cell transplantation, was associated with a significantly longer time to disease progression and significantly improved overall survival among patients with myeloma.¹⁶ Current studies are evaluating vaccines

TABLE 103.1 Hematologic Disorders Treated by Hematopoietic Stem Cell Transplantation

Hematologic Malignancies	Chapters
Acute lymphoblastic leukemia	65 (pediatric), 66, 104 (adult)
Acute myeloid leukemia	61, 104 (adult), 62 (pediatric)
Myelodysplasia	61, 104 (adult), 63 (pediatric)
Myeloproliferative disorders	63 (pediatric), 70 (myelofibrosis)
Chronic lymphocytic leukemia	77, 104
Chronic myeloid leukemia	63 (pediatric), 67 (adult)
Multiple myeloma	86, 104
Hodgkin lymphoma	75, 104 (adult), 84 (pediatric)
Non-Hodgkin lymphoma	80 (follicular), 81 (mantle cell), 82 (diffuse large B cell), 84 (pediatric), 104 (all types)
Nonmalignant Disorders	
Hemoglobinopathies

TABLE 103.2 Donor Choice

	Mismatched Unrelated Donor	Haploidentical Donor	Cord
Availability	Over 80%	Over 95%	Over 80%
Time to procure	1–4 months	Immediate	2–5 days
Engraftment	Over 95%	Over 95%	Over 90% with slower engraftment
GVHD	Moderate	More genetic disparity but moderate with most modern regimens	Moderate—may be less acute but chronic similar
Availability donor for posttransplant immune therapy	Usually, but takes 2–4 weeks	Yes	No
Relative cost	Moderate	Low if unmanipulated product. Moderate if ex vivo selection	Moderate (1 unit) or high (2 units)
Risk of relapse	Moderate	Higher with regimens that are effective in preventing GVHD	Moderate

and immune effector cells posttransplant to reduce the risk of relapse.

Both American Society for Blood and Marrow Transplantation and National Comprehensive Cancer Network guidelines recommend autologous transplantation in patients with relapsed or refractory diffuse large B-cell lymphoma as well as selected patients with follicular lymphoma. Several large studies have also showed benefit from consolidating with an autograft after initial therapy in patients with mantle-cell lymphoma. A number of different myeloablative conditioning regimens are used in patients with non-Hodgkin lymphoma with the most common being BCNU, etoposide, cytosine arabinoside, and melphalan (BEAM), often in combination with rituximab.

SOURCE OF HEMATOPOIETIC STEM CELLS

The major sources of stem cells for transplant are BM, mobilized PB, and cord blood.

Autologous Donors

In autologous transplantation, the source of HSCs is mobilized PB in almost all adults and more than 90% of pediatric patients. Cytokine-mobilized PB stem cells (PBSCs) can be harvested either after treatment with recombinant human granulocyte colony-stimulating factor (G-CSF) alone or with G-CSF given after chemotherapy. In patients who are heavily pretreated and difficult to mobilize, plerixifor, an antagonist of CXCR4 that interferes with adhesion of hematopoietic progenitors in the microenvironment thereby promoting their circulation in the PB, can be used to increase the mobilization of CD34⁺ stem cells when given in combination with standard G-CSF therapy.

The success of HSC mobilization is related to the amount of previous chemotherapy with some drugs such as alkylating agents having a particularly adverse effect on the success of HSC mobilization. The International Myeloma Working Group has therefore recommended early mobilization of stem cells, preferably within the first four cycles of initial therapy.¹⁷

Allogeneic Donors

BM was the historic source of HSCs for transplant and remains the most widely used source in children. Marrow can be harvested from the posterior iliac crests of allogeneic donors in amounts up to 10–20 mL per kilogram of recipient weight to obtain sufficient HSCs for engraftment. Cytokine-mobilized allogeneic PBSC harvest has become an alternative to marrow as a source of HSCs and is now the most widely used source in adults receiving allogeneic transplants. In both single-center randomized studies and CIBMTR registry studies, use of this source of stem cells from matched sibling donors resulted in more rapid engraftment with no increase in acute GVHD. However, there was a higher incidence of chronic GVHD associated with a lower risk of relapse, which translated to improved DFS in patients transplanted for advanced hematologic malignancies. However, this survival benefit was not seen in patients with early stage disease. A large, prospective, randomized trial in recipients of unrelated HSCs who were randomized to receive BM-versus-PB grafts for hematologic malignancies shows no difference in overall survival at 2 years but a higher incidence of chronic GVHD in the recipients who received PB.¹⁸ Longer follow up is needed to determine if this more frequent development of chronic GVHD will be associated with higher late mortality.

Umbilical Cord Blood

Another alternative source of stem cells is cord blood. There are several large cord banks where cord blood is collected, cryopreserved,

and tested for infectious agents in accordance with standards developed by governmental and specialty oversight organizations. This worldwide network for UCB cell procurement, typing, and storage has collected a large inventory of cords and has facilitated more than 20,000 unrelated donor UCB transplants. A major advantage of cord transplant is the immediate availability of cryopreserved units. Cord transplants have slower engraftment, but they also may also induce less GVHD because of the relative naivety of cord T cells. One limitation is the cell count, which can be limiting for individuals weighing more than 50 kg. However, several studies show that double cord blood transplant, with each unit sharing at least 4/6 HLA antigens with the recipient, can overcome this problem and extend the use of cord transplant to larger adult recipients (see [Chapter 107](#)).

CONDITIONING REGIMENS

The conditioning regimen has different roles in autologous and allogeneic transplant. In autologous transplant, the aim of the conditioning regimen is to intensify doses of chemotherapy agents that would be limited by hematopoietic toxicity. In allogeneic transplant, the goal of conditioning is to achieve immunosuppression of the recipient sufficient to prevent rejection of the donor BM cells and to destroy residual malignant cells (see [Chapter 104](#)). Historically, patients transplanted for malignancy have received intensive fully ablative regimens in which hematopoietic reconstitution would not occur without HSC support. Conditioning regimens are discussed in more detail in [Chapter 104](#), but the most commonly used allogeneic regimens use total-body irradiation and cyclophosphamide or chemotherapy alone with combinations such as busulfan and cyclophosphamide. Biologic agents, such as antithymocyte globulin and monoclonal antibodies, may also be included in some regimens to increase immunosuppression. Reduced-intensity conditioning regimens were developed in the late 1990s and are primarily immunosuppressive, relying on graft-versus-leukemia mechanisms to eradicate malignancy. Reduced-intensity conditioning is often used in older patients or patients with comorbidities in whom the toxicity associated with ablative conditioning would be unacceptable. A variety of regimens based on low-dose total-body irradiation or fludarabine have been used.

COMPLICATIONS AFTER STEM CELL TRANSPLANTATION

Patients who receive transplants are at risk of a number of short- and long-term complications and require long-term follow up. Guidelines for screening and monitoring long-term survivors have been published,¹⁹ and there is increasing interest in research to define the quality of life in long-term transplant survivors. Recipients of both allogeneic and autologous transplant have risks of infection during the period of hematopoietic and immune reconstitution and short- and long-term complications from toxicities from the conditioning regimen. Allograft recipients are also at risk of graft failure and GVHD because of the genetic disparity between donor and recipient.

Acute Graft-Versus-Host Disease

GVHD is the most important cause of mortality, morbidity, and diminished quality of life after allogeneic HCT and results from alloreactivity between donor and recipient. The process is initiated by donor T lymphocytes that recognize antigenic disparities between donor and recipient. In the initial phase, chemotherapy or radiation given as part of the conditioning regimen results in production of inflammatory cytokines secreted by damaged host cells.²⁰ The release of microbial products that are produced by intestinal flora, as well as the release of cytokines by damaged host tissues, lead to the activation of innate immune cells by pathogen recognition receptors such as Toll-like receptors. After infusion of the HSC product, donor T cells

become activated by exposure to host antigens and further activate other immune effectors, resulting in secretion of cytokines and clinical manifestations of GVHD. Chronic GVHD is defined as GVHD occurring after day 100 after transplant, although this definition is somewhat arbitrary. Chronic GVHD often occurs in a patient who has had preceding acute GVHD, although it may arise de novo. It targets the skin, liver, and gastrointestinal tract but may also target other organs and shares features with autoimmune diseases such as scleroderma.

Graft Failure

Graft failure results when recipient immune system cells that survive the conditioning regimen are able to eliminate the incoming donor BM. It is uncommon after fully ablative allogeneic HSCT for hematologic malignancies, but higher incidences are seen after reduced-intensity conditioning and when cord blood is the source of HSCs. Other risk factors include the degree of mismatch between donor and recipient, a low nucleated cell dose, and T-cell depletion of the donor product. Patients who experience graft failure may be retransplanted after additional immunosuppressive conditioning, but mortality from infection caused by prolonged neutropenia is significant.

Infections

After engraftment of the donor HSCs, donor-derived cells reconstitute the recipient's immune system. This is usually a rapid process after autologous transplant but is more prolonged after allogeneic transplant and may be further delayed in a recipient who develops GVHD and requires additional immunosuppression. During the early period after HSC infusion, neutropenic patients are at risk for bacterial infection, fungal infection, and infection with respiratory viruses (see [Chapter 89](#)). After engraftment, allogeneic recipients are at risk for viral infection, particularly reactivation of herpes viruses such as cytomegalovirus. Late infectious complications are mainly seen in allogeneic recipients, in whom a major risk factor is chronic GVHD. International consensus guidelines on the management of infections posttransplant have been published.²¹

Regimen-Related Toxicity

A number of early and late posttransplant complications are related to the conditioning regimen as well as previous therapies and pretransplant comorbidities. These include pneumonitis, sinusoidal obstruction syndrome, hemorrhagic cystitis, growth impairment, and endocrine abnormalities and are described in [Chapter 109](#).

Secondary Malignancies

After HSCT, recipients have a twofold to sevenfold increased risk of developing a secondary neoplasm, with the most frequently seen malignancies being Epstein-Barr virus-related posttransplant lymphoproliferative disease (EBV-PTLD), therapy-related AML and myelodysplasia, and a variety of solid tumors.²² As discussed earlier, autologous transplant recipients are at risk of developing therapy-related MDS and AML because of previous therapy as well as transplant conditioning. Recipients of allogeneic transplant have an increased incidence of both PTLD and solid cancers.

Treatment of Relapse

Relapse remains a major cause of treatment failure after HSCT for hematologic malignancies, and present treatment options are inadequate. Maneuvers that are commonly used are withdrawal of immune suppression, donor lymphocyte infusions, chemotherapy,

and second transplants. Chemotherapy may induce some responses but rarely results in long-term disease control. Increasing knowledge of the molecular basis of graft-versus-tumor responses has stimulated interest in the use of immunotherapy to treat relapse. Infusion of unmanipulated donor lymphocytes can result in significant clinical responses in patients with relapsed CML, but responses are less frequent in other hematologic malignancies.²³ More recently, T cells genetically modified with chimeric antigen receptors have shown very encouraging response rates when treating relapse of CD19+ve malignancies after autologous or allogeneic transplant, but longer follow up is needed.^{24–26} Other current research is focusing on targeting lineage-specific antigens, such as Wilms Tumor 1, preferentially expressed antigen of melanoma, or proteinase 3 or mutation specific antigens.²⁷ Additional immunotherapy approaches under investigation include the administration of antitumor vaccines or NK cells.²⁸

FUTURE DIRECTIONS

An ongoing challenge is to delineate the indications for transplant as new drugs are incorporated in primary therapies for many hematologic malignancies and as risk factors continue to be redefined by new information from genetic sequencing and proteomics studies. The wider use of reduced-intensity transplant offers the prospect of using such transplants as a platform for immunotherapy, and transplant will likely be integrated more closely with other cell therapies such as infusions of NK cells, cytotoxic T cells, and regulatory T cells. The question of optimal stem cell source for patients who lack a matched sibling or 10/10 matched unrelated donor is an open issue as novel regimens to improve outcomes are being evaluated for cord and haploidentical transplants. Finally, there is a need for comparative effectiveness studies that include quality of life measures to compare transplant with other therapeutic options.

INDICATIONS AND OUTCOMES OF ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION FOR HEMATOLOGIC MALIGNANCIES IN ADULTS

Mehdi Hamadani and Parameswaran N. Hari

BACKGROUND

Thomas et al¹ first reported long-term leukemia-free survival following human leukocyte antigen (HLA) identical sibling hematopoietic cell transplantation (HCT) in patients with refractory acute leukemia in the 1970s. Since then, allogeneic HCT has evolved to become a frequently used and effective therapy for many hematologic malignancies. Changes in both HCT and nontransplant therapies have modified the indications and applicability of HCT over time. In chronic myelogenous leukemia (CML), HCT (once the mainstay for cure), is now largely supplanted by molecularly targeted therapy. In recent years, and especially after the advent of reduced intensity conditioning (RIC) in the late 1990s, allogeneic HCT is increasingly used in older patients and as a salvage strategy for lymphoma or myeloma not responding to chemotherapy or autologous HCT. Transplant-related mortality (TRM), while steadily declining, still remains a challenge. General principles, indications and optimal timing of allogeneic HCT for hematologic malignancies and long-term outcomes following HCT are discussed in this chapter.

Allogeneic HCT involves administration of a conditioning (or preparative) regimen of chemotherapy (with or without radiation) and immune suppressive medications, followed by infusion of donor hematopoietic progenitor cells. Most patients then receive prolonged (several months) therapy with immune suppressive agents to prevent or treat graft-versus-host disease (GVHD). The purpose of the conditioning regimen is generally twofold: to eradicate malignant cells and to eliminate host immune cells (capable of rejecting even HLA-identical sibling donor cells). The ability to restore hematopoiesis with donor hematopoietic progenitor cells permits the administration of substantially higher (myeloablative) doses of cytotoxic therapy, than is otherwise possible. Although originally regarded primarily as a way of rescuing patients from therapy-induced marrow aplasia, it is now accepted that graft-versus-malignancy (GVM) effects conferred by alloreactive donor cells contribute substantially to cancer eradication and longer-term relapse prevention.

PATIENT POPULATION

Accompanying the growth of HCT, a coordinated, international effort evolved to collect and analyze data on transplant outcomes through the International Bone Marrow Transplant Registry (IBMTR), established in 1972. The IBMTR affiliated with the United States (US) National Marrow Donor Program (NMDP) in 2004 to become the Center for International Blood and Marrow Transplant Research (CIBMTR). The CIBMTR currently collects data on HCT outcomes from more than 400 transplant centers worldwide and on all allogeneic transplants in the US. In 2013, approximately 9600 allogeneic transplants were performed in adults (age >18 years) in the US. These data show that hematologic malignancies (and premalignant conditions) remain the most common indications for allogeneic HCT. Acute myeloid leukemia (AML), myelodysplastic syndrome/myeloproliferative disorders (MDS/

MPD) and acute lymphoblastic leukemia (ALL) currently constitute the three most common indication of allogeneic transplantation (Fig. 104.1).

Improved immunosuppression and supportive care and the use of RIC have led to an increase in allogeneic HCT for older adults in recent years. Only 4% of allogeneic HCT recipients in 1987–1992 were older than 50 years. In 2013, 34% were older than 55 years and 10% were 65 years or older. Allogeneic transplantation in patients without HLA-identical siblings was facilitated by establishment of large unrelated donor registries. In 1987–1992, <10% of HCTs for hematologic malignancies used unrelated donors; in 2013, this figure was >50%. More transplantation in older adults and increasing use of unrelated donors were the main reasons for the steady growth in allogeneic HCT over the last decade. Similarly, the use of haploidentical related donor HCT is on the rise. In 2001, less than 50 related donor haploidentical transplants were reported to the CIBMTR, compared with nearly 500 transplants in 2013.

CONDITIONING REGIMENS

Historically, conditioning regimens included myeloablative doses of cytotoxic drugs with or without radiation, intended not only to provide disease control, but also host immunosuppression (to prevent graft rejection). Myeloablative regimens for hematologic malignancies often involve a combination of cyclophosphamide (commonly 60 mg/kg/day for 2 days) and total-body irradiation (TBI) (5–15 Gy, single or fractionated doses). Many regimens substitute busulfan (typically 3.2 mg/kg/day intravenously for 4 days or pharmacokinetic guided similar dose) in place of TBI. Posttransplant survival rates with cyclophosphamide and TBI and with cyclophosphamide and busulfan (BuCy) are similar though recent prospective data suggest an advantage for BuCy in myeloid malignancies (AML/MDS/CML). Other drugs such as etoposide, melphalan and thiopeta, are sometimes added to or substituted for cyclophosphamide and/or busulfan in a variety of regimens in efforts to provide better, generally disease-specific, antineoplastic activity. Large prospective trials comparing efficacy of these regimens are lacking. A CIBMTR study suggested better outcomes in ALL in second complete remission (CR2) with either higher doses of TBI or substitution of cyclophosphamide by etoposide in a standard dose TBI regimen.

Myeloablative conditioning regimens are associated with significant risk of regimen-related toxicity. Toxicity can be minimized and efficacy improved with careful pharmacokinetic monitoring of certain drugs, e.g., busulfan. Another strategy for lowering treatment related mortality is by reducing the dose-intensity of the conditioning regimen. This approach uses lower doses of cytotoxic drugs and/or radiation to facilitate donor cell engraftment and relies more on GVM effects to eradicate malignant cells. The lower doses of cytotoxic agents produce less host tissue damage and less inflammatory cytokine secretion resulting in lower rates of regimen-related morbidity and mortality. Use of RIC regimens has greatly increased the applicability of allogeneic HCT in patients ineligible for traditional myeloablative regimens because of age or comorbidities. The development of these

Fig. 104.1 INDICATIONS FOR ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION IN ADULTS (US DATA), 2013. *ALL*, acute lymphoblastic leukemia; *AML*, acute myeloid leukemia; *CLL*, chronic lymphocytic leukemia; *CML*, chronic myeloid leukemia; *HD*, Hodgkin disease; *Leuk*, leukemia; *Malign*, malignancy; *MDS*, myelodysplastic syndrome; *MM*, multiple myeloma; *MPD*, myeloproliferative syndrome; *NHL*, non-Hodgkin lymphoma; *PSD*, plasma cell dyscrasia; *SAA*, severe aplastic anemia.

novel conditioning regimens produced a major change in practice in the past decade (Fig. 104.2).

Consensus criteria have been developed by the CIBMTR and the European Society for Blood and Marrow transplantation (EBMT) to distinguish between myeloablative, reduced intensity and nonmyeloablative regimens based on the likelihood of the regimen to produce toxicity to the recipient marrow (Table 104.1).² Myeloablative regimens produce profound pancytopenia and are usually fatal in the absence of stem cell rescue. Nonmyeloablative regimens cause brief and often less severe pancytopenia and in the absence of donor stem cell rescue, autologous hematopoietic recovery is likely to occur. RIC regimens are an intermediate category not fitting well in either of the above, since they produce pancytopenia that may recover without stem cell rescue but which is prolonged and, in clinical practice, requires stem cell support.

RIC regimens induce less immune compromise in the immediate post-HCT setting as the duration and depth of neutropenia is reduced and host-derived immunocompetent cells are not immediately eliminated. In addition, the reduced risk of organ toxicity makes RIC regimens attractive for patients ineligible for conventional high-dose regimens.³ Whether these benefits outweigh the risks of potentially reduced antitumor effects in patients fit for myeloablative conditioning regimens, remains controversial.

It is generally accepted that reduced intensity regimens allow HCT to be done in some patients who will not be offered HCT with myeloablative conditioning. For example, in the US, the proportion of transplantations done in patients older than 60 years increased from <5% before 2000 to ~22% in 2013. Two-thirds of the latter patients received RIC regimens. The Seattle consortium described the outcomes of 372 “older” patients (aged 60–75 years) receiving nonmyeloablative regimens.³ Increasing age was not associated with increase in organ toxicity or GVHD and 5-year survival of the entire

cohort was 35%. However, RIC regimens are increasingly used in patients of all ages receiving both related and unrelated donor transplants, as is shown in Fig. 104.2.

Despite the growing popularity of RIC regimens, large retrospective database studies from the EBMT and CIBMTR (summarized in Table 104.2) have generally failed to show a definite survival advantage resulting from the use of such conditioning regimens. Although RIC regimens allow a potent graft-versus-leukemia response to occur with lower toxicity, there are concerns about a higher risk of disease relapse following RIC regimens. Since the distribution of conditioning regimens in registry studies reflects physician choice or patient selection bias, retrospective data are of limited use. Randomized trials have been performed to gauge the true impact of regimen intensity. The US prospective trial Bone Marrow Transplant-Clinical Trial Network (BMT-CTN 0901) randomized patients with myeloid malignancies eligible for myeloablative conditioning to RIC-versus-myeloablative regimens. This trial was suspended after enrolling 272 out of the planned 356 patients when early results indicated better outcomes for myeloablative regimens (National Heart, Lung and Blood Institute clinical advisory and personal communication—Mary Horowitz). Detailed results are not available yet and RIC transplants remain the standard of care for those not eligible for myeloablative conditioning. A recently concluded prospective European trial (RICMAC) showed similar 2-year relapse-free and overall survival for busulfan based RIC versus myeloablative regimens in patients with MDS and secondary AML.⁴

GRAFT SOURCES

The sources of hematopoietic cells for transplantation, historically donor bone marrow, now also include peripheral blood hematopoietic

Allogeneic Transplants Registered with the CIBMTR in the United States, 2002–2013, by Conditioning Regimen Intensity & Patient Age

Fig. 104.2 CONDITIONING REGIMEN INTENSITY AND PATIENT AGE: CHANGING TREND OVER TIME (2002–2013). *MAC*, myeloablative conditioning; *NMA*, nonmyeloablative; *RIC*, reduced intensity conditioning.

TABLE 104.1 Consensus Definition of Conditioning Regimen Intensity

Myeloablative Conditioning

Profound Cytopenia, Not Likely to Recover Without Hematopoietic Cell Rescue

Total body irradiation >5 Gy single dose or >8 Gy fractionated
Busulfan >8 mg/kg orally or intravenous equivalent

Nonmyeloablative

Minimal Cytopenia, Autologous Recovery of Hematopoiesis Likely Even Without Transplant

Total body irradiation <2 Gy + purine nucleoside analogue
Fludarabine + cyclophosphamide + antithymocyte globulin
Fludarabine + cytarabine + idarubicin
Cladribine + cytarabine
Total lymphoid irradiation + antithymocyte globulin

Reduced Intensity Conditioning

Regimens that are intermediate between the above categories

cells collected by leukapheresis and umbilical cord blood. The composition of grafts from bone marrow, peripheral blood and cord blood varies in terms of the proportion of pluripotent stem cells to lineage-committed late progenitor cells and in the characteristics of immune reactive cells. Bone marrow is the primary source of allogeneic donor cells for transplantation in children and peripheral blood the main source in adults (Fig. 104.3). Among all allografts, umbilical cord blood is used for nearly 30% of transplants in children (younger than 20 years). The proportion of transplants in adults using cord blood grafts increased from about 2% in 2004 to 4.5% in 2013.

Several randomized trials have compared matched sibling bone marrow-versus-peripheral blood grafts in patients with hematologic malignancy following myeloablative conditioning regimens. These

studies in general, showed no difference in the rates of acute GVHD between the two graft sources and a higher risk of chronic GVHD with peripheral blood grafts. While survival outcomes were similar in most studies, the US and Canadian randomized studies reported a disease-free and overall survival advantage respectively favoring peripheral blood grafts.^{5,6} A metaanalysis using individual patient-level data from nine randomized trials of related donor peripheral blood-versus-bone marrow transplants suggested that patients receiving peripheral blood grafts had faster hematopoietic recovery,⁶ a lower relapse rate if transplanted for hematologic malignancy and higher overall and disease-free survival if transplanted for advanced-stage disease. However, peripheral blood was also associated with a significantly increased risk of extensive chronic GVHD. Prospective data evaluating graft sources for unrelated donor transplantation are sparse. The BMT-CTN 0201 is the only randomized trial ($n = 551$) comparing unrelated donor marrow versus peripheral blood grafts for hematologic malignancies. This study showed a higher risk of chronic GVHD in patients receiving peripheral blood grafts (53% versus 41% for marrow grafts). Notably, survival and the incidence of relapse and acute GVHD were similar, while graft failure was more common among recipients of marrow grafts.⁷ The relative importance of graft sources in patients receiving lower-intensity conditioning is not known, but a recent CIBMTR study comparing unrelated bone marrow versus peripheral blood grafts following RIC, showed no difference between the two sources in terms of rates of acute or chronic GVHD, relapse risk and survival outcomes.⁸

ALTERNATIVE DONOR TRANSPLANTS—CORD BLOOD AND HAPLOIDENTICAL GRAFTS

A major obstacle to allogeneic HCT is donor availability for the majority (70%) of adult patients without an HLA-identical sibling.

TABLE 104.2**Retrospective Registry-Based Comparisons of NMA/RIC versus Myeloablative Allogeneic HCT**

Group	Disease	Donor	RIC vs. MAC (N)	TRM RIC vs. MAC	Relapse	Comments
EBMT ³³	MDS or sAML >50	MUD 39%	315 vs. 407	32% vs. 44% at 4 years	41% vs. 33% at 4 years	Survival 31% at 4 years. RIC predicted for greater relapse but lower TRM in multivariate model. Wide variety of different conditioning regimens used.
EBMT ³⁴	MM	MUD 12%	320 vs. 196	24% vs. 37% at 2 years	27% vs. 54%	TRM lower after RIC but relapse risk is double
EBMT ³⁵	AML	Sibling	215 vs. 621	22% vs. 32% at 3 years	45% vs. 27% at 3 years	Relapse rate higher and TRM lower in RIC but OS similar (41% vs. 45%) in both groups.
EBMT ³⁶	CLL	MUD 22%	73 vs. 82	19% vs. 26%	28% vs. 11%	Similar TRM but higher relapse risk after RIC
EBMT ³⁷	HL	MUD 13%	89 vs. 79	23% vs. 46% at 1 year	57% vs. 30%	Relapse rate higher and TRM lower in RIC but OS similar
CIBMTR ³⁸	Follicular NHL	Sibling	88 vs. 120	23% in both at 1 year	17% vs. 8%	RIC associated with higher risk of relapse but similar TRM while lower KPS impacted on TRM. OS was similar.
EBMT ³⁹	ALL	Sibling	127 vs. 449	21% vs. 29%	32% vs. 38%	TRM lower after RIC but higher relapse rate. Leukemia-free survival similar to MAC
CIBMTR ⁴⁰	AML/MDS	MUD/Sibling	1448 vs. 3731	3-year TRM similar	Lower risk of relapse in Myeloablative	Overall and disease-free survival was highest for myeloablative group

ALL, Acute lymphoblastic leukemia; AML, acute myeloid leukemia; CIBMTR, Center for International Blood and Marrow Transplant Research; CLL, chronic lymphocytic leukemia; EBMT, European Society for Blood and Marrow transplantation; HCT, hematopoietic cell transplantation; HL, Hodgkin lymphoma; KPS, Karnofsky performance score; MAC, myeloablative conditioning; MDS, myelodysplastic syndrome; MM, multiple myeloma; MUD, matched unrelated donor; NHL, Non-Hodgkin lymphoma; NMA, nonmyeloablative; OS, overall survival; RIC, reduced intensity conditioning; TRM, transplant-related mortality; sAML, secondary acute myeloid leukemia.

Fig. 104.3 ALLOGENEIC STEM CELL SOURCES, BY DONOR TYPE VERSUS DONOR AGE, 2000–2013.

The likelihood of finding an optimal adult unrelated donor (i.e., a donor matched at high resolution at HLA-A, HLA-B, HLA-C, and -DRB1) varies among racial and ethnic groups depending on the size and composition of unrelated donor registries. Within the US population, the highest likelihood for finding an optimal donor is for whites of European descent, at 75%, and the lowest among blacks of South or Central American descent, at 16%.⁹ The unrelated donor search process can be time-consuming, raising the risk of disease progression before transplantation can be performed. As a source of hematopoietic stem cells for unrelated donor transplantation, umbilical cord blood offers several advantages. It is readily available and entails no risk to the donor. Current data also indicate that HLA-matching criteria for cord blood transplantation need not be as stringent as for adult donor transplantation. Hence cord-blood units mismatched at one or two HLA loci are available for almost all patients <20 years of age and for more than 80% of patients ≥20 years of age, regardless of racial and ethnic background.⁹ Drawbacks of cord blood transplants include procurement costs, often limited number of hematopoietic cells in each cord blood unit and relatively high rates of TRM.

The numbers of cord blood transplants have increased steadily, especially in children but also in adults. Comparative data on cord blood versus adult donor transplantation in adults come from registry studies and consistently suggests slower hematopoietic recovery but lower rates of GVHD with cord blood grafts. A CIBMTR comparison of adult leukemia patients receiving cord blood versus matched or mismatched unrelated marrow grafts indicated that rates of relapse, TRM, treatment failure and overall mortality were not significantly different between recipients of cord blood or mismatched marrow transplants.¹⁰ Based on current data, a one or two HLA-antigen mismatched cord blood graft of appropriate cell dose is an acceptable alternative for patients with hematologic malignancies who need HCT but do not have a readily available HLA-identical adult (sibling or unrelated) donor. Patients without a single cord unit of adequate cell dose may receive two units to facilitate engraftment.¹¹ Other approaches to facilitate engraftment with limited cord blood cell doses, including ex vivo cell expansion techniques are in clinical trials.

HLA haploidentical related-donor HCT (mismatched at ≥2 loci HLA-A, HLA-B, HLA-C and HLA-DR; usually parents, siblings, or children of patients) is another option for patients without matched sibling or unrelated donors. Despite the potential benefit of a strong GVM effect, the risk of severe GVHD, graft rejection and infectious complications have historically limited the applicability of haploidentical HCT. Newer strategies using intense ex vivo or in vivo T-cell depletion or the use of cyclophosphamide posttransplantation have improved the safety of haploidentical transplants. Immediate and near-universal donor availability, theoretically lower costs and the potential to select donors with a favorable killer-cell immunoglobulin-like receptor (KIR) phenotype that enhances antileukemia activity are advantages. Limited retrospective data suggest haploidentical HCT performed using T-cell-replete grafts and posttransplant cyclophosphamide achieves outcomes comparable with those of transplantation performed using matched related or unrelated donors.¹² Administration of high dose cyclophosphamide posttransplantation promotes tolerance in alloreactive host and donor T cells, leading to suppression of graft rejection and GVHD without toxicity to donor hematopoietic cells. A variety of myeloablative and RIC haploidentical regimens with posttransplant cyclophosphamide administration have been described and represent another option for patients who lack timely access to a conventional unrelated donor.

In patients lacking matched adult (sibling or unrelated) donors, the choice between cord blood versus haploidentical HCT is a matter of much ongoing debate. The BMT-CTN conducted two parallel multicenter phase 2 trials in patients with leukemia or lymphoma and no suitable adult donors using either double cord blood units or haploidentical marrow grafts (BMT-CTN 0603) after RIC.¹³ Survival at 1 year was similar: 54% after cord blood HCT and 62% after haploidentical marrow grafts. The incidence of TRM and relapse

after cord blood grafts were 24% and 31%, respectively; corresponding incidences after haploidentical marrow grafts were 7% and 45%. The ongoing BMT-CTN 1101 study comparing umbilical cord blood versus haploidentical marrow grafts will hopefully inform clinical decision making about the relative risks/benefits of these two alternative donor sources.

GRAFT VERSUS MALIGNANCY EFFECTS

Donor derived alloreactive cells are capable of mounting a potent anticancer immune response. Barnes and Loutit^{13a} studied leukemic mice treated with high-dose TBI and compared those receiving syngeneic and allogeneic bone marrow infusions. Mice receiving syngeneic marrow died quickly of leukemia whereas those receiving allogeneic cells survived longer but eventually developed fatal GVHD. Importantly, the allografted mice had no evidence of leukemia at death. Several canine and murine experiments reproduced these results.¹⁴ Antitumor effects of allogeneic cells could be specific, i.e., after sensitization of the donor or the donor's cells to antigens present on malignant cells, or nonspecific, i.e., associated with GVHD, an immune reaction of donor lymphocytes against normal and malignant host cells presumably triggered by differences in histocompatibility antigens.¹⁵ The term graft-versus-leukemia was coined by Bortin and coworkers¹⁴ to indicate the adoptive immunotherapeutic effect of transplanted donor cells against the recipient's leukemia cells. Clinical evidence for the importance of GVM effects in eradicating tumor includes: 1) lower incidence of disease relapse in allograft recipients with acute and/or chronic GVHD than in those without GVHD¹⁵; 2) higher relapse rates after syngeneic versus allogeneic HCT¹⁵; 3) higher relapse rates after T-cell depleted transplants¹⁵; 4) durable remissions induced after posttransplant relapse by infusion of donor lymphocytes without other antileukemia therapy; and 5) durable remissions achieved after very low doses of conditioning agents (e.g., 2 Gy TBI) and allogeneic HCT.³ GVM effects are associated with GVHD and measures that prevent or suppress GVHD may allow more relapse but significant anticancer effects are demonstrable even in the absence of clinically significant GVHD, especially in AML and CML. The efficacy of immune-mediated antitumor effects varies by disease; they are most evident in myeloid leukemias and indolent lymphomas.

The role of natural killer (NK) cells in the posttransplant setting is of increasing interest. After HCT, donor-derived NK cells promote engraftment, reduce the risk of GVHD, enhance immune reconstitution and also decrease the risk of relapse especially in AML.¹⁶ In the physiologic state, NK cells can engage and kill target cells lacking major histocompatibility (HLA) class I molecules. This function is regulated by signaling through the KIR family. In the allogeneic HCT setting; lack of expression of the inhibitory KIR ligand on the recipient's leukemic cells can trigger donor NK cell alloreactivity against leukemia. The KIR family represents a second immunogenetic system inherited independently of HLA that can affect transplant outcomes especially relapse-free survival in AML. It has been proposed that in the setting of HCT for AML, KIR genotyping be used in addition to HLA typing by selecting donors with favorable KIR haplotypes.¹⁷ In the setting of haploidentical and T-cell depleted HCT for myeloid malignancies, donor-recipient KIR ligand mismatching is associated with favorable outcomes in some studies.

PROGNOSTIC FACTORS

Although allogeneic HCT has efficacy in hematologic malignancies, the procedure carries a substantial risk of morbidity and mortality. TRM may result from toxicity of the pretransplant conditioning regimen to lung, liver, and other organs, complications of cytopenia, GVHD, and infection related to delayed immune reconstitution especially in the setting of GVHD or its treatment. The risk of TRM may be 30% or higher in adults receiving unrelated or alternative donor transplantation. In addition, many patients have recurrence of

Fig. 104.4 CAUSES OF DEATH AFTER TRANSPLANTATION, 2008–2013. *ARDS*, adult respiratory distress syndrome; *GVHD*, graft-versus-host disease; *HLA*, human leukocyte antigen; *IPn*, idiopathic pneumonia syndrome.

their malignancy despite intensive conditioning and GVM effects. Primary causes of death after allogeneic transplantation for hematologic malignancy are shown in (Fig. 104.4). The prognosis of transplant recipients is influenced by several factors associated with risk of TRM and/or cancer recurrence or progression.

Donor Factors

TRM rates are generally lower after HLA-identical sibling than after unrelated donor or alternative donor transplants because of less graft failure, faster immune reconstitution and less GVHD. However, considerable progress has been made in reducing TRM rates after both HLA-identical sibling and alternative donor HCT. For matched sibling donor HCT in AML in CR1, the incidence of TRM decreased from 29% from 1985–1989 to about 15% from 2000–2004 and 14% from 2005–2009. For unrelated donor HCT, the incidence of TRM from 1990–1994 was 39%, which decreased to 31% by 2000–2004 and 21% from 2005–2009.¹⁸ Among alternative donor transplants, those from more closely HLA-matched donors tend to have lower risks of GVHD and TRM. Donor-recipient HLA mismatching is associated with increased risk of posttransplant complications including graft rejection, acute and chronic GVHD and mortality; risks increase progressively with multiple HLA mismatches. With modern molecular HLA typing techniques (allowing selection of more closely HLA-matched donors) and current GVHD prevention strategies, the difference in outcomes between HLA-matched sibling and unrelated donor transplantation has narrowed (Fig. 104.5).

Adoption of molecularly-defined HLA matching techniques, calcineurin inhibitor-based GVHD prophylaxis, fungal prophylaxis with azoles, leukocyte reduction of blood products, newer assays for viral reactivation, pharmacokinetic testing of conditioning

agents and posttransplant cyclophosphamide for induction of allogeneic tolerance are some of the major innovations that have impacted TRM.

Timing of Transplantation

In general, HCT outcomes are better when transplantation is done earlier in the disease course. Transplantation for advanced disease is associated with higher risks of both relapse and TRM. High TRM in the setting of advanced disease likely reflects patients' poorer clinical status and the cumulative effects of more extensive prior treatment. Since some hematologic malignancies have excellent prognosis with nontransplant therapy, e.g., children with standard risk ALL or adults with acute promyelocytic leukemia, appropriate timing of transplantation requires consideration of likely outcomes with transplant and nontransplant therapies. However, even when not used early, transplantation should not be inordinately delayed, since patients with refractory disease or severe complications from extensive prior therapy are unlikely to benefit. For patients with diseases potentially curable by allografting, appropriate timing of transplantation should be considered early in planning management strategies. This includes determining the availability of suitable related or unrelated donors. The American Society for Blood and Marrow Transplantation (ASBMT) developed evidence-based guidelines (see Pink Box 104.1) based upon current clinical practice and available literature (available online at <http://www.asbmt.org/?page=GuidelineStatements>)

Patient- and Disease-Related Factors

TRM is lower and, consequently, survival is higher, in patients who are young, cytomegalovirus antibody screen-negative, and have good

One-Year Survival after a Myeloablative Conditioning Regimen for Acute Leukemias in any Remission, CML or MDS, Age <50 yrs, in the United States, 1998–2013, by Year of Transplant and Donor Type

Fig. 104.5 ONE-YEAR SURVIVAL AFTER MYELOABLATIVE HCT IN YOUNGER PATIENTS (RELATED VERSUS UNRELATED DONOR). *HCT*, hematopoietic cell transplantation; *URD*, unrelated donors.

BOX 104.1 ASBMT Consensus Policy for Allogeneic Transplantation

Disease State	Policy Regarding: Allogeneic Transplantation
AML in adults	1. Survival advantage is established for allogeneic HCT vs. chemotherapy for patients under age 55 years with high risk cytogenetics. 2. Insufficient evidence to routinely recommend allogeneic HCT for patients with intermediate risk cytogenetics. 3. No survival advantage for allogeneic HCT in patients under age 55 years with low-risk cytogenetics. 4. Insufficient data to make a recommendation for the use of myeloablative regimens for patients over age 55 years. 5. Insufficient data to make a recommendation for RIC followed by HCT vs. chemotherapy. 6. For patients in second complete remission, allogeneic HCT is recommended if there is an available donor. <i>Details available at: http://c.ymcdn.com/sites/www.asbmt.org/resource/resmgr/Docs/AdultAML_PositionStatement.pdf</i>
ALL in adults	1. In first CR, allogeneic HCT as first-choice therapy is appropriate for all risk groups. In younger patients (<35 years), with standard risk, Ph-negative ALL, HCT results in superior survival compared with chemotherapy. In older (>35 years) patients, with standard risk Ph-negative ALL, higher TRM diminishes survival benefits of HCT. 2. In second CR, allogeneic HCT is recommended over chemotherapy. 3. There is similar survival after related and unrelated donor HCT for ALL. 4. RIC may produce similar outcomes to myeloablative but available data are limited. RIC is appropriate only for patients with ALL in remission and unsuited for myeloablative conditioning. <i>Details available at: http://c.ymcdn.com/sites/www.asbmt.org/resource/resmgr/Docs/Adult_ALL_PositionStatement.pdf</i>
Diffuse Large B-cell Lymphoma	1. Survival outcomes are equivalent for autologous and allogeneic HCT; neither option is recommended over the other. Comparison between the two techniques is biased by different patient selection criteria. 2. Based on limited data, RIC is an acceptable alternative for selected patients who cannot tolerate a myeloablative regimen. <i>Details available at: http://c.ymcdn.com/sites/www.asbmt.org/resource/resmgr/Docs/DLBCL_PositionStatement.pdf</i>
Follicular Lymphoma	1. Autologous versus allogeneic HCT: there are insufficient data to recommend one option over the other as comparison between the two techniques is biased by different patient selection criteria. 2. Based on limited data and expert opinion, RIC is an acceptable alternative approach to myeloablative conditioning. 3. Based on expert opinion, matched unrelated donor transplants are considered as effective as matched related donor transplants. <i>Details available at: http://c.ymcdn.com/sites/www.asbmt.org/resource/resmgr/Docs/FollicularLymphoma_PositionS.pdf</i>
Myeloma	1. Autologous transplant is preferred over allogeneic HCT based on current evidence. Studies are ongoing to further evaluate the role of allogeneic HCT. <i>Details available at: http://c.ymcdn.com/sites/www.asbmt.org/resource/resmgr/Docs/MultipleMyeloma_PositionStat.pdf</i>

ALL, Acute lymphoblastic leukemia; AML, acute myeloid leukemia; ASBMT, American Society for Blood and Marrow Transplantation; CR, complete remission; HCT, hematopoietic cell transplantation; Ph, Philadelphia chromosome; RIC, reduced intensity conditioning; TRM, transplant-related mortality.

BOX 104.2 Hematopoietic Cell Transplantation-Specific Comorbidity Index (HCT-CI)

Comorbidity	Explanation	HCT-CI score
Arrhythmia	Atrial fibrillation or flutter, sick sinus syndrome, or ventricular arrhythmias	1
Cardiac	Coronary artery disease, congestive heart failure, myocardial infarction, or ejection fraction $\leq 50\%$	1
Inflammatory bowel disease	Crohn disease or ulcerative colitis	1
Diabetes	Requiring treatment with insulin or oral hypoglycemics	1
Cerebrovascular disease	Transient ischemic attack or cerebrovascular accident	1
Psychiatric disturbance	Depression or anxiety requiring psychiatric consult or treatment	1
Hepatic, mild	Chronic hepatitis, bilirubin $> \text{ULN}$ to $1.5 \times \text{ULN}$, or AST/ALT $> \text{ULN}$ to $2.5 \times \text{ULN}$	1
Obesity	Patients with a body mass index $> 35 \text{ kg/m}^2$	1
Infection	Requiring treatment after day 0	1
Rheumatologic	SLE, rheumatoid arthritis, polymyositis, mixed connective tissue disease, or polymyalgia rheumatica	2
Peptic ulcer	Requiring treatment	2
Moderate/severe renal	Serum creatinine $> 2 \text{ mg/dL}$, on dialysis, or prior renal transplantation	2
Moderate pulmonary	DLCO and/or FEV ₁ 66% to 80% or dyspnea on slight activity	2
Prior solid tumor	Treated at any time point in the patient's past history, excluding nonmelanoma skin cancer	3
Heart valve disease	Except mitral valve prolapse	3
Severe pulmonary	DLCO and/or FEV ₁ $\leq 65\%$ or dyspnea at rest or requiring oxygen	3
Moderate/severe hepatic	Liver cirrhosis, bilirubin $> 1.5 \times \text{ULN}$, or AST/ALT $> 2.5 \times \text{ULN}$	3
HCT-CI of 0 predicts 2 year TRM of 14%		
HCT-CI of 1-2 predicts 2 year TRM of 21%		
HCT-CI of ≥ 3 predicts 2 year TRM of 41%		

ALT, Alanine aminotransferase; AST, aspartate aminotransferase; CI, confidence interval; DLCO, diffusing capacity of the lungs for carbon monoxide; FEV₁, forced expiratory volume in the first second of expiration; HCT, hematopoietic cell transplantation; SLE, systemic lupus erythematosus; ULN, upper limit of normal.

BOX 104.3 Refined Disease Risk Index (DRI)

Refined DRI Category	Definition of Refined DRI category	2-Year Overall Survival
Low	- Hodgkin lymphoma, mantle cell lymphoma, indolent non-Hodgkin lymphoma (NHL), chronic lymphocytic leukemia (CLL) or favorable-cytogenetics acute myeloid leukemia (AML) in complete remission (CR) - CLL or indolent NHL in partial remission (PR) - First or second chronic phase chronic myelogenous leukemia (CML).	66%
Intermediate	- CML advance phase - Mantle cell lymphoma, T-cell NHL, Hodgkin lymphoma, or aggressive NHL in PR - CLL or indolent NHL with stable or progressive disease - Acute lymphoblastic leukemia (ALL) in first CR - Intermediate-cytogenetics AML or aggressive NHL in CR - Myeloproliferative neoplasm - Low-risk myelodysplastic syndrome (MDS) with adverse-cytogenetic or high-risk MDS with intermediate-cytogenetics	51%
High	- Multiple myeloma in CR/very good PR/PR - T-cell NHL, Hodgkin lymphoma, mantle cell lymphoma, myeloma with stable or progressive disease - Burkitt lymphoma in CR - ALL in second or third CR - Adverse-cytogenetics AML in CR - Intermediate-cytogenetic AML with induction failure or active relapse - High-risk MDS with intermediate cytogenetics and advanced disease - Any-risk MDS with adverse cytogenetics and advanced disease	33%
Very High	- CML blast phase - Burkitt lymphoma in PR - Adverse-cytogenetic AML or ALL with induction failure or active relapse - Aggressive NHL with stable or progressive disease	23%

performance scores and no active infection. While age is still a significant barrier to successful allogeneic HCT, the presence and extent of medical comorbid conditions rather than an arbitrary chronologic age cutoff, is increasingly recognized as a major determinant of TRM. Box 104.2 depicts the commonly used HCT-Comorbidity Index (HCT-CI), for estimating risk of TRM posttransplantation.¹⁹

Although many factors influence the outcome of allogeneic HCT, disease type and disease status at the time of transplantation are the strongest determinants of post-HCT survival. The CIBMTR recently reported a Refined Disease Risk Index (R-DRI) (see Box 104.3), as a useful prognostic tool to predict overall survival postallogeneic HCT, based on patient's disease type and remission status.²⁰ Both

HCT-CI and R-DRI are increasingly used in clinical decision making to determine patient eligibility and optimal conditioning intensity pre-HCT.

CLINICAL RESEARCH IN ALLOGENEIC TRANSPLANTATION

The number of HCTs performed in the US is increasing at a rate of approximately 5% per year. Only a minority of patients have their transplants performed on clinical trials. Challenges unique to the field of HCT such as small numbers treated at individual centers, the wide variety of indications and multiple competing risks in the peritransplant period, make it difficult to perform single center studies. To overcome these challenges, in the US, a national multicenter transplant study network (BMT-CTN) has been established. The BMT-CTN has thus far launched 36 multicenter trials and accrued more than 7000 patients.

While clinical trials focus on short- and intermediate-term outcomes, there is also a need for long-term follow up of transplant recipients. Outcomes registries, such as those maintained by the CIBMTR and EBMT, are important in facilitating additional clinical research. The CIBMTR maintains a large database of clinical information on the outcome of HCTs performed in 500 transplant centers in nearly 50 countries. The database includes information on more than 370,000 transplant recipients. Data quality and consecutive registration are ensured through extensive computer checks and on-site audits. Data collection is through a web-based data entry program. Some important questions, such as results of HCT in specific patient groups and rare diseases, analysis of prognostic factors, evaluation of new transplant regimens, comparison of HCT with nontransplant therapy, defining intercenter variability in practice and outcome are difficult to address in randomized trials and can be studied using registry data. Analysis of outcomes after transplantation needs an understanding of statistic methodologies such as multistate modeling. Such models involve competing risks problems such as the study of relapse versus death in remission or the complex interrelationship between engraftment, transplant complications (such as infection or GVHD), and primary events such as death or relapse.²¹ Outcomes registries also provide a platform to analyze the availability, access, disparities, and economics of HCT. A biospecimen repository maintained by the NMDP and associated with the CIBMTR database allows the linkage of clinical and immunologic data for analysis and has led to important insights into transplant immunobiology.

LONG-TERM SURVIVAL AFTER ALLOGENEIC TRANSPLANTATION

Most deaths related to HCT occur within the first 2 years. However, an analysis of 2 year survivors found that, compared with age and nationality matched death rates among the general population, subsequent survival was still inferior for HCT recipients.²² Overall, 85% of 2-year survivors were still alive at 10 years post-HCT. Late relapse was the major cause of late deaths and was associated with advanced disease at HCT. Older age and GVHD were the other major predictors of late mortality.

The number of long-term HCT survivors is growing. Most 5-year survivors are well, off all immune suppression and leading normal lives. However, transplant recipients remain at risk for late complications including late infections, cataracts, abnormalities of growth and development, thyroid disorders, chronic lung disease and avascular necrosis. There is also an increased incidence of leukemias, myelodysplasia, and solid tumors in transplant recipients compared with the general population. Lifelong surveillance is necessary, as is increased awareness of late complications among the many nontransplant physicians who will care for these patients. Recommended long-term follow up of HCT recipients is summarized in [Box 104.4](#).

DISEASE-SPECIFIC INDICATIONS FOR ALLOGENEIC TRANSPLANTATION

Acute Myeloid Leukemia

There is general agreement that most patients under the age of about 60 years who fail conventional therapy and who have good performance status are best treated with allogeneic transplantation if an appropriate related or unrelated donor is available. HCT is not recommended for those with favorable risk cytogenetics in first complete remission (CR1).

The National Comprehensive Cancer Network (NCCN) guidelines, widely used to guide cancer therapy in the US, distinguishes between patients ≤ 60 versus those > 60 years. Among younger patients, the panel recommended a postremission strategy based on factors such as the expected relapse rates with high dose cytarabine therapy alone, salvage treatment options at relapse and patient-specific comorbidities that predict for TRM. The guidelines uniformly endorsed allogeneic HCT, from related or unrelated donors including cord blood HCT, in first CR for patients with unfavorable cytogenetic or molecular abnormalities, therapy-related AML or prior myelodysplasia. Among those older than 60 years, the recommendation was to consider HCT as an early option in those achieving a CR and as treatment for induction failure only in patients with low volume residual disease. For relapsed AML, HCT was recommended irrespective of age but only after a second CR was achieved or in the context of a clinical trial. For patients with acute promyelocytic leukemia, the recommendation was to reserve allogeneic HCT for relapsed patients with persistent disease despite salvage therapy.

The ASBMT evidence-based policy for allogeneic HCT in AML recommends HCT in the relapse setting (after achievement of CR2) and in patients with poor-risk cytogenetics in first remission. The ASBMT guidelines did not routinely recommend: allogeneic HCT for patients with intermediate risk cytogenetics; or the routine use of myeloablative conditioning for patients over age 55 years. The European Leukemia-Net guidelines are mostly in line with the ASBMT evidence-based policy, but provide greater detail about allogeneic HCT in cytogenetically normal (CN) AML.²³ These guidelines recommend considering HCT for patients with CN-AML and unfavorable molecular markers, that is, those who lack the favorable genotypes of mutated nucleophosmin 1 (NPM1) without FMS-related tyrosine kinase 3-internal tandem duplication (FLT3-ITD) or mutated CCAAT/enhancer binding protein alpha (CEBPA). In addition, allogeneic HCT was endorsed for FLT3-ITD + AML.

A systematic review of various national guidelines found the following²⁴:

- Consistent recommendations that patients with relapsed or refractory disease or high-risk cytogenetics be considered for HCT early;
- Consistent recommendations that patients with good prognosis cytogenetics receive HCT only after failure of nontransplant therapy;
- Inconsistent recommendations for patients with intermediate risk disease or without a family donor regarding transplantation in first remission;
- Lack of consensus regarding the efficacy of reduced-intensity conditioning;
- Most national guidelines recommend a risk-based approach to guide selection of chemotherapy versus transplant approaches using factors such as patient age, comorbid conditions, disease phenotype at diagnosis and the number of cycles of therapy before remission.

Acute Lymphoblastic Leukemia

Allogeneic HCT in first remission from related or unrelated donors is generally accepted as the most effective available therapy for

patients with Philadelphia chromosome (Ph)-positive ALL. For adults with Ph-negative ALL, the appropriate timing of HCT is more controversial despite the largest prospective study (Medical Research Council/Eastern Cooperative Oncology Group [MRC/ECOG]) and a metaanalysis suggesting a survival advantage for those assigned to transplant in CR1.^{25,26} Allogeneic transplantation is currently considered by NCCN expert consensus as the best curative therapy for adult patients with high-risk features such as Ph+ ALL or those with a poor response to initial induction therapy and among adults with t(4;11) ALL. Evidence-based policy statement from the ASBMT recommended allogeneic HCT for standard-risk, young (<35 years) adults in first CR and for ALL in second or higher remission. Related and unrelated donor HCT were recommended as being similar in outcomes.²⁷ For those without suitable matched adult donors, cord blood grafts should be considered.

Chronic Myelogenous Leukemia

In general, HCT is indicated for patients whose initial presentation is in blast phase and should be considered for those with a suboptimal response or relapse while on tyrosine kinase inhibitors (TKIs). HCT

is also a consideration for patients who have BCR-ABL mutations that predict for TKI nonresponse (e.g., T325I mutation). It is important to establish a monitoring plan for early signs of progression and for mutation screening since outcomes are significantly better if HCT is performed before transformation to advanced disease. Definitions of suboptimal response and failure with TKIs and guidelines for monitoring have been developed.²⁸ European Leukemia-Net guidelines recently addressed timing of allogeneic HCT in CML.²⁸ Allogeneic HCT was recommended in all CML patients presenting in blast phase, and for the accelerated phase patients who do not achieve an optimal response. HCT transplantation was also recommended for TKI-treated chronic phase patients subsequently progressing to accelerated or blast phase, after achieving optimal disease control. For patients in chronic phase, recommendation was to reserve allogeneic HCT for those who are resistant or intolerant to at least one second-generation TKI, and in patients developing T315I mutation.

Chronic Lymphocytic Leukemia

Current NCCN guidelines recommend allogeneic HCT in chronic lymphocytic leukemia (CLL) for those of younger age with high-risk

disease (TP53 deletion, 11q deletion) in the frontline setting and for those with CLL relapsing shortly after initial response (<2 years) irrespective of cytogenetics. The EBMT consensus group has recommended allogeneic HCT as a reasonable treatment option for younger patients with nonresponse, or relapse (within 12 months) after purine analogue therapy.²⁹ Patients who relapse within 24 months after having a response to purine analogue-based combinations and patients with TP53 abnormalities and those with Richter transformation requiring treatment are also considered candidates for transplant evaluation. The role and timing of allogeneic HCT in the era of Bruton Tyrosine Kinase inhibitors will need to be redefined.

Diffuse Large B-Cell Lymphoma

The ASBMT panel recommends autologous transplantation as the treatment of choice for relapsed or refractory chemosensitive diffuse large B-cell lymphoma. Allogeneic HCT is a consideration in the context of clinical trials and in select situations such as autologous mobilization failure, persistent bone marrow disease, and after a failed autologous transplant.³⁰

Follicular Lymphoma

A systematic review by the ASBMT noted the lack of high-quality evidence regarding indications for allogeneic HCT in follicular lymphoma.³¹ The consensus panel recommended autologous HCT for relapsed disease or transformed follicular lymphoma. In the allogeneic setting, RIC was considered an acceptable alternative to myeloablative regimens. The panel found no differences in outcomes between HLA identical sibling donors and matched unrelated donors. Given the efficacy of rituximab-based salvage treatments and autologous HCT for follicular lymphoma, allogeneic HCT is generally used for patients who have failed, are likely to fail, or are unable to proceed to salvage autologous HCT. However, late application of allogeneic HCT may be less effective especially for chemotherapy refractory disease. The NCCN guideline panel recommended autologous transplantation in second or third remission as a standard consolidative strategy for relapsed follicular lymphoma.³² Allogeneic HCT was a consideration for highly selected patients and those with histologic transformation to a higher grade (especially in the context of a clinical trial).

Mantle Cell Lymphoma

NCCN guidelines recommend autologous transplantation as an adjunct to initial therapy in eligible patients.³² Expert opinion is that allogeneic HCT has a limited role as upfront consolidation in chemotherapy-sensitive disease. Given the poor prognosis of recurrent mantle cell lymphoma and the curative potential of allogeneic HCT, it is a reasonable option for patients relapsing after upfront autologous transplantation or those with chemotherapy refractory disease.

T-Cell Lymphoma

NCCN guidelines recommend consideration of allogeneic HCT in the relapsed or refractory setting in T-cell lymphoma.³² In cutaneous T-cell lymphoma, allogeneic HCT is considered in the setting of progressive or refractory stage IIB–IV disease after failure of biologic agents and at least one line of chemotherapy.

Hodgkin Lymphoma

NCCN guidelines currently consider allogeneic HCT in progressive or relapsed Hodgkin lymphoma as a category 3 recommendation

(major disagreement) and recommend that this treatment should therefore ideally be performed as part of a clinical trial.

Multiple Myeloma

The NCCN guidelines consider allogeneic HCT with myeloablative conditioning as an accepted option in the setting of a clinical trial, in those responding to primary therapy or with primary progressive disease. The guidelines did not recommend allogeneic HCT with nonmyeloablative conditioning alone as an option. RIC with allogeneic HCT following autologous HCT was considered a category 2A recommendation (reflecting uniform NCCN consensus, based on lower-level evidence including clinical experience, that the recommendation is appropriate). Allogeneic HCT in the relapsed setting after a prior autograft was considered a grade III recommendation reflecting major disagreement.

UNRELATED DONOR HEMATOPOIETIC CELL TRANSPLANTATION

Effie W. Petersdorf and Claudio Anasetti

The outcomes of unrelated donor hematopoietic cell transplantation (HCT) have greatly improved as a result of better understanding of the diversity of genes that give rise to host-versus-graft (HVG) and graft-versus-host (GVH) allorecognition. Development of robust typing methods that define functional variation of human leukocyte antigen (HLA) genes have greatly accelerated understanding of gene–gene interactions that lead to graft failure, graft-versus-host disease (GVHD), and graft-versus-leukemia (GVL). Continued growth of registries of volunteer donors worldwide now provides the potential for identifying suitable donors for up to 75% of white patients in need of a transplant. The major challenges are to increase the safety and efficacy of unrelated donor HCT therapy through improved prevention and treatment of GVHD while leveraging control of leukemia through GVL effects. For unrelated HCT to be more widely applied to patients of diverse ethnic and racial backgrounds, more information on permissible HLA mismatches is needed so that mismatched donors can be safely used when matched donors are not available. This chapter chronicles genotyping methods used for donor selection and the clinical results of unrelated donor HCT in the era of DNA typing for *HLA* genes.

DONOR IDENTIFICATION AND LIKELIHOOD OF TRANSPLANTATION

The field of unrelated donor HCT has witnessed a rapid growth over the past 25 years. Data from the Center for International Bone Marrow Transplant Research (CIBMTR) show that among all allogeneic transplantations performed in the United States, the number of transplants from unrelated donors has exceeded that from related donors since 2006 (<http://www.CIBMTR.org>). Similar statistics from the European Group for Blood and Marrow Transplantation show that 52% of all allogeneic transplants are performed with unrelated donors (<http://www.ebmt.org>). The primary indications for unrelated donor HCT are acute myeloid leukemia, myelodysplastic syndrome/myeloproliferative disorders, acute lymphoblastic leukemia, non-Hodgkin lymphoma, and other nonmalignant disorders. Between 2002 and 2006, patients older than 60 years of age comprised the fastest growing group of transplant recipients as a result of the introduction of nonmyeloablative and reduced-intensity conditioning regimens (<http://www.CIBMTR.org>).

Unrelated HCT has been made feasible by the establishment of registries of volunteer donors worldwide. The Anthony Nolan Appeal was the first effort to demonstrate the feasibility of donor recruitment. Now known as the Anthony Nolan Research Institute, this registry was the first to promote access to HLA-matched bone marrow (BM) donors for patients around the world. In the United States, early efforts for donor recruitment were spearheaded by individual centers. Growing interest in unrelated donor HCT led the US Congress to authorize the creation of a national registry comprising a network of donor centers, transplant centers, and a national coordinating center through the Transplant Act of 1984. Two years later, a federal contract to establish a national registry was awarded to the National Marrow Donor Program (NMDP). In the Netherlands, Professor Jon J. van Rood led the Europdonor Foundation in the collection of HLA data from donor registries around the world and in the formation of a database of HLA phenotypes known as Bone Marrow Donors Worldwide (<http://www.bmdw.org>). Continued

growth in registry size worldwide has increased the chances that well-matched donors can be identified. The NMDP registers 52,000 new donors each month (<http://www.bethematch.org>). Today, more than 10.5 million donors are available through the NMDP, and more than 25 million donors are available through international cooperative agreements with registries around the world (<http://www.worldmarrow.org>).¹ With this database of 25 million donors, North American white patients have a 75% chance of identifying an unrelated donor matched at HLA-A, HLA-B, HLA-C, and HLA-DRB1 (HLA “8/8”).² This number increases to 97% if the donor selection criteria are relaxed to accommodate one HLA mismatch (HLA “7/8”). The situation is not as favorable for patients of non-European white background. For African Americans, the likelihood of finding an HLA 8/8-matched donor is only 19% but improves to 76% with HLA 7/8 donors. These statistics emphasize that although the total number of donors is climbing, the challenges for the future remain achieving the ideal optimal registry size and composition to improve the odds that every patient in need of a transplant has at least one suitable donor.

The availability of HLA-matched donors is only one potential barrier to transplantation for patients. In a single center study of 531 patients who initiated a search for an unrelated donor,³ an 8/8 HLA-A, HLA-B, HLA-C, HLA-DRB1-matched donor was available for 54% of these patients; a further 30% had a donor with a single HLA mismatch, and 16% had no suitable donor. Factors that increased the chances of a patient undergoing unrelated donor transplantation included race (white patients are more likely; $p = .03$), younger age ($p = .01$), lower disease risk ($p = .005$), and availability of an HLA 8/8-matched donor ($p = .005$; [Box 105.1](#)). The reasons for patients not pursuing transplant can be varied, but most often are caused by disease progression, alternative treatment plan choices, and medical ineligibility. Having a suitable donor not only allowed patients to reach transplantation but also improved the overall survival of patients with good performance status, compared with not having a suitable donor.³

DONOR EVALUATION AND SELECTION

Selection of unrelated donors includes consideration for the level of the HLA tissue-type match with the recipient and the presence of recipient antidonor HLA antibodies, which place the patient at high risk for nonengraftment in the setting of HLA mismatching.⁴ One of the earliest studies to highlight the importance of anti-HLA antibodies in nonengraftment found an over twofold higher risk of graft failure after haploidentical related donor transplantation when the patient possessed antidonor lymphocytotoxic antibodies.⁵ More recently, anti-HLA-DP antibodies were associated with graft failure after transplantation from otherwise HLA-A, HLA-B, HLA-C, HLA-DR, HLA-DQ-matched unrelated donors.⁶ The increased utilization of cord blood sources for stem cells in transplantation has prompted evaluation of the role of anti-HLA antibodies in cord blood, and the experience has paralleled that of unrelated donor transplantation.^{7–11} Collectively, this experience has led to the formulation of strategies for antibody screening before allogeneic transplantation.¹²

Evaluation of unrelated donors includes a screening medical history, physical examination, and laboratory testing for risks

BOX 105.1**Clinical Relevance to Reaching Transplantation From the Initiation of an Unrelated Donor Search: Patient and Donor Factors**

Outcome	Patient Factors	Donor Factors
Probability of the patient reaching transplantation	Increased age ^a	HLA-A, HLA-B, HLA-C, HLA-DRB1, HLA-DQB1 match status ^c
Probability of patient survival	Advanced disease risk ^b Karnofsky performance status (KPS) ^a	Donor availability ^d

After the initiation of a search for an unrelated donor, older patients with more advanced disease and no HLA-matched donor are associated with lower odds of reaching transplantation. Patients whose Karnofsky performance status is 90% to 100% and who have an available donor have significantly reduced hazard of death.^a

associated with transmissible elements akin to blood transfusion donors. Special focus is placed on risks of transmission of hepatitis, human immunodeficiency virus (HIV), malaria, West Nile virus, transmissible spongiform encephalitis (Creutzfeldt-Jacob disease), and Chagas disease. Donor screening includes blood tests for HIV 1 and 2, hepatitis B virus, hepatitis C virus, *Treponema pallidum*, human T-cell lymphotropic virus I and II, and cytomegalovirus.

Increased awareness for the health and safety of the unrelated donor has led to the establishment of standards for donation.^{13,14} These standards include donor recruitment, confidentiality, health assessment and eligibility, donors as research participants, and adverse events following donation. With the use of peripheral-blood stem cells as a primary source of progenitor cells for transplantation,¹⁵ a comprehensive review of the long-term effects of granulocyte colony-stimulating factor has not revealed increased incidence of hematologic malignancies among volunteer donors.¹⁶

PROCESS OF IDENTIFYING A SUITABLE UNRELATED DONOR

Human Leukocyte Antigen Typing and Donor Matching in the DNA Era: Genetics of the Human Leukocyte Antigen Complex

The advent of molecular techniques has made possible the definition of unique sequence variants (alleles) that encode each HLA molecule that is recognized by an antibody (antigen; Table 105.1). Polymorphism ensures that a large array of foreign peptides can be presented to the immune system by HLA molecules. As of October 2015, more than 3285 HLA-A, 4077 HLA-B, 2801 HLA-C, 1825 HLA-DRB1, 876 HLA-DQB1, and 587 HLA-DPB1 alleles have been defined in diverse human populations (<http://www.ebi.ac.uk/ipd/imgt/hla/stats.html>; Table 105.2). HLA nomenclature accommodates the steady discovery of new human variants. The HLA prefix is followed by a hyphen and the gene name (e.g., HLA-A). The gene is listed followed by an asterisk to separate the gene from the unique sequence (HLA-A*). The unique sequence name embodies up to four kinds of information, each delimited by a colon. The first set of numbers after the asterisk and before the first colon correspond to the serologic antigen equivalent (e.g., HLA-A*02 refers to sequences of the

TABLE 105.1**Common Definitions in Human Leukocyte Antigen Genetics**

Term	Definition	Example
Allele	Unique sequence of an <i>HLA</i> gene defined by molecular methods	DRB1*04:01 allele is a unique sequence defined as DR4 by serologic methods
Antigen	Antibody-defined protein	DR4 antigen is a serologically-defined protein product of an <i>HLA</i> gene
Haplotype	<i>HLA</i> genes inherited as a chromosomal unit	HLA-A1, HLA-B8, HLA-DR3 is a common haplotype among white populations
Genotype	Molecularly-defined <i>HLA</i> allele or sequence	Genotypically-matched donor and recipient are identical for the <i>HLA</i> alleles at a given <i>HLA</i> gene (e.g., HLA-DRB1*04:01)
Phenotype	Serologically-defined <i>HLA</i> protein or antigen	Phenotypically-matched donor and recipient share the same <i>HLA</i> antigen (e.g., HLA-DR4)

HLA, Human leukocyte antigen.

HLA-A2 antigen family). The second set of numbers provides the unique protein that correspond to the subtype (HLA-A*02:101). The third set of numbers indicate synonymous substitutions (HLA-A*02:101:01). The last series of numbers give information on non-coding variation often denoting expression (HLA-A*02:101:01:02 N). Letter suffixes are used to denote alleles that are not expressed (also known as “null”; N), low cell surface expression (L), a soluble secreted molecule not present on the surface of the cell (S), a cytoplasmic product not expressed on the cell surface (C), a protein with aberrant expression (A), and a sequence of questionable expression (Q). This new nomenclature has no limits on the number of digits for each of the four categories and in this way, obviates the need for constant renumbering.

DNA genotyping was adopted as the standard technique for selection of HLA-matched unrelated donors because unrelated individuals who are matched for HLA antigens may not necessarily share the same HLA sequences. If HLA alleles can be expressed in any combination and if inheritance of alleles were random, then the total estimated number of possible five-locus HLA-A, HLA-B, HLA-C, HLA-DRB1, and HLA-DQB1 genotypes would be exceedingly high, and the chances of identifying a fully matched donor would be very low. Clinical experience demonstrates that donor identification is successful, and is caused by the underlying genetic hallmark of the major histocompatibility complex known as linkage disequilibrium (LD). LD refers to the observation that HLA alleles

are found in association with each other at an observed frequency that exceeds their expected frequency. The probability of identifying a matched donor for a given patient is higher when the patient and donor share a similar ethnic background. Linked *HLA* genes are inherited from each parent as a haplotype in classic Mendelian fashion (see [Assessment of Human Leukocyte Antigen Haplotypes](#) later). *HLA* gene and haplotype frequencies provide important data for estimating optimal registry size and composition (<http://www.allelefrequencies.net>). Given the polymorphism of allele sequences that encompass variants of a single serologically defined antigen, it is not surprising that antigen-matched donor and patient pairs may differ for their alleles ([Table 105.3](#)).

HUMAN LEUKOCYTE ANTIGEN TYPING METHODS

HLA antigens important in transplantation were historically characterized using serologic typing methods. Typing by serology entails reacting alloantisera containing antibodies against cells in a complement-dependent microcytotoxicity assay. The development of standardized tissue typing reagents and methods of nomenclature for *HLA* genes have been facilitated by a series of 16 international

histocompatibility workshops ([Table 105.4](#)). The advent of polymerase chain reaction (PCR) in the 1980s revolutionized donor typing and matching and has greatly accelerated understanding of the *HLA* barrier in transplantation. Guidelines for typing volunteer donors using DNA-based methods are available. To transition from

TABLE 105.3 Definition of Matching for Alleles and Antigens

Match Status	Donor	Recipient
Antigen ^a -matched	HLA-B*44	HLA-B*44
Antigen-matched and allele ^b -matched	HLA-B*44:02	HLA-B*44:02
Antigen-matched but allele-mismatched	HLA-B*44:03	HLA-B*44:02
Antigen-mismatched	HLA-B*44	HLA-B*27

Human leukocyte antigen (HLA) alleles and antigens are designated according to the World Health Organization Nomenclature for Factors of the HLA System.

serologic to DNA-based methods, development of dictionaries of HLA alleles and antigen equivalents has become a necessity because many donors in the registries have been typed only by serologic assays. Interpretation and use of molecular typing data for donor search and selection has required the development of informatics programs.

Low-resolution DNA-based typing methods can define groups of alleles that are serologic equivalent (e.g., HLA-A*02 is DNA-defined and is equivalent to HLA-A2 that is serologically defined). Intermediate-resolution DNA typing methods provide additional information but not to the level of the complete DNA sequence that distinguishes one allele from another (e.g., the information is sufficient to delineate one group of alleles that include HLA-A*02:01 and another that include HLA*02:05 but cannot definitely assign the allele). High-resolution typing defines the unique DNA sequence of an allele (e.g., HLA-A*02:01). The term “6/6” matched refers to recipients and donors who share the same low-resolution-defined HLA-A, HLA-B, and HLA-DR genes. The term “8/8” refers to high-resolution matching at the four loci HLA-A, HLA-B, HLA-C, and HLA-DRB1. When HLA-DQB1 is added, “10/10” refers to high-resolution matching at the five loci. When HLA-DPB1 is added, “12/12” refers to donor–recipient pairs that are allele matched at all six genetic loci.

Several PCR-based HLA typing approaches are widely used by clinical tissue typing laboratories in support of unrelated HCT programs. The sequence-specific primer method uses a panel of primers to amplify the *HLA* locus or alleles. The PCR products are electrophoresed on a gel, and assignment of an HLA type is made by examining the composite pattern of positive and negative PCR reaction methods.

The sequence-specific oligonucleotide probe hybridization (SSOPH) method uses a solid phase support to immobilize PCR-amplified products. Nonradioactive-labeled oligonucleotide probes are allowed to hybridize to the support. Whereas probes with sequences complementary to the target DNA will hybridize, probes with as few as one nucleotide difference will fail to hybridize. Alternatively, SSOPH methods can use probes that are immobilized to the solid phase support and allow PCR-amplified target DNA to hybridize to the support.

A variation of the SSOPH method is oligonucleotide array technology. Arrays can simultaneously query multiple regions of polymorphisms in many *HLA* genes. Oligonucleotide probes can be designed to all four potential nucleotides, thereby enabling detection of new sequence polymorphisms with the same sensitivity and specificity as sequencing-based typing. Redundancy of probe sequences allows combinations of alleles to be distinguished in heterozygous individuals. Commercial platforms are now available and provide quality-controlled reagents for high throughput genotyping.^{17,18}

In addition to probe-based assays, Sanger sequencing of *HLA* genes has been an established method for high-resolution typing.¹⁹ Newer sequencing approaches include “next generation sequencing” (NGS) platforms that provide not only high resolution of HLA alleles but also have the advantage of short-range phasing of exons 2, 3, and 4 of class I genes, and of exons 2 and 3 of class II genes.^{20,21} The capability of linking sequences across exons substantially reduces the number of theoretical ambiguities of allele combinations. NGS approaches for HLA typing are supported by software for automated assignment of HLA alleles.²² Because many samples may be tested simultaneously, NGS is a cost-effective typing method for typing donors recruited into registries.^{23,24}

ASSESSMENT OF THE VECTOR OF MISMATCHING

The “vector” or “direction” of HLA compatibility between a donor and a recipient has biologic relevance in defining the risks of graft failure and GVHD. The concept of the vector was first demonstrated in cases of haploidentical related mismatched transplantation and defines HVG and GVH alloreactivity.²⁵ Patients homozygous for the mismatched *HLA* locus had lower rates of severe acute GVHD but

TABLE 105.5 Vector of Mismatch

Vector	Definition	Examples	
		Donor	Recipient
HVG	Presence of donor alleles not present in the recipient	DRB1*01:01,04:01 ^a DRB1*01:01,04:01 ^b	DRB1*01:01,04:10 DRB1*01:01,01:01
GVH	Presence of recipient alleles not present in the donor	DRB1*01:01,04:01 ^a DRB1*01:01,01:01 ^b	DRB1*01:01,04:10 DRB1*01:01,04:10

^aThese combinations contain bidirectional (both HVG and GVHD) mismatch vectors.

^bUnidirectional mismatches.

GVH, Graft-versus-host; HVG, host-versus-graft.

higher rates of graft failure than heterozygous patients. These clinical observations led to the establishment of the “vector of HLA incompatibility” in allogeneic transplantation: whereas the presence of donor alleles not shared by the recipient determines HVG allorecognition, the presence of recipient alleles not shared by the donor provides the immunologic basis for GVH allorecognition (Table 105.5). “Bidirectional” mismatching refers to the situation in which both HVG and GVH vectors are present at a given *HLA* locus. “Unidirectional” mismatching describes the situation in which either the donor or the recipient is homozygous for the same allele at the mismatched locus. A unidirectional GVH vector mismatch occurs when the donor is homozygous and the recipient is heterozygous and shares one allele with the donor (e.g., patient DRB1*01:01, *04:10 versus donor DRB1*01:01, *01:01). A unidirectional HVG vector mismatch occurs when the patient is homozygous and the donor is heterozygous and shares one allele with the patient (e.g., patient DRB1*01:01, *01:01 versus donor DRB1*01:01, *04:01).

Clinical outcomes analyses that evaluate the association between HLA disparity and risk of graft failure or GVHD should specify the vector of incompatibility that is used to define the comparison groups. In a recent evaluation of unrelated donor transplants performed through the NMDP and CIBMTR,²⁶ unidirectional GVH vector mismatching among patients and HLA 7/8–matched donors was associated with similar risk as bidirectional HLA mismatches among HLA 7/8 transplant pairs. Patients who were homozygous at an *HLA* locus, receiving a transplant from a donor heterozygous at that locus (HLA 7/8 HVG vector mismatch) had lower risk of GVHD than patients receiving an HLA 7/8 transplant involving a GVH vector mismatch. These observations are consistent with the early haploidentical transplant experience and demonstrate the importance of the HLA vector of incompatibility in defining risks of GVHD and graft failure.

ASSESSMENT OF HUMAN LEUKOCYTE ANTIGEN HAPLOTYPES

Patients who are candidates for allogeneic transplantation undergo a pedigree analysis to determine the availability of potential HLA genotypically identical siblings who could serve as a donor (Box 105.2). The family study, which includes typing of the proband’s mother, father, and all full siblings, provides an internal verification of the patient’s HLA haplotypes. Because *HLA* genes segregate in classic Mendelian fashion, the probability that a sibling inherits the same parental haplotypes is 25% (genotypically identical). The probability that a sibling inherits one identical paternal or maternal haplotype plus one nonshared haplotype is 50% (haploidentical). The probability of inheriting neither of the same haplotypes is 25% (complete mismatch).

When no related donor is available or suitable, a search for an unrelated donor is initiated. A search of all available international registries today includes consideration of more than 25 million donors worldwide (<http://www.nmdp.org>; <http://www.worldmarrow.org>). In the assessment of every unrelated donor, matching for each *HLA* genetic locus allele is considered. However, gene-by-gene identity for *HLA-A*, *HLA-B*, *HLA-C*, *HLA-DR*, and *HLA-DQ* between two unrelated individuals does not necessarily signify that the *HLA* alleles are linked on the same chromosomal haplotype. Hence it is possible

for two unrelated individuals who share the same *HLA* genotype to have different *HLA* haplotypes. The clinical significance of haplotype matching is described in the section entitled [Beyond Classic HLA: Major Histocompatibility Complex Resident Variation](#).

CLINICAL IMPORTANCE OF DONOR HLA MATCHING IN CASES OF UNRELATED DONOR HCT

The first successful human allogeneic BM transplantations were performed in 1968. Early clinical experience in allogeneic transplantation identified both *HLA* and non-*HLA* factors as important in defining posttransplantation complications. Donor *HLA* mismatching was identified as a risk factor for graft failure after HCT from relatives. Non-*HLA* factors associated with an increased risk of graft failure included transplantation of a lower BM cell dose, use of T cell-depleted BM, and transplantation of BM from a cross-match-positive donor (presence of antidonor lymphocyte antibodies in the patient's serum pretransplant). *HLA* mismatching was also shown to increase the incidence and severity of acute GVHD.

Use of *HLA*-matched unrelated donors as the source of BM was first applied in the case of a patient with severe aplastic anemia. Durable engraftment and immunologic reconstitution were early barriers to successful unrelated donor HCT. As clinical experience matured and tissue typing methods became more robust, unrelated donor HCT was established as a therapeutic approach for treatment of hematologic disorders when an *HLA*-identical sibling is not available. DNA-based methods have become established as the gold standard for *HLA* testing because serologically identical recipients and potential unrelated donors can be mismatched for one or more alleles that are identified by DNA testing methods.

The collective worldwide experience demonstrates that patients have superior outcome after *HLA*-matched unrelated HCT than after *HLA*-mismatched transplantation ([Table 105.6](#)). The general recommendations for donor selection are: (1) If the patient has many potential 8/8 donors, additional matching for *HLA-DQB1* (*HLA* 10/10) and *HLA-DPB1* (*HLA* 12/12) may further enhance patient outcomes. (2) When an *HLA* 8/8- or 10/10-matched donor cannot be identified, use of a donor mismatched for a single allele can be considered (see [Table 105.6](#)). A mismatch for *HLA-DQB1* alone seems forgiving (*HLA* 9/10), but mismatch for *HLA-DQB1* plus another locus appears to increase mortality. Among *HLA-A*, *HLA-B*, *HLA-C*, *HLA-DRB1*, *HLA-DQB1* 10/10-matched donors, criteria for the selection of donors with one *HLA-DPB1* (*HLA* 11/12) mismatch have recently become available, and provide additional means to optimize overall transplant outcomes. (3) Multiple mismatches are less well tolerated and should be limited. (4) When *HLA-DRB1*-mismatched donors are identified, assessment of *HLA-DRB3*, *HLA-DRB4*, or *HLA-DRB5* may help to uncover coincident mismatching at these loci; cumulative mismatching at multiple *HLA-DRB* genes increases risks after transplantation. (5) Permissible *HLA*

BOX 105.2 Principles of Patient-Donor Human Leukocyte Antigen Matching and Selection

Establish the Patient's Haplotypes

When an allogeneic transplant is being considered a part of the treatment regimen for a patient, *HLA* typing of the patient and first degree relatives is performed early in the planning process to identify suitable related donors. Typing of family members provides two key pieces of information: (1) the availability of an *HLA* genotypically-matched sibling or a suitable haploidentical related donor, and (2) confirmation of the patient's *HLA* tissue type. When both parents of the patient are available for tissue typing, the family study allows confirmation of the paternal and maternal *HLA* haplotypes, and this information is invaluable for predicting the probability of finding unrelated donors. In the absence of parents, tissue typing of available siblings might yield sufficient information for the four parental haplotypes.

Characterize Human Leukocyte Antigens at High Resolution

DNA-based methods are the mainstay for tissue typing. Molecular methods provide information of allelic variants at *HLA-A*, *HLA-B*, *HLA-C*, *HLA-DRB1*, *HLA-DQB1*, and *HLA-DPB1* that have been shown to have biologic implications in graft-versus-host and host-versus-graft allorecognition. When a search for an unrelated donor yields potential registry donors that lack high-resolution typing, often knowledge of the patient's haplotypes may help to direct typing of donors that have the highest probability of matching the patient's alleles.

Determine the Presence of Antidonor Antibodies Against Mismatched Human Leukocyte Antigen Mismatches

The risk of graft failure is significantly increased when the patient has mounted an anti-*HLA* response against donor-mismatched antigens. Screening donors with patient sera, especially when the donor has known *HLA* mismatches, is an essential step of donor selection. When no *HLA*-matched donors are available, avoiding the use of donors whose *HLA* mismatches are the same specificity as the anti-*HLA* antibodies in the patient may reduce the risk of graft failure.

Identify Backup Donors

Efficiency of the unrelated donor search process is highly dependent on the racial and ethnic background of the recipient and on the composition of the donor registries. The availability of unrelated donors must also factor into the planning of the transplant, including the identification of a primary donor and backup donors.

TABLE 105.6 Impact of Specific Single-Locus *HLA* Mismatches on Risks After Unrelated Donor Transplantation

Mismatched Locus	Graft Failure	GVHD	GVL Effect	Survival	Notes
<i>HLA-A</i>	↑ ^{27,28}	↑ ^{29,30}		↓ ^{29,31}	Allele and antigen mismatches are similarly risky; in some reports, antigen mismatches are riskier than allele mismatches.
<i>HLA-B</i>	↑ ²⁸	↑ ^{29,30}		↓ ³¹	Insufficient data on allele versus antigen mismatches.
<i>HLA-C</i>	↑ ^{28,32}	↑ ^{29,30,33,34}	Yes ³¹	↓ ^{31,33}	Antigen mismatches much riskier than allele mismatches. C*03:03,03:04 mismatch is low risk. GVL effect present.
<i>HLA-DRB1</i>		↑↓ ^{29,30}		↓ ³¹	Insufficient data on allele versus antigen mismatches. Global trend for lower survival.
<i>HLA-DQB1</i>		↓ ²⁹			Only when <i>DQB1</i> is the only mismatched locus (<i>HLA</i> 9/10).
<i>HLA-DPB1</i>		↑ ³⁵⁻³⁸	Yes ³¹	↓ ³¹	GVL effect present.

HLA, Human leukocyte antigen; GVHD, graft-versus-host disease; GVL, graft-versus-leukemia.

mismatches have been proposed as defined by polymorphism for selected HLA class I residues that participate in selecting the peptide repertoire or direct contact with the T-cell receptor. (6) Polymorphisms outside of the classic *HLA* loci may be clinically significant.

HUMAN LEUKOCYTE ANTIGEN–MATCHED UNRELATED DONOR HEMATOPOIETIC CELL TRANSPLANTATION

The impact of more complete and precise donor HLA matching is dramatic. Overall survival after transplantation for the treatment of acute myeloid leukemia, myelodysplastic syndrome, acute lymphoblastic leukemia, and CML from an HLA 8/8-matched unrelated donor can approach the results observed after HLA-identical sibling transplantation (<http://www.marlow.org>). For all modalities, the underlying disease diagnosis and stage of disease at transplantation remain the most important prognostic features that affect disease-free survival. The general rules for donor HLA matching are applicable to different graft sources (BM or peripheral blood stem cells) and to different intensities of the conditioning regimen (ablative, reduced intensity, nonmyeloablative) in which HLA matching is globally associated with better outcome than HLA mismatching.^{39,40}

SINGLE-LOCUS MISMATCHED UNRELATED HEMATOPOIETIC CELL TRANSPLANTATION

Early studies of patients receiving HLA antigen-matched, MLC-compatible unrelated donor HCT uniformly reported a relatively high incidence of acute GVHD and transplant-related mortality (TRM) compared with transplantations from HLA-identical siblings. The possibility that undetected donor–recipient mismatching for HLA allele variants could be responsible for increased complications in cases of unrelated donor HCT suggested that the safety and success of unrelated donor transplantations could be improved by further advances in HLA typing and donor matching and prompted close examination of serologically identical unrelated transplant pairs using DNA typing methods.

The importance of high-resolution matching of unrelated donors for HLA-A, HLA-B, HLA-C and HLA-DRB1 was confirmed by several large analyses (see Table 105.6). In summary, when an HLA-matched donor is not available, distinguishing allele mismatches and antigen mismatches at HLA-A, HLA-B, and HLA-C provides an algorithm for the prioritization of mismatched donors; in general, avoidance of antigen mismatches is preferred.

The importance of the HLA-DP locus has been demonstrated in several recent analyses in which the role of specific HLA-DPβ epitopes as well as level of HLA-DP expression have been shown to have clinical relevance, as described later. Population studies have shown that HLA-DP is unique among other *HLA* genes because of very weak LD between HLA-DP and HLA-A, HLA-B, HLA-C, HLA-DR, and HLA-DQ. As a result, fewer than 20% of HLA-A, HLA-B, HLA-C, HLA-DRB1, and HLA-DQB1-matched unrelated donor pairs are also matched for HLA-DP. Retrospective examination of HLA-DP has required very large transplant populations so that sufficient numbers of HLA-DP-matched pairs could be compared with mismatched pairs. Furthermore, the measured effects attributed to single loci in early studies likely measured additive effects of HLA-DP with HLA-A, HLA-B, and HLA-DR. HLA-DP does function as a classic transplantation antigen with respect to GVHD. Mismatching for two DPB1 allele increases the risk of acute GVHD compared with one or no HLA-DP mismatch. Analysis of the structural basis of HLA alloreactivity sheds light on specific epitopes encoded by HLA-DP exon 2 that are responsible for increased GVHD risk.⁴¹

New information from the Japan Marrow Donor Program (JMDP) suggests that the beneficial graft-versus-leukemia (GVL) effect is not equally apparent for every HLA mismatch.⁴² In a retrospective analysis of 7898 Japanese patients transplanted with T-cell replete marrow from Japanese unrelated donors, only HLA-C and HLA-DPB1 mismatching were associated with lower risk of relapse.

These novel observations suggest that the underlying mechanisms leading to GVL may involve T- and/or NK-mediated effects of these two loci.

Beyond *HLA-A*, *HLA-B*, *HLA-C*, *HLA-DR*, and *HLA-DQ* genes, a series of class II genes known as *HLA-DRB3*, *DRB4*, and *DRB5* exist on certain HLA-DRB1 haplotypes and have recently been shown to contribute to clinical outcome.⁴³ *HLA-DRB3* is linked to HLA-DR3, DR5, and DR6 haplotypes; *DRB4* to HLA-DR4, DR7, and DR9 haplotypes, and *DRB5* to DR2 haplotypes. When a patient and donor are mismatched HLA-DRB1, the probability of additional mismatching at *DRB3/4/5* is increased on these specific HLA-DR haplotypes. The cumulative impact of multiloci mismatching inclusive of *DRB3/4/5* on mortality was significant, particularly when three or more mismatches are present. These data suggest that when an HLA-DRB1-mismatched donor is identified, additional characterization of HLA-DRB3/4/5 on relevant HLA-DR haplotypes, is warranted.

Selection of Mismatched Donors: Emerging Concepts for Permissible Mismatches

Given that many patients have only HLA-mismatched unrelated donors,² research efforts have been focused on identifying properties of HLA mismatches that do not increase risks to patients, also known as “permissible HLA mismatches” (Box 105.3). Three major

BOX 105.3

Research in Progress: New Immunogenetic Factors for Consideration in Transplantation

Permissible HLA Mismatches

When an HLA-matched donor is not available, criteria for the selection of mismatched donors is needed. There are currently four concepts for evaluating HLA-mismatched donors. Extensive registry and transplant center data suggest that where possible, limiting the total number of HLA mismatches is associated with lower posttransplant complications.

Second, defining a given patient–donor mismatch as “allele” (detectable by high-resolution DNA methods, for example HLA-A*02:01) or “antigen” (equivalent to the serologic phenotype of the antigen, for example HLA-A2) has utility in lower risks, particularly for the *HLA-C* locus where HLA-C allele mismatches have less associated risk of mortality than HLA-C antigen mismatches.

A third area of active research is the definition of residues of class I and II molecules and their amino acid substitutions that are associated with transplant risks. Hypervariable positions having direct influence on the peptide-binding region of the molecule have been most commonly studied and show that some amino acid substitutions at certain positions are more detrimental than others. The most noteworthy residues identified to date include residues 99 and 116 of HLA-C and residue 9 of HLA-B. The ability of T cells to recognize these epitopes lends functional support to this model.

A fourth new concept is the role of the level of HLA expression. Mismatched patient HLA-C antigens that are expressed at lower levels on the cell surface are associated with lower risk of graft-versus-host disease than patient antigens expressed at higher levels. Mismatching between low-expression donor HLA-DP and high-expression patient HLA-DP alleles is associated with high risks of clinically significant GVHD.

Haplotypes

The Japanese transplant experience strongly suggests a role for highly conserved HLA haplotypes and transplant outcome.

Novel Markers

Surveys of the major histocompatibility complex with the aid of single nucleotide polymorphism markers have uncovered undetected variation that is associated with transplant outcome. These data suggest that HLA haplotype encode additional genes that have clinical relevance. Future research into the identification of the causative genes will shed light on the pathways involved in graft-versus-host allorecognition.

GVHD, Graft-versus-host disease; HLA, human leukocyte antigen.

approaches have been taken including understanding whether there are differences in risks associated with patient–donor mismatching for (1) DNA-defined alleles (“high-resolution mismatches”) compared with antigens (“low-resolution mismatches”); (2) specific amino acid positions, or groups of alleles defined by T-cell reactivity (“T-cell epitope” or TCE mismatches), and (3) low- or high-expression HLA allotypes.

Alleles and Antigens

With the availability of molecular methods for defining the HLA alleles of transplant recipients and donors, it now is possible to evaluate the impact of the location and number of mismatched amino acid residues as potential factors defining the permissibility of a mismatch. In a single-center study of graft failure after myeloablative unrelated HCT, donor–recipient mismatching for HLA-A, HLA-B, or HLA-C antigens conferred greater risk for graft failure than did single allele mismatches at these loci.⁴⁴ The allele and antigen mismatches represented in this study population differed in the number of nonsynonymous substitutions (a change in amino acids) and in the location of the mismatch in the α_1 and α_2 domains of the molecule, suggesting that multiple mismatches for residues that affect peptide binding and T-cell receptor contact might have been instrumental in evoking T-cell responses that led to graft failure in these patients.

Single-center and registry-based studies have examined allele and antigen mismatches and the risks conferred by each kind of mismatch on TRM and survival (see Table 105.6). In an early CIMBTR analysis, each HLA-A, HLA-B, HLA-C, or HLA-DRB1 mismatch was found to confer a 9% to 10% lower overall survival compared with a baseline of 8/8 allele matches.⁴ A follow-up registry analysis of patients receiving growth factor mobilized peripheral blood stem cell transplants confirms the high-risk nature of HLA-C antigen mismatches, more so than HLA-C allele mismatches.³⁹ Among HLA-C allele mismatches, the high frequency mismatch between C*03:03 and C*03:04 appears to be associated with risks comparable with HLA-C–matching, described in detail later in the section entitled *The Level of HLA Expression*. These data are consistent with the graft failure study discussed earlier in which a predominance of HLA-C mismatches and allele disparities did not contribute to increased risk. These studies demonstrate that avoidance of HLA-A, HLA-B, HLA-C, and HLA-DRB1 allele mismatches lowers the risks of posttransplant complications.

Mismatching at Amino Acid Residues and T-Cell Epitopes

The hypothesis that donor–recipient mismatching at certain amino acid substitutions in the class I HLA molecule may be associated with higher posttransplant risks compared with mismatching at other residues was first tested by Ferrara et al.⁴⁵ Amino acid mismatching at residue 116 was found to be associated with significantly increased risks of acute GVHD and TRM compared with matching at this residue. Following these intriguing findings, the JMDP evaluated 5210 Japanese recipients of unrelated donor transplants to identify mismatched residues of HLA-A, HLA-B, HLA-C, HLA-DRB1, HLA-DQB1, or HLA-DPB1 molecules that correlate with clinical outcome.⁴⁶ Analysis of each allele-defined mismatch yielded four HLA-A, one HLA-B, seven HLA-C, two HLA-DR/DQ, and two HLA-DP mismatch combinations to be significantly associated with increased posttransplant complications. Each allele was subsequently defined by its putative amino acid sequence, and all polymorphic donor–recipient mismatched positions at each locus were individually analyzed for associations. Donor–recipient mismatching for Tyr9–Phe9 of HLA-A and for Tyr9–Ser9, Asn77–Ser77, Lys80–Asn80, Tyr99–Phe99, Leu116–Ser116, and Arg156–Leu156 of HLA-C were identified to be clinically significant. When the study group was restricted to pairs matched at HLA-C for positions 77 and 80 that

define killer-cell immunoglobulin-like receptor (KIR) ligands, donor–recipient mismatching at positions 9, 99, 156, and 163 were found to correlate strongly with GVHD risk. This study demonstrates that mismatching for positions of HLA-A or HLA-C that participate in peptide binding is functional and provides a basis for defining nonpermissive HLA allele mismatches. Of the 10 mismatch combinations associated with GVHD risk, the JMDP explored whether the same mismatch combinations were involved in both GVHD and relapse (GVL effects) or only one.⁴⁷ In a population of 4643 transplants, 10 mismatch combinations (4 for HLA-C and 6 for HLA-DPB1) were statistically significantly associated with lowered relapse; however, only a subset were also involved in GVHD.

A recent CIMBTR analysis of HLA-matched and HLA-mismatched unrelated donor transplants performed in the United States has identified three critical amino acid substitutions of class I and their role in GVHD.⁴⁸ Patient–donor mismatching at residue 116 of HLA-C is associated with severe acute GVHD, and mismatching at residue 99 with increased transplant-related mortality. Residue 9 of HLA-B was identified as a susceptibility position, associated with increased risk of chronic GVHD. These results suggest that HLA mismatches do not confer equivalent risks to GVHD and relapse and that approaches for separating GVH from GVL may be possible through selected HLA combinations. Statistic models have been developed to predict peptide binding of HLA molecules as an approach to predict HLA alleles that lead to diverse binding of peptide and that may consequently affect T-cell recognition of HLA and its minors.

Initial observations suggested a role for HLA-DPB1 mismatching in graft failure.⁴¹ The importance of T-cell epitope (TCE) recognition of HLA-DPB1 mismatches in GVHD, relapse, and mortality was subsequently elucidated in a large population of unrelated donor transplants. In this retrospective analysis of 8539 transplants performed worldwide, HLA-DPB1 TCE groups were assigned according to alloreactive T-cell cross-reactivity patterns established in a patient with graft failure after transplantation for thalassemia.^{49,50} Compared with permissive HLA-DPB1 mismatches (i.e., outcomes similar for mismatches compared with matches), nonpermissive HLA-DPB1 mismatches (i.e., outcomes associated with mismatches were worse than those associated with other mismatches or matches) were associated with significantly higher risks of severe acute GVHD, nonrelapse mortality, and overall mortality. The TCE concept that mismatching at certain amino acid positions of HLA class I and II molecules may affect transplant outcomes differently than mismatching at other amino acid positions, has recently been validated by the NMDP/CIMBTR.⁵¹ In this large US study of 8003 transplants, nonpermissive HLA-DPB1 mismatching was associated with higher transplant-related mortality compared with permissive mismatches or HLA-DPB1 matches.

THE LEVEL OF HLA EXPRESSION

HLA expression has recently emerged as a key feature of alloimmunity in infections and autoimmune diseases including HIV-AIDS and Crohn disease.⁵² The level of expression of HLA-C and HLA-DP allotypes has recently been found to be an important feature of the permissibility of donor–recipient mismatching at these two loci. Whereas high expression of HLA-C is associated with low viral set-point in HIV-AIDS, high expression of HLA-C is associated with increased risk of Crohn disease. In a recent analysis of unrelated donor transplants mismatched for only a single HLA-C determinant, the level of HLA-C expression was found to be informative for permissive and nonpermissive HLA-C mismatches.⁵³ As the level of expression of the patient's mismatched HLA-C allotype increased, the risks of acute GVHD and nonrelapse mortality also increased. When mismatches were examined for C*03 and 07 (allotypes expressed at the lowest levels) and C*01 and 14 (allotypes expressed at the highest levels), mismatching for high-expression mismatches was associated with increased risk when the HLA-C mismatch was also mismatched at residue 116 and for natural KIR ligands. Residue 116 and KIR

ligand mismatches that were low-expression had similar risks as HLA-C matches.

The 3' untranslated region of the *HLA-DPB1* locus is resident to a single nucleotide polymorphism that affects the level of expression of HLA-DP allotypes, and the ability of hepatitis B–infected individuals to control infection from this virus. In unrelated donor transplantation, an HLA-DPB1 mismatch between a low-expression HLA-DPB1 donor allele and a high-expression HLA-DPB1 recipient allele was recently identified as a risk factor for severe acute GVHD. These data demonstrate that polymorphisms that reside within regulatory regions of *HLA* genes have clinical significance, and underscore a need for a more complete understanding of HLA expression in defining permissible HLA mismatches. Taken together, the results offer a new approach for understanding HLA-mediated immune responses in transplantation, infectious diseases, and autoimmune disorders.

BEYOND CLASSIC HLA: MAJOR HISTOCOMPATIBILITY COMPLEX RESIDENT VARIATION

Currently, gene-by-gene matching between recipients and unrelated donors is performed to approximate the haplotype matching that is feasible between genotypically identical sibling pairs. However, HLA-matched unrelated donors and recipients are not related to one another; therefore they are described as identical by state. This opens the possibility that genes other than classic HLA may be clinically relevant. The major histocompatibility complex (MHC) is the most diverse region in the human genome known to date. More than 300 loci have been verified within the extended 7.6-megabase (Mb) MHC region have immune function.⁵⁴ Hence, current donor matching is performed for less than 5% of the total gene content of the MHC.

In addition to the classic *HLA* loci, the MHC is residence to the nonclassic *HLA-E*, *HLA-F*, *HLA-G*, *MICA*, and *MICB* genes. Data suggest a role for HLA-E in transplant outcome.⁵⁵ Increased risk for bacterial infections and corresponding TRM at day 180 posttransplant were found in recipients transplanted from HLA-E*01:01,01:01 homozygous unrelated donors. HLA-E*01:03,01:03 homozygosity among HLA-identical siblings conferred protection against acute GVHD and TRM, leading to increased overall survival. These data point to the potential involvement of the innate immune system in GVHD. New information on *MICA* in transplantation has become available.⁵⁶ In a retrospective study of 236 patients transplanted from HLA-matched and HLA-mismatched unrelated donors, 8.4% were mismatched for *MICA*. The presence of *MICA* disparity was associated with higher risk of overall grades II–IV acute GVHD and higher gastrointestinal GVHD independent of HLA mismatching. Because the gastrointestinal epithelium is the sole organ where *MICA* is expressed, the data suggest that *MICA* serves as a classic transplantation antigen.

Mapping with microsatellite (Msat) markers was among the earliest approaches for discovering disease-causing variation in many model systems, including autoimmunity and cancer. Msats provide indirect information because Msats themselves are not functional. Their LD with putative functional genes, however, provides the basis for its application in estimating optimal donor registry size and composition and for donor selection. Studies have used Msats to query the MHC region for novel determinants. Tumor necrosis factor variation within the class III region of the HLA complex has recently been identified as a risk factor for transplant outcomes.⁵⁷ These studies provide key evidence that variation outside of the classic *HLA* genetic loci both exist and are potentially functional in transplantation.

More recently, with the availability of a complete sequence of the MHC, mapping with the use of single-nucleotide polymorphisms (SNPs) has provided investigators with a robust tool for disease mapping.⁵⁸ The MHC is characterized by LD of discrete segments or blocks of sequences that reside between *HLA* genes. Although the specific content of these blocks is under investigation, donor–recipient matching for these regions is associated with superior clinical

outcome. The map of the MHC continues to be refined for both simple variation such as that represented by SNPs to more complex variation, including insertions and deletions (<http://www.sanger.ac.uk/HGP/Chr6/MHC>). The content of several common HLA haplotypes, including HLA-A1, B8, DR3 and HLA-A2, B DR15, showcases the extreme levels of sequence conservation over long stretches of the MHC, upward of 4 Mb in some haplotypes.⁵⁸ This work importantly shows the need for similarly dense sequence information on common as well as rare haplotypes in all ethnicities and racial populations to understand how such variation may be clinically relevant.

How can knowledge of haplotype content facilitate the discovery of new transplantation determinants? The available sequence alignments demonstrate that the classic *HLA* loci serve as robust markers for the undetected linked variation on the haplotype. To test the hypothesis that the HLA haplotype serves as a tool for querying such areas outside of classic loci, a novel long-range phasing technique has been developed.⁵⁹ By physically linking *HLA-A* with *HLA-B* with *HLA-DR* on the same strand of DNA, this technique has been applied to test the hypothesis that HLA-identical unrelated donors and recipients encode different HLA haplotypes, and furthermore, haplotype mismatching is associated with increased posttransplant risks conferred by variation that is linked to the different haplotypes.⁶⁰ In this study, a homogeneous population of HLA-A, HLA-B, HLA-C, HLA-DRB1, HLA-DQB1 allele-matched unrelated transplants were characterized using the phasing method. Of these pairs, 20% were found to have different physical linkage of HLA-A, HLA-B, and HLA-DR. Haplotype mismatching was associated with a significantly increased risk of grade III–IV acute GVHD. The increased risk of GVHD was offset by lower relapse, leading to similar overall survival. This study demonstrates that variation linked to the haplotype is functional and that the HLA haplotype can be used as a surrogate marker for GVHD risk.

Fine mapping will entail comprehensive analysis of both simple and complex MHC variation. In this way, comparative sequences analysis of common and rare haplotypes continues to be an important research area.⁶¹ The JMDP carried out an extensive analysis of three commonly observed HLA haplotypes in their transplant population.⁶² This work has provided invaluable information on the degree of conservation within and across haplotypes of the Japanese population and provides insight into the possible genetic basis for differences in GVHD risk among Japanese patients compared with white patients. In North American populations, SNPs, the most common and simplest form of human genetic variation, have been used to identify candidate regions within the MHC that may harbor novel variants that have functional consequences in unrelated donor transplantation.^{63,64} In HLA-A, HLA-B, HLA-C, HLA-DRB1, HLA-DQB1-matched transplantation, two novel markers have been validated as determinants of survival and acute GVHD.⁶³ In single-locus mismatched unrelated donor transplantation, candidate markers have been identified and validation is underway.⁶⁴ The data in HLA-mismatched transplantation provides new information on susceptibility genes but also sheds light on the risks associated with mismatching for classic *HLA* genes. When the effects of SNP genotype or mismatching are accounted, comparison of mismatching at HLA-A, HLA-B, HLA-DRB1, and HLA-DQB1 relative to HLA-C demonstrates the deleterious nature of HLA-A, and HLA-C mismatching, but also highlights the permissive nature of HLA-DQB1 mismatches. These data point towards new understanding of the alloimmunogenicity of HLA in unrelated donor transplantation.

FUTURE DIRECTIONS

The HLA genetic system regulates the transplantation barrier. Clinical outcome after unrelated donor transplantation can be achieved with donor matching for the highly polymorphic *HLA* loci. When HLA disparity cannot be avoided, judicious selection of a donor with the fewest HLA mismatches and avoidance of certain loci may provide patients with the opportunity for lifesaving transplantation.

Disease stage remains a strong predictor of overall transplant outcome, and expediency in timing of transplantation for patients with high-risk disease is paramount. New research avenues include identification of novel MHC resident genetic variation that may contribute to risks of GVHD and TRM and the precise role of HLA region variation in preventing transplant complications and disease relapse.

HAPLOIDENTICAL HEMATOPOIETIC CELL TRANSPLANTATION

Ephraim Fuchs

Allogeneic hematopoietic stem cell transplant (alloHSCT) is a potentially effective treatment for a wide range of hematologic malignancies and nonmalignant hematologic or immunologic disorders. Sources of donor stem cells for alloHSCT include human leukocyte antigen (HLA)-matched siblings, suitably HLA-matched unrelated adult donors, partially HLA-mismatched unrelated donors, related or unrelated donor umbilical cord blood, or partially HLA-mismatched related (HLA-haploidentical ["haplo"]) donors. Historically, the paramount consideration in choosing between graft sources has been the degree of HLA match between donor and recipient. A fully HLA-matched sibling has been the preferred donor for alloHSCT because transplants from HLA-matched siblings have been associated with the lowest incidence of graft failure, graft-versus-host disease (GVHD), and nonrelapse mortality (NRM), as well as with the highest overall survival (OS) and event-free survival. Unfortunately, only 30% of patients referred for alloHSCT have an HLA-matched sibling, and the availability of closely matched unrelated donors varies significantly by patient ethnicity, being as low as 19% for African Americans or as high as 80% for white people of Northern European origin.¹ HLA mismatching between donor and recipient is associated with increased alloreactivity of donor and recipient T cells, leading to higher risks of GVHD and NRM, as well as to worse outcomes. In the past two decades, techniques have been developed to mitigate alloreactivity to the point that outcomes of HLA-haploidentical stem cell transplant (SCT) rival those of umbilical cord blood and unrelated donor (URD) transplants. This chapter starts by defining what is an HLA-haploidentical donor and presents the immunobiology of the immune response to allogeneic HLA molecules. A history of HLA-haploidentical hematopoietic cell transplantation (HCT) is provided, culminating in a presentation of modern approaches and results. Finally, considerations that are unique to or enabled by HLA-haploidentical HCT are discussed.

DEFINITIONS: WHAT IS AN HLA HAPLOTYPE, AND WHO IS AN HLA-HAPLOIDENTICAL DONOR?

A haplotype is a set of genes that are arranged closely together on a chromosome and are inherited as a biologic unit. The HLA locus on chromosome 6p13.2 comprises a set of tightly linked genes encoding molecules that present peptide antigens to T cells. The HLA locus contains three regions:

1. The class I region encodes the "classical" class I genes HLA-A, HLA-B, and HLA-C, which present antigens to CD8⁺ T cells, as well as nonclassical HLA-E, HLA-F, and HLA-G molecules.
2. The class II region encodes HLA-DRB1, HLA-DQB1, and HLA-DPB1, which present antigens to CD4⁺ T cells, as well as nonclassical class II molecules HLA-DM and HLA-DO.
3. The class III region encodes molecules not known to be involved in histocompatibility reactions.

An HLA haplotype is defined as the set of histocompatibility genes that are on the same chromosome 6 and so are inherited together. Each individual has two HLA haplotypes, one on the chromosome 6 inherited from the individual's mother and the other on the chromosome 6 inherited from the individual's father.

An HLA-haploidentical donor is a related donor who shares, by common inheritance, exactly one HLA haplotype with the transplant

recipient and differs by a number of HLA genes on the unshared HLA haplotype. When typing is performed for three HLA class I genes, HLA-A, HLA-B, and HLA-C, and three class II genes, HLA-DRB1, HLA-DQB1, and HLA-DPB1, HLA disparity between the HLA-haploidentical donor and recipient ranges from 0 to 6 alleles or antigens. By definition, a parent and a child are HLA haploidentical to each other, and each biological sibling or half-sibling of a patient has a 50% chance of being HLA haploidentical to each other. Other potential haplo donors include aunts, uncles, nieces, and nephews, who each have a 50% chance of being HLA haploidentical, and cousins, who have a 25% chance of being HLA haploidentical.

Mismatching of HLA alleles or antigens can occur in the graft-versus-host (GVH) direction only, the host-versus-graft (HVG) direction only, or bidirectionally. When the donor is homozygous for an HLA allele but the recipient is heterozygous at the same genetic locus, there is a mismatch in the GVH direction only. Conversely, when the recipient is homozygous for an HLA allele but the donor is heterozygous, there is a mismatch in the HVG direction only. HLA mismatches in the GVH direction stimulate GVHD, whereas HLA mismatches in the HVG direction stimulate rejection of the hematopoietic stem cell (HSC) graft by host T cells. The number of HLA mismatches between an HLA-haploidentical donor and recipient should be expressed as the number of mismatches in the GVH direction as well as the number of mismatches in the HVG direction. For example, the patient in Fig. 106.1 differs from sibling 2 by four antigens (and alleles) in the GVH direction and by five antigens (and alleles) in the HVG direction, and from sibling 3 by three antigens (versus four alleles) in the GVH direction and by three antigens (versus five alleles) in the HVG direction.

WHY HLA-HAPLOIDENTICAL BONE MARROW TRANSPLANT? (see Box 106.1)

Advantages and Limitations of Haploidentical Donors

The major advantages of the HLA-haploidentical donor option over the other donor types include:

1. *Near-universal availability of highly motivated donors:* Patients have an average of 2.7 potential HLA-haploidentical donors among first-degree relatives. By comparison, only approximately 30% of patients have an HLA-matched sibling, and availability of a URD genotypically matched at eight of eight alleles (HLA-A, HLA-B, HLA-C, and HLA-DRB1) ranges from 19% to 80%, depending on the recipient's ethnic background.¹
2. *Rapid availability:* The time to identify and mobilize an adult URD can be longer than 3 months for up to 25% of patients. An HLA-haploidentical donor can be identified and mobilized within 2 weeks to 1 month.
3. *Adequate doses of HSCs:* HLA-haploidentical grafts have sufficient doses of HSCs for transplant of adult recipients and of memory T cells for immune reconstitution. In contrast, the total dose of nucleated cells in a single umbilical cord blood unit may be suboptimal for engraftment in larger adults, leading to delayed immune reconstitution.
4. *Low cost of graft acquisition:* The costs of acquiring grafts from adult URDs and especially from umbilical cord blood banks can be substantially higher than acquiring them from related donors.

Fig. 106.1 HIGH-RESOLUTION HUMAN LEUKOCYTE ANTIGEN TYPING IN A REPRESENTATIVE FAMILY. (A) Nomenclature employed for high-resolution typing. The human leukocyte antigen (HLA) genetic locus is identified by the capital letter after the hyphen. The first two digits after the asterisk are the antigen designation, which facilitates comparisons of results of low- or intermediate-resolution versus high-resolution HLA typing. The four-digit code designates allele level type by high-resolution methods, such as sequence-based typing or a combination of sequence-specific priming and sequence-specific oligonucleotide probes. (B) Family study. Results of high-resolution HLA typing are shown for the parents. Based upon HLA typing of the children, membership of individual HLA alleles in haplotypes, designated “a,” “b,” “c,” and “d,” are assigned. The allele composition of the haplotypes is then used to assign haplotype inheritance in the children. The patient is genotypically HLA matched to sibling 1 and is completely mismatched for both HLA haplotypes with sibling 4. Siblings 2 and 3 are partially HLA mismatched, or HLA haploidentical, to the patient, and would be considered potential donors for allogeneic stem cell transplant only if sibling 1 is not a suitable or willing donor. (C) High-resolution HLA typing of the patient is aligned with typing of the HLA-haploidentical siblings to facilitate analysis of the degree of mismatching in both the rejection (host-versus-graft) and graft-versus-host directions. Alleles of the shared haplotype are aligned in columns A1, B1, Cw1, DRB1-1, and DQB1-1. Alleles that are mismatched in the graft-versus-host direction are in blue boxes, whereas alleles that are mismatched in the host-versus-graft direction are outlined in red boxes.

5. *Availability of the donor for repeated donations of HSCs to treat graft failure or lymphocytes to treat relapse:* Umbilical cord blood is a nonrecurring source of cells. If a patient has a relapse of the underlying hematologic malignancy after umbilical cord blood transplant (UCBT), donor lymphocytes to treat the relapse will not be available.
6. *Graft-versus-leukemia (GVL) effect:* For patients with high-risk acute leukemia, HLA-haploidentical HCT may be associated with a stronger GVL effect than HLA-matched sibling HCT, resulting in a lower cumulative incidence of relapse² and an improved OS.³

The major challenge of HLA-haploidentical HCT is the high frequency of host and donor T cells reactive to HLA alloantigens,⁴ resulting in intense bidirectional alloreactivity and, in the absence of effective prophylactic measures, high incidence of fatal graft rejection or severe or fatal GVHD.

The problems associated with bidirectional alloreactivity were exemplified by an analysis of over 2000 allogeneic HCTs performed between 1985 and 1991 and reported to the International Bone Marrow Transplant Registry.⁵ Compared with HLA-matched sibling HCTs, two HLA antigen-mismatched related donor transplants resulted in higher rates of transplant-related mortality (55% vs. 21% at 3 years after transplant among leukemia patients), graft failure (16% vs. 1%), moderate-severe acute GVHD (56% vs. 29%), and chronic GVHD (60% vs. 42%). T-cell depletion (TCD) of the donor graft reduced the incidence of acute GVHD, but at the cost of increased incidence of graft rejection, and it did not improve leukemia-free survival (LFS).⁶ Several advances in graft engineering beginning in the 1990s, as well as in pharmacologic modulation of alloreactivity beginning in the 2000s, have reduced the incidence of GVHD and NRM, improved OS and progression-free survival (PFS), and made this graft source an acceptable alternative for

BOX 106.1

The Increasing Popularity of Human Leukocyte Antigen–Haploidentical Donors

The number of human leukocyte antigen (HLA)-haploidentical stem cell transplant procedures performed is increasing on a global scale. China is the leader in HLA-haploidentical (“haplo”) stem cell transplants (SCTs) on a per-country basis, perhaps because the one-child policy there nullifies the availability of an HLA-matched sibling for many patients. In the past 5 years, the number of haplo transplants performed in Europe and the United States has more than doubled. Reports of successful haplo SCTs are appearing in the published literature from countries with more limited economic resources, such as Brazil, India, and Romania.

There are clinical, practical, and economic reasons for the increasing popularity of HLA-haploidentical SCT. Clinically, results of the procedure have improved dramatically over the past 10 to 15 years, to the point that the outcomes of haplo SCT approach or equal those of HLA-matched sibling or unrelated donor transplantation (see “Integrating HLA-Haploidentical SCT into Clinical Practice: Comparison of Outcomes With Other Graft Sources”). Absent these improvements, all other advantages of haplo donors would be meaningless. A major practical advantage of the haplo option is donor availability. A haplo donor can be found for nearly every patient referred for allogeneic SCT, because every biologic child or parent of a patient is HLA haploidentical, and each sibling or half-sibling has a 50% chance of being HLA haploidentical. The likelihood of finding a haplo donor increases further if one is willing to consider second-degree relatives, such as aunts, uncles, nieces, nephews, or cousins, as donors. The wide availability of haplo donors is especially important for members of ethnic minority groups that are underrepresented in registries of volunteer unrelated donors. Relatives, especially parents and children, tend to be highly motivated to donate and can do so more than once if needed to treat graft failure or relapse. The treating center has greater control over the timing of transplants when haplo donors than when unrelated donors are used. Clinical trials and advances in adoptive cellular therapy of cancer may be easier using related donors, because unrelated donor lymphocytes for infusion are regulated by the U.S. Food and Drug Administration as a biologic. Thus an investigational new drug application must be filed for any clinical trial employing the infusion of lymphocytes from unrelated donors, but not for minimally manipulated lymphocytes from related donors.

Finally, haplo stem cells are inexpensive compared with stem cells from unrelated adult volunteers or from umbilical cord blood. This, combined with the growing availability of inexpensive methods of graft-versus-host disease prophylaxis for haplo SCT (especially posttransplant cyclophosphamide), makes the haplo option increasingly attractive in countries with limited economic resources. In many countries, the government allocates a fixed budget for allogeneic stem cell transplantation. By lowering the total cost of the transplant for each patient, the haplo option permits more patients to receive this potentially lifesaving procedure.

patients lacking an HLA-matched sibling or URD (see Modern Approaches to HLA-Haploidentical SCT section later).

IMMUNOLOGIC CONSIDERATIONS IN HLA-HAPLOIDENTICAL HSCT

The HLA class I and class II molecules play a central role in the human immune response to infection and to transplanted tissues. The HLA class I molecules HLA-A, HLA-B, and HLA-C present peptide antigens, generally 8–11 amino acids in length, for recognition by CD8⁺ T cells. These molecules can also deliver stimulatory or inhibitory signals to natural killer (NK) cells. The HLA class II molecules HLA-DRB1, HLA-DQB1, and HLA-DPB1 present peptide antigens, generally 14–18 amino acids in length, for recognition by CD4⁺ T cells.

The biologic mechanisms underlying the high incidence of graft rejection and severe GVHD when crossing the HLA barrier remain to be elucidated, but two fundamental characteristics of T-cell alloreactivity are likely responsible. The first is the high frequency of T

cells reactive against allogeneic HLA molecules. T cells recognize a complex determinant comprising specific amino acid residues of the HLA molecule as well as amino acid residues of the bound peptide. It has been estimated that there are 50,000 to 100,000 copies of each HLA molecule on a cell surface, with as many as 5000 different peptides being presented. Thus each allogeneic HLA molecule provides as many as 5000 distinct recognition units corresponding to 5000 distinct alloreactive T cells. In contrast, a non-HLA or “minor” histocompatibility antigen consists of a single allelic peptide presented by a single species of HLA molecule. Thus whereas the frequency of T cells reactive to a single minor histocompatibility antigen is on the order of 1 in 50,000, the frequency of anti-HLA alloreactive T cells has been estimated to be on the order of 5% to 10%.⁴ The higher frequency of T cells reactive to allogeneic HLA molecules than to minor histocompatibility antigens corresponds to a higher incidence of graft rejection and GVHD after HLA-haploidentical SCT than after HLA-matched SCT. The second property of alloreactive T cells that contributes to a high incidence of graft failure and GVHD after haploSCT is a significant proportion of HLA-alloreactive memory T cells,⁷ even in donors and recipients who have not been exposed to allogeneic HLA molecules through pregnancy or blood transfusions. T cells that are immunized against environmental antigens, especially viruses, can cross-react against allogeneic major histocompatibility complex (MHC) molecules.^{8,9} The phenomenon in which viral infection triggers cross-reactive memory against allogeneic HLA molecules is termed *heterologous immunity* and may be a formidable barrier to the establishment of donor hematopoietic cell chimerism¹⁰ or the induction of tolerance to transplanted organs.¹¹ Unlike naive T cells, which are sensitive to chemotherapy-induced apoptosis and to immunologic tolerance induction by antigen without costimulation,¹² memory T cells are more resistant to chemotherapy-induced death, can induce costimulatory signals on antigen-presenting cells that they encounter,¹³ and are resistant to tolerance induction by regulatory T cells (Tregs)^{14,15} or to T cell–depleting antibodies.^{16–18} The presence and substantial number of memory T cells reactive to allogeneic HLA molecules make control of graft rejection and GVHD more challenging after HLA-haploidentical SCT than after HLA-matched SCT.

B cells and NK cells also participate in the immune response to HLA-mismatched tissues. Allogeneic HLA molecules can elicit the formation of alloantibody. Preexisting donor-specific antibodies (DSA) against HLA molecules are a major risk factor for graft failure after HLA-haploidentical SCT. Pregnancy and blood transfusions are sensitizing events that can lead to the formation of antibodies against HLA molecules. The prevalence of antidonor HLA antibodies in parous women has been reported to be as high as 42%¹⁹; such sensitization is directed against unshared HLA molecules expressed by their children. DSA can be detected by flow cytometric crossmatch tests using beads coated with a single HLA or by complement-dependent cytotoxicity (CDC) testing, in which the patient's serum is mixed with donor lymphocytes in the presence of complement. In one study, a positive crossmatch for antidonor lymphocytotoxic antibody was associated with a 2.3-fold increased risk of graft failure.²⁰ A positive crossmatch by CDC assay should be considered a contraindication to the use of the donor against whom the antibodies are directed. Patients with DSA detectable by flow cytometric crossmatch assay but not by CDC assay may be considered for a desensitization protocol to reduce the level of antibody in the serum so as to allow engraftment of the transplanted cells, as discussed later.

NK Cell Alloreactions After Allo-SCT

NK cells may play a significant role in inducing GVL effects after haploidentical SCT in humans. NK cells belong to the family of innate lymphoid cells. Unlike T and B cells, they do not express rearranging receptors for antigen, but like CD8⁺ T cells, they express receptors for HLA class I molecules, including HLA-B and HLA-C. Moreover, like CD8⁺ T cells, they secrete interferon- γ and kill target cells via granzyme- and perforin-mediated cytotoxicity.

A current consensus, the “missing self” hypothesis,^{21,22} is that NK cells have evolved to detect and rapidly eliminate virally infected or tumor cells that have downregulated cell surface expression of MHC class I molecules to evade the CD8⁺ T-cell arm of the immune response.

The molecular basis of NK cell alloreactivity is incompletely understood, but it involves a dynamic balance of signals through activating as well as inhibitory receptors on the NK cell. The killer immunoglobulin-like receptors (KIRs) are encoded by a set of linked genes called the leukocyte receptor complex (LRC) on human chromosome 19q13.4.²³ KIRs contain two or three extracellular Ig-like domains and either a short (S) or a long (L) cytoplasmic tail, which mediates activating or inhibitory signals, respectively. The LRC is marked by significant interindividual variation in KIR gene content as well as significant allelic variation in individual KIR genes.²⁴ As a consequence, the KIR locus is second only to the HLA locus in the number of polymorphisms, and unrelated individuals are unlikely to share KIR genotypes.

Distinct HLA class I molecules comprise the ligands for specific inhibitory KIRs (iKIRs). An organizing principle of NK cell biology is that NK cell self-tolerance is mediated by inhibitory signals delivered by self HLA class I molecules through iKIRs. The ontogeny of receptor expression on individual NK cells is poorly understood, but it is currently thought that each NK cell expresses at least one inhibitory receptor for a self HLA class I molecule.²⁵ There are four distinct categories of HLA ligands for iKIRs (Fig. 106.2). The C1 group of HLA ligands is characterized by the presence of an asparagine residue at position 80 of the HLA-C molecule and is recognized by either KIR2DL2 or KIR2DL3. The complementary C2 group of HLA ligands is distinguished by a lysine residue at position 80 of the HLA-C molecule and is recognized by KIR2DL1. The Bw4 serologic group is recognized by KIR3DL1. Finally, KIR3DL2 recognizes HLA-3 and HLA-11 molecules. Developing NK cells undergo a host MHC class I-dependent functional maturation process, termed *licensing*^{26,27} or, more recently, *education*.²⁸ Education endows an NK cell with the ability to kill MHC class I-deficient targets but also provides a mechanism for self-tolerance because the same MHC class I ligand that licenses the developing NK cell also inhibits the activity of the mature NK cell. Licensing is not an all-or-none phenomenon, and there are degrees of licensing depending upon the affinity of an iKIR for its HLA ligand. Further, there is evidence that transplanted

NK cells can attune themselves to the new HLA environment, indicating that NK cell alloreactivity is a complex and dynamic phenomenon.²⁹ Because the genes comprising the LRC and the HLA locus are on chromosomes 19 and 6, respectively, KIR and HLA molecules are inherited independently, so individuals can inherit an iKIR but not its ligand, resulting in an NK cell that cannot be licensed during development. Unlicensed NK cells would be predicted to be poorly functional; unexpectedly, however, they dominate the early response to cytomegalovirus (CMV) infection in mice,³⁰ and they also may be potent mediators of antibody-dependent cellular cytotoxicity.³¹ DNA damage resulting from transplant conditioning or inflammatory conditions such as viral infection may be sufficient to induce stress ligands of NK cell activation receptors,³² break tolerance in unlicensed NK cells, and generate autoreactivity,^{33–35} including tumor regression. In contrast to HLA-matched transplants, where donors and recipients express the same ligands for iKIRs, in HLA-haploidentical SCTs, the recipient may lack the HLA ligand for the iKIR on a licensed donor NK cell, releasing the cell from inhibition and resulting in donor NK cell alloreactivity. Unlicensed donor NK cells may also be activated by a dominance of stimulatory NK cell ligands in the inflammatory milieu of a conditioned recipient, but this scenario is not unique to HLA-haploidentical SCT and may also occur after HLA-matched SCT as long as the recipient lacks HLA ligands for iKIR molecules. Although the mechanisms of NK cell alloreactivity remain to be fully elucidated, there is great interest in harnessing their activity for preventing or controlling relapse of hematologic malignancy after HLA-haploidentical SCT.

Models of NK Cell Reactivity After SCT

The KIR ligand incompatibility model was first formulated by Ruggeri et al^{36–38} to account for NK alloreactivity after rigorously T cell-depleted, stem cell-enriched, HLA-haploidentical SCT.^{39,40} The model predicts NK cell alloreactivity when the donor expresses, but the recipient lacks, an HLA ligand (HLA group C1, C2, or Bw4) for an iKIR. In this situation, the donor is predicted to contain NK cells that have been licensed by, and are self-tolerant of, an HLA molecule that is present in the donor, but after HLA-haploidentical SCT, these NK cells are activated by recipient cells lacking expression of that HLA molecule. Support for the ligand incompatibility model was

Fig. 106.2 INTERACTIONS BETWEEN INHIBITORY KILLER IMMUNOGLOBULIN-LIKE RECEPTORS AND THEIR HUMAN LEUKOCYTE ANTIGEN LIGANDS OF RELEVANCE TO NATURAL KILLER CELL ALLOREACTIVITY AFTER ALLOGENEIC STEM CELL TRANSPLANT. For convenience, a single natural killer (NK) cell expressing four distinct inhibitory killer immunoglobulin-like receptors (iKIRs) is shown. Each NK cell need express only one molecular species of iKIR for functional maturation to occur. Individual members of the HLA-C1, HLA-C2, and HLA-Bw4 groups are listed in Table 106.1. High-resolution HLA typing is required to determine whether specific alleles of HLA-B and HLA-Cw are ligands of specific iKIRs. High-resolution typing of HLA-B and HLA-Cw loci are incorporated into the ligand incompatibility, receptor ligand, and missing ligand models of NK cell alloreactivity (see Fig. 106.3). Interactions between KIR3DL2 and HLA-A3 or HLA-A11 are generally not considered in these models.

provided by the ability to generate donor alloreactive NK clones in all 51 ligand incompatible donor–recipient pairs but in none of the 61 donors who were KIR ligand matched with their recipients.³⁸ NK alloreactivity in the GVH direction was predicted to have three functional consequences³⁷: (1) a GVL effect arising from donor NK cytotoxicity against leukemia cells; (2) a decreased rate of graft rejection arising from donor NK cell killing of host T cells; and (3) a decreased rate of GVHD arising from donor NK cell elimination of host antigen-presenting cells such as dendritic cells, which are required to initiate GVH reactions.⁴¹ Clinical trials performed by Ruggeri et al (hereinafter the Perugia group) have consistently demonstrated a strong antitumor effect of KIR ligand incompatibility in acute myeloid leukemia (AML) but not in acute lymphoblastic leukemia (ALL).

The missing ligand model predicts NK-mediated GVH reactions when the transplant recipient is missing at least one of the three major classes of HLA ligands for iKIR. The missing ligand model differs from the ligand incompatibility model only in that it does not require the presence on donor cells of the HLA ligand that is missing in the recipient. Consequently, donors who are predicted by the ligand incompatibility model to contain alloreactive NK cells against their recipients are a subset of the donors who are predicted by the missing ligand model to contain antirecipient alloreactive NK cells.

The KIR ligand incompatibility and missing KIR ligand models were compared for their ability to predict relapse after T cell–replete (TCR), URD SCT for hematologic malignancies.⁴² Among recipients of HLA-mismatched transplants, recipient homozygosity for HLA-B or HLA-C KIR epitopes was used to define “missing” KIR ligands and was associated with a decreased hazard of relapse (hazard ratio [HR], 0.61; 95% confidence interval [CI], 0.43–0.85; $p = .004$). The effect was observed in patients with AML, chronic myeloid leukemia, or ALL. The same effect was not observed in HLA-identical unrelated transplants. KIR ligand incompatibility was not associated with a decreased risk of relapse in recipients of either HLA-mismatched or HLA-matched grafts.

COMPLICATIONS OF HLA-HAPLOIDENTICAL SCT

Regardless of the immunologic disparity between donor and recipient, all patients undergoing allogeneic SCT are at risk for the same complications, namely conditioning regimen toxicity, graft failure, GVHD, infection, and relapse. Intense bidirectional alloreactivity after HLA-haploidentical SCT results in higher risks of both graft failure and acute GVHD than HLA-matched sibling SCT. Strategies employed to reduce the risk of one complication of haploidentical SCT have, to much frustration, resulted in an increased incidence of another serious complication. For example, TCD of the donor graft reduces the risk of GVHD but increases the risk of fatal graft failure.^{6,43} Consequently, in early studies, TCD did not improve the outcome of HLA-haploidentical SCT.⁶ Increased conditioning regimen intensity reduces the risk of graft failure but increases the risk of regimen-related toxicity⁴⁴ and also may increase the risk of GVHD.^{45,46} Finally, low rates of graft rejection and GVHD can be achieved by giving rigorously T cell–depleted grafts to intensively conditioned recipients, but immune reconstitution is significantly delayed, and NRM approaches or exceeds 40%,^{39,40,47,48} much of it due to infection. The following section describes transplant complications whose incidence and/or severity may be affected by the immunologic disparity between donor and recipient.

Graft Failure

Graft failure is a serious complication of allogeneic SCT and is nearly always fatal after myeloablative conditioning.⁴⁹ Graft failure may be primary, marked by the lack of initial engraftment (neutrophils $>500/\mu\text{L}$) and absence of donor hematopoietic chimerism, or it may be secondary, manifested as initial hematologic recovery followed by neutropenia and loss of donor chimerism. The primary cause

of graft failure is immunologic rejection mediated by radioresistant host T and/or NK cells.^{50,51} Among patients receiving myeloablative conditioning, the incidence of either primary or secondary (late) graft failure was 2.0% in recipients of HLA-matched sibling marrow, but it was 12.3% in recipients of marrow from HLA-haploidentical related donors ($p < .0001$).²⁰ The incidence of graft failure correlated with the degree of HLA incompatibility, occurring in 3 (7%) of 43 patients receiving haploidentical grafts mismatched for 0 HLA antigens (HLA phenotypically matched grafts from a parent or child), 11 (9%) of 121 recipients of 1 HLA antigen-mismatched graft, 18 (21%) of 86 recipients of 2 HLA antigen-mismatched grafts, and 1 of 19 recipients of 3 HLA antigen-mismatched grafts ($p = .028$). The effect of increasing HLA disparity on the risk of graft rejection after myeloablative SCT was also confirmed in an analysis performed by the Center for International Blood and Marrow Transplant Research (CIBMTR) consortium.⁶ In this study, the risk of graft rejection among recipients of grafts mismatched for two or three HLA antigens was approximately six to eight times greater than among recipients of grafts from HLA-matched siblings. TCD of the donor graft increased the risk of graft failure after HLA-mismatched as well as HLA-matched SCT. In another study, the risk of graft failure was increased in patients mismatched with the donor for both HLA-B and HLA-DR antigens, as well as in patients with a positive lymphocytotoxic crossmatch against donor cells.²⁰ The presence of a positive crossmatch predicts both graft failure^{52–54} and poor OS for patients receiving HLA-mismatched grafts.⁵⁵ Crossmatching, either by lymphocytotoxic or by solid-phase immunoassay (SPI) (the “virtual crossmatch”),⁵⁶ is strongly recommended as a step in determining donor eligibility before HLA-mismatched SCT. If the crossmatch is positive, further testing is recommended to assess for the presence in the patient of antidonor HLA antibodies. In cases where the flow cytometric crossmatch is positive but the cytotoxic crossmatch is negative or predicted to be negative by virtual crossmatching, plasmapheresis or immunoadsorption can be used to clear antidonor HLA antibodies and permit engraftment after HLA-haploidentical SCT.^{19,57} If the cytotoxic crossmatch is or is predicted to be positive, then a search for a different donor is recommended.

In addition to the degree of HLA disparity between donor and recipient, several other factors influence the risk of graft rejection after HLA-haploidentical bone marrow transplant (BMT), including characteristics of the patient, the graft, the conditioning regimen, and posttransplant immunoprophylaxis.⁵⁸ A competent host immune system is clearly required for allogeneic graft rejection, because the barrier to engraftment is lower in patients with severe combined immunodeficiency than in patients with hematologic malignancies.⁵⁹ Conversely, sensitization of immunocompetent recipients, for instance by blood transfusions, increases the risk of graft rejection following allogeneic SCT. The dose of donor T cells and stem cells also has a powerful influence on donor cell engraftment after haploidentical SCT. Early studies clearly established that depletion of T cells from the graft significantly increases the risk of graft failure following HLA-haploidentical SCT.⁶ In some series, the risk of graft failure following TCD approached 50%.⁵⁹ However, the detrimental effects of TCD on donor cell engraftment can be overcome by augmenting recipient immunosuppression and escalating the dose of transplanted stem cells.^{60,61} These studies ultimately led to the concept and practice of using “megadoses” of haploidentical CD34⁺ stem cells ($>10^7/\text{kg}$ of recipient body weight) obtained from granulocyte colony-stimulating factor (G-CSF)–mobilized peripheral blood collections.^{62,63} Studies in mice suggest that megadoses of mismatched stem cells induce tolerance by the “veto” mechanism,^{64–66} in which the cytotoxicity of alloreactive donor cells is inhibited by recipient cells expressing the alloantigen.^{67,68} Transplant of megadoses of stem cells into intensively conditioned recipients enables TCD of haploidentical grafts to decrease the risk of acute GVHD without increasing the risk of fatal graft failure.^{39,40}

Increasing the intensity of transplant conditioning also lowers the risk of graft failure after HLA-haploidentical SCT. For example, increased intensity of total body irradiation (TBI) was inversely correlated with the rate of graft failure among patients with leukemia receiving

transplants from HLA-haploidentical donors.²⁰ Finally, posttransplant pharmacologic immunosuppression is likely to decrease the risk of graft failure following mismatched SCT. Although this has not been studied intensively in the HLA-haploidentical setting, the risk of graft failure after HLA-matched sibling BMT was significantly lower among patients receiving posttransplant prophylaxis with methotrexate (MTX), cyclosporine (CsA), or both than among patients receiving no GVHD prophylaxis.⁴³

GVHD

Severe acute GVHD was a major complication of early trials of TCR, HLA-haploidentical SCT.⁶⁹ These early studies examined the relationship of serologic HLA incompatibility to the incidence and severity of GVHD. Among patients receiving MTX as sole posttransplant prophylaxis, the cumulative incidence of acute GVHD by day 100 was 34% among recipients of phenotypically HLA-matched grafts and 84% among recipients of three-loci-incompatible marrow.⁷⁰ The vector of incompatibility has been found to influence the risk of GVHD. In a study conducted at the Fred Hutchinson Cancer Research Center, recipients of grafts with one HLA antigen mismatch were categorized according to the vector of incompatibility. The cumulative incidence of acute GVHD by day 100 was 18% when the incompatibility was solely in the HVG direction (homozygous recipient of a heterozygous graft [$n = 17$]), but it was greater than 50% when there was incompatibility in the GVH direction (heterozygous recipients of a homozygous or heterozygous graft [$n = 87$]; $p = .03$).⁶⁹ There was no significant difference in the incidence of acute GVHD between recipients of grafts mismatched for a single HLA class I antigen versus a single HLA class II antigen. In a CIBMTR study,⁶ recipients of bone marrow mismatched for two or three HLA antigens had a three- to fivefold higher risk of GVHD compared with recipients of HLA-matched sibling grafts. TCD of the graft significantly reduced the risk of GVHD after HLA-mismatched as well as HLA-matched sibling BMT.

The adverse effect of HLA mismatch on the incidence of acute GVHD was confirmed in a subsequent analysis by the CIBMTR.⁵ The incidence of grades II–IV acute GVHD was 29% among 1176 recipients of HLA-matched sibling marrow, 44% among 223 recipients of one HLA antigen-mismatched related marrow ($p < .001$), and 56% among 86 recipients of 2 HLA antigen-mismatched marrow ($p < .001$). The incidence of grades III–IV acute GVHD also differed significantly according to degree of incompatibility: 13% for HLA-matched siblings, 27% for two antigen-mismatched donors ($p < .001$), and 36% for two antigen-mismatched relatives ($p < .001$). Among patients surviving at least 90 days with evidence of donor engraftment, the incidence of chronic GVHD by 2 years was 42% for recipients of HLA-matched sibling marrow, 52% for recipients of one HLA antigen-mismatched marrow ($p < .001$), and 60% for recipients of two HLA antigen-mismatched marrow ($p = .02$).

An analysis of the outcomes of allogeneic SCTs performed in Japan between 1991 and 2000 identified serologic HLA mismatch, higher age, and high-risk disease as independent risk factors for both short survival and the development of grades III–IV acute GVHD.² Importantly, the correlation between HLA mismatch and the risk of acute GVHD was preserved when the data were analyzed according to the degree of HLA allele mismatch, as determined by molecular typing methods. There was no significant difference in the risk of acute GVHD between patients mismatched for a single HLA class I allele versus a single HLA class II allele. The risk of grades III–IV acute GVHD was significantly higher after one HLA antigen-mismatched SCT than after HLA-matched URD BMT (30% vs. 16%; $p = .0013$). These data demonstrate that recipients of one HLA antigen-mismatched related grafts have a higher risk of severe acute GVHD than recipients of HLA-matched sibling or unrelated grafts.

The increased risk of acute GVHD with increasing HLA mismatch between donor and recipient has also been confirmed among recipients of HLA-haploidentical stem cells after reduced-intensity conditioning (RIC).⁷¹ The cumulative incidence of acute GVHD in

this study was 39% (95% CI, 33% to 45%) in recipients with HLA-matched donors, 44% (95% CI, 30% to 57%) in those with one-locus-mismatched donors, and 50% (95% CI, 29% to 68%) in those with two- or three-loci-mismatched donors. In a multivariable analysis, patients who received a graft from a one-locus-mismatched donor and a two- or three-loci-mismatched donor had an HR for acute GVHD of 1.83 (95% CI, 1.04–3.22; $p = .035$) or 2.44 (95% CI, 1.14–5.21; $p = .021$), respectively, compared with those from an HLA-matched donor. There was no increased risk of chronic GVHD among recipients of partially HLA-mismatched grafts after RIC as compared with recipients of HLA-matched sibling SCTs.

Hyperacute GVHD is defined in the literature as GVHD occurring within the first 14 days after allogeneic SCT.⁷² Hyperacute GVHD may be accompanied by high fever ($>40^{\circ}\text{C}$) and may involve a more extensive skin rash and lower response to therapy than GVHD diagnosed after transplant day 14. HLA mismatch is associated with hyperacute GVHD: HLA-haploidentical donors carry a 4.1-fold higher relative risk of developing the syndrome compared with recipients of grafts from HLA-matched siblings.

In the past decade, novel methods of preventing GVHD after HLA-haploidentical SCT have been developed, and these methods appear to have reduced or eliminated the detrimental impact of HLA mismatch on GVHD, NRM, and OS. These methods and their clinical effects are discussed later in the Modern Approaches to HLA-Haploidentical SCT section.

Impaired Immune Reconstitution and Infection

Rapid reconstitution of innate and adaptive immunity is critical for resistance to opportunistic infections after allogeneic SCT. Patients who undergo HLA-haploidentical SCT have had significantly impaired immune reconstitution as measured by delayed recovery of CD4⁺ T cells compared with recipients of HLA-matched sibling grafts.⁷³ A number of factors contribute to impaired immune reconstitution after HLA-haploidentical SCT. Damage to lymphoid tissues resulting from conditioning may interfere with T-cell homing and the generation of immunologic memory. The rigorous TCD necessary to prevent GVHD in the haploidentical setting results in profound posttransplant immunodeficiency.^{74,75} Finally, acute and chronic GVHD both interfere with immune reconstitution,⁷⁶ in part through inhibition of thymopoiesis.⁷⁷ The result of delayed immune reconstitution after T cell-depleted haploidentical SCT is an increased incidence of morbidity and NRM secondary to opportunistic infection. For example, among 101 patients receiving intensive conditioning and megadoses of rigorously T cell-depleted grafts in Perugia, Italy, 27 died as a result of opportunistic infection.⁴⁰ Infection was the cause of death in 7 of 29 patients with hematologic malignancies receiving RIC and haploidentical grafts depleted of CD3⁺ and CD19⁺ cells by magnetic cell sorting.⁷⁸ Infectious complications remain high even in the context of strategies designed to selectively deplete alloreactive T cells while sparing immunity to pathogens. In a study done at the Dana-Farber Cancer Institute, haploidentical donor grafts were exposed to recipient cells in the presence of T-costimulatory blockade, either CTLA4-Ig ($n = 19$) or a combination of antibodies to B7-1 and B7-2 ($n = 5$), to induce selective tolerance in alloreactive T cells before their transplant into lethally conditioned recipients. Despite this maneuver, 12 of the 24 patients died as a result of treatment-related causes, 6 as a result of infection with or without GVHD.⁷⁹ Conditioning agents that deplete host and donor T cells, such as antithymocyte globulin (ATG) or alemtuzumab (a monoclonal antibody against CD52 expressed on both B and T cells), may also increase the incidence of opportunistic infection after haploidentical SCT. Among 49 patients receiving haploidentical SCT after a non-myeloablative conditioning regimen containing alemtuzumab, the rate of CMV reactivation was 86%, and 11 patients (22%) died as a result of opportunistic infections.⁸⁰ These results illustrate the general observation that strategies employed to reduce graft rejection and/or GVHD tend to increase the incidence and severity of opportunistic infections after haploidentical SCT.

Fig. 106.3 COMPONENTS OF EACH TRANSPLANTATION PLATFORM. Interventions on the donor or the recipient for each transplantation platform are shown at each stage of the transplant procedure. *ATG*, Antithymocyte globulin; *BM*, bone marrow; *BMT*, blood or bone marrow transplant; *G-CSF*, granulocyte colony-stimulating factor; *GIAC*, granulocyte colony-stimulating factor stimulation of the donor; intensified immunosuppression including cyclosporine A, mycophenolate mofetil, and methotrexate; antithymocyte globulin; and combination of peripheral blood and bone marrow allografts; *G-PBSCs*, granulocyte colony-stimulating factor-mobilized peripheral blood stem cells; *MMF*, mycophenolate mofetil; *PBSCs*, peripheral blood stem cells; *PTCy*, posttransplant cyclophosphamide; *TCD*, T-cell depletion; *TCR*, T-cell receptor.

MODERN APPROACHES TO HLA-HAPLOIDENTICAL SCT

“Megadose” T Cell–Depleted Stem Cell Grafts

A turning point for haploidentical, T cell–depleted BMT came in 1993⁶² with the clinical application of an extensively T cell–depleted megadose of stem cells, a concept pioneered in animal models by Reisner in the late 1980s.^{60,63} “Megadose” SCTs (Fig. 106.3), piloted by Aversa and colleagues, initially consisted of G-CSF–mobilized peripheral blood stem cells (PBSCs) and bone marrow cells, both depleted of T cells *ex vivo* by soybean agglutination and erythrocyte rosetting⁶² and a conditioning regimen including TBI, cyclophosphamide, thiopeta, and ATG, with no additional pharmacologic immunosuppression after transplant. The Perugia group subsequently modified this regimen extensively, with fludarabine replacing cyclophosphamide in the TBI-based conditioning regimen after the observation in the mouse model that fludarabine and TBI provided equivalent immunosuppressive effect.⁸¹ The substitution of fludarabine for cyclophosphamide represented an attempt to reduce the conditioning regimen toxicity without jeopardizing its immunosuppressive effect. In addition, the total lung dose of radiation was decreased from 6 to 4 Gy. Other advances included implementation of a CD34⁺ selection device that provided a 4.5-log TCD, as well as not treating the recipient with filgrastim (G-CSF) after transplant, which may impair dendritic cell production of interleukin (IL)-12, leading to abnormalities in antigen-presenting function and T-cell reactivity.^{82,83} Over the past two decades, the Perugia group has demonstrated that full HLA haplotype–mismatched transplants can be successful in patients with acute leukemia in first or second complete remission (CR1 or CR2, respectively) when a megadose of stem cells is infused after an immunoablative and myeloablative conditioning regimen.⁸⁴ Among 104 patients who underwent transplants for acute leukemia, acute GVHD occurred in only 8 of 101 assessable patients, and chronic GVHD developed in 5 of 70 evaluable patients.⁴⁰ However, the megadose SCT regimen is associated with an increased rate of infectious morbidity and mortality, secondary to a prolonged time to immune reconstitution. Early results showed a transplant-related mortality risk of approximately 40%,³⁹ with infection being the leading cause of death. Somewhat improved

immune reconstitution and fewer deaths secondary to infection occurred when G-CSF was discontinued.

Those who have reported other approaches using myeloablative conditioning and high-dose CD34⁺ cell–selected grafts described similarly favorable engraftment and GVHD rates, but, unfortunately, recurrent malignancy and problems with infection-related deaths were encountered. In a Canadian multicenter study, all 11 study patients engrafted without GVHD, but 10 of 11 patients died as a result of leukemic relapse or infection.⁴⁷ Waller et al reported a 93% mortality rate in patients who received T cell–depleted, CD34⁺ enriched, HLA-haploidentical SCT after an ATG-based regimen, with most deaths being a result of infection or relapse.⁸⁵ In a retrospective analysis done in Japan, severe infections occurred in 20 of 32 patients receiving CD34⁺–selected PBSCs from two or three HLA antigen–mismatched related donors.⁸⁶ Seventeen (53%) of 32 patients died as a result of treatment-related causes, including 10 (31%) caused by infection, and 9 patients died as a result of complications of progressive disease. These results suggest that transplant of highly purified CD34⁺ PBSCs from haploidentical donors is associated with a low incidence of GVHD but an increased risk of disease progression or fatal infection.

The Acute Leukemia Working Party of the European Blood and Marrow Transplant Group Registry has reported outcomes of 266 patients with acute leukemia receiving myeloablative conditioning and CD34⁺–selected, “megadose” PBSC grafts from HLA-haploidentical related donors.⁸⁷ For the 119 patients who were not in remission at the time of transplant, the cumulative incidence of transplant-related mortality was 66% for AML and 44% for ALL, and the cumulative incidence of relapse was 32% and 49%, respectively. Only five patients were alive between 5 and 56 months after transplant. Eighty-six patients with AML and 61 patients with ALL underwent transplant in remission. Grade II–IV acute GVHD was observed in 4 patients with AML (5%) and 11 patients with ALL (18%). Among patients who survived more than 100 days, chronic GVHD was observed in 6 (10%) of 56 patients with AML and 7 (19%) of 39 patients with ALL. The cumulative incidence of NRM for patients with AML who underwent transplant in CR1 ($n = 25$) or CR>2 ($n = 61$) was 36% or 54%, respectively, and for patients with ALL, the corresponding incidence rates were 61% ($n = 24$) and 44% ($n = 37$) for patients in CR1 and CR≥2, respectively.

Refinements to the TCD Platform to Improve Immune Reconstitution

Early studies of T cell–depleted, megadose HLA-haploidentical SCT were characterized by low rates of graft failure and GVHD but a high incidence of NRM, mostly due to infection. These outcomes spurred efforts to improve immune reconstitution after TCD haploSCT. The Tübingen and Memphis groups introduced CD3/CD19 depletion rather than positive selection of CD34⁺ cells to produce a graft containing other CD34⁺ progenitors (such as NK cells, monocytes, dendritic cells, and other myeloid cells) that might enable immune recovery without inciting GVHD.⁸⁸ This approach was used in combination with RIC in an attempt to lower treatment-related toxicity.⁷⁸ In one study, all but 1 of 29 patients engrafted; however, grades II–IV acute GVHD occurred in 48% of patients, 8 patients (28%) still had NRM, 7 died as a result of infection, and 1 died as a result of GVHD. In a study of 46 children receiving CD3- and CD19-depleted grafts after myeloablative conditioning, successful engraftment after 5 years of follow-up was shown in 88% of patients, and grades II–IV acute GVHD occurred in 20%, grades III–IV acute GVHD in 7%, chronic GVHD in 21%, and NRM in 20%.⁸⁸ In this latter study, relapse occurred in 63% of patients after 2 years of follow-up, although 43% of patients undergoing transplant had active disease at the time of treatment. Overall, the use of CD3/CD19 depletion may reduce NRM, but at the cost of a higher risk of GVHD compared with CD34⁺ selection.

The increased risk of infection seen after TCD haploSCT may be due to the depletion from the adult donor graft of pathogen-specific memory T cells that provide protection from infection until new donor T cells differentiate from hematopoietic precursors in the recipient thymus. Research has been focused on infusing grafts containing selected populations of T cells to enhance immune reconstitution without substantially increasing the risk of GVHD. Adding back low numbers of T cells that have been depleted of alloreactive cells or that have been anergized by IL-10 is a straightforward and promising approach to improving immune reconstitution without exacerbating GVHD.^{89,90}

A second approach is focused on depleting only T cells expressing the $\alpha\beta$ T-cell receptor (TcR $\alpha\beta$). TcR $\gamma\delta$ ($\gamma\delta^+$) T cells have been found to mediate virus-specific responses to both CMV and Epstein-Barr virus,^{91–93} both of which cause substantial posttransplant morbidity and mortality. Furthermore, $\gamma\delta^+$ T cells have antitumor activity^{91,92,94} while potentially also posing a lower risk for initiating GVHD than $\alpha\beta^+$ T cells.^{95,96} Following successful clinical scale depletion of $\alpha\beta^+$ but not $\gamma\delta^+$ T cells,⁹⁷ results of a small study of 23 pediatric patients with nonmalignant disorders were published in 2014.⁹⁸ The researchers in this study used combined depletion of $\alpha\beta^+$ T cells and B cells and detected GVHD rates similar to those seen in patients who received CD34⁺-selected TCD haploBMT, but with an encouragingly low NRM of 9.3%.⁹⁸

Another approach, reported by the Perugia group, involves infusing immunomagnetically selected Tregs 4 days before transplant and infusing conventional T cells on the same day as the TCD allograft.^{99,100} In the first study of 28 patients, 26 successfully engrafted.⁹⁹ Only two patients developed grades II–IV acute GVHD, and both received the highest T-cell doses in the study cohort; no chronic GVHD was observed. T-cell reconstitution was markedly improved, including expanded T-cell repertoires and improved pathogen-specific responses. No patients developed CMV-associated disease. Unfortunately, NRM still occurred in 13 patients (50%), 8 of whom died following infection. An updated report of an expanded cohort of patients showed similar results and suggested that, in both mouse and human models, the infusion of Tregs did not seem to affect graft-versus-tumor immunity.¹⁰⁰ Indeed, relapse rates in patients treated in this study, using add-back of low numbers of Tregs and conventional T cells, were strikingly lower than those in historical control subjects. Still, NRM remained high, particularly death as a result of infection, despite laboratory evidence of improved immune reconstitution.

A fourth approach involves infusing virus-specific cytotoxic T-cell lines for the prevention or treatment of viral infections.¹⁰¹ These T cells expand *in vivo* following infusion and exert antiviral effects without causing GVHD and might also have antitumor activity.^{101,102} Another approach involves infusing donor lymphocytes expressing suicide genes that could be activated if GVHD developed.^{103,104} In a study of 50 patients, use of this treatment strategy markedly accelerated immune reconstitution.¹⁰³ When GVHD did occur, it could be abated effectively by induction of the suicide gene. However, NRM still occurred in 40% of the patients.

Blood Versus Marrow From Filgrastim-Primed Donors: the “GIAC” Protocol

Treatment of bone marrow donors with G-CSF before donation increases marrow CD34⁺ cells and granulocyte-macrophage colony-forming units, reduces total lymphocytes, and reverses the CD4⁺/CD8⁺ T-cell ratio (Fig. 106.3). To enhance engraftment by increasing the dose of transplanted HSCs, 15 patients with high-risk leukemia received myeloablative conditioning with cytarabine; cyclophosphamide; and 1000-cGy TBI; G-CSF-primed bone marrow from haploidentical donors; and GVHD prophylaxis with rabbit ATG (5 mg/kg/day on days –4 through –1), CsA, MTX, and mycophenolate mofetil (MMF).¹⁰⁵ At the time of reporting, all 15 patients had prompt trilineage hematopoietic engraftment; the cumulative incidence of GVHD was 33%; and 9 of 15 patients were alive at a median follow-up of 22 months (range, 13–35 months). On the basis of these results, Lu et al compared the outcomes of 293 patients with leukemia receiving HLA-matched sibling ($n = 158$) or HLA-haploidentical related grafts ($n = 135$) from G-CSF-primed donors.¹⁰⁶ Patients undergoing haploidentical SCT were conditioned with cytarabine, oral busulfan, cyclophosphamide, and methyl-CCNU (1-[2-chloroethyl]-3-[4-methylcyclohexyl]-1-nitrosourea); received G-CSF primed bone marrow on day 0 ($n = 134$) and/or G-CSF-primed peripheral blood on day 1 ($n = 131$); and received GVHD prophylaxis with ATG 2.5 mg/kg/day on days –4 through –1, CsA, MTX, and MMF. This protocol is now termed the *GIAC protocol*: (1) G-CSF stimulation of the donor; (2) intensified immunosuppression, including CsA, MMF, and MTX; (3) antithymocyte globulin; and (4) combination of peripheral blood and bone marrow allografts. All but two haploidentical SCT patients on the GIAC protocol had sustained engraftment of donor neutrophils. The cumulative incidence of acute grades II–IV, grades III–IV, and chronic GVHD in recipients of matched versus mismatched SCT were 32% versus 40% ($p = .13$), 11% versus 16% (no p value provided), and 56% versus 55% ($p = .90$). Mismatched patients had a higher incidence of CMV antigenemia (65% vs. 39%; $p < .001$) and hemorrhagic cystitis (35% vs. 13%; $p < .001$) but not of CMV disease. Two-year rates of relapse and NRM were 13% versus 18% ($p = .40$) and 14% versus 22% ($p = .10$) for recipients of matched versus mismatched transplants, respectively. The 2-year probability of LFS was 71% versus 64% and that of OS was 72% versus 71% ($p = .72$) in the matched and mismatched cohorts, respectively. In a follow-up report of 157 consecutive recipients of G-CSF-primed bone marrow plus peripheral blood from haploidentical related donors, recipients of CD3⁺ T-cell doses higher than the median (1.77×10^8 /kg) had a significantly lower NRM, better LFS, and better OS.¹⁰⁷ The Beijing results are extremely encouraging. Novel aspects of the regimen that may contribute to the low rates of graft failure and GVHD may be the use of low-dose rabbit ATG¹⁰⁸; the use of G-CSF-mobilized bone marrow plus peripheral blood^{82,109}; and the combination of CSP, MTX, and MMF.

Two other Chinese research groups reported very similar results of retrospective studies comparing outcomes of patients who received haploBMT with those of patients who received HLA-matched sibling or HLA-matched unrelated alloBMT.^{110,111} Researchers in a prospective, multicenter study of haploBMT ($n = 231$) versus HLA-matched sibling ($n = 219$) alloBMT using biologic randomization based on donor availability confirmed similar outcomes between the two groups.¹¹²

Several groups have attempted to reduce the incidence of GVHD seen with use of the GIAC protocol. In a Korean study, researchers used a modification of this platform with RIC and only G-CSF-PBSC allografts, and their results showed lower rates of grades II–IV acute (20%) and chronic (34%) GVHD.¹¹³ The Air Force General Hospital group modified its protocol, which used TBI-based conditioning and only G-CSF-primed bone marrow, by adding basiliximab for further GVHD prophylaxis.^{114,115} This approach resulted in a markedly lower rate of grades II–IV acute GVHD of 11%; although chronic GVHD was still seen in most patients, it was mostly limited in severity. The Rome Transplant Network employed this same GVHD prophylaxis approach in 97 patients and had encouraging results in terms of GVHD (grades II–IV and grades III–IV acute GVHD of 31% and 9%, respectively, and extensive chronic GVHD of 12%), but 1-year NRM was 32%.¹¹⁶

Survival outcomes of patients with acute leukemia who received haploBMT using the GIAC protocol have been particularly encouraging. In fact, results of one study suggested that even patients treated for very high-risk acute leukemia with haploBMT had better outcomes than patients receiving HLA-matched sibling alloBMT, owing primarily to a much lower incidence of relapse in the haploBMT group (26% vs. 49%; $p = .008$).³ In 2009, the Peking University research group reported the results of a study of 250 consecutive patients with acute leukemia, 108 of whom had AML and 142 of whom had ALL.¹¹⁷ Survival outcomes of patients with AML were particularly favorable, with 3-year OS outcomes of 73% and 56% reported for standard-risk and high-risk groups, respectively. Similarly excellent outcomes were seen in a second study of adult patients with AML in CR1.¹¹² However, outcomes of patients with high-risk ALL appear poor because of very high rates of NRM (51% after 3 years of follow-up) and relapse (49% after 3 years of follow-up).¹¹⁷ Patients with standard-risk ALL, however, had an encouraging 3-year OS of 60%.¹¹⁷ Two other studies have confirmed excellent survival of patients with ALL in CR1 treated with haploBMT using the GIAC protocol.^{112,118} Researchers in another study retrospectively investigated adult patients with ALL who had high-risk disease and were in CR1 but lacked an HLA-matched sibling or HLA-matched URD.¹¹⁹ Consolidation with either 2 years of chemotherapy ($n = 104$) or haploBMT ($n = 79$) was chosen by the patients; those who received haploBMT had markedly better 3-year disease-free survival (DFS) (64% vs. 21%), OS (72% vs. 27%), and cumulative incidence of relapse (19% vs. 61%) than chemotherapy-treated patients.¹¹⁹ In multivariate analyses, treatment with haploBMT was the only factor associated with less relapse and better OS.

In these studies of haploBMT using the GIAC protocol, the extent of HLA disparity did not affect OS.^{110,120,121} Although findings of a later study suggested that HLA-B mismatching was associated with higher acute GVHD and NRM as well as worse DFS and OS,¹²² the Peking University group's latest analysis did not confirm this finding.¹²¹ In an analysis of the effects of donor characteristics on patient outcomes, the lowest NRM and highest OS were seen when using younger, male donors.¹²¹ Less acute GVHD was seen when the donor was the patient's child or an HLA-haploidentical relative who was mismatched for noninherited maternal HLA antigens (NIMA); however, neither of these donor types was associated with improved survival. By contrast, use of maternal donors was associated with higher acute and chronic GVHD and worse survival. Overall, the authors suggested that a NIMA-mismatched male child was the best possible donor for haploBMT using the GIAC protocol, whereas use of older mothers and noninherited paternal antigen-mismatched donors should probably be avoided.¹²¹

Posttransplant Cyclophosphamide

The effects of cyclophosphamide, one of the oldest chemotherapeutic agents, on immunologic tolerance have been studied since the early 1960s.¹²³ High-dose cyclophosphamide was found to be effective in prolonging the survival of MHC-mismatched mouse skin allografts only when the drug was given shortly after allograft placement or up

to the fourth posttransplant day, with the optimal effectiveness of this treatment being at 2 days posttransplant.¹²⁴ This work was continued by a number of other investigators, but it was most fully explored by a Kyushu University group whose results were published in a series of 13 related reports from 1984 to 1987, with related mechanistic studies continuing into the mid-1990s.^{125,126} By administering donor spleen cells followed 48–72 hours later by cyclophosphamide, long-lasting tolerance to MHC-compatible, but not MHC-incompatible, skin allografts was established. Three primary mechanisms of posttransplant cyclophosphamide (PTCy)-induced tolerance were delineated in this model: (1) direct elimination of host T cells responding to donor antigens in the periphery, (2) intrathymic clonal deletion of donor-reactive host T cells, and (3) generation of tolerogen-specific host suppressor T cells.¹²⁷ Suppressor T cells were found to inhibit responses to both major and minor histocompatibility antigens through active suppression but not clonal deletion of alloreactive T cells.¹²⁸ Induction of tolerance by PTCy was disrupted by the administration of CsA or corticosteroids before adoptive cell transfer and cyclophosphamide treatment,^{129,130} but it was not affected by the administration of G-CSF starting the day after PTCy treatment.¹³¹

Subsequently, the PTCy approach was extended to alloBMT. In MHC-mismatched mouse models, treatment with PTCy reduced the dose of radiation required to induce reliable engraftment¹³² and also prevented GVHD and prolonged survival.¹³³ Graft failure could be further reduced by the use of antilymphocyte globulin,¹³⁴ and radiation in the conditioning regimen could be replaced entirely by fludarabine, although high levels of donor chimerism required at least 100 cGy of TBI.¹³⁵ The resultant mixed chimeras were tolerant to both donor and host but maintained reactivity against third-party alloantigens in mixed lymphocyte culture.^{132–134} This tolerogenic effect allowed skin and heart allografts from the MHC-mismatched donor strain to survive, whereas MHC-disparate third-party grafts were rejected.^{132,135}

Parallel to the effects seen on host T cells in skin allograft models, in mouse alloBMT models treatment with PTCy inhibited GVHD through elimination of alloreactive donor T cells.¹³⁶ Donor T cells exposed to antigen on day 0 were largely depleted by PTCy, whereas nonalloreactive donor T cells, which divided more slowly in a lymphopenic environment, were relatively spared (Fig. 106.4).¹³⁶ However, destruction of alloreactive donor T cells was necessary but not sufficient for PTCy-induced tolerance. The role of Tregs in inducing, as opposed to maintaining, tolerance is controversial. In mouse models of MHC-matched alloBMT in which donor CD4⁺ T cells promote GVHD, donor Tregs were necessary to prevent lethal GVHD after PTCy treatment,^{137,138} an effect consistent with the results from skin allograft models. In these mouse and human studies, donor Tregs were resistant to PTCy-induced cytotoxicity, owing to increased expression of aldehyde dehydrogenase, the enzyme primarily responsible for in vivo detoxification of cyclophosphamide,¹³⁹ upon allogeneic stimulation in a lymphopenic environment.^{137,138} In contrast, PTCy can induce tolerance in alloreactive CD8⁺ T cells in the absence of CD4⁺ T cells, including CD4⁺ Tregs.¹³⁷ Other studies have shown that Tregs are not required for cyclophosphamide-induced tolerance of tumor-reactive T cells¹⁴⁰ or for transplant tolerance induced by bendamustine.¹⁴¹

PTCy is the most commonly employed approach to selective alloreactive TCD, although ex vivo approaches also have been explored. These strategies include using mixed lymphocyte cultures to eliminate alloactivated cells that either express the activation marker CD25 or retain a dye that becomes highly cytotoxic upon activation with visible light.^{142–144} This latter photodepletion approach also spares Tregs and has reportedly shown promise in ongoing clinical studies.^{145,146}

Clinical Outcomes of HaploSCT With PTCy

In a phase I study of 13 patients at the John Hopkins Hospital (JHH), patients received PTCy 50 mg/kg 3 days after receiving TCR haploBMT using RIC with fludarabine and low-dose (200 cGy) TBI

Fig. 106.4 CYCLOPHOSPHAMIDE-INDUCED TOLERANCE TO HISTOCOMPATIBILITY ANTIGENS. On the day of transplant, alloreactive donor and host T cells encounter alloantigen on the surface of host and donor antigen-presenting cells, which also provide costimulatory ligands for T-cell activation (*top left*). The alloreactive T cells secrete cytokines such as interleukin (IL)-2 and proliferate. Because cyclophosphamide is more toxic to proliferating than to resting cells, the drug induces substantial killing of the alloreactive population while relatively sparing the resting, nonalloreactive T cells, including cells responsible for immunity to pathogens (*bottom*). Thus this protocol provides for selective allopeletion while permitting rapid immune reconstitution. *CMV*, Cytomegalovirus; *HSV*, herpes simplex virus; *MHC*, major histocompatibility complex; *TCR*, T-cell receptor.

with ($n = 10$) or without ($n = 3$) cyclophosphamide.¹⁴⁷ For additional GVHD prophylaxis, MMF and tacrolimus were administered the day after patients received PTCy (posttransplant day 4) and continued for at least 30 days. Among the 10 patients in the second cohort, 8 successfully engrafted and 6 had grades II–IV acute GVHD. Six of these ten patients, five of whom had active disease at haploBMT, were alive at a median follow-up of 284 days.

Researchers in a phase I/II study of 68 patients at two institutions sought to improve upon this regimen by further reducing the incidence of GVHD and graft failure.¹⁴⁸ Twenty-eight patients were treated at the Fred Hutchinson Cancer Research Center in Seattle and received TCR haploBMT in line with the protocol described previously, except that tacrolimus was continued until 180 days posttransplant. Forty patients treated at JHH also received a second dose of PTCy on the fourth posttransplant day. Twelve (13%) of sixty-eight patients had graft failure; however, owing to the low-intensity conditioning used, all but one experienced rapid autologous neutrophil recovery at a median of 15 days posttransplant. Engrafted patients achieved complete or near-complete donor chimerism by 1–2 months posttransplant. Grades II–IV and grades III–IV acute GVHD occurred in 34% and 6% of patients, respectively. The incidence of extensive chronic GVHD was low in both cohorts, but it was significantly lower in patients receiving two doses of PTCy (5% vs. 25%). NRM was 15% after 1 year of follow-up. Consistent with preclinical data suggesting sparing of nonalloreactive T cells,^{136,149} no patient had CMV disease; only two died as a result of fungal infections (one had graft failure). Longer follow-up of an expanded cohort of 210 patients treated in line with the JHH protocol confirmed low rates of NRM, acute GVHD, and chronic GVHD.¹⁵⁰ The extent of HLA disparity had no negative effects on acute GVHD or PFS.¹⁵¹ The relatively high rate of relapse (55%) in part reflected the advanced disease state of patients who received transplants; a disease risk–stratified analysis of 372 patients showed that survival outcomes were comparable with those of patients receiving HLA-matched alloBMT.¹⁵²

Nevertheless, in an effort to reduce relapse rates, the impact of intensifying the conditioning of the PTCy haploBMT protocol was

investigated. In two studies, myeloablative conditioning was associated with similar rates of acute GVHD and slightly higher, but still favorable, rates of chronic GVHD (26% and 35%, respectively), similar rates of NRM (18% and 10%, respectively), and lower rates of relapse (22% and 40%, respectively).^{153,154} The first of these two studies also spaced the PTCy to be administered on posttransplant days 3 and 5 and started MMF and CsA treatment before PTCy.¹⁵³ Unlike in preclinical studies,¹²⁹ tolerance was not abrogated by starting CsA before PTCy, as evidenced by low rates of grades II–IV acute GVHD (12%) and chronic GVHD. Researchers in another study used TBI-based ablative conditioning with PBSCs for haploBMT and showed excellent survival (78%) with low rates of NRM (3%) and relapse (24% for all patients and 0% for patients with low to intermediate disease risk) after 2 years of follow-up, albeit with higher rates of acute (23% grades III–IV) and chronic (56% overall and 22% moderate/severe disease) GVHD.¹⁵⁵ An alternative two-step approach to myeloablative PTCy haploBMT separates the induction of tolerance to donor cells (step 1) from hematopoietic rescue (step 2). Thus patients lethally conditioned with total body irradiation (TBI) are given peripheral blood cells containing a fixed dose of T cells on pretransplantation day -6 and cyclophosphamide 60 mg/kg/day on days -3 and -2 for tolerance induction (step 1), and then receive a CD34-selected PBSC graft from the same donor on day 0.^{156,157} This procedure mimicked the timing of the standard PTCy platform, except that stem cells were spared exposure to cyclophosphamide. Results for patients who were in remission at the time of haploBMT have been quite encouraging: Grades III–IV acute (4%) and chronic (21%) GVHD rates were low, NRM was only 3.6%, and relapse-related mortality was 19%, leading to 2-year DFS and OS of 74% and 77%, respectively.

Several groups have explored the use of PBSCs for PTCy haploBMT in an attempt to further improve engraftment and reduce relapse.^{154,155,158,159} However, the effects of this substitution are currently unclear, particularly because heterogeneity between studies makes a definitive assessment of the impact on relapse challenging. Graft failure appears to be similar to that of, or at most only slightly

improved by, the use of PBSCs. The substitution of PBSCs for bone marrow would be expected to produce higher rates of chronic GVHD,¹⁶⁰ although it is not obvious if this is indeed true for PTCy. Three studies investigating the replacement of bone marrow with PBSCs have shown higher but still favorable rates of chronic GVHD,^{154,155,157} whereas two others have demonstrated rates of chronic GVHD similar to those seen using haploBMT plus PTCy.^{158,159} In these studies, the rates of grades III–IV acute GVHD and NRM were not consistently higher than previously seen in patients who received bone marrow. A matched pairs analysis found no significant increase in the incidence of acute or chronic GVHD or NRM, but relapse incidence was significantly lower and event-free survival was significantly improved with HLA-haploidentical PBSC grafts as compared with bone marrow.¹⁶¹

HaploBMT with PTCy has generally been well tolerated, although a few potential complications are of particular note. Fever characteristically occurs within the first few days posttransplant, particularly when using PBSCs.^{154,156,162} These fevers can become quite severe, are generally culture negative, and are thought to be cytokine mediated and related to uncontrolled alloreactivity; therefore they tend to abate within hours to days of cyclophosphamide administration. Severe cytokine release syndrome has been reported in patients receiving HLA-haploidentical PBSCs and posttransplant cyclophosphamide, and it is associated with increased NRM.¹⁶³ In these cases, the syndrome is associated with elevated serum levels of IL-6, and symptoms of cytokine release syndrome can be abated by the administration of tocilizumab, a humanized antibody against IL-6. Hemorrhagic cystitis occurs not infrequently after haploBMT with PTCy, but it generally is of limited severity and is regularly attributable to polyomavirus (predominantly BK virus) infection.^{154,164–166} Graft rejection remains a potential complication of haploBMT using either PTCy or TCD and can be related to DSA present pretransplant in the recipient.^{19,52} In patients with detectable DSA to all potential HLA-haploidentical donors, desensitization procedures can reduce DSA titers such that haploBMT can be performed successfully.^{19,167,168} Notably, Epstein-Barr virus–related posttransplant lymphoproliferative disease within the first year posttransplant was not seen among 785 patients treated with PTCy,¹⁶⁹ and no increase in donor-derived malignancies was detected.¹⁷⁰

PTCy in Other Transplant Settings

PTCy has shown promise in facilitating solid-organ transplant. One group reported an approach to combined kidney transplant/BMT in which fludarabine/cyclophosphamide conditioning was administered before renal transplant and column-selected PBSCs were given the day after renal transplant.^{171–173} MMF and tacrolimus were started 2 days before kidney transplant and PTCy was given at 50 mg/kg 3 days posttransplant. According to the latest report, 12 of 19 patients¹⁷³ achieved functional tolerance as demonstrated by successful cessation of all immunosuppression without graft rejection; tolerance induction appeared to be dependent on achieving sustained donor chimerism.¹⁷²

Studies Comparing Modern Haploidentical Transplant Platforms

There are only two published studies comparing different HLA-haploidentical transplant platforms. In both of them, data were analyzed retrospectively. In a retrospective study of 65 adult patients receiving haploBMT using either PTCy or megadose T cell–depleted stem cells for GVHD prophylaxis, survival was significantly better after PTCy.¹⁷⁴ Disease progression was similar between the patient groups; therefore this difference was largely a result of markedly lower NRM after PTCy (16% vs. 42% at 1 year) with a lower risk of viral (twofold lower) and fungal (fivefold lower) infections. Following PTCy, T-cell reconstitution was more rapid, and the incidence of chronic GVHD was lower (7% vs. 18%).

Posttransplant cyclophosphamide has also been compared with ATG as GVHD prophylaxis after HLA-haploidentical SCT for patients with AML.^{174a} Patients in the PTCy group ($n = 193$) had significantly less severe (grades III–IV) acute GVHD than the 115 patients in the ATG group (5% vs. 12%, respectively; $p = .01$); the incidence of chronic GVHD was not significantly different. Recipients of PTCy had a significantly lower incidence of NRM (22% vs. 30%; $p = .02$), with no difference in relapse incidence. Compared with patients in the ATG group, patients receiving PTCy had improved LFS (HR, 1.48; 95% CI, 1.03–2.12; $p = .03$) and a trend for higher OS (HR, 1.43; 95% CI, 0.98–2.09; $p = .06$). Taken together, these results suggest that TCR haploBMT with PTCy may be associated with a lower incidence of NRM, a similar incidence of disease relapse, and improved LFS compared with haploSCT using either megadose T cell–depleted grafts or TCR grafts with ATG-based prophylaxis.

Integrating HLA-Haploidentical SCT Into Clinical Practice: Comparison of Outcomes With Other Graft Sources

A long-standing dogma in the field of allogeneic SCT has been that (1) HLA-matched sibling donors are associated with the best outcomes; (2) if an HLA-matched sibling donor is not available, the next best donor is a well-matched (10/10 allele match at HLA-A, HLA-B, HLA-Cw, HLA-DRB1, and HLA-DQB1) URD; and (3) in the absence of a well-matched sibling or URD, the choices boil down to partially HLA-mismatched adult URDs, URD umbilical cord blood, and HLA-haploidentical first-degree relatives (Table 106.1). It is worth noting that no prospective, randomized trials comparing different graft sources have been published, so the dogma is based upon retrospective, registry-based studies. Several recent studies, albeit nonrandomized, call into question the positioning of HLA-haploidentical SCT at or near the bottom of the list of preferred donors.

HLA-Haploidentical BMT Versus UCBT

The Acute Leukemia Working Party of the European Blood and Marrow Transplant Organization compared outcomes after UCBT and haplo-SCT in adults with de novo AML ($n = 918$, comprising 360 haploSCT, 558 UCBT) and ALL ($n = 528$, comprising 158 haploSCT, 370 UCBT).¹⁷⁵ Conditioning regimens were a mixture of myeloablative conditioning and RIC, and GVHD prophylaxis for recipients of haplo transplants included PTCy in 163, ATG in 244, and neither ATG nor PTCy in 111. UCBT was associated with delayed engraftment and a higher incidence of graft failure, but a lower incidence of chronic GVHD, for both AML and ALL patients. There were no significant differences between graft sources in the incidence of NRM or relapse or in LFS. The authors concluded that both haplo and UCBT grafts are acceptable approaches for patients with acute leukemia lacking an HLA-matched donor.

The Blood and Marrow Transplant Clinical Trials Network (BMT CTN) in the United States conducted two parallel trials of RIC followed by either double-UCBT (dUCBT) (BMT CTN 0604) or HLA-haploidentical BMT with posttransplant cyclophosphamide for patients with acute leukemia or lymphoma.^{176,177} The 100-day cumulative incidence of grades II–IV acute GVHD was 40% after dUCBT and 32% after haploBMT. The 1-year cumulative incidence rates of NRM and relapse after dUCBT transplant were 24% and 31%, respectively, with corresponding results of 7% and 45% after haploBMT. OS and PFS were 39% (95% CI, 26%–53%) and 36% (95% CI, 23%–49%), respectively, after dUCBT and 54% (95% CI, 39%–67%) and 35% (95% CI, 21%–48%), respectively, after haploBMT. The similar PFS seen in these two trials provided equipoise for the current phase III, prospective randomized BMT CTN trial (ClinicalTrials.gov identifier NCT01597778) comparing these two different graft sources after RIC.

ALL, Acute lymphocytic leukemia; AML, acute myeloid leukemia; ATG, antithymocyte globulin; CML, chronic myeloid leukemia; GIAC, granulocyte colony-stimulating factor stimulation of the donor; intensified immunosuppression including cyclosporine A, mycophenolate mofetil, and methotrexate; antithymocyte globulin; and combination of peripheral blood and bone marrow allografts; Haplo, human leukocyte antigen haploidentical; HLA, Human leukocyte antigen; MA, myeloablative conditioning; MDS, myelodysplastic syndrome; MSD, human leukocyte antigen–matched sibling donor; MUD, human leukocyte antigen–matched unrelated donor; NRM, nonrelapse mortality; Ph, Philadelphia chromosome; SCT, stem cell transplant.

HLA-Haploidentical Versus HLA-Matched URD SCT

GIAC Protocol

The Beijing group and the European Society for Blood and Marrow Transplantation conducted a retrospective comparison of patients with AML and intermediate-risk cytogenetics receiving haploidentical transplants using the GIAC protocol ($n = 87$) versus control subjects receiving fully matched (10/10) URD transplants ($n = 87$).¹⁷⁸ Cases and control subjects were matched for age ± 5 years, interval from CR1 to transplant, and the number of induction courses required to achieve CR1. Outcomes were similar in both groups: The 5-year LFS was 60.3% in the URD group versus 73.5% in the haplo group ($p = .15$), OS was 63.6% versus 78.2% ($p = .15$), relapse incidence was 24% versus 12.7% ($p = .08$), and NRM was 15.7% versus 13.8% ($p = .96$).

Posttransplant Cyclophosphamide

The CIBMTR has compared outcomes of URD BMT with those of haploBMT plus PTCy for patients with AML¹⁷⁹ as well as for patients with lymphoma.¹⁸⁰ For patients with AML, neutrophil recovery by day 30 was lower after haploidentical compared with matched unrelated donor (MUD) transplants (90% vs. 97%; $p = .02$), but 3-month acute GVHD grades II–IV (16 vs. 33%; $p < .0001$) and 3-year chronic GVHD (30% vs. 53%; $p < .0001$) incidence favored the haploidentical group. Similar differences in GVHD were also seen after nonmyeloablative conditioning. Three-year probability of OS after myeloablative conditioning was 45% after haplo transplants versus 50% after MUD transplants ($p = .38$). Corresponding rates after RIC were 46% for haplo and 44% for MUD transplants ($p = .71$).

The study of patients with lymphoma was restricted to those receiving RIC only and compared three groups: haploidentical transplants with PTCy versus URD transplants, with or without ATG. The 1-year cumulative incidence rates of chronic GVHD were 13%, 51%, and 33% among patients receiving haploBMT with PTCy, URD BMT without ATG, and URD BMT with ATG, respectively ($p < .001$). In multivariate analysis, grades III–IV acute GVHD was higher in URD without ATG ($p = .001$), as well as URD with ATG ($p = .01$), relative to haploidentical transplants. Cumulative incidence rates of relapse/progression at 3 years were 36%, 28%, and 36% in the haploidentical, URD without ATG, and URD with ATG groups, respectively ($p = .07$). Corresponding 3-year OS rates were 60%, 62%, and 50%, respectively, in the three groups, with multivariate analysis showing no survival difference between URD without ATG ($p = .21$) or URD with ATG ($p = .16$) relative to haploidentical transplants. The data demonstrate that, for patients with lymphoma, haploidentical transplants with PTCy produce survival outcomes as good as those seen after transplants using URDs, but with less chronic GVHD.

HLA-Haploidentical Versus HLA-Matched Sibling Donors

GIAC Protocol

Single-center, nonrandomized studies suggested that survival after HLA-haploidentical SCT using the GIAC protocol or after HLA-matched sibling SCT was similar.^{106,181} These studies motivated a prospective, multicenter trial in which patients with AML in CR1 were assigned to receive a transplant after myeloablative conditioning from an HLA-matched sibling ($n = 219$) or, if a matched sibling was not available, an HLA-haploidentical donor ($n = 231$) with treatment to the GIAC protocol.¹⁸² Patients assigned to the haplo arm were significantly younger (median age, 28 years) than patients receiving matched sibling grafts (median age, 40 years). Patients receiving haplo grafts had significantly higher incidence of grades II–IV acute

GVHD (36% vs. 13%; $p < .001$), grades III–IV acute GVHD (10% vs. 3%; $p = .004$), and chronic GVHD (42% vs. 15%; $p < .001$) than patients receiving grafts from matched siblings. However, there were no significant differences between recipients of haplo versus matched sibling transplants in the 3-year incidence of relapse (15% vs. 15%; $p = .98$) or NRM (13% vs. 8%; $p = .13$) or for 3-year DFS (74% vs. 78%; $p = .34$) or 3-year OS (79% vs. 82%; $p = .36$).

Posttransplant Cyclophosphamide

A variety of reports from single centers have retrospectively analyzed the outcomes of transplants from either matched siblings or haploidentical first-degree relatives.^{183–186} Bashey et al¹⁸⁵ reported that patients treated with haploBMT plus PTCy experienced a higher incidence of acute GVHD (41% vs. 21%; $p = .005$) and significantly worse survival (58% vs. 72%; $p = .02$). The other studies did not show significantly worse survival after haploidentical BMT, and two^{185,186} showed a significantly lower incidence of chronic GVHD without a corresponding increase in relapse.

The CIBMTR recently compared outcomes of patients with lymphoma undergoing RIC followed by either HLA-matched sibling SCT ($n = 807$) or HLA-haploidentical BMT with PTCy as part of GVHD prophylaxis ($n = 180$).¹⁸⁷ Although platelet recovery was delayed among those treated with haploBMT plus PTCy, the cumulative incidence of chronic GVHD was significantly lower after haploBMT (12% vs. 45%; $p < .001$), and there were no significant differences between haploBMT and HLA-matched sibling BMT in 3-year rates of NRM (15% vs. 13%; $p = .41$), relapse/progression (37% vs. 40%; $p = .51$), PFS (48% vs. 48%; $p = .96$), or OS (61% vs. 62%; $p = .82$).

PRACTICAL CONSIDERATIONS IN HLA-HAPLOIDENTICAL STEM CELL TRANSPLANT

The following sections provide management recommendations for clinical situations that are frequently encountered and for which the donor relationship and immunologic disparity require unique consideration.

Selection of the HLA-Haploidentical Donor (see Box 106.2)

Potential HLA-haploidentical donors include parents, children, siblings, half-siblings, cousins, nieces, nephews, and grandchildren. In our experience, each patient has, on average, two or three potential HLA-haploidentical first-degree relatives who are willing and medically able to donate. Several patient and donor characteristics influence the choice of donor, including medical and psychologic suitability of the donor, donor age, sex, and parity, presence of antidonor HLA antibodies in the patient's serum, donor-recipient HLA mismatch, red blood cell ABO group compatibility, and donor and recipient CMV serology. Regardless of transplant platform, there are two absolute contraindications to donation: (1) the donor is medically or psychologically unfit to donate, or (2) the recipient has antibodies against donor HLA molecules at a level that would produce a positive result in a CDC assay (see Management of the Patient with Antidonor HLA Antibodies section later).

The transplant platform used may also influence donor choice. In a study of 118 patients receiving megadose T cell-depleted transplants, 5-year event-free survival was better in patients who received transplants from the mother than from the father ($50.6\% \pm 7.6\%$ vs. $11.1\% \pm 4.2\%$; $p < .001$), with better survival resulting from both a reduced incidence of relapse and transplant-related mortality. The 5-year event-free survival was $27.0\% \pm 6\%$ and $25.5\% \pm 9\%$ for patients who received transplants from an HLA haploidentical sister ($n = 30$) or brother ($n = 49$), respectively ($p = .63$). On the basis of these results, the authors suggested that the mother of the patient

BOX 106.2**Case Study of Donor Selection for Human Leukocyte Antigen–Haploidentical Stem Cell Transplant**

A 58-year-old woman is found to have acute myeloid leukemia (AML) harboring the FLT3 internal tandem duplication. She achieves complete remission with induction chemotherapy. Human leukocyte antigen (HLA) typing reveals that her 65-year-old brother is an HLA-matched sibling. On evaluation, he appears to be healthy but is found to have a white blood cell count of 3200/ μ L and a platelet count of 140,000/ μ L. The patient also has three children: a 32-year-old son and two daughters, ages 30 and 27 years. All three children are healthy and have normal blood counts. The patient is mismatched with the son bidirectionally at HLA-A, HLA-B, HLA-C, HLA-DRB1, and HLA-DQB1, whereas she is mismatched to the daughters, who are HLA matched to each other, bidirectionally at HLA-A, and bidirectionally at HLA-DRB1. Solid-phase immunoassays demonstrate antibodies against HLA-DRB1*1501, present in the daughters, with a mean fluorescence intensity of 15,000, and a weaker antibody against HLA-DQB1*0501, present in the son, with a mean fluorescence intensity of 1000. The patient and both daughters are blood type A+ and cytomegalovirus (CMV) seropositive, but her son is blood type O– and CMV seropositive.

This case presents a number of considerations for selection of the appropriate donor. Remissions in patients with AML and the FLT3 tend to be brief, so there may not be time to search, identify, and mobilize an unrelated donor. Ordinarily, an HLA-matched sibling would be the first choice of donor, but the patient's 65-year-old brother has abnormal blood counts, raising the possibility of an underlying clonal hematopoietic disorder. Caution should be exercised in using this donor, even if examination of his bone marrow and an AML mutation panel are both normal. The strength of the antibody against HLA-DRB1, a high-expression HLA molecule, is consistent with a positive crossmatch result on a complement-dependent cytotoxicity (CDC) assay. Antidonor HLA antibodies resulting in a positive CDC assay are an absolute contraindication to donation, so the daughters are ruled out. In contrast, the patient's antibody against HLA-DQB1*0501 would not rule out her son as a donor. It is a weak antibody that would not result in a positive flow cytometric or CDC assay. Low-level antibodies against the low-expression HLA molecules, such as HLA-DQB1 or HLA-DRB3, HLA-DRB4, or HLA-DRB5, are generally not a contraindication to the use of a donor. However, the bone marrow transplant physician should always consult closely with the immunogenetics laboratory in cases where antidonor antibodies are present.

Although the son has a minor ABO incompatibility and is heavily HLA mismatched with the mother, neither is a contraindication to transplant, and modern approaches to HLA-haploidentical stem cell transplant have reduced if not eliminated the detrimental impact of HLA mismatching on outcome. He is therefore an appropriate donor for transplant for his mother. Umbilical cord blood is another potential source of stem cells for this patient. At present, there are no clinical data that would mandate the choice of an HLA-haploidentical donor over umbilical cord blood, or vice versa.

is the preferred HLA-haploidentical donor for megadose, T cell–depleted HSCT. Wang et al studied outcomes of 1210 patients treated with the GIAC protocol. With this platform, younger donors and male donors were found to be associated with less NRM and better survival. Less acute GVHD was seen when using the patient's child or an HLA-haploidentical relative who was mismatched for NIMA as the donor; however, use of either of these donor types was not associated with any significant improvement in patient survival outcomes. By contrast, use of maternal donors was associated with higher acute and chronic GVHD and worse survival. Overall, the authors suggested that a NIMA-mismatched male child was the best possible donor for haploBMT using the GIAC protocol, whereas use of older mother donors and noninherited paternal antigen-mismatched donors should be avoided.¹⁸⁸

Management of the Patient With Antidonor HLA Antibodies

HLA-mismatch was also historically associated with graft failure, with rates of 12% and 2% after HLA-mismatched and HLA-matched

related donor allografting, respectively.¹⁵ The same study showed that the presence of antidonor lymphocytotoxic antibodies on crossmatch was associated with a 39% graft failure rate, compared with 10% in patients with a negative crossmatch. In haploBMT with PTCy, Ciurea et al found that graft failure occurred in 75% of recipients with DSA compared with 5% of recipients without DSA ($p = .008$) and that antibodies to HLA-DRB1 were most frequent.¹⁶ In subsequent analyses by Ciurea et al, the overall incidence of DSA in haploBMT assessments was 18%, 86% of whom were women.⁵³ Thirty-two percent of patients with DSA experienced graft rejection. The mean fluorescence intensity (MFI) of antidonor HLA antibody was 10,055 for patients who experienced rejection versus 2065 for those with engraftment. Graft failure was associated with a complement assay that detects C1q-binding DSA, with only one C1q-negative patient (who had an MFI of 6265) without engraftment. Patients with C1q-binding DSA also had a higher median MFI than C1q-negative patients (15,279 vs. 2471). All male patients were C1q negative, and their median MFI levels were much lower. Pregnancy was associated with a much higher risk of developing DSA than transfusion of blood products.

DSA can be quantified by SPI using fluorescent beads coated with a single phenotype and single HLA antigens. SPI results can be correlated with crossmatching by flow cytometry or CDC assays to generate a “virtual crossmatch.”¹⁸ Gladstone et al found that HLA-directed DSA occurred in 14.5% of all patients and 42% of women undergoing haplotransplant evaluation.¹⁹ In patients without alternative available donors, plasmapheresis combined with anti-CMV intravenous immunoglobulin, tacrolimus, and MMF starting 1 to 2 weeks before conditioning, depending on the level of DSA, was associated with a 64.4% mean reduction in DSA levels.^{19,167} Fifteen patients received this treatment, and the fourteen patients who achieved DSA reduction to negative or weak levels underwent transplant and engrafted. Ciurea et al proposed an alternative desensitization method of plasma exchange, rituximab, and intravenous immunoglobulin, which they found to be only partially effective.⁵³ However, combining that regimen with the infusion of donor HLA antigens via a buffy coat 24 hours before SCT was highly effective. They also reported that clearing of DSA may be unnecessary, with reduction to non-complement-binding levels sufficient to achieve engraftment.

The management of a patient with antidonor HLA antibodies depends to a great extent upon the strength of the antibodies and upon the availability of other donors. All other factors being equal, preference should be given to donors against whom the patient does not have antibodies. Not all antibody specificities are equal. For example, antibodies against low-expression HLA molecules such as HLA-DQB1 or HLA-DRB3, HLA-DRB4, or HLA-DRB5 may not carry as high a risk of graft rejection as antibodies against the high-expression HLA molecules, HLA-A, HLA-B, HLA-Cw, and HLA-DRB1. We quantify antibody strengths using SPI with single HLA antigen-coated beads. The SPI reports antibody strength as MFI. An antibody with an MFI of 1000 to 3000 is considered a weak antibody, one with an MFI of 3000 to 15,000 is considered a moderate antibody, and one with an MFI greater than 15,000 is considered a strong antibody. Antibodies with an MFI greater than 10,000 are generally associated with a positive CDC crossmatch. It is critically important to consult with an immunogeneticist with experience in the management of patients with DSA. As a general rule, we never use a donor if the MFI of antidonor HLA antibody is greater than 10,000. For patients with antibodies associated with a positive flow cytometric crossmatch but a negative CDC crossmatch (MFI 3000 to 10,000), strategies to reduce the risk of graft rejection by lowering the concentration of antidonor HLA antibody have been developed. One such method of desensitizing patients includes plasma exchange and intravenous immunoglobulin every other day combined with tacrolimus and MMF,^{19,168} which was followed by sustained engraftment of HLA-haploidentical stem cells in 14 of 15 treated patients.¹⁶⁷ Other methods to desensitize patients with antidonor HLA antibodies include treatment with bortezomib, transfusion of platelets expressing the targeted HLA antigens, or the combination of rituximab and plasma exchange, with⁵³ or without¹⁸⁹ intravenous immunoglobulin.

In summary, the presence of antidonor HLA antibodies that produces a positive result on a CDC assay, or an MFI greater than 10,000 determined by SPI, is an absolute contraindication to the use of a donor who expresses the targeted HLA molecule. Antibodies of intermediate strength, corresponding to a positive flow cytometric crossmatch test or an antibody against a high-expression HLA molecule with MFI of 3000 to 10,000, may be reduced by a desensitization protocol to allow the use of a donor expressing the targeted HLA molecules. Antidonor HLA antibodies with an MFI less than 3000 measured by SPI may not require desensitization. Management of the patient with antidonor HLA antibodies must involve a close collaboration of the transplant physician and the immunogenetics laboratory.

Management of Suspected Graft Failure

Graft failure occurs when donor HSCs are unable to support long-term hematopoiesis in the recipient, resulting in loss of donor hematopoietic chimerism. Potential causes of graft failure include a poor-quality graft containing a low number of CD34⁺ cells; viral infection in the recipient (such as CMV, human herpesvirus 6, adenovirus, or parvovirus); or immunologic rejection by antidonor HLA antibodies, alloreactive recipient T cells, or both. Immunologic rejection of the donor graft almost certainly accounts for the higher incidence of graft failure after HLA-haploidentical as compared with HLA-matched SCTs.

The definition of graft failure depends upon the intensity of the conditioning regimen employed. Chimerism studies are required to make a diagnosis of graft failure. Management of graft failure depends to some extent on the perceived risk of irreversible pancytopenia and upon the risk of disease relapse. Graft failure after myeloablative conditioning is likely to be fatal unless the patient is effectively salvaged by a second stem cell graft, whereas autologous hematopoiesis often returns in the event of graft failure after nonmyeloablative conditioning.

PBSCs from HLA-haploidentical donors have been used successfully to salvage graft failure after myeloablative conditioning and HCT from partially HLA-mismatched URDs, from URD umbilical cord blood,^{190,191} or from HLA-haploidentical donors.^{192,193} When salvaging graft failure after HLA-haploidentical SCT, the question arises whether to use the same donor or switch to a different donor for the second transplant. It is important to test the patient for the presence of antibodies against the mismatched HLA molecules of the original donor because a positive test would demonstrate immunity against this donor's cells and a strong risk of rejection if the same donor is used. Preclinical studies demonstrate that graft rejection after nonmyeloablative conditioning can induce cellular immunity against donor cells without detectable antidonor antibody.¹⁹⁴ Thus lack of antidonor antibody does not mean lack of sensitization against a failed HLA-haploidentical allograft. If it is possible to switch to an HLA-haploidentical donor who does not share the same mismatched HLA haplotype as the original donor, then a new donor is preferred.

Treatment of Relapsed Hematologic Malignancy After HLA-Haploidentical SCT

Relapse remains a significant complication of allogeneic SCT, including HLA-haploidentical SCT. There is substantial controversy regarding whether HLA disparity between donor and recipient reduces relapse through a more intense GVH reaction. Most studies have not shown decreased relapse rates after HLA-haploidentical as compared with HLA-matched SCT,^{180,187,195} though such studies may be confounded by significant differences between donor types in the GVHD prophylaxis regimens employed. Other studies have shown a decreased risk of relapse associated with HLA mismatching,¹⁹⁶ especially for patients with poor-risk hematologic malignancies.² Approximately one-third of leukemic relapses after

HLA-haploidentical SCT are associated with loss of the mismatched HLA locus via acquired uniparental disomy, a process in which the unshared HLA haplotype on chromosome 6 is replaced by the shared HLA haplotype.^{197,198} HLA-alloreactive T cells must be providing the selective pressure that results in the emergence of these variants, because relapse is never associated with loss of the shared HLA haplotype, and HLA loss by uniparental disomy has not been described after HLA-matched SCT. Clinically, relapses of AML associated with loss of mismatched HLA tend to occur later than relapses with preserved HLA expression (307 days vs. 88 days; $p < .001$),¹⁹⁹ but they tend to carry a similar poor prognosis. Donor lymphocyte infusion (DLI) may not be effective in light of the loss of the major targets of alloreactive T cells. OS at 6 months after relapse was 28.5% for patients with HLA loss and 27.4% for patients with "classical" relapse. Survival may be improved by performing a second transplant, especially from a different donor, though NRM is high (7 of 17 patients).

DLIs have been administered to patients with relapsed hematologic malignancy after HLA-haploidentical SCT plus PTCy. In one study, DLI was administered as a series of escalating infusions (ranging from 10^3 to 10^7 T cells/kg), with or without preceding chemotherapy, to patients with acute leukemia in molecular ($n = 20$) or hematologic ($n = 12$) relapse, or to patients with Hodgkin lymphoma ($n = 10$).²⁰⁰ The incidence rates of acute GVHD after DLI in these groups were 15%, 17%, and 10%, respectively, and the response rates were 45%, 33%, and 70%. Two-year actuarial survival rates were 43%, 19%, and 80%, respectively. In a second report, 40 patients, including 16 with AML and 11 with lymphoma, received DLI starting at a dose of 10^5 CD3⁺ T cells/kg with subsequent dose escalation.²⁰¹ The most commonly used first dose was 10^6 CD3⁺ T cells/kg. Acute GVHD developed in 10 patients, 6 patients had grades III–IV, and 3 developed chronic GVHD. Twelve patients (30%) achieved a complete response with a median duration of 11.8 months. Eight patients were alive in complete response at the time of reporting, six for more than 1 year.

The Beijing group developed a modified DLI approach in which patients with relapsed leukemia after haploBMT received chemotherapy and peripheral blood leukocytes from filgrastim-treated donors followed by an immunosuppressive drug (CsA or MTX) for 2 to 8 weeks after DLI.²⁰² One hundred twenty-four patients in relapse after haploBMT received chemotherapy followed by modified DLI containing a median of 4×10^7 CD3⁺ T cells/kg of recipient weight. The cumulative incidence of DLI-associated acute GVHD was 53.2% for grades II–IV and 28.4% for grades III–IV. The duration of GVHD prophylaxis after DLI was the only risk factor for DLI-associated grades III–IV acute GVHD ($p < .05$). The 2-year OS, NRM, and cumulative incidence of relapse after DLI were 47.2%, 34.1%, and 34.6%, respectively. A subsequent study compared the antileukemic effects of chemotherapy alone ($n = 32$) versus chemotherapy followed by modified DLI ($n = 50$), with immunosuppression given for 4 to 8 weeks after DLI, in patients with relapsed acute leukemia after haploBMT.²⁰³ In patients receiving chemotherapy followed by modified DLI, the CR rate was significantly higher (64.0% vs. 12.5%; $p = .000$), the incidence of relapse was significantly lower (50.0% vs. 100.0%; $p = .000$) and DFS was significantly improved (36.0% vs. 0.0%; $p = .000$) compared with patients receiving chemotherapy alone. Multivariate analysis demonstrated that patients with chronic GVHD after intervention ($p = .000$) and patients receiving chemotherapy followed by modified DLI ($p = .037$) were associated with a lower relapse rate.

In summary, hematologic malignancies in relapse after HLA-haploidentical SCT can be treated with DLIs. Patients with relapse of acute leukemia in the first 6 months after transplant generally have a poor prognosis. For patients with relapse of leukemia after 6 months, HLA typing of the leukemia blasts is recommended. If mismatched HLA expression is preserved, DLI with or without preceding chemotherapy may be used. For patients in overt hematologic relapse, a starting dose of 10^6 CD3⁺ T cells/kg may be used. If mismatched HLA alleles have been lost, a second transplant procedure from a different donor may provide the best outcome.

CONCLUSIONS

HLA-haploidentical donors are a rapid and near universally available source of HSCs for transplant into patients with poor-risk hematologic malignancies. HLA mismatch between donor and recipient stimulates not only alloreactive T cells but also NK and B cells, which generates unique biologic and clinical considerations. The major drawback of HLA-haploidentical SCT is intense bidirectional alloreactivity resulting in higher incidences of graft failure, GVHD, and NRM. Three modern approaches to haploSCT have mitigated these complications substantially: (1) megadose T cell-depleted SCTs; (2) the GIAC protocol involving administration of ATG, filgrastim-mobilized marrow plus PBSCs, and intensive posttransplant immunosuppression; and (3) high-dose, posttransplant cyclophosphamide as part of GVHD prophylaxis. Outcomes of haploSCT for hematologic malignancies using these strategies now approach those seen after HLA-matched SCT. Prospective randomized trials comparing different graft sources will be needed to determine the donor priority for patients referred for allogeneic SCT. Priorities for future research include improving immune reconstitution and preventing or treating relapsed malignancy.

UNRELATED DONOR CORD BLOOD TRANSPLANTATION FOR HEMATOLOGIC MALIGNANCIES

Rohtesh S. Mehta, Amanda Olson, Doris M. Ponce, and Elizabeth J. Shpall

Cord blood (CB) is now routinely used as an alternative stem cell source for patients without a matched related or unrelated peripheral blood (PB) or bone marrow (BM) graft. In the late 1980s, Broxmeyer and colleagues¹ reported that CB is a rich source of hematopoietic stem cells (HSCs) and progenitors, setting the stage for the first related donor CB transplantation (CBT) in 1988.² Subsequently, placental blood banking programs were initiated in 1992 to 1993 in New York, Milan, Dusseldorf, and Paris.^{3,4} The first unrelated donor CBT was performed in 1993, and the first unrelated donor CBT series were published in 1996.^{5,6} Public CB banks have since grown in number with an estimated 600,000 public CB units banked globally.⁷ Furthermore, the number of CBT continues to increase.⁸ In 2010–2011, CBT accounted for more than one-fourth of all allogeneic stem cell transplants (SCT) in patients younger than 20 years, but less than 10% among patients older than 20 years.⁸

The use of CB stem cells has several unique benefits. Given it is a cryopreserved product, it has rapid accessibility, does not carry the risk of donor unavailability, minimizes the risk of infection transmission, has less stringent human leukocyte antigen (HLA) match requirements because of the naive neonatal immune system, and is associated with lower than expected rates of graft-versus-host disease (GVHD). Barker et al⁹ reported that recipients of CB grafts were transplanted a median of 25 days earlier than unrelated donor transplant recipients. This is particularly advantageous for patients in need of an urgent transplant. Further, CB has facilitated the extension of transplant access especially to racial and ethnic minorities. Although there are more than 11 million potential marrow donors in the National Marrow Donor Program (NMDP) registry, only 27% are from racial and ethnic minority groups compared with CB units where 45% belong to the minority group.¹⁰ A recent NMDP registry analysis showed that the likelihood of finding an optimal (8/8 or 7/8 HLA-matched) adult donor is 75% for whites of European decent, but it is less than 20% for American blacks and varies from 27% to 52% for other ethnicities. By contrast, a suitable CB graft can be obtained for 80% to 96% of adult patients across all races and almost universally for younger patients.¹¹ (Fig. 107.1)

SINGLE UNIT CORD BLOOD TRANSPLANTATION

Engraftment

Unrelated donor CBT was initiated using single-unit grafts. Studies have demonstrated that higher cell dose and better donor–recipient HLA match are independent factors associated with improved neutrophil engraftment.^{12–19} The 1997 Eurocord analysis was the first large series reporting on 143 related and unrelated donor CBT recipients. In unrelated donor CBT recipients, improved neutrophil and platelet engraftment were both associated with a higher total nucleated cell (TNC) dose above the median of $3.7 \times 10^7/\text{kg}$ and donor–recipient HLA match.¹⁵ In 1998, Rubinstein et al¹⁸ confirmed these findings in an analysis of 562 CBT facilitated by the New York Blood Center (NYBC) as did an updated analysis by Gluckman and Rocha²⁰ in 2004. In 2002, Wagner et al¹⁹ reported that infused

CD34⁺ cell dose was superior to infused TNC dose in determining the success of neutrophil and platelet engraftment in an analysis of 102 CBT (median age, 7.4 years) with recipients of units with less than 1.7×10^5 CD34⁺ cells/kg having a significantly lower neutrophil engraftment incidence of 72% at a median of 34 days compared with higher cell doses ($p < .01$).

These analyses have the limitation that cell dose and HLA match are analyzed separately and yet these graft characteristics must be considered together in the selection of individual units. In 2009, Rocha and Gluckman²¹ reported on 925 recipients of single-unit CBT transplanted for malignant disease and found that neutrophil engraftment was related to the number of cells infused ($p < .0001$) and HLA match with a significant difference between zero and one (81%), two (75%), and three and four (63%) HLA disparities ($p = .037$). The role of HLA match was partially abrogated by an increase in cell dose except for recipients of highly mismatched grafts. In 2010, Barker et al¹² analyzed the combined effect of TNC dose and donor–recipient HLA match in 1061 single-unit CBT recipients transplanted for hematologic malignancies after myeloablative conditioning. The best neutrophil engraftment was associated with a fully HLA-A, HLA-B antigen, and HLA-DRB1 matched unit or a cryopreserved TNC greater than $10.0 \times 10^7/\text{kg}$ with one or two mismatches. The worst was with a unit with three mismatches or a cryopreserved TNC below $2.5 \times 10^7/\text{kg}$ with one or two mismatches (Fig. 107.2). There was no difference in neutrophil engraftment in recipients of one versus two mismatched units, and in this setting, the TNC dose determined neutrophil engraftment.

Graft-Versus-Host Disease

Single-unit CBT is associated with a lower than expected incidence of GVHD for the degree of donor–recipient HLA mismatch, which allows use of units with a less stringent HLA match (i.e., only a 4-6/6 HLA-A, HLA-B antigen, HLA-DRB1 allele match). Incidences of grade II–IV acute GVHD have been reported between 10% and 50% and likely vary according to the GVHD prophylaxis used and the inclusion of antithymocyte or antilymphocyte globulin (ATG/ALG) in the conditioning.^{12,15,22–26} As with transplantation of adult donors, the major graft determinant of acute GVHD is the HLA match, although with CB, the permissible mismatch is considerably greater than can be tolerated with HSC transplantation from adult donors.

Although an effect of HLA mismatch could not be demonstrated in early series of unrelated donor CBT,^{14,15,18,19} a later large NYBC retrospective analysis of 1061 single-unit CBT recipients demonstrated that recipients of matched CB units had significantly less grade III–IV acute GVHD and that increasing mismatch was associated with a progressively increased risk of severe acute GVHD.¹² There was also an association between the degree of mismatch and chronic GVHD, although this only reached significance in recipients of units with three mismatches.¹²

The influence of deeper HLA-matching using allele-level high resolution typing as well as the impact of HLA-C matching have also been explored in single-unit CBTs. In the Cord Blood

Fig. 107.1 COMPARISON OF PATIENT ANCESTRY IN RECIPIENTS OF UNRELATED VOLUNTEER DONOR (URD) OR CORD BLOOD (CB) TRANSPLANTATION, OR THOSE WHO LACKED A SUITABLE GRAFT. (From Barker JN, Byam CE, Kernan NA, et al: *Availability of cord blood extends allogeneic hematopoietic stem cell transplant access to racial and ethnic minorities*. Biol Blood Marrow Transplant 16:1541, 2010.)

Fig. 107.2 NEUTROPHIL ENGRAFTMENT AFTER MYELOABLATIVE SINGLE-UNIT CORD BLOOD TRANSPLANTATION FACILITATED BY THE NEW YORK BLOOD CENTER ACCORDING TO CRYOPRESERVED TOTAL NUCLEATED CELL (TNC) DOSE AND HUMAN LEUKOCYTE ANTIGEN MATCH. CI, Cumulative incidence; MM, mismatched. (From Barker JN, Scaradavou A, Stevens CE: *Combined effect of total nucleated cell dose and HLA match on transplantation outcome in 1061 cord blood recipients with hematologic malignancies*. Blood 115:1843, 2010.)

Transplantation Study involving 191 children (median age 7.7 years), Kurtzberg et al²³ showed that high-resolution matching at HLA-A, HLA-B, and HLA-DRB1 alleles was protective against GVHD. There was a significantly higher incidence of grade II–IV ($p = .02$) and grade III–IV ($p = .02$) acute GVHD in recipients of units with less than 5/6 allele match. A later study by Eapen et al²⁷ in 803 recipients of single CB units examined the effect of match at HLA-A, HLA-B, HLA-C at intermediate resolution and HLA-DRB1 at allele resolution. The

authors did not find a significant effect of HLA-match on grade II–IV acute GVHD, but high-resolution matching was not examined at HLA class I. A recent study by Eapen et al²⁸ analyzed the effect of allele-level matching at HLA-A, HLA-B, HLA-C, and HLA-DRB1 in 1568 children with single-unit CBT. The risk of grade II–IV acute GVHD was higher with three or four mismatches, but not with one, two or five mismatches, compared with matched CBT. There was no difference in the risk of chronic GVHD between matched or any mismatched CBT. Also, there was no impact of mismatching at a specific HLA loci on any of the outcomes. Of note, allele level typing was not available for 50% of the patients, which was then estimated using the *Haplogenic III* developed by the NMDP based on the available low/intermediate level testing.

Relapse

During the early years of CBT, there was concern that the neonatal immune system would not adequately protect against relapse. However, multiple series have demonstrated a strong protection against relapse after CBT with the major determinant of relapse being the recipients' disease status.^{19,22,23,29} The NYBC series of 1061 single-unit CBT recipients showed no association between HLA match and the incidence of relapse. Subgroup analysis in only relapsed patients, only remission patients, and only those who engrafted also failed to demonstrate any association.¹² However, the 2011 analysis of Eapen et al²⁷ ($n = 803$) showed a lower relapse incidence after CBT mismatched at more than one loci compared with recipients of units matched at HLA-A, HLA-B, HLA-C, and HLA-DRB1, although the number of mismatched loci had no effect. Moreover, in the recent study by Eapen et al²⁸ assessing allele level matching at HLA-A, HLA-B, HLA-C, and HLA-DRB1, reduced relapse was noted only for units mismatched at four alleles (but not <3 or 5 alleles) compared with matched units (hazard ratio [HR] 0.50; $p = .001$). The reason for disparity in the findings of these studies is not known, and this area requires further investigation before definitive conclusions can be drawn.

Transplant-Related Mortality and Survival

Early series of single-unit CBT demonstrated high transplant-related mortality (TRM) and consequently poor survival after single-unit CBT. This likely related to the high-risk nature of the patient population and standards of supportive care as well as the characteristics of the transplanted units. Factors such as disease status and recipient cytomegalovirus (CMV) positivity are strong determinants of survival after single-unit CBT.²³ From the standpoint of the graft, both TNC dose and HLA-match influence TRM and survival. In addition to low TNC dose being associated with increased TRM and decreased survival,^{12,15,18,19} the 68 adult patient analysis of Laughlin et al¹⁶ and the Wagner et al¹⁹ 102 patient analysis demonstrated a higher CD34⁺ cell dose (>1.2 and 1.7 , respectively) were associated with significantly improved disease-free survival (DFS). Also, increasing HLA-mismatch is significantly associated with increased TRM and lower survival.^{12,19,27} The 2010 NYBC analysis of combined TNC dose and HLA match showed that recipients of 6/6 HLA-matched units had the lowest TRM and best survival regardless of the dose at least within the dose range tested (Fig. 107.3).¹² Recipients of units with one HLA-mismatch and a TNC dose 2.5 to $4.9 \times 10^7/\text{kg}$ had a similar TRM as those receiving units with two mismatches and a TNC greater than $5.0 \times 10^7/\text{kg}$ despite the higher cell dose in the latter group (see Fig. 107.3). Recipients of single units with one or two mismatches and a TNC below $2.5 \times 10^7/\text{kg}$ had very high TRM and poor survival.

In the 2011 Eapen series evaluating the contribution of HLA-C matching after single unit CBT, patients matched at HLA-A, HLA-B, and HLA-DRB1 had a higher TRM if mismatched at HLA-C ($n = 23$; HR 3.97; $p = .018$) as compared with those matched at all four loci ($n = 69$).²⁷ TRM was also higher in 5/6 but 6/8 matched CBT recipients mismatched at one of HLA-A, HLA-B, or HLA-DRB1 plus HLA-C ($n = 234$; HR 1.70; $p = .029$) compared with those who were 5/6 and 7/8 matched (i.e., when there was a single HLA mismatch at HLA-A, HLA-B, or HLA-DRB1 but a match at HLA-C; $n = 127$). This study suggests that HLA-C matching is an important determinant of survival and should be considered in unit selection algorithms. In a recent study by Eapen et al²⁸ using allele level matching, significantly higher nonrelapse mortality (NRM) was noted with units mismatched at any number of alleles (HLA-A, HLA-B, HLA-C, or HLA-DRB1) compared with HLA-matched

units (HR ranging from 2.8 to 4.6 for 1 to 5 allele mismatches).²⁸ The author recommended avoiding CB units with greater than three allele mismatches. Of note, only 7% of the units in their study were complete allele matched and 90% of the 4/6 matched patients by current standard were reported to have greater than or equal to three allele-level mismatches. Therefore, if greater than three allele mismatches are to be avoided, that would require massive addition of high-quality CB units to the global inventory.³⁰ Therefore, the application of the study results, which are highly informative, is impractical for current clinical practice.

Comparison of Single-Unit Cord Blood Transplantation and Adult Donor Allografts

Although the use of CBT as an alternative HSC source has increased substantially, no randomized studies evaluating survival after CBT versus adult donor allografts have yet been reported. Retrospective comparisons have demonstrated varying results depending on whether the series evaluated children or adults and if matched versus mismatched unrelated volunteer donors were included. Selected series are summarized in Table 107.1. In 2007, Eapen and colleagues²⁶ compared the outcomes of pediatric single-unit CBT with those of unrelated volunteer BM recipients who were transplanted for the treatment of acute leukemia. Compared with the recipients of 8/8 allele-matched unrelated donor BM transplantation (BMT), the 5-year LFS in recipients of one or two HLA-mismatched CBT was similar. Notably, however, a significantly higher LFS was observed in recipients of 6/6 HLA-matched units. Interestingly, TRM was similar in 6/6 HLA-matched and 5/6 HLA-matched high cell dose compared with that of allele-matched unrelated donor recipients' transplant ($p = .0659$ and $.1332$, respectively). By contrast, TRM was higher in recipients of one antigen HLA-mismatched low cell dose and two antigen HLA-mismatched of any cell dose compared with allele-matched unrelated donor recipients ($p = .0455$ and $.0003$, respectively).

A similar analysis done in adult patients with acute leukemia demonstrated that single-unit CBT recipients had a higher TRM compared with recipients of 8/8 HLA-matched unrelated donor transplants but a similar TRM to that of 7/8 HLA-mismatched unrelated donor transplant recipients.²² The Japanese group of Takahashi et al²⁵ compared CBT recipients with unrelated donor BM or PB HSC transplantation for the treatment of hematologic malignancies. They demonstrated a slower neutrophil recovery in CBT recipients but a similar rate of neutrophil engraftment. The incidences of grade III–IV acute GVHD and extensive chronic GVHD were higher after unrelated donor transplantation. No differences were demonstrated in TRM, relapse, or DFS between the groups. Atsuta et al³¹ conducted a disease-specific analysis comparing CBT to unrelated donor BMT in patients with acute leukemia. The patients had similar age distribution, and all received myeloablative conditioning. In the acute myeloid leukemia group, there was a similar relapse rate but higher TRM in CBT recipients, resulting in lower survival, but similar relapse and survival rates were seen in the acute lymphoblastic leukemia (ALL) group. The risk of developing extensive chronic GVHD was lower in CBT recipients.

DOUBLE-UNIT CORD BLOOD TRANSPLANTATION

The transplantation of HSC from more than one donor is an approach that was originally reported by Mathé et al,³² who infused multiple aliquots of BM from different donors. In 1972, Ende and Ende³³ published the first case of allogeneic CBT using multiple small CB units. Subsequently, double-unit CBT (DCBT) was formally investigated by the University of Minnesota as a method to augment graft cell dose. These investigators demonstrated the safety and feasibility of this approach.³³ Barker et al³⁴ reported two series of DCBT after myeloablative and reduced-intensity conditioning (RIC) conditioning in patients with high-risk hematologic malignancies.³⁵ The myeloablative series evaluated 23 patients (median age 24 years) and

Fig. 107.3 CUMULATIVE INCIDENCE (CI) OF TRANSPLANT-RELATED MORTALITY (TRM) ACCORDING TO THE COMBINED TOTAL NUCLEATED CELL (TNC) DOSE AND HUMAN LEUKOCYTE ANTIGEN MISMATCH AFTER SINGLE-UNIT MYELOABLATIVE CORD BLOOD TRANSPLANTATION. MM, Mismatched. (From Barker JN, Scaradavou A, Stevens CE: Combined effect of total nucleated cell dose and HLA match on transplantation outcome in 1061 cord blood recipients with hematologic malignancies. *Blood* 115:1843, 2010.)

demonstrated that all evaluable patients achieved donor-derived neutrophil engraftment at a median of 23 days. The striking finding of this report was the high level of engraftment despite sustained hematopoiesis being mediated by a single donor in nearly all patients and the high 1-year overall survival (OS) of 72%. The RIC series demonstrated that it was possible to engraft CB after conditioning with cyclophosphamide 50 mg/kg, fludarabine 200 mg/m², and 200 cGy of total body irradiation. In 2007, Brunstein et al³⁶ updated the RIC experience in 110 adults (17 single-unit CBT and 93 DCBT) and demonstrated neutrophil engraftment in 92% but a higher probability of 3-year event-free survival of 39% in DCBT recipients compared with 24% in single-unit recipients ($p = .05$). The high incidences of donor-derived neutrophil engraftment have been subsequently replicated at other centers.^{37–41}

Determinants of Unit Dominance

After DCBT single cord provides long-term engraftment while the second unit is lost in a majority of cases usually within 30–60 days and evidently within 1 year.^{34,36,38,40,42,43} Myeloablative conditioning regimens lead to an early dominance of single unit,³⁴ while nonmyeloablative conditioning regimens are associated delayed emergence of single dominant unit.³⁶ Less than 5% of patients may have evidence of stable persistent mixed-unit chimerism,^{41,44–49} defined as detection of both CB units at varying proportions for at least 1 year posttransplantation.⁵⁰ This is more common after nonmyeloablative conditioning regimens and if two CB units are closely HLA-matched to each other.³⁶ Moreover, a review of studies with persistent mixed-unit chimerism suggests that HLA-C matching between the cords may be associated with a higher likelihood of mixed-unit chimerism through intercord tolerance induction.⁵⁰ The determinants of DCBT unit dominance remain to be fully elucidated. Better HLA match, ABO group, and higher infused TNC or

CD34⁺ cell doses have not predicted which unit will win. Current evidence suggests that unit dominance is predominantly immune-mediated, although unit hematopoietic potential can also play a role (Table 107.2).

Host Factors as Determinants of Unit Dominance

Based on earlier studies using DCBT murine models and correlating findings that the dominant unit in mice correlated clinically in 18 of 21 patients, it was suggested that unit dominance is not related to host-versus-graft factors.⁵¹ Later studies showed that there was no effect of donor-specific anti-HLA antibodies in on the speed of engraftment or unit dominance in recipients of DCBT,⁵² providing further evidence that host factors do not play a major role in unit dominance.

Hematopoietic Potency as a Determinant of Unit Dominance

Although the infused CD34⁺ cell or colony-forming unit dose has not been associated with unit dominance, studies suggest that high CD34⁺ cell viability, which correlates with colony-forming unit potential, predicts unit dominance.^{41,53,59,60} Thus, damage to the unit as reflected by a low percentage of viable CD34⁺ cells likely impairs engraftment potential.

Immune Factors as Determinants of Unit Dominance

The role of graft T-cells in predicting unit dominance is supported by the studies showing that higher infused CD3⁺ cell dose correlates with the engrafting unit.^{41,61} Murine models have also suggested

TABLE 107.2

Potential Determinants of Unit Dominance After Double-Unit Cord Blood Transplantation

Potential Mechanism	Reference	Finding	Implications
Host factors	Eldjerou et al ⁵¹	Unit dominance in mice correlated with clinical engraftment.	Host factors do not influence unit dominance.
	Brunstein et al ⁵²	Donor specific anti-HLA antibodies had no influence on unit dominance.	
Unit factors Hematopoietic potential	Scaradavou et al ⁵³	Infused TNC/kg, CD34 ⁺ /kg, and CFU doses were not associated with unit engraftment. However, units with low CD34 ⁺ viability were very unlikely to engraft.	Infused CD34 ⁺ cell dose and CFU, CFC, or CAFC content do not directly influence unit dominance, but poor-quality units are very unlikely to engraft in humans.
	Eldjerou et al ⁵¹	In vitro CFC and CAFC content did not correlate with unit dominance.	
Immune factors	Barker et al ³⁴	Higher infused CD3 ⁺ cell dose is associated with unit dominance.	Graft-versus-graft interactions dictate unit dominance.
	Scaradavou et al ⁵³		
	Avery et al ⁴¹		
	Kim et al ⁵⁴	DCBT with MNC associated with unit dominance whereas coengraftment achieved with lineage depletion or MSC infusion.	
	Yahata et al ⁵⁵	Mixed chimerism achieved by CD34 ⁺ selection.	
	Eldjerou et al ⁵¹	Loss of unit dominance with CD34 ⁺ DCBT restored with addition of CD34 ⁺ cells.	
	Delaney et al ⁵⁶	Unmanipulated unit is dominant when coinfect with T-cell depleted expanded CB.	
	Gutman et al ⁵⁷	Dominant unit CD8 ⁺ T cells directed against the nondominant unit detected in patients with single unit dominance.	
	Avery et al ⁴¹	High level of unit–unit match associated with increased likelihood of coengraftment.	
	Brunstein et al ⁵⁸	Higher prevalence of dual chimerism after Treg infusion.

that an immune mechanism accounts for unit dominance. Studies in nonobese diabetic severe combined immunodeficient interleukin-2 receptor gamma null (NOD/SCID/IL-2R- γ^{null}) mice demonstrated that despite each unit engrafting alone, coinfusion of mononuclear cells as a double-unit graft was associated with predominance of one CB unit.^{54,55} Further, unit dominance could be mitigated (and engraftment of both units achieved) with either lineage depletion of the units or cotransplantation of third-party BM-derived mesenchymal stromal cells and mixed chimerism could be generated by CD34⁺ cell selection.^{54,55} It was also shown that the unit dominance was T-cell-mediated and involved both CD4⁺ and CD8⁺ cells. Furthermore, it can be hypothesized that the failure of sustained engraftment of ex vivo expanded CB units in clinical trials of DCBT in which one of two units is expanded is not attributable to failure to expand or maintain sufficient progenitors in the manipulated unit but because the expanded unit is T-cell depleted and therefore cannot compete with a T-cell replete unmanipulated unit.⁵⁶

Graft-versus-graft interactions also play a role in determining unit dominance. This is suggested from NOD/SCID/IL2R- γ^{null} murine study showing that DCBT using CD34⁺ cells was associated with loss of both unit dominance, and addition of CD34⁻ cells from only one of the two units restored unit dominance, with engraftment being mediated by the origin of the CD34⁻ cells.⁵¹ Moreover, Brunstein et al.⁵⁸ evaluated the safety of ex vivo expanded regulatory T cells (Tregs) in DBCT recipients and found an increased prevalence of coengraftment of both units (dual donor chimerism), suggesting that graft-versus-graft interactions could be ameliorated by suppressing T-cell responses.

Additional evidence in favor of an immune basis for unit dominance comes from the study by Gutman et al.,⁵⁷ who identified CD8⁺ T cells derived from the dominant unit that recognized the

nondominant unit were present in the PB 28 days after transplantation in 9 of 10 DCBT recipients engrafting with single units regardless of the conditioning regimen. Interestingly, the three patients who had persistent mixed chimerism also did not develop an alloreactive CD8⁺ T-cell response.

Clinical data from Avery et al.⁴¹ have demonstrated a role of HLA-match in unit dominance. Interestingly, in this analysis of 84 DCBT recipients, the dominant units were not necessarily better HLA-matched to the recipient compared with the nondominant unit of a double-unit pair (Fig. 107.4). However, the unit-unit HLA match influenced the length of time the ultimately nonengrafting unit was able to be detected. Specifically, recipients of double-unit grafts in whom the unit-unit HLA match was 7/10 or greater HLA-allele matched were significantly more likely to have initial coengraftment and transient persistence of the ultimately nonengrafting unit with one patient having sustained engraftment of both units long term. By contrast, recipients of units highly mismatched (<6/10) to each other were more likely to have engraftment with only a single unit. This is likely because of an enhanced unit-versus-unit immune response, whereas closely HLA-matched units are more likely to be relatively tolerant of each other, and in this setting, at least transient coengraftment is possible.

Taken together, these findings suggest that unit dominance likely involves a complex interplay of hematopoietic potential as suggested by the role of CD34⁺ cell viability as well as immune factors that are likely T-cell-mediated because no role for natural killer (NK) cells has been identified to date.⁶² Future studies need to elucidate the specific cell population mediating the graft-versus-graft effect in the setting of the transplantation of two units with adequate engraftment potential. This will enhance our CB unit selection process for infusion and for novel graft manipulation techniques elaborated later.

Fig. 107.4 INFLUENCE OF HIGH RESOLUTION UNIT-RECIPIENT HUMAN LEUKOCYTE ANTIGEN MATCH ON SUSTAINED DONOR ENGRAFTMENT AFTER DOUBLE-UNIT D BLOOD TRANSPLANTATION ($n = 84$). The engrafting units were not better matched to the recipient. (From Avery S, Shi W, Lubin M, et al: *Influence of infused cell dose and HLA match on engraftment after double-unit cord blood allografts*. Blood 117:3277, 2011.)

CORD BLOOD UNIT SELECTION

Efficient search and selection of CB units requires decision making as to what banks to consider and what factors to prioritize in unit selection. The unit selection algorithm currently used at the Memorial Sloan-Kettering Cancer Center (MSKCC) is shown in Fig. 107.5.⁶³ The M.D. Anderson Cancer Center (MDACC) uses a similar approach. Primary unit selection criteria are based on the prethaw cryopreserved TNC/kg, the unit-recipient HLA match (4-6/6 of HLA-A, HLA-B antigen, and HLA-DRB1 allele), and the bank of origin based on the authors' experience with the bank and their accreditation. Other factors such as the availability of confirmatory HLA typing on an attached segment and the completeness of maternal infectious disease marker and hemoglobinopathy testing are also taken into account.

The exact threshold for acceptable TNC/kg has yet to be established and varies with HLA match. For example, the 2010 NYBC analysis of single-unit CBT demonstrated that recipients of units with a 6/6 HLA match had the best transplantation outcomes regardless of the cryopreserved TNC dose. By contrast, recipients of 4/6 units required a TNC dose of $5.0 \times 10^7/\text{kg}$ or greater to achieve similar TRM and DFS to that of recipients of 5/6 units with TNC of $2.5\text{--}4.9 \times 10^7/\text{kg}$.¹² Although the numbers of DCBT recipients available do not yet permit such analysis, it is likely that similar principles will be found associated with the engrafting unit in DBCT recipients. Indeed, Avery et al⁴¹ have reported that a higher infused TNC and CD34⁺ cell dose in the engrafting unit of a double-unit pair was strongly associated with the speed and success of neutrophil engraftment. However, because it is not currently possible to predict which unit will predominate at the time of

double-unit graft selection, a minimum threshold for each unit of a double-unit graft is needed. Based on the analysis by Avery et al⁴¹ a minimum TNC dose threshold of at least $2.0 \times 10^7/\text{kg}$ is currently recommended in DCBT. The age of cryopreserved CB units should not be criteria when selecting CB units. A study showed that units cryopreserved for up to 11 years before transplantation had no impact on postthaw TNC recovery or neutrophil or platelet engraftment in 288 single CBT recipients.⁶⁴

Recent analyses have highlighted new factors to be considered in unit selection. The 2009 NYBC analysis evaluated the impact of fetal exposure to noninherited maternal antigens (NIMAs) on the outcome of CBT.⁶⁵ The 79 single-unit CBT recipients that had an HLA-mismatched antigen that was identical to a donor NIMA engrafted earlier and had lower TRM and overall mortality. There was also a lower tendency toward relapse among patients with myeloid malignancies. Subsequently, in 2011, the NYBC analyzed the effect of HLA-mismatch vector in 1202 single-unit CBT recipients.⁶⁶ They identified 98 donor-recipient pairs with only unidirectional mismatches (58 in the graft-versus-host direction and 40 in the rejection direction). The graft-versus-host vector group had faster engraftment and decreased TRM and overall mortality compared with the one-bidirectional mismatch reference group, but recipients of rejection only mismatched units had slower engraftment, a higher incidence of graft failure, and higher relapse rates. Also in 2011, Eapen et al²⁷ reported that HLA-C matching is important in addition to HLA-A, HLA-B, and HLA-DRB1, although how to balance this against TNC dose needs to be further investigated. Finally, the potential importance of antigens in the patients that are shared with inherited paternal antigens in the CB donor that could be a target for maternal T cells has recently been reported as a potential mechanism of reduced relapse after CBT.⁶⁷

The findings concerning the importance of HLA-mismatch vector and HLA-C can be immediately incorporated into CB unit selection algorithms, but incorporation of NIMA and inherited paternal antigen will require banks to provide maternal typing. In addition, although the best available CB unit or units are selected as the graft, it is important to identify and reserve at least one backup unit in the event of problems with unit shipment, mislabeling, problems with thaw, or graft failure.⁶⁸⁻⁷⁰ At both MSKCC and MDACC, the authors select one domestic unit as backup to ensure the timely infusion of an optimal CB product.

It is unclear if recipients should be assessed pretransplant for anti-HLA antibodies possessing specific alloreactivity against CB units (donor specific antibodies, DSAs), as these may have an impact on post-DCBT outcomes although the data are rather conflicting. Cutler et al⁷¹ analyzed the outcomes of 73 DCBT recipients after either myeloablative or RIC regimens. DSAs were detected in 24% of the patients, of which about 60% were directed against one CB unit and the rest targeted both units. Rate of graft failure was drastically higher in patients with DSAs directed against both units (57%) compared with those with DSAs against single unit (18%) or those with no DSAs (5.5%). Also, time to neutrophil engraftment was prolonged (29 days versus 21 days; $p = .004$) and day 100 mortality or relapse was increased in patients with any DSA. Noteworthy, more than 70% of patients received RIC regimens that included ATG. Another study using RIC regimens in 294 CBT recipients found DSAs in 14 patients (4.7%), half of whom received single CBT.⁷² As seen in the Cutler study,⁷¹ patients with DSAs had significantly worse neutrophil engraftment (44% versus 81%, $p = .006$), 1-year TRM (46% versus 32% $p = .06$) and a trend towards poor OS (42% versus 29%; $p = .07$) compared with those without DSAs. On the contrary, Brunstein et al⁵² found no impact of DSAs in their study of 126 DCBT recipients. Overall, DSAs were present in about 15% of the patients, of which two-thirds were directed against one CB unit and one-third against both units. The cumulative incidence of neutrophil engraftment was similar in patients with DSAs against at least one CB unit (78%; median, 24.5 days) compared with patients with irrelevant anti-HLA antibodies (84%; median, 24 days) and those with no antibody (86%; median, 19 days), $p = .54$. Overall, 35% of entire study cohort received myeloablative conditioning, but the type

Fig. 107.5 CURRENT MEMORIAL SLOAN-KETTERING CANCER CENTER AND M.D. ANDERSON CANCER CENTER SCHEMA OF HOW TO SELECT CORD BLOOD (CB) UNITS. CT, Confirmatory typing; HLA, human leukocyte antigen; RBC, red blood cell; TNC, total nucleated cell. (From Barker JN, Byam C, Scaradavou A: *How I treat: the selection and acquisition of unrelated cord blood grafts*. Blood 117:2332, 2011.)

of conditioning specifically used in patients with DSAs was not reported. Similar to these findings, more recently Dahi et al⁷³ also showed no impact of DSAs on engraftment in 82 DCBT recipients who were transplanted with either myeloablative (82%) or nonmyeloablative (18%) conditioning. DSAs were present in about 15% of patients, half of which targeted both CB units. There was no difference in cumulative incidence of engraftment at day 42 in patients with DSAs (92%), without DSAs (95%), or those with nonspecific HLA-antibodies (100%). Intriguingly, half of the patients with DSAs against one CB unit actually engrafted with that unit. Of note, all patients with DSAs in this study received myeloablative conditioning. Therefore, it is possible that the use of DCBT and myeloablative conditioning may overcome any potential adverse effect of DSAs. Some of the differences in these studies could be explained by differences in underlying patient population, type of conditioning regimen, GVHD prophylaxis, use of ATG or not, assay used to detect DSAs, threshold for labeling DSAs as positive and the median fluorescence intensity of DSAs. Although virtual cross-match techniques may be used to screen for DSAs,⁷⁴ it is debatable if their presence should be assessed in all patients being considered for CBT. It certainly adds to health care costs and may delay search for an “appropriate” unit.

DOUBLE-UNIT VERSUS SINGLE-UNIT CORD BLOOD TRANSPLANTATION

Engraftment

The use of double-unit CB grafts is now a standard approach to augment cell dose, although DCBT does not improve or hasten engraftment compared with adequately dosed single-unit CBT.^{75–77} A recent phase III, multicenter, randomized trial conducted by the Blood and Marrow Transplant Clinical Trials Network (BMTCTN) in collaboration with Children's Oncology Group (BMTCTN-0501 trial), involving children (median age 9.9 years) with hematologic malignancies compared the use of single ($n = 112$) with double ($n = 108$) CBT after myeloablative conditioning.⁷⁷ The study found no difference in the incidence of neutrophil recovery (88% versus 89%), or the time to neutrophil engraftment between the groups (23 versus 21 days respectively). On the contrary, the recipients of single CBT had significantly faster platelet engraftment compared with DCBT recipients (median 58 versus 84 days, respectively).

In the absence of a randomized controlled trial in adults, data from retrospective series and a small prospective study suggest similar rapidity and cumulative incidence of engraftment between single or double CBT recipients. A retrospective analysis of the CIBMTR and the NYBC registries compared single ($n = 106$) with double ($n = 303$) CBT after myeloablative ($n = 216$) or RIC regimens ($n = 193$) in adults with acute leukemia.⁷⁶ The median time to neutrophil engraftment (20 days in both groups) and the probability of neutrophil engraftment by day 42 were identical in both groups (81% after single CBT versus 78% after DCBT, $p = .83$).

A prospective study in adults (median age 53.5 years) compared single CBT ($n = 27$) with DCBT ($n = 23$) after RIC regimens.⁷⁵ Patients underwent single CBT if cryopreserved TNC dose in one unit was $>2.5 \times 10^7/\text{kg}$ recipient weight. Once again, there were no differences in the median time to neutrophil engraftment among single CBT (25 days) or DCBT (23 days), or the cumulative incidence of neutrophil engraftment at day 100 posttransplantation (88.4% versus 91.3% respectively, $p = .99$).

Graft-Versus-Host Disease

GVHD is a major cause of morbidity and one of the leading causes of mortality after DCBT.^{22,26,38,78–81} Also, DCBT may be associated with an increased incidence of acute GVHD compared with single CBT in a specific subset of patients, especially if transplantation is performed without the use of ATG or ALG.^{78,82} The results across studies are variable because of heterogeneity in study population,

transplant procedures and study designs. The following section highlights some of these differences.

In the BMTCTN-0501 randomized trial,⁷⁷ a higher incidence of grade III–IV acute GVHD was noted in children receiving double-unit than those receiving single-unit CBT (23% versus 13%, $p = .02$). Similarly, the incidence of chronic extensive GVHD was higher in the DCBT group at 1 year after transplantation (15% versus 9%, $p = .05$). A retrospective study conducted by the Eurocord and Acute Leukemia Working Party of European Blood and Marrow Transplant (EBMT) group⁸¹ in adults with acute leukemia ($n = 239$) receiving myeloablative conditioning found higher risk of grade II–IV acute GVHD after DCBT compared with single CBT (43% versus 26%, $p = .005$); however, two-thirds of these events were grade II acute GVHD. Age less than 35 years (HR 0.55, 95% CI, 0.34–0.88, $p = .01$) and the use of single CBT (HR 0.84, 95% CI, 0.41–0.96, $p = .02$) were independently associated with lower risk of acute GVHD.

In a retrospective analysis by MacMillan et al⁸² comparing single-unit ($n = 80$) and double-unit ($n = 185$) CBT, the incidence of grade II–IV acute GVHD was noted to be significantly higher in recipients of DCBT (58% versus 39%, $p < .01$). However, the increased risk was predominantly accounted by grade II skin acute GVHD, and the overall incidence of grade III–IV acute GVHD was similar among the groups (19% versus 18%). Of note, differential use of ATG, differences in age, year of transplant, conditioning regimens and GVHD prophylaxis between the groups are some of the important biases in the study. For instance, the single CBT group was younger (median age 23 years) and ATG was used in more than half of them. In contrast, the median age of patients in the double-CBT group was 45 years and only about a quarter received ATG. Younger age and higher use of ATG may explain lower incidence of acute GVHD seen after single CBT.

On the other hand, the CIBMTR-NYBC registry analysis of adequately dosed single ($n = 106$, median age 33 years) or double ($n = 303$, median age 43 years) CBT in adults also showed significantly higher risk of grade II–IV acute GVHD in recipients of DCBT compared with single CBT.⁷⁶ However, this increased risk was noted only during the early study period (2002–2004), but not in the later period (2005–2009). In the early period, the day 100 probabilities of grade II–IV acute GVHD after single and DCBT were 18% and 58% respectively ($p < .001$). In the later period, the corresponding probabilities were 27% and 31% respectively. Likewise, there were no differences in the rates of grade III–IV acute GVHD (14% versus 18%) or chronic GVHD at 2-years (24% versus 31%) among the groups. Notably, significantly more patients in the single CBT group received myeloablative conditioning compared with DCBT group (72% versus 45% respectively, $p < .0001$). As the use of myeloablative regimens is generally associated with a higher risk of GVHD compared with RIC regimens, this may have biased the study results. Another study in patients with lymphoid malignancies ($n = 104$, median age 41 years), found no impact of using single or double CBT after RIC regimens on the incidences of acute or chronic GVHD.⁸³

The effect of in vivo T-cell depletion on GVHD has also been investigated.^{84–87} However, the results across studies must be interpreted with caution, taking into consideration the type of in vivo depletion used (ATG, ALG, or alemtuzumab), type of ATG used (rabbit versus horse), dose (high versus low) and the timing (early versus delayed) in addition to baseline patient characteristics and transplant practices.

A study evaluated the impact of rabbit ATG (total dose 10 mg/kg) on CBT outcomes in 127 children after either myeloablative or RIC regimens.⁸⁴ GVHD prophylaxis consisted of cyclosporine with either prednisolone or mycophenolate mofetil (MMF). Patients were divided into three groups: early ATG group (between days –9 and –5), late ATG group (between days –5 and 0), and no-ATG group. The study found an increased risk of acute GVHD and lower rates of viral infections and infection related deaths in the group that did not receive ATG compared with the groups that did. Further, the risk of acute GVHD was significantly higher in the no-ATG group (HR 8.2, $p < .001$) and early-ATG group (odds ratio [OR] 3.9, $p = .005$) compared with the late-ATG group. However, there were no

differences in chronic GVHD or other outcomes including neutrophil engraftment, NRM, relapse and OS between the groups. Although patients in the early-ATG group had significantly faster CD3+, CD4+, and CD4+naive T-cell immune reconstitution at 1 and 2 months post-CBT compared with patients in the late-ATG group, yet, there were no differences in viral reactivation episodes in early and late-ATG groups. This is likely related to attainment of similar immune reconstitution by 3 months post-CBT in both groups. Therefore, the early use of ATG does not offer any clinical advantage over not using ATG at all.

Series of DCBT in adults incorporating ATG have demonstrated lower rates of GVHD than what is typically seen after CBT without the use of ATG. For example, Cutler et al⁸⁵ reported an overall incidence of grade II–IV acute GVHD of 9.4% and chronic GVHD of 12.5% in adults ($n = 32$, median age 53 years) after RIC using rabbit ATG (days $-7, -5, -3, -1$; total dose 6.0 mg/kg) and GVHD prophylaxis with sirolimus plus tacrolimus. Unsurprisingly, immune reconstitution was remarkably prolonged; the CD4+CD45RA+, CD4+CD45RO+, and CD4+CD25+ T-cell subsets did not reach the pretransplantation levels even at 2-years posttransplantation. Consequently, five patients developed Epstein Barr virus (EBV) reactivation leading to fatal posttransplant lymphoproliferative disorder and five additional patients died of sepsis (4 caused by human herpesvirus-6 and EBV-related meningoencephalitis). The NRM at 2-years was 34.4%, which is considerably higher than what is reported by other RIC CBT series.^{78,86,88–94} Another study included 42 adults RIC DCBT patients (median age 49 years) who received rabbit ATG and tacrolimus/sirolimus (69%) or cyclosporine based (31%) GVHD prophylaxis.⁸⁶ The dose and timing of ATG were not mentioned. Although there were low incidence of grade II–IV acute GVHD (21%) and chronic GVHD (24%), but as expected, T-cell immune reconstitution was substantially prolonged. The median number of CD4+ T cells did not reach >200 cells/mL even 9 months post-transplant leading to high rate of early infection (59%) within the first 100 days after transplantation. Similarly, Brunstein et al⁸⁷ showed an increased risk of EBV-related complications with the use of high dose equine ATG (15 mg/kg given every 12 hours for 6 doses, days $-5, -4$, and -3) after Fludarabine/Cytarabine/total body irradiation (TBI) RIC regimen but not after myeloablative regimens. The incidence of EBV-related complications was 3.3% in patients with myeloablative CBT, but in patients with RIC CBT the incidence was 21% if ATG was used and 2% if was omitted, $p < .01$.

Although the use of ATG is associated with a higher risk of serious infections, including fatal EBV-related complications,^{85,87,95} delayed immune reconstitution,^{85,86,96} increased risk of TRM,^{36,83} and possibly increased risk of relapse,⁹⁷ the exclusion of ATG on the other hand is associated with an increased incidence of acute GVHD. Series of studies from MSKCC omitted the use of ATG in DCBT recipients after either myeloablative (70%, median age 24 years) or RIC (30%, median age 10 years).^{78,98,99} GVHD prophylaxis consisted of a calcineurin inhibitor and MMF. The omission of ATG led to rapid T-cell immune reconstitution (median CD4+ T-cell count >200 cells/ μ L by day 120 post-CBT) with resultant low incidence of serious infections or deaths caused by infections. Consequently, cumulative incidence of 2-year TRM was low (21% at day +100 and 25% at 2-years), but cumulative incidences of grade II–IV acute GVHD were high (43%).

Thus, better understanding of the pathophysiology of GVHD after DCBT is needed to incorporate effective prevention and treatment strategies balancing the risks of GVHD and infections.

Relapse and Disease-Free Survival

Disease relapse is the most common cause of mortality after CBT, contributing to 30% to 60% of deaths. In general, various DCBT studies reported an average relapse risk of approximately 10% to 35% and DFS of about 30% to 55% at 2–5 years depending upon underlying patient characteristics, disease risk and type, type of conditioning regimen and transplant practices.^{38,76,79,81,100–103} A few retrospective series suggest that DCBT is associated with a lower risk of relapse

compared with single CBT in certain patients,^{36,42,83} while other studies did not find a similar association.^{76,81}

The Eurocord-Netcord investigators showed that the use of DCBT with either myeloablative conditioning or RIC was associated with a significantly lower risk of relapse or progression at 2-years compared with single CBT (13% versus 38%; $p = .009$) in adults with lymphoid malignancies, but without any difference in DFS.⁸³ Verneris et al⁴² analyzed the risk of acute leukemia relapse in 177 recipients of myeloablative CBT and found that for patients in first or second complete remission, the risk of relapse was markedly reduced in DCBT recipients compared with single CBT recipients (19% versus 34%, $p = .03$). Again, no differences in leukemia-free survival (LFS) were noted between the groups (55% in single and 58% in DCBT group at 1-year, $p = .35$). However, the single CBT group included pediatric patients ($n = 84$, median age 8 years) while the DCBT arm included mostly adults ($n = 93$, median age 24 years). Another study in 110 adults with various hematologic malignancies noted a trend towards lower relapse after DCBT with nonmyeloablative conditioning (30% versus 41%, $p = .07$) and significantly improved 3-year DFS after DCBT (39% versus 24%, $p = .05$) compared with single CBT.³⁶ Another large registry study ($n = 239$) by the Eurocord and the EBMT group in adults with acute leukemia in first complete remission receiving myeloablative conditioning found significantly improved 2-year DFS in DCBT group (48%) and single CBT patients who received thiopeta/busulfan/fludarabine conditioning (48%), compared with single CBT performed with either busulfan- or TBI-based conditioning (30%), $p = .003$. No difference in the risk of relapse at 2-years (20% versus 19%, $p = .72$) was noted in single or double CBT recipients respectively.⁸¹ Of note, DCBT recipients were younger, received higher cell dose, and ATG was used less frequently than other groups.

Contrarily, the CIBMTR-NYBC registry study of adult leukemia patients did not find any difference in 2-year probabilities of relapse (32% versus 36%) or DFS (30% versus 32%) after single or double CBT, respectively. Correspondingly, the BMTCTN-0501 phase III randomized study in pediatric patients found similar rates of 1-year relapse (12% versus 14%, $p = .12$) and DFS (70% versus 64%, $p = .11$) among single-unit or DCBT recipients respectively.⁷⁷ Therefore, it is likely that the dissimilarities in relapse or DFS risk noted across studies are reflections of differences in patients, disease type, risk and remission status, and transplant characteristics.

Nonrelapse Mortality and Overall Survival

In general, the use of myeloablative conditioning is associated with lower risk of relapse at the expense of higher toxicity and NRM. On the other hand, RIC regimens are well tolerated and result in lower TRM but are associated with higher risk of relapse, thus resulting in similar OS as seen after myeloablative conditioning.^{104,105} The use of double-unit graft does not add to NRM compared with the use of single CBT.^{42,76,77,81} The average 2–3 year cumulative incidence of NRM reported by various DCBT studies is about 20% to 45% and OS is in the range of 35% to 65%, which are comparable with those observed after single CBT.

The BMTCTN-0501 randomized trial in pediatric patients reported similar 1-year OS (65% versus 73%; $p = .17$) and 1-year TRM (19% versus 22%; $p = .43$) among single-unit or DCBT recipients respectively.⁷⁷ In adults, the Eurocord and the EBMT registry study found similar 2-year NRM after myeloablative single or double CBT (38% versus 34%, $p = .95$).⁸¹ Similarly, the CIBMTR-NYBC registry analysis found a trend toward lower 6-month probability of TRM after DCBT compared with single CBT (21% versus 31%, $p = .06$) in adult patients with acute leukemia, without any difference in 2-year OS (35% versus 33%, $p = .66$).⁷⁶

Studies also imply that DCBT recipients who survive early post-transplant period are very unlikely to die of delayed transplant-related causes. In the MSKCC series of DCBT recipients of either myeloablative ($n = 53$; 71%) or nonmyeloablative ($n = 22$; 29%) conditioning, 2-year TRM of 25% was almost entirely accounted for by

patients dying in the first 6 months after transplant.⁷⁸ In another study, the median time to TRM was 3 months; few deaths occurred after 1-year posttransplantation which resulted in 1- and 3-year OS rates of 57% and 52% respectively.³⁸ Steady immune recovery observed after 6 months of transplantation likely contributes to this protection against late mortality.⁹⁸

Comparison of Double-Unit Cord Blood Transplantation With Adult Donor Allografts

A number of retrospective studies have shown comparable outcomes after DCBT and adult donor transplantation, supporting the use of double-unit grafts as an alternative stem cell source (Table 107.3). However, DCBT is associated with significantly prolonged engraftment of neutrophils and platelets, and increased NRM compared with other types of allografts.^{22,26,94,100,102,106–109}

After **myeloablative** conditioning DCBT, the median time to neutrophil engraftment is 3 weeks and that to platelet engraftment is 5 weeks approximately.^{22,26,102,106–109} The risks of acute GVHD, especially grade III–IV (5–25%), and chronic GVHD (20–40% at 3 years), especially extensive, are significantly lower after DCBT compared with other graft sources.^{102,107,109} The risk of NRM at 2–5 year is typically higher after CBT (about 35–40%) than after other types of transplants (15–35%).^{107,109} One of the most important factors contributing to high NRM is delayed neutrophil engraftment. As

shown by Brunstein et al,¹⁰⁷ 5-year NRM was 41% in DCBT patients who engrafted beyond 26 days compared with 16% in patients who achieved neutrophil engraftment within 26 days, which was similar to NRM seen with other donor types. The risk of relapse at 3–5 years is about 12% to 22% after DCBT. Various studies comparing DCBT with other types of transplants showed inconsistent findings. A study by Gutman et al¹⁰⁶ in 31 CBT patients (87% DCBT) showed significantly lower cumulative incidence of relapse at 2-years after CBT (3.2%) compared with matched unrelated donors (MUD; 23%) and mismatched unrelated donors (MMUD; 26%). A subsequent larger study by Brunstein et al¹⁰⁷ similarly showed marked reduction in relapse risk at 5-year after DCBT (15%) compared with matched related donors (MRD; 43%), MUD (37%) and MMUD (35%), $p < .01$. However, a few recent studies involving patients with either single or double CBT did not find a similar advantage of relapse prevention after CBT.^{102,108,109} However, these studies have some notable differences between CBT group and their comparative arms. In the study by Liu et al,¹⁰⁹ there were appreciably more high-risk patients in the CBT group (87%) compared with the MRD recipients (47%). Also, conditioning regimens differed significantly between the groups. Another study included ALL patients in complete remission (CR)1 and CR2, and ATG was used more commonly in the CBT group compared with other allografts (31% versus 21%).¹⁰² A third study by Konuma et al¹⁰⁸ included high-risk patients (65%) older than 45 years of age who received CBT with methotrexate-based GVHD prophylaxis compared with MMF-based regimen used in

ATG, Antilymphocyte globulin; Bu/Flu, busulfan/fludarabine; CBT, cord blood transplantation; CI, confidence interval; DCBT, double-unit CBT; DFS, disease-free survival; GVHD, graft-versus-host disease; LFS, leukemia-free survival; MA, myeloablative; MMUD, mismatched unrelated donor; MRD, matched related donor; MUD, matched unrelated donor; NMA, nonmyeloablative; OS, overall survival; PB, peripheral blood; PBSCT, peripheral blood stem cell transplantation; PFS, progression-free survival; RD, related donor; RIC, reduced-intensity conditioning; TBI, total body irradiation; TCD, T-cell depleted; TRM, transplant-related mortality; URD, unrelated donor.

other studies. Also, the authors do no mention if the patients received single or double CB grafts.

Other long-term outcomes such as DFS and OS are similar after DCBT and other types of transplants.^{22,26,102,106–109} Therefore, DCBT with myeloablative conditioning is an appealing alternative as it offers a substantial advantage of lower risk of GVHD without jeopardizing graft-versus-tumor effect.

The introduction of RIC regimens extends the application of DCBT in older (>45–50 years) and infirm individuals who are otherwise not candidates for myeloablative conditioning. Multiple studies showed encouraging results after RIC DCBT compared with other graft sources.^{86,88–92,94,100,101} Time to neutrophil engraftment is faster after RIC (average 15 ± 5 days) compared with myeloablative CBT; however it is still slower than what is achieved with other types of transplants.^{86,88–92,94,100,101} The risk of chronic GVHD at 1–3 years is lower after CBT (15–30%), while other outcomes such as grade II–IV acute GVHD (15–50%), 1–3 years relapse (30–45%), DFS (30–60%), and OS (35–60%) are comparable with other transplants types.^{86,88–92,94,100,101} As seen with myeloablative DCBT, a few studies using RIC regimens also showed an increased risk of TRM after DCBT (10–30% at 0.5–3 years).^{91,100} Most of the TRM and other

complications seen after CBT are encountered during the early post-transplantation period. These are related to delayed time to hematopoietic recovery and immune reconstitution compared with the transplantation of related and unrelated donor PB HSCs. This leads to prolonged hospitalization, higher rates of early infectious complications, and increased early TRM. Thus, strategies to enhance engraftment are of immense interest.

NOVEL STRATEGIES TO ENHANCE ENGRAFTMENT

Studies investigating the infusion of multiple small CB units have not enhanced engraftment.¹¹⁰ Results of direct intra-BM injection of CB have been mixed,^{111,112} with a study at the University of Minnesota being abandoned for futility. New approaches focusing on enhancing engraftment are summarized in Table 107.4.

The Spanish group of Fernandez et al¹²⁵ evaluated the coinfusion of CD34⁺ cells from a related haploidentical donor with a single-unit CBT as a “bridge” strategy to shorten the period of posttransplant neutropenia. Subsequently, these investigators updated their experience using mobilized PB HSCs from either a haploidentical or an

TABLE 107.4 Potential Strategies to Enhance Cord Blood Engraftment

Strategy	Reference	Protocol	Patients (n)	Median Age (year)	Neutrophil Engraftment	Platelet Engraftment ($\geq 20,000/\text{mm}^3$)	Outcomes
Coinfusion of HSC	Bautista et al ¹¹³	Single CB units + coinfusion of TCD HSC from haploidentical or third-party donors	55	34	96%; median ANC, 10 days (9–36 days)	78%; median time, 32 days (13–98 days)	DFS 47% and OS 56% at 5 years
	Liu et al ¹¹⁴	Single CB units + coinfusion of TCD HSC from haploidentical related donors	45	50	95%; median ANC 11 days (9–15 days)	83%; median time, 19 days (15–33 days)	PFS 42% and OS 55% at 1 year

Stem cell homing	Campbell et al ¹²⁰	CD26 inhibition	N/A (mice)	N/A	Significant increase in engraftment	Unknown	N/A
	Christopherson et al ^{121,122}						
	Cutler et al ¹²³	CB treated with PGE ₂ Cohort 1	9	43	Median ANC, 24 days in 7/9	Median, 72.5 days	2 graft failures
		CB treated with PGE ₂ Cohort 2	12	57.5	Median ANC, 17.5 days (14–31 days)	Median, 43 days (20–60 days)	No graft failure
	Popat et al ¹²⁴	Fucosylation of CB CD34 ⁺ cells	22	42	Median ANC, 17 days (12–34 days)	Median, 35 days (18–100 days)	1 patient died from sepsis on day 23; 1 had secondary graft failure.

ANC, Absolute neutrophil count; CB, cord blood; DFS, disease-free survival; HSC, hematopoietic stem cell; MSC, mesenchymal stem cell; N/A, not applicable; OS, overall survival; PGE₂, prostaglandin E₂; PFS, progression-free survival; TCD, T cell depleted; TEPA, tetraethylenepentamine.

unmatched third-party donor to support single-unit CBT.¹¹³ This series included 55 patients with high-risk hematologic malignancies. The median time to neutrophil recovery was 10 days, and the maximum cumulative incidence of neutrophil engraftment was 96%; the median time to platelets greater than $20,000/\text{mm}^3$ was 32 days with an incidence of 78%. The cumulative incidence of full CB chimerism was 91% and took a median of 44 days. Grade II–IV acute GVHD developed in 10 patients and grade III–IV acute GVHD in 6 patients. Twenty-two patients died (3 relapses, 6 organ failures, 4 GVHD, 8 infections, 1 graft failure). The 5-year OS and DFS were 56% and 47%, respectively. The van Besien group recently reported similar findings that included 45 patients with hematologic malignancies (47% had refractory or untreated relapse) who received RIC followed by transplantation of a single CB unit and CD34⁺ cells from a haploidentical donor.¹¹⁴ Rapid engraftment was obtained with cumulative incidences for neutrophil and platelet ($>20,000/\text{mm}^3$) engraftment of 95% at day 50 and 83% at day 100, respectively, with a median time to recovery of 11 days for neutrophils and 19 days for platelets. However, the percentage of host-derived hematopoiesis was 5% by day 180, and four patients had graft failure (2 primary and 2 secondary). The cumulative incidence of grade II–IV acute GVHD was 25%, and the 1-year OS and progression-free survival (PFS) rates were 55% and 42%, respectively.

A recent study from the MSKCC assessed the use of DCBT combined with haploidentical CD34⁺ cells in 39 patients (median 48 years) after myeloablative ($n = 2$) or RIC ($n = 37$).¹²⁶ The median infused TNC dose of CB units was $2.30 \times 10^7/\text{kg}$ and $1.86 \times 10^7/\text{kg}$ and the median infused CD34⁺ cell dose from haploidentical donors was $3.1 \times 10^6/\text{kg}$. One patient with DSAs to the haploidentical and both CB units had graft rejection. In the remaining evaluable patients, the median time to neutrophil engraftment was 13 days (range 11–38), one of which had graft rejection at a later time. All of the remaining 36 patients had sustained CB engraftment and rejected the haploidentical graft at some point. In these patients, haploidentical graft contributed to either bridge engraftment without transient neutropenia ($n = 20$), bridge engraftment with transient neutropenia ($n = 5$), or no engraftment ($n = 11$). One of the significant complications noted in the study was occurrence of preengraftment syndrome in 76% of patients, which was severe in 8%, but responded to steroids in all cases.¹²⁶

Ex vivo CB expansion is another approach to enhance neutrophil recovery. Given that cellular copper has been implicated in the regulation and differentiation of HSCs, Peled et al^{127,128} cultured CD34⁺38[−] CB HSCs with a copper chelator tetraethylenepentamide (TEPA). A group of investigators at the MDACC conducted a phase I/II clinical trial in which CD133⁺ selected CB hematopoietic progenitors from

a portion of a single CB unit were cultured with TEPA and cytokines for 21 days and coinfused with the unmanipulated portion in 10 patients.¹¹⁵ Although this technique led to an average expansion of 219-fold for TNC and sixfold for CD34⁺ cells, yet the time to hematopoietic recovery was not improved. The median time to neutrophil recovery was 30 days and median time to platelets engraftment was 48 days. Of note, this study used tacrolimus and methotrexate as GVHD prophylaxis, which may have contributed to delayed engraftment. Subsequently, Stiff et al¹¹⁶ reported a prospective multicenter trial using this technique in patients undergoing single CBT with myeloablative conditioning, but replacing methotrexate with MMF. A portion of CB unit was expanded ex vivo and infused with the unmanipulated fraction of the same CB unit in 101 patients (median age 37 years). In contrast to the MDACC study, this group attained an average expansion of 400-fold for TNC and 77-fold for CD34⁺ cells. Compared with DCBT controls from the CIBMTR and the Eurocord registries, the times to neutrophil engraftment (21 versus 28 days, $p < .0001$) and platelet engraftment (54 versus 105 days, $p = .008$) were significantly faster in the study group. There were no differences in the rates of acute (19.4%) or chronic (18.4%) GVHD and 100-day survival was significantly improved compared with the controls.

Delaney et al⁵⁶ studied a double-unit CB strategy in which CD34⁺ selected CB progenitors were transduced with an engineered Notch ligand (Delta1^{ext-igG}) and cultured for 16 days with cytokines. This led to an average expansion of 562-fold for TNC and 164-fold for CD34⁺ cells. A phase I study is ongoing in leukemia patients receiving myeloablative DCBT, in which an entire expanded unit is infused after the infusion of an unmanipulated unit. In the preliminary analysis ($n = 10$), the median time to neutrophil engraftment was 16 days. No infusional toxicities were noted but primary graft rejection occurred in one patient. All evaluable patients developed grade II acute GVHD, except one who had grade III acute GVHD. There was no extensive chronic GVHD, while limited chronic GVHD was noted in three patients. Two patients had long-term persistence of the expanded cells, until day 180 and day 240, but not beyond one year, after which the unexpanded CB unit completely contributed to engraftment.

The MDACC group explored another approach to expand CB CD34⁺ cells by coculturing with mesenchymal stromal cells derived from either haploidentical family member BM or “off-the-shelf” universal donors.¹¹⁷ This approach was tested in a clinical trial in 31 patients (median age 31 years) after myeloablative DCBT and low dose rabbit ATG (1.25 mg/kg on day -4 and 1.75 mg/kg on day -3). After 14 days of coculture, they achieved median 40-fold expansion of CD34⁺ cells and 14-fold for TNC. The expanded unit was infused following the infusion of the unmanipulated unit. This resulted in significantly improved engraftment compared with the CIBMTR controls. The cumulative incidence of engraftment at day 42 was 96% (compared with 78% in the controls, $p < .001$), with faster neutrophil recovery (median 15 days versus 24 days, $p < .001$) and platelet recovery (42 days versus 49 days, $p = .03$). The cumulative incidences of grade II–IV (42%) and III–IV acute GVHD (13%) and chronic GVHD (45%) were similar to the controls. In the 28 evaluable patients, 54% had hematopoiesis derived solely from unmanipulated cord, while the rest had hematopoiesis derived from both units by day 30. At 6 months post-CBT, the expanded CB was detected in 13% of the patients.

Horwitz et al¹¹⁸ reported results of a phase I clinical trial using CB expansion with nicotinamide, which inhibits differentiation and enhances functionality of hematopoietic stem and progenitor cells. In this study, 11 patients (median age 45 years) received TBI-based myeloablative conditioning DCBT, where the CD133⁺ selected fraction of one CB unit was expanded ex vivo for 3 weeks with nicotinamide and then infused along with its CD133⁺-fraction and a second unmanipulated cord. This led to significantly improved median times to neutrophil (13 days) and platelet (33 days) engraftment compared with their institutional controls. One patient had primary graft failure. Five patients developed grade II–IV acute GVHD and there was no cases of grade III–IV acute GVHD. One-year OS was 82% and PFS was 73%.

Preclinical data with aryl hydrocarbon receptor antagonists¹²⁹ and novel cytokines^{130,131} with enhanced HSC expansion capacity are promising approaches that are currently under investigation. The University of Minnesota group presented the results of a phase I/II study using StemRegenin1 (SR1), an aryl hydrocarbon receptor antagonist.¹¹⁹ This technique led to 328-fold expansion of CD34⁺ cells resulting in 100% neutrophil engraftment in 17 DCBT patients after myeloablative conditioning. The median time to neutrophil engraftment was shorter in 11 patients in whom the SR1-expanded cord predominated (11 days) compared with patients in whom the unmanipulated cord predominated (23 days). This group are now evaluating the safety and feasibility of infusing a single cord expanded with SR1.

A different approach to improving engraftment is to enhance stem cell homing to the BM niche. The Broxmeyer group reported that endogenous CD26 expression negatively regulates the homing and engraftment of stem cells.^{120,121} Campbell et al¹²⁰ evaluated pretreated purified CD34⁺ human CB cells with a CD26 peptidase inhibitor (Ditropin A) and found a significant enhanced engraftment in NOD/SCID mice. Christopherson et al¹²² demonstrated that transplantation of either CD34⁺ or lineage depleted human CB cells in NOD/SCID/B2m^{null} mice after treatment with a CD26 inhibitor was associated with a significant improvement in the engraftment of long-term repopulating.

Cutler et al¹²³ investigated the safety and efficacy of ex vivo treatment of one of the CB units with a prostaglandin E₂ (PGE₂) derivative (dmPGE₂) as a method to enhance engraftment by improved homing. The trial included 21 patients undergoing DCBT with fludarabine, melphalan, and ATG (4 mg/kg) conditioning. During their initial study period, the smaller CB unit was thawed on the day of transplantation and treated with dmPGE₂ for 60 minutes at 4°C, but as the authors found two graft failures without any engraftment improvement in this set of patients, they decided to treat the larger of the units at 37°C for 120 minutes. The treated CB unit was then infused within 4 hours of the untreated unit. The median time to neutrophil engraftment was 24 days and 17.5 days in the two cohorts respectively. The corresponding times for platelet engraftments were 72.5 and 43 days. In the second cohort, 10 of 12 patients had 100% hematopoiesis from the dmPGE₂ treated CB unit which was sustained for up to 27 months post-CBT.

Hidalgo et al¹³² found that the defect in CB homing was associated with a reduced α -1,3-fucosyltransferase expression and activity in CB CD34⁺ cells, decreasing their ability to bind to P- and E-selectins expressed by the BM vasculature. Subsequently, investigators at the MDACC¹³³ demonstrated that human CD34⁺ CB cells fucosylated using a recombinant fucosyl transferase in a murine model exhibited improved engraftment. The group reported results of their phase I clinical trial using this approach in 22 adults undergoing myeloablative or RIC DCBT and rabbit ATG (total dose 3 mg/kg infused over 2 days), where one CB unit was infused unmanipulated while the other unit was ex vivo fucosylated for 30 minutes at room temperature before infusion.¹²⁴ The cumulative incidence of neutrophil engraftment was 95.5% and all evaluable patients had 100% donor chimerism by day +30 posttransplantation. The median times to neutrophil engraftment (17 days versus 26 days, $p = .0023$) and platelet engraftment (35 days versus 45 days, $p = .0520$) were significantly improved compared with the institutional historical controls. There were no differences in the cumulative incidences of acute grade II–IV GVHD (41%), acute grade III–IV GVHD (9%), or chronic GVHD (5%) compared with the controls. This approach is especially attractive as it is quick and does not require prolonged ex vivo culture or a Good Manufacturing Practice (GMP) laboratory, thus making it universally adoptable across centers. The multicenter phase III study has been approved by the FDA and is expected to open to accrual soon.

Although these novel techniques have led to significant improvement in the rapidity of hematopoietic recovery, the impact of these strategies on immune reconstitution is still unclear. This is of interest because disease relapse is the leading cause of mortality and viral infections (especially CMV, EBV, adenovirus, and BK virus) contribute to significant morbidity and mortality in the post-CBT period.

Further, in addition to delayed quantitative immune reconstitution after DCBT,^{86,134,135} there are delays in functional recovery of viral-specific T-cells for the first year posttransplantation.¹³⁶ Therefore, strategies to enhance immune recovery after CBT are critically needed.

ADOPTIVE IMMUNOTHERAPY

Adoptive immunotherapy is an attractive strategy not only to enhance antitumor responses but also to prevent GVHD and treat viral infections.¹³⁷ (Table 107.5). Sun et al¹³⁸ have reported the generation of CD4⁺ EBV-specific cytotoxic lymphocytes from CB, and Park et al¹³⁹ have generated CMV pp65-specific T cells from CB. The O'Reilly group at MSKCC has investigated the alternative approach of using third-party EBV-specific cytotoxic T lymphocytes (CTLs) to successfully treat EBV-associated posttransplant lymphoma in two CBT recipients who failed tapering of immunosuppression and rituximab therapy.¹⁴⁰ A group of investigators at the Baylor College of Medicine has generated multivirus-specific T cells from CB lymphocytes to prevent and treat CMV, EBV, and adenovirus.^{141,142} The preliminary results of a phase I trial evaluating the efficacy of this approach in eight patients showed it to be safe. No patient developed GVHD from infusion of these cells. More strikingly, the CTLs were able to clear CMV reactivation within weeks of infusion in most of the patients without the use of conventional treatment. Similarly, all patients with high EBV loads and almost every patient with adenovirus infection were able to clear the viruses.¹⁴³ Furthermore, the same group generated genetically modified CD19-chimeric receptor antigen T-cells that not only possess an antitumor activity against B-cell ALL cells but are also active against EBV, CMV, and adenovirus.¹⁴⁴ This is a fascinating approach to treating viruses and disease relapse with a single infused product.

The use of donor lymphocyte infusion to prevent or treat disease relapse, which has been successfully used after PB or BM transplants, has been historically limited in the setting of CBT because of limitation of cell dose. However, the advent of ex vivo expansion techniques has now made this feasible and has created opportunities to develop tumor specific CB CTLs.¹⁴⁶ Ex vivo expanded CB NK cells have demonstrated in vitro and in vivo antitumor effects.^{145,147} Several early phase clinical trials are evaluating the safety and efficacy of prophylactic CB NK infusion in the setting of CBT for patients with chronic

lymphocytic leukemia [ClinicalTrials.gov: NCT01619761, NCT02280525] and other high-risk myeloid malignancies [ClinicalTrials.gov: NCT01823198], and in conjunction with autologous SCT for patients with multiple myeloma [ClinicalTrials.gov: NCT01729091].

Adoptive immunotherapy using ex vivo expanded Tregs is another area of investigation to prevent or treat GVHD. Brunstein et al⁵⁸ reported the results of a phase I clinical trial of CB derived ex vivo expanded Tregs from a third CB unit, which were infused in addition to a double-unit CB grafts in 23 patients (median age 52 years) using Flu/Cy/TBI RIC regimen. The incidence of grade II–IV acute GVHD was significantly lower in the group that received Tregs compared with historical controls (43% versus 61%, $p = .05$), but there were no differences in grade III–IV acute GVHD between the groups (17% versus 23%). The cumulative incidence of viral and fungal infections by day +100 in Treg treated patients (39%) was similar to controls (53%). Further, there were no differences in the risks of relapse or mortality between the groups. Of note, the infused Tregs persisted in circulation for 2 weeks. The MDACC group recently demonstrated enhanced in vivo persistence of fucosylated CB derived Tregs in a xenogenic GVHD mouse model.¹⁴⁸ Moreover, the infusion of fucosylated Tregs was associated with improved clinical GVHD score as well as OS at day 30 compared with mice that received nonfucosylated Tregs (70% versus 23%, $p < .0001$). The clinical impact of this novel GVHD prophylaxis approach in CBT recipients is of interest.

FUTURE DIRECTIONS

CB is a promising alternative HSC source for use in the transplantation of patients with high-risk hematologic malignancies. CBT extends transplant access to patients from ethnic and racial minorities and those in need of urgent transplantation. Furthermore, survival after CBT has greatly improved because of larger CB inventory; possibly better unit quality; and improved conditioning regimens, grafts, and supportive care. Single-unit CBT has been shown to be comparable with unrelated donor transplantation in children,²⁶ and DCBT has had DFS comparable with the transplantation of adult donor HSC.^{22,26,102,106–109} CBT should be considered as an immediate alternative in patients with high-risk hematologic malignancies who are candidates for allogeneic HSC transplantation but lack a suitable related donor.

TABLE 107.5 Cellular Therapeutic Strategies to Mitigate Viral Infections, Relapse, and Graft-Versus-Host Disease After Cord Blood Transplantation

Target	Strategy	Results
Antiviral	Multivirus specific CTLs (CMV, EBV, adenovirus) ¹⁴² Third-party EBV-specific CTLs ¹⁴⁰	Lysed antigen-pulsed and virus infected targets 2 EBV PTLD patients achieved durable CR
Antitumor	IL-2 expansion of CB NK cells ¹⁴⁵	Cytolytic effect in vitro and in vivo against leukemia cells
Antitumor and antiviral	CB-derived CTLs against CD19 and viruses (CMV, EBV, adenovirus) ¹⁴⁴	In vitro antileukemic and antiviral effect
GVHD prevention	Infusion of ex vivo expanded CB Treg ⁵⁸	23 patients accrued; aGVHD incidence decreased without increase in relapse

aGVHD, Acute graft-versus-host disease; CB, cord blood; CMV, cytomegalovirus; CR, complete remission; CTL, cytotoxic T-cell lymphocyte; EBV, Epstein-Barr virus; GVHD, graft-versus-host disease; IL-2, interleukin-2; NK, natural killer; PTLD, posttransplant lymphoproliferative disease; Treg, regulatory T cell.

GRAFT-VERSUS-HOST DISEASE AND GRAFT-VERSUS-LEUKEMIA RESPONSES

Pavan Reddy and James L.M. Ferrara

The ability of allogeneic hematopoietic cell transplantation (HCT) to cure certain hematologic malignancies is widely recognized. An important therapeutic aspect of HCT in eradicating malignant cells is the graft-versus-leukemia (GVL) effect. The importance of the GVL effect in allogeneic HCT has been recognized since the earliest experiments in stem cell transplantation. Forty years ago, Barnes and colleagues noted that leukemic mice treated with a subtherapeutic dose of radiation and a syngeneic (identical twin) graft transplant were more likely to relapse than mice given an allogeneic stem cell transplant.^{1,2} They hypothesized that the allogeneic graft contained cells with immune reactivity necessary for eradicating residual leukemia cells. They also noted that recipients of allogeneic grafts, though less likely to relapse, died of a “wasting syndrome” now recognized as graft-versus-host disease (GVHD). Thus in addition to describing GVL, these experiments highlighted for the first time the intricate relationship between GVL and GVHD. Since these early experiments, both GVHD and the GVL effect have been studied extensively.³ This chapter reviews the pathophysiology, clinical features, and treatment of GVHD and summarizes current understanding of the relationships between GVHD and the GVL effect.

GRAFT-VERSUS-HOST DISEASE: CLINICAL AND PATHOLOGIC ASPECTS

Ten years after the work of Barnes and Loutit, Billingham formulated the requirements for the development of GVHD: the graft must contain immunologically competent cells, the recipient must express tissue antigens that are not present in the transplant donor, and the recipient must be incapable of mounting an effective response to destroy the transplanted cells.⁴ According to these criteria, GVHD can develop in various clinical settings when tissues containing immunocompetent cells (blood products, bone marrow, and some solid organs) are transferred between persons. The most common setting for the development of GVHD is following allogeneic HCT; without prophylactic immunosuppression, most allogeneic HCTs will be complicated by GVHD. GVHD is induced by mismatches between histocompatibility antigens between the donor and recipient. Matching of the major histocompatibility complex (MHC) antigens hastens engraftment and reduces the severity of GVHD.⁵ In humans, the MHC region lies on the short arm of chromosome 6 and is called the HLA (human leukocyte antigen) region.⁶ The HLA region is divided into two classes, class I and class II, each containing numerous gene loci that encode a large number of polymorphic alleles. MHC class I molecules are involved in the presentation of peptides to CD8⁺ T cells, and class II molecules present peptides to CD4⁺ T cells.^{6,7} The determination of HLA types has become much more accurate with molecular techniques that replace earlier serologic or cellular methods. In patients whose ancestry involves extensive interracial mixing, the chances of identifying an HLA identical donor are diminished.⁸

Despite HLA identity between a patient and donor, substantial numbers of patients still develop GVHD because of differences in minor histocompatibility antigens (MiHAs) that lie outside the HLA loci. Most minor antigens are expressed on the cell surface as degraded peptides bound to specific HLA molecules, but the precise elucidation of many human minor antigens is yet to be accomplished.⁹ In

the United States, the average patient has a 25% chance of having an HLA match within his or her immediate family.⁸ Patients who lack an HLA-identical family member donor must seek unrelated donor volunteers or cord blood donations.

Acute Graft-Versus-Host Disease

Acute GVHD can occur within days (in recipients who are not HLA-matched with the donor or in patients not given any prophylaxis) or as late as 6 months after transplantation. The incidence ranges from less than 10% to more than 80%, depending on the degree of histoincompatibility between donor and recipient, the number of T cells in the graft, the patient's age, and the GVHD prophylactic regimen.¹⁰ The principal target organs include the immune system, skin, liver, and intestine. GVHD occurs first and most commonly in the skin as a pruritic maculopapular rash, often involving the palms, soles, and ears; it can progress to total-body erythroderma, with bullae formation, rupture along the epidermal-dermal border, and desquamation in severe cases.¹⁰ Gastrointestinal (GI) and liver manifestations often appear later and rarely represent the first and only findings. Intestinal symptoms include anorexia, nausea, diarrhea (sometimes bloody), abdominal pain, and paralytic ileus.¹⁰ Liver dysfunction includes hyperbilirubinemia and increased serum alkaline phosphatase and aminotransferase values. Coagulation studies may become abnormal, and hepatic failure with ascites and encephalopathy may develop in severe cases.^{10–12} Hepatic GVHD can be distinguished from hepatic venoocclusive disease by weight gain or pain in the right upper quadrant in the latter.¹² Acute GVHD also results in the delayed recovery of immunocompetence.¹⁰ The clinical result is profound immunodeficiency and susceptibility to infections, often further accentuated by the immunosuppressive agents used to treat GVHD.¹⁰

Pathologically, the *sine qua non* of acute GVHD is selective epithelial damage of target organs.^{13,14} The epidermis and hair follicles are damaged and sometimes destroyed. Small bile ducts are profoundly affected, with segmental disruption. The destruction of intestinal crypts results in mucosal ulcerations that may be either patchy or diffuse. Other epithelial surfaces, such as the conjunctivae, vagina, and esophagus, are less commonly involved. A peculiarity of GVHD histology is the early paucity of mononuclear cell infiltrates; however, as the disease progresses, the inflammatory component may be substantial. Studies that identified inflammatory cytokines as soluble mediators of GVHD have suggested that direct contact between target cells and lymphocytes is not always required (see following sections). GVHD lesions are not evenly distributed: in the skin, damage is prominent at the tip of rete ridges; in the intestine, at the base of the crypts; and in the liver, in the periductular epithelium. These areas all contain a high proportion of stem cells, giving rise to the idea that GVHD targets may be undifferentiated epithelial cells with primitive surface antigens.¹⁵

The histologic severity of GVHD is at best semiquantitative, and consequently pathologic scores are not used to grade GVHD. Because it is often difficult to obtain an adequate tissue biopsy, and because it can be very difficult to distinguish GVHD from other post-HCT complications such as drug eruptions or infectious complications, the physician is left to use clinical judgment.

An independent committee of a multicenter phase III trial that assessed the presence and severity of GVHD was unable to confirm a high incidence of GVHD.^{16,17} Standard grading systems generally include clinical changes in the skin, GI tract, liver, and performance status (Table 108.1).¹⁸ Although the severity of GVHD is often difficult to quantify, the overall maximal grade correlates with disease outcome: mild GVHD (grade I or II) is associated with little mortality, whereas higher grades are associated with significantly decreased survival.^{18,19} Recent advances in the use of biomarkers at the onset of disease may soon be sufficiently accurate to guide therapy.¹⁹

Clinical Features of Acute Graft-Versus-Host Disease

The clinical features, staging, and grading of acute GVHD are summarized in Tables 108.1 and 108.2. In a comprehensive review of patients receiving therapy for acute GVHD, Martin and colleagues²⁰ found that 81% had skin involvement, 54% had GI involvement, and 50% had liver involvement at the initiation of therapy. After high-intensity (myeloablative) conditioning, acute GVHD generally occurs within 14–35 days of stem cell infusion. The time of onset may depend on the degree of histocompatibility, the number of donor T cells infused, and the prophylactic regimen for GVHD. A

rapid and severe form of GVHD may occur in patients with severe HLA mismatches and in patients who receive T-cell replete transplants without or with inadequate in vivo GVHD prophylaxis.²¹ Although such GVHD is sometimes called “hyperacute,” this term is misleading because it is pathophysiologically distinct from hyperacute rejection after solid organ allografting, which is caused by preformed antibodies. This form of GVHD, which is manifested by fever, generalized erythroderma and desquamation, and often edema, typically occurs about 1 week after stem cell infusion and may be rapidly fatal. In patients receiving standard (in vivo) GVHD prophylaxis such as a combination of cyclosporine and methotrexate, the median onset of GVHD is typically 21–25 days after transplantation; however, after in vitro T-cell depletion of the graft, the onset of GVHD symptoms may be much later.²¹ Thus the findings of rash and diarrhea by 1 week after transplantation would very likely be because of ineffective prophylaxis and would be very unlikely with the use of calcineurin inhibitors or in vitro T-cell depletion of the stem cell inoculum. A less ominous syndrome of fever, rash, and fluid retention occurring in the first 1–2 weeks after stem cell infusion is the “engraftment syndrome.” These manifestations may be seen with either allogeneic or autologous transplantation. Although this syndrome’s pathophysiology is poorly understood, it is thought to be caused by a wave of cytokine production as the graft starts to recover. These symptoms are related to, but distinct from, the “cytokine storm”²² of acute GVHD because there is no concomitant T-cell-mediated attack. This syndrome responds immediately to steroids in most patients, and it typically presents earlier than acute GVHD.¹⁵

Skin is the most commonly affected organ (Fig. 108.1). In patients receiving transplants after myeloablative conditioning, the skin is usually the first organ involved, and GVHD often coincides with engraftment. However, the presentation of GVHD is more varied following nonmyeloablative transplants or donor lymphocyte infusions.²³ The characteristic maculopapular rash can spread throughout

TABLE 108.1 Clinical Manifestations and Staging of Acute Graft-Versus-Host Disease

Organ	Clinical Manifestations	Staging
Skin	Erythematous, maculopapular rash involving palms and soles; may become confluent Severe disease: bullae	Stage 1: <25% rash Stage 2: 25%–50% rash Stage 3: generalized erythroderma Stage 4: bullae
Liver	Painless jaundice with conjugated hyperbilirubinemia and increased alkaline phosphatase	Stage 1: bili 2–3 mg/dL Stage 2: bili 3.1–6 mg/dL Stage 3: bili 6.1–15 mg/dL Stage 4: bili >15 mg/dL
Gastrointestinal tract	Upper: nausea, vomiting, anorexia Lower: diarrhea, abdominal cramps, distension, ileus, bleeding	Stage 1: diarrhea >500 mL/day Stage 2: diarrhea >1000 mL/day Stage 3: diarrhea >1500 mL/day Stage 4: ileus, bleeding

TABLE 108.2 Glucksberg Criteria for Staging of Acute Graft-Versus-Host Disease^a

Overall Grade	Skin	Liver	Gut
I	1–2	0	0
II	1–3	1	and/or 1
III	2–3	2–4	and/or 2–3
IV	2–4	2–4	and/or 2–4

^aSee Table 108.1 for individual organ staging. Traditionally, individual organs are staged without regard to attribution. The overall grade of graft-versus-host disease, however, reflects the actual extent of graft-versus-host disease. To achieve each overall grade, skin disease, liver and/or gut involvement are required.

Fig. 108.1 GRAFT-VERSUS-HOST DISEASE, SKIN BIOPSY. This 40-year-old man with a history of relapsed Hodgkin lymphoma was status-postallogeneic stem cell transplant with donor lymphocyte infusion. He developed painful oral ulcers and a macular-papular rash on the arms, hand, and chest. The skin biopsy is from the palmar surface of the hand (A). It shows a scant lymphoid infiltrate in the dermis with a developing subepithelial blister (right). There is basal vacuolar change with single lymphocytes in the epithelium, as well as apoptotic keratinocytes accompanied by lymphocytes (B, and detail, C). (Courtesy Vesna Petronic-Rosic and Mark Racz, University of Chicago.)

the rest of the body but usually spares the scalp; it is often described as feeling like a sunburn, tight or pruritic. In severe cases the skin may blister and ulcerate.²⁴ Histologic confirmation is critical to rule out drug reactions, viral infections, etc. Apoptosis at the base of dermal crypts is characteristic. Other features include dyskeratosis, exocytosis of lymphocytes, satellite lymphocytes adjacent to dyskeratotic epidermal keratinocytes, and dermal perivascular lymphocytic infiltration.²⁵

GI tract involvement of GVHD may present as nausea, vomiting, anorexia, diarrhea, and/or abdominal pain.²⁶ It is a panintestinal process, often with differences in severity between the upper and lower GI tracts. Gastric involvement gives rise to postprandial vomiting that is not always preceded by nausea. Although gastroparesis is seen after bone marrow transplant, it is usually not associated with GVHD. The diarrhea of GVHD is secretory; significant GI blood loss may occur as a result of mucosal ulceration and is associated with a poor prognosis.²⁷ In advanced disease, diffuse, severe abdominal pain, and distension is accompanied by voluminous diarrhea (>2 liters/day).^{19,28}

Radiologic findings of the GI tract include luminal dilatation with thickening of the wall of the small bowel and air/fluid levels suggestive of an ileus on abdominal flat plates or small bowel series. Abdominal computed tomography may show the “ribbon” sign of diffuse thickening of the small bowel wall.²⁴ Little correlation exists between the extent of disease and the appearance of mucosa on endoscopy, but mucosal sloughing is pathognomonic for severe disease.²⁹ Nevertheless, some studies have shown that antral biopsies correlate well with the severity of GVHD in the duodenum and in the colon even when the presenting symptom is diarrhea.²⁹ Histologic analysis of tissue is imperative to establish the diagnosis. The histologic features of GI GVHD are the presence of apoptotic bodies in the base of crypts, crypt abscesses, crypt loss, loss of Paneth cells, and flattening of the surface epithelium.^{28,30,31}

Liver function test abnormalities are common after bone marrow transplant and occur secondary to venoocclusive disease, drug toxicity, viral infection, sepsis, iron overload, and other causes of extrahepatic biliary obstruction.¹² The exact incidence of hepatic GVHD is unknown because many patients do not undergo liver biopsies. The development of jaundice or an increase in the alkaline phosphatase and bilirubin may be the initial features of acute GVHD of the liver. The histologic features of hepatic GVHD are endothelialitis, lymphocytic infiltration of the portal areas, pericholangitis, and bile duct destruction and loss.^{19,32}

Other Organs

Whether GVHD affects organs other than the classic triad of skin, liver, and gut has remained a matter of debate, although numerous reports suggest additional organ manifestations. The most likely candidate is the lung. Lung toxicity, including interstitial pneumonitis and diffuse alveolar hemorrhage, may occur in 20% to 60% of allogeneic transplant recipients but in fewer autologous transplant recipients. Causes of pulmonary damage other than GVHD include engraftment syndrome (see earlier), infection, radiation pneumonitis, and chemotherapy-related toxicity (e.g., methotrexate, busulfan).^{21,33} One retrospective analysis failed to link severe pulmonary complications to clinical acute GVHD per se.³⁴ The mortality caused by pneumonia increases with the severity of GVHD, but this association may be related to increased immunosuppressive therapy.²¹ A histopathologic signature of lymphocytic bronchitis has been associated with GVHD,³³ although not always.

Despite the ability of kidneys and hearts to serve as targets of transplant rejection, there is no convincing evidence for direct renal or cardiac damage from acute GVHD that is not secondary to drugs or infection. Similarly, neurologic complications are also common after transplantation but most can be attributed to drug toxicity, infection, or vascular insults.

Differential Diagnosis

Acute GVHD ought to be distinguished from any process that causes a constellation of fever, erythematous skin rash, and pulmonary edema that may occur during neutrophil recovery and has been

termed engraftment or capillary leak syndrome.^{35,36} In allogeneic transplant recipients distinction from acute GVHD is difficult. Engraftment syndrome is thought to reflect cellular and cytokine activities during early recovery of (donor-derived) blood cell counts and/or homeostatic proliferation of lymphocytes, but a precise delineation of the activated cells and mechanisms has not been demonstrated. Engraftment syndrome may be associated with increased mortality, primarily but not exclusively from pulmonary failure. Corticosteroid therapy may be effective particularly for the treatment of pulmonary manifestations.³⁷ Skin rashes may reflect delayed reactions to the conditioning regimen, antibiotics, or infections; furthermore, histopathologic skin changes consistent with acute GVHD can be mimicked by chemoradiotherapy and drug reactions.^{21,38} Diarrhea can be a consequence of total-body irradiation (TBI), viral infection (especially with cytomegalovirus and other herpes viruses), parasitic infection, *Clostridium difficile* infection, nonspecific gastritis, narcotic withdrawal, and drug reactions: all of which mimic GVHD of the gut. Liver dysfunction can be caused by parenteral nutrition, venoocclusive disease, and viral or drug-induced hepatitis.

Genetic Basis of Graft-Versus-Host Disease

The graft-versus-host (GVH) reaction was first noted when irradiated mice were infused with allogeneic marrow and spleen cells.³⁹ Although mice recovered from radiation-induced injury and marrow aplasia, they subsequently died with “secondary disease,”³⁹ a phenomenon subsequently recognized as acute GVHD. Three requirements for the development of GVHD were formulated by Billingham.⁴ First, the graft must contain immunologically competent cells, now recognized as mature T cells. In both experimental and clinical allogeneic HCT, the severity of GVHD correlates with the number of donor T cells transfused.^{40,41} The precise nature of these cells and the mechanisms they use are now understood in greater detail (see later). Second, the recipient must be incapable of rejecting the transplanted cells (i.e., immunocompromised). After allogeneic HCT, the recipient is typically immunosuppressed by chemotherapy and/or radiotherapy before the hematopoietic cell infusion.⁴² Third, the recipient must express tissue antigens that are not present in the transplant donor. Thus Billingham’s third postulate stipulates that the GVH reaction occurs when donor immune cells recognize disparate host antigens.⁴ These differences are governed by the genetic polymorphisms.⁴²

HLA Matching

Recognition of alloantigens depends on the match with the presenting major histocompatibility molecule.^{43–45} In humans, the MHC is governed by the HLA antigens that are encoded by the MHC gene complex on the short arm of chromosome 6 and can be categorized as class I, II, and III. Class I antigens (HLA-A, HLA-B, and HLA-C) are expressed on almost all cells of the body.⁴⁶ Class II antigens (DR, DQ, and DP) are primarily expressed on hematopoietic cells, although their expression can also be induced on other cell types following inflammation.⁴⁶ The incidence of acute GVHD is directly related to the degree of MHC mismatch.⁴² The role of HLA mismatching of cord blood (CB) donors is more difficult to analyze compared with unrelated donor HCT, because allele typing of CB units for HLA-A, HLA-B, HLA-C, DRB1, and DQB1 is not routinely performed.⁴⁷ Nonetheless, the total number of HLA disparities between the recipient and the CB unit has been shown to correlate with risk for acute GVHD as the frequency of severe acute GVHD is lower in patients transplanted with HLA-matched (6/6) CB units.^{47–49}

Minor Histocompatibility Antigens

In most clinical allogeneic transplants where MHC of donor and recipient are matched, donor T cells recognize MHC-bound peptides derived from the protein products of polymorphic genes (MiHAs) that are present in the host but not in the donor.^{9,50–55} Substantial numbers (50%) of patients will develop acute GVHD despite receiving HLA-identical grafts as well as optimal

postgrafting immune suppression.^{9,42,56} MiHAs are widely but variably expressed in different tissue,^{51,56} which is one possible explanation for the unique target organ distribution in GVHD. Many MiHAs such as HA-1 and HA-2 are expressed on hematopoietic cells, which may be one reason for the host immune system to be a primary target for the GVH response, and helps explain the critical role of direct presentation by professional recipient antigen-presenting cells (APCs) in the GVH response.⁵⁷ By contrast, other MiHAs such as H-Y and HA-3 are expressed ubiquitously.⁵⁶ MiHAs do not all equally induce lethal GVHD but show hierarchic immunodominance.^{58,59} Furthermore, the difference in a single immunodominant MiHA is insufficient to elicit GVHD in murine models, even though a single MiHA can elicit T-cell-mediated damage in a skin explant model.^{60,61} However, the role of specific MiHAs that are able to induce clinical GVHD has not been systematically evaluated in large groups of patients.⁶²

Other Non-HLA Genes

Genetic polymorphisms in several non-HLA genes such as in killer-cell immunoglobulin-like receptors (KIRs), cytokines, and nucleotide-binding oligomerization domain containing 2 (NOD2) genes have recently been shown to modulate the severity and incidence of GVHD.

KIRs on natural killer (NK) cells that bind to the HLA class I gene products are encoded on chromosome 19. Polymorphisms in the transmembrane and cytoplasmic domains of KIRs govern whether the receptor has inhibitory (such as KIR2DL1, 2DL2, 2DL3, and 3DL1) or activating potential. Two competing models have been proposed for HLA-KIR allorecognition by donor NK cells following allogeneic HCT: the “mismatched ligand” and the “missing ligand” models.^{5,63–66} Both models are supported by several clinical observations, albeit in patients receiving very different transplant and immunosuppressive regimens (see Chapters 20 and 102).^{64,67–69}

Proinflammatory cytokines involved in the classic cytokine storm of GVHD cause pathologic damage to target organs, such as the skin, liver, and GI tract (see later).²² Several cytokine gene polymorphisms in both recipients and donors have been implicated. Specifically, tumor necrosis factor (TNF) polymorphisms (TNF α 3/d3 in the recipient, TNF863 and TNF857 in donors and/or recipients and TNF α 4, TNF- α -1031C, and tumor necrosis factor receptor (TNFR) II-196R in the donors) have been associated with an increased risk for acute GVHD and transplant-related mortality (TRM).^{70,71} The three common haplotypes of the interleukin (IL)-10 gene promoter region in recipients, representing high, intermediate, and low production of IL-10, have been associated with severity of acute GVHD following HLA-matched sibling donor allogeneic HCT.⁷² By contrast, smaller studies have found neither IL-10 nor TNF- α polymorphisms to be associated with GVHD following HLA-mismatched cord blood transplantation.^{71,73} Interferon-gamma (IFN- γ) polymorphisms of the 2/2 genotype (high IFN- γ production) and 3/3 genotype (low IFN- γ production) have been associated with decreased or increased acute GVHD, respectively.^{71,74}

NOD2/caspase-activating recruitment domain 15 (CARD15) gene polymorphisms in both the donors and recipients were recently shown to have a striking association between GI GVHD and overall mortality following related and unrelated donor allogeneic HCT.⁷⁵ Several of the associations with non-HLA polymorphisms will need to be confirmed in larger and more diverse populations. Furthermore, it is likely that the importance of non-HLA gene polymorphisms in GVHD will differ depending on the donor source (related versus unrelated), HLA disparity (matched versus mismatched), graft source (CB versus bone marrow [BM] versus peripheral blood stem cells), and the intensity of the conditioning.

PATHOPHYSIOLOGY OF ACUTE GRAFT-VERSUS-HOST DISEASE

It is helpful to remember two important principles when considering the pathophysiology of acute GVHD. First, acute GVHD represents exaggerated but normal inflammatory responses against foreign

antigens (alloantigens) that are ubiquitously expressed in a setting where they are undesirable. The donor lymphocytes that have been infused into the recipient function appropriately, given the foreign environment they encounter. Second, donor lymphocytes encounter tissues in the recipient that have been often profoundly damaged. The effects of the underlying disease, prior infections, and the intensity of conditioning regimen all result in substantial changes not only in the immune cells but also in the endothelial and epithelial cells. Thus the allogeneic donor cells rapidly encounter not simply a foreign environment, but one that has been altered to promote the activation and proliferation of inflammatory cells. Therefore the pathophysiology of acute GVHD may be considered a distortion of the normal inflammatory cellular responses that, in addition to the absolute requirement of donor T cells, involves multiple other innate and adaptive cells and mediators.⁷⁶ The development and evolution of acute GVHD can be conceptualized in three sequential phases (Fig. 108.2) to provide a unified perspective on the complex cellular interactions and inflammatory cascades that lead to acute GVHD: (1) activation of the APCs; (2) donor T-cell activation, differentiation, and migration; and (3) effector phase.⁷⁶ It is important to note that this three-phase description permits a unified perspective on GVHD biology but it is not meant to suggest that all three phases are of equal importance or that GVHD occurs in a stepwise and sequential manner. The spatiotemporal relationships among these biologic processes, depending on the context, are likely to vary and their relevance to the induction, severity, and maintenance of GVHD may depend on the factors cited earlier.

Phase 1: Activation of Antigen-Presenting Cells

The earliest phase of acute GVHD is initiated by the profound damage caused by the underlying disease and infections and further exacerbated by bone marrow transplantation (BMT) conditioning regimens (which include TBI and chemotherapy) that are administered even before the infusion of donor cells.^{77–81} This first step results in activation of the APCs.⁷ Specifically, damaged host tissues respond with multiple changes, including the secretion of proinflammatory cytokines, such as TNF- α , IL-1 and IL-6 described as the cytokine storm.^{79,80,82,83}

Such changes increase expression of adhesion molecules, costimulatory molecules, MHC antigens, and chemokine gradients that alert the residual host and the infused donor immune cells.⁸⁰ These “danger signals” activate host APCs.^{84,85} Damage to the GI tract from the conditioning is particularly important in this process because it allows for systemic translocation of immunostimulatory microbial products such as lipopolysaccharide (LPS) that further enhance the activation of host APCs, and the secondary lymphoid tissue in the GI tract is likely the initial site of interaction between activated APCs and donor T cells.^{80,86,87} This scenario accords with the observation that an increased risk for GVHD is associated with intensive conditioning regimens that cause extensive injury to epithelial and endothelial surfaces with a subsequent release of inflammatory cytokines and increases in expression of cell surface adhesion molecules.^{80,81} The relationship among conditioning intensity, inflammatory cytokine, and GVHD severity has been supported by elegant murine studies.⁸² Furthermore, the observations from these experimental studies have led to two recent clinical innovations to reduce clinical acute GVHD: (1) reduced intensity conditioning to decrease the damage to host tissues and thus limit activation of host APC and (2) KIR mismatches between donor and recipients to eliminate the host APCs by the alloreactive NK cells.^{65,88}

Host-type APCs that are present and have been primed by conditioning are critical for the induction of this phase; recent evidence suggests that donor-type APCs exacerbate GVHD, but in certain experimental models, donor-type APC chimeras also induce GVHD.^{85,89–91} In clinical situations, if donor-type APCs are present in sufficient quantity and have been appropriately primed, they too might play a role in the initiation and exacerbation of GVHD.^{92–94} Among the cells with antigen-presenting capability, dendritic cells

Fig. 108.2 PATHOPHYSIOLOGY OF GRAFT-VERSUS-HOST DISEASE. During step 1, irradiation and chemotherapy both damage and activate host tissues, including intestinal mucosa, liver, and the skin. Activated cell hosts then secrete inflammatory cytokines (e.g., TNF- α and IL-1), which can be measured in the systemic circulation. The cytokine release has important effects on APCs of the host, including increased expression of adhesion molecules (e.g., ICAM-1, VCAM-1) and of MHC class II antigens. These changes in the APCs enhance the recognition of host MHC and/or minor H antigens by mature donor T cells. During step 2, donor T-cell activation is characterized by proliferation of GVHD T cells and secretion of the Th1 cytokines IL-2 and IFN- γ . Both of these cytokines play central roles in clonal T-cell expansion, induction of CTL and NK cell responses, and the priming of mononuclear phagocytes. In step 3, mononuclear phagocytes primed by IFN- γ are triggered by a second signal such as endotoxin LPS to secrete cytopathic amounts of IL-1 and TNF- α . LPS can leak through the intestinal mucosa damaged by the conditioning regimen to stimulate gut-associated lymphoid tissue or Kupffer cells in the liver; LPS that penetrates the epidermis may stimulate keratinocytes, dermal fibroblasts, and macrophages to produce similar cytokines in the skin. This mechanism results in the amplification of local tissue injury and further production of inflammatory effectors such as nitric oxide, which, together with CTL and NK effectors, leads to the observed target tissue destruction in the stem cell transplant host. CTL effectors use Fas/FasL, perforin/granzyme B, and membrane-bound cytokines to lyse target cells. *APC*, Antigen-presenting cell; *CTL*, cytotoxic T lymphocyte; *GVHD*, graft-versus-host disease; *ICAM*, intercellular adhesion molecule; *IFN*, interferon; *IL*, interleukin; *LPS*, lipopolysaccharide; *MHC*, major histocompatibility complex; *NK*, natural killer; *TNF*, tumor necrosis factor; *VCAM*, vascular cell adhesion molecule.

(DCs) are the most potent and play an important role in the induction of GVHD.⁹⁵ Experimental data suggest that GVHD can be regulated by qualitatively or quantitatively modulating distinct DC subsets.^{96–101} Langerhans cells were also shown to be sufficient for the induction of GVHD when all other APCs were unable to prime donor T cells, although the role for Langerhans cells when all APCs are intact is dispensable.^{102,103} Studies have yet to define roles for other DC subsets. In one clinical study persistence of host DC after day 100 correlated with the severity of acute GVHD, whereas elimination of host DCs was associated with reduced severity of acute GVHD.⁹³ The allostimulatory capacity of mature monocyte-derived DCs (mDCs) after reduced-intensity transplants was lower for up to 6 months compared with the mDCs from myeloablative transplant recipients, thus suggesting a role for host DCs and the reduction in danger signals secondary to less intense conditioning in acute

GVHD.¹⁰⁴ Nonetheless, this concept of enhanced host APC activation explains a number of clinical observations such as increased risks for acute GVHD associated with advanced-stage malignancy, conditioning intensity, and histories of viral infections. However, recent data suggest that even in the absence of all host hematopoietic derived APCs, GVHD can still be initiated by host nonhematopoietic cells.¹⁰⁵ The exact nature of the host nonhematopoietic cells that can initiate GVHD and the context under which they may play a more dominant role remains to be understood. Moreover when all of host CD11c⁺ DCs are eliminated, the severity of GVHD was found to be enhanced demonstrating a role for host DCs in mitigating GVHD severity.^{106,107} Furthermore, a specific subset of host DCs, the CD8⁺ DCs might mitigate GVHD severity.^{108,109} By contrast donor-derived DCs, specifically, CD103⁺CD11b[−] DCs migrate from the colon and markedly enhance alloantigen presentation within the mesenteric lymph nodes

(mLNs).¹¹⁰ Critically, alloantigen presentation in the mLNs imprints gut-homing integrin signatures on donor T cells, leading to their emigration into the GI tract where they mediate fulminant disease. Thus anatomically distinct, donor DC subsets amplify GVHD. GVHD once initiated by host hematopoietic and/or nonhematopoietic recipient APCs, generates a profound, localized, and lethal feed-forward cascade of donor DC-mediated indirect alloantigen presentation and cytokine secretion within the GI tract and aggravates its severity.

Other professional APCs such as monocytes/macrophages or semiprofessional APCs might also play a role in this phase.⁷ For example, recent data suggest that host-type B cells might play a regulatory role under certain contexts,¹¹¹ whereas in other contexts, they were dispensable for GVHD induction. Similarly, host basophils have been shown not to affect the induction or severity of acute GVHD.^{112,113} A small subset of radioresistant host-derived neutrophils infiltrate intestines after allo-HCT and the infiltration levels are dependent on the local microbial flora while such infiltration is not seen in germ-free conditions. Depletion of these neutrophils has been shown to reduce GVHD mortality.¹¹⁴ Data suggest that radiosensitive hematopoietic-derived APCs may not be obligatory for induction of APCs. Also, host or donor-type nonhematopoietic stem cells (such as endothelial cells, epithelial cells, or stromal cells) can function as APCs in the context of inflammation.¹⁰⁵ The role of these cells in the presence and absence of professional hematopoietic-derived APCs remains to be elucidated.

Alloantigen presentation by the host APCs has been shown to be modulated by the local microflora and by the release of PAMPs and also by the release of damage associated molecular patterns (DAMP) molecules from condition-mediated damage. Classically, tissue damage releases exogenous and endogenous damage/pathogen-associated molecules termed DAMPs/PAMPs that are detected by pattern recognition receptors. Examples of pattern recognition receptors include Toll-like receptors (TLR) and NOD-like receptors that result in the activation of APCs.¹¹⁵ The purine nucleoside adenosine triphosphate (ATP) is one DAMP whose release has been implicated as an early danger signal following tissue damage after allogeneic HCT. Elevated levels of ATP are found in peritoneal fluids of humans and mice following GVHD or irradiation. ATP interaction with the purinergic receptor P2X₇ on host APCs resulted in increased expression of costimulatory molecules CD80/CD86 and production of inflammatory cytokines. Interrupting this interaction reduced GVHD in experimental models.¹¹⁶ More recently, a multiprotein complex termed the Nlrp3 inflammasome was shown to respond to DAMPs/PAMPs such as uric acid.¹¹⁷ Mice deficient in critical components of Nlrp3 or adaptor protein for caspase-1 cleavage demonstrated less severe GVHD. Emerging data have demonstrated a role for negative regulators of DAMP responses in controlling the severity of GVHD. Siglecs are a family of sialic acid binding Ig-like lectins, which function as counter regulators to immune activation and Siglec-G^{-/-} animals have increased GVHD, an effect confined to radiosensitive host APCs. In contrast, the enhanced Siglec-G signaling with CD24 in wild-type animals was protective.¹¹⁸ Likewise inhibition of endogenous DAMPs such as heparan sulfate by endogenous protease inhibitors such as alpha-1 antitrypsin also mitigated GVHD in mice.^{119,120} These and other data suggest that DAMPs such as ATP, heparin sulfate, and uric acid may have nonredundant roles in the aggravation of GVHD.

In addition to the role of LPS, recent observations have brought back renewed interest in the role of the quantitative and qualitative contributions of microbiota-driven inflammatory signals on GVHD. These signals are influenced by the variety and pathogenicity of organisms present, and have been demonstrated to affect the severity of GVHD.^{121–123} It is apparent that GVHD mediates a loss of Paneth cell-derived antimicrobial peptides that play an important role in shaping the diversity of microbiota, in addition to the use of pharmaceutical antimicrobials, nonetheless our mechanistic understanding of the changes in microflora is currently limited. Understanding these mechanisms may offer manipulable targets to alter this primary, inflammation-mediated, initiation phase of GVHD.

Phase 2: Donor T-Cell Activation, Differentiation, and Migration

The infused donor T cells interact with the primed APCs leading to the initiation of the second phase of acute GVHD. This phase includes antigen presentation by primed APCs and the subsequent activation, proliferation, differentiation, and migration of alloreactive donor T cells. After allogeneic hematopoietic stem cell transplants, both host and donor-derived APCs are present in secondary lymphoid organs.^{124,125} The T-cell receptor (TCR) of the donor T cells can recognize alloantigens either on host APCs (direct presentation) or donor APCs (indirect presentation).^{126,127} In direct presentation, donor T cells recognize either the peptide bound to allogeneic MHC molecules or allogeneic MHC molecules without peptide.^{127,128} During indirect presentation, T cells respond to the peptide generated by degradation of the allogeneic MHC molecules presented on self-MHC.¹²⁸ Experimental studies demonstrated that APCs derived from the host, rather than from the donor, are critical in inducing GVHD across MiHA mismatch.^{7,126} Recent data suggest that presentation of distinct target antigens by the host-type and donor-type APCs might play a differential role in mediating target organ damage.^{7,129,130} In humans, most cases of acute GVHD developed when both host DCs and donor DCs were present in peripheral blood after BMT.⁹³

Costimulation

The interaction of donor lymphocyte TCR with the host allopeptide presented on the MHC of APCs alone is insufficient to induce T-cell activation.^{7,131} Both TCR ligation and costimulation via a “second” signal through interaction between the T-cell costimulatory molecules and their ligands on APCs are required to achieve T-cell proliferation, differentiation, and survival.¹³² The danger signals generated in phase 1 augment these interactions and significant progress has been made on the nature and impact of these second signals.^{133,134} Costimulatory pathways are now known to deliver both positive and negative signals and molecules from two major families: the B7 family and the TNF receptor (TNFR) family play pivotal roles in GVHD.¹³⁵ Interruption of the second signal by the blockade of various positive costimulatory molecules (CD28, ICOS, CD40, CD30, 4-1BB, and OX40) reduces acute GVHD in several murine models, whereas antagonism of the inhibitory signals (programmed death (PD)-1 and cytotoxic T lymphocyte antigen (CTLA)-4) exacerbates the severity of acute GVHD.^{136–142} The role of adhesion molecule DNAX accessory molecule-1 (DNAM-1) was recently explored in GVHD.^{143,144} Splenocytes deficient in DNAM-1 and prophylactic treatment with anti-DNAM-1 antibody prevented and treated GVHD. The various T-cell and APC costimulatory molecules and the impact on acute GVHD are summarized in Table 108.3. The specific context and the hierarchy in which each of these signals plays a dominant role in the modulation of GVHD remain to be determined.

T-Cell Subsets

T cells consist of several subsets whose responses differ based on antigenic stimuli, activation thresholds, and effector functions. The alloantigen composition of the host determines which donor T-cell subsets proliferate and differentiate.

CD4⁺, CD8⁺ Cells and Naive/Memory T-Cell Subsets

CD4 and CD8 proteins are coreceptors for constant portions of MHC class II and class I molecules, respectively.¹⁴⁵ Therefore MHC class I (HLA-A, HLA-B, HLA-C) differences stimulate CD8⁺ T cells and MHC class II (HLA-DR HLA-DP, HLA-DQ) differences stimulate CD4⁺ T cells.^{145–148} In the majority of HLA-identical BMT, acute GVHD can be induced by either or both CD4⁺ and CD8⁺ subsets in response to MiHAs.¹⁴⁹

Several independent groups have found that although the naive (CD62L⁺) T cells were alloreactive and caused acute GVHD, this was

TABLE 108.3 T Cell–Antigen-Presenting Cell Interactions

T Cell	APC
Adhesion	
ICAMs	LFA-1
LFA-1	ICAMs
CD2 (LFA-2)	LFA-3
CD 226 (DNAM-1)	CD155, CD112
Recognition	
TCR/CD4	MHC II
TCR/CD8	MHC I
Costimulation	
CD28	CD80/86
CD152 (CTLA-4)	CD80/86
ICOS	B7H/B7RP-1
PD-1	PD-L1, PD-L2
Unknown	
CD154 (CD40L)	B7-H3
CD134 (OX 40)	CD40
CD137 (4-1BB)	CD134L (OX40L)
HVEM	CD137L (4-1BBL)
	LIGHT

APC, Antigen-presenting cell; CTLA-4, cytotoxic T lymphocyte antigen 4; DNAM-1, DNAX accessory molecule-1; HVEM, HSV glycoprotein D for herpesvirus entry mediator; ICAM, intercellular adhesion molecule; L, ligand; LFA, leukocyte function–associated antigen; LIGHT, homologous to lymphotoxins, shows inducible expression, and competes with HVEM, a receptor expressed by T lymphocytes; MHC, major histocompatibility complex; PD, programmed death; TCR, T-cell receptor.

not the case for the memory (CD62L⁺) T cells across different donor/recipient strain combinations.^{150–153} Furthermore, expression of naive T-cell marker CD62L was also found to be critical for regulation of GVHD by donor natural regulatory T cells.¹⁵⁴ By contrast, another recent study demonstrated that alloreactive memory T cells and their precursor cells (memory stem cells) caused robust GVHD.^{155,156}

Regulatory T Cells

Recent advances indicate that distinct subsets of regulatory CD4⁺CD25⁺, CD4⁺CD25⁺IL10⁺ Tr cells, $\gamma\delta$ T cells, DN⁺ T cells, NKT cells, and regulatory DCs control immune responses by induction of anergy or active suppression of alloreactive T cells.^{97,98,157–165} Several studies have demonstrated a critical role for the natural donor CD4⁺CD25⁺ Foxp3⁺ regulatory T cells (Treg), obtained from naive animals or generated ex vivo, in the outcome of acute GVHD. Some studies have demonstrated that donor CD4⁺CD25⁺ T cells suppressed the early expansion of alloreactive donor T cells and their capacity to induce acute GVHD without abrogating GVL effector functions, while others have shown that depending on the tumors used and the context, GVL may be reduced as well.^{166–168} The mechanisms by which donor Tregs suppress GVHD are being better understood. The presence of signal transducer and activation of transcription (STAT)1 signaling has been shown to enhance Treg-mediated suppression of GVHD.¹⁶⁹ A key role for host APCs in the induction of GVHD protection, and for donor APCs in the sustenance of the protection by the infused mature Tregs has been demonstrated.¹⁷⁰ Several small clinical trials that either include expanding Tregs in vivo with IL-2, or by epigenetic targeting of histone acetylation at the *Foxp3* locus, or by preferential expansion of Tregs by cyclophosphamide have shown clinical benefit in early phase II trials.^{171–174} Direct infusion of ex vivo expanded donor Tregs has also demonstrated potential clinical benefit in small early phase trials and several clinical trials are underway in the United States and Europe with attempts to substantially expand these cells ex vivo and use for prevention of GVHD.^{175,176}

Host NK1.1⁺ T cells are another T-cell subset that has been shown to suppress acute GVHD in an IL-4 dependent manner.^{164,165,177} By contrast, donor NKT cells were found to reduce GVHD and enhance

perforin-mediated GVL in an IFN- γ dependent manner.^{178–180} Recent clinical data suggest that enhancing recipient NKT cells by repeated TLI conditioning promoted Th2 polarization and dramatically reduced GVHD.¹⁶⁵ Experimental data also show that activated donor NK cells can reduce GVHD through the elimination of host APCs or by secretion of transforming growth factor- β (TGF- β).¹⁷⁹ A murine BMT study using mice lacking SH2-containing inositol phosphatase, in which the NK compartment is dominated by cells that express two inhibitory receptors capable of binding either self or allogeneic MHC ligands, suggests that host NK cells may play a role in the initiation of GVHD.¹⁸¹

T-Cell Apoptosis and Signaling

Deletional mechanisms of tolerance fall into two categories: (1) central (thymic) deletion and (2) peripheral deletion.¹⁸² Central deletion is an effective way to eliminate continued thymic production of alloreactive T cells. To this end, lymphoablative treatments have been used as a condition to create a mixed hematopoietic chimeric state in murine BMT models.¹⁸³ In this strategy, donor cells seed the thymus and maturing donor-reactive T-cell clones are deleted through intrathymic apoptosis.^{184,185} The pathways of T-cell apoptosis by which peripheral deletion occurs can be broadly categorized into activation-induced cell death (AICD) and passive cell death (PCD).¹⁸⁶ An important mediator of AICD in T cells is the Fas receptor.¹⁸⁷ Activated T cells expressing the Fas molecule undergo apoptotic cell death when brought into contact with cells expressing Fas ligand. A critical role for Fas-mediated AICD has been clearly demonstrated in attenuation of acute GVHD by several type 1 T helper (Th1) cytokines.⁴² PCD, or “death by neglect,” illustrates the exquisite dependence of activated T cells on growth factors (e.g., IL-2, IL-4, IL-7, and/or IL-15) for survival; apoptotic cell death in this instance is largely because of rapid downregulation of B-cell lymphoma 2.^{188–190} Transplantation of B-cell lymphoma-extra large T cells into nonirradiated recipients significantly exacerbates GVHD; however, no difference in GVHD mortality is observed in animals that have been lethally irradiated.¹⁹¹ Selective elimination of donor T cells in vivo after BMT using transgenic T cells in which a thymidine kinase (TK) suicide gene is targeted to T cells has also been shown to attenuate the severity of acute GVHD.^{191–194} Another recent approach to prevent GVHD is the selective depletion of alloantigen-specific donor T cells by a photodynamic cell-purging process, wherein donor T cells are treated with photoactive 4,5-dibromorhodamine 123 and subsequently exposed to visible light.¹⁹⁵ Targeting alloreactive T-cell bioenergetics has emerged as a newer strategy to mitigate GVHD in mice.^{196,197} Thus several deletional mechanisms have been shown to reduce acute GVHD but the conditions under which one or another of these deletional mechanisms predominate remain to be determined.

APC and T-cell activation results in rapid intracellular biochemical signaling cascades that activate or negatively regulate alloreactive donor T-cell responses. The calcineurin-nuclear factor of activated T cell (NFAT) pathway has been shown to be an effective target for mitigating GVHD and forms the bedrock of clinical care. Specifically, the calcineurin inhibitors cyclosporine and tacrolimus. Cyclosporine binds to the cytosolic protein peptidyl prolyl cis-trans isomerase A (also known as cyclophilin), whereas tacrolimus binds to the peptidyl-prolyl cis-trans isomerase FK506-binding protein (FKBP)12, and these complexes (cyclosporine–cyclophilin or tacrolimus–FKBP12) inhibit calcineurin, thereby blocking the dephosphorylation of NFAT and its nuclear translocation.¹⁹⁸ These events prevent NFAT from exerting its transcriptional function, resulting in the inhibition of transcription of IL-2 and of other cytokines and ultimately leading to a reduced function of T-cells and mitigation of GVHD. Merging data have identified several key T-cell signaling pathways, many of which are being targeted in the clinic. Notably, the mammalian target of rapamycin (mTOR) pathway has been shown to be critical for blocking IL-2–mediated signal transduction and prevents cell-cycle progression in naive T cells.¹⁹⁹ Inhibition of mTOR with

sirolimus is being used clinically to prevent and treat GVHD. Several additional signaling pathways that regulate alloreactive T-cell responses have recently been identified, such as Notch, protein kinase C (PKC) θ , spleen tyrosine kinase (syk), Janus-activated kinase (JAK)2, signal transducer and activator of transcription (STAT)3 and nuclear factor kappa-B (NF κ B).¹¹⁵ Emerging data are further defining a role for regulation T-cell proliferation/apoptosis epigenetic regulation through posttranslational modification by ubiquitination^{200,201} or acetylation,²⁰² or by microRNAs (miRNAs). Specifically miRNAs such as miRNA 412 and miRNA 155 modulate alloimmunity by regulation of T-cell cycling and thus mitigate GVHD.^{203,204}

Cytokines and T-Cell Differentiation

Classically the Th1 cytokines (IFN- γ , IL-2), TNF- α and IL-6 have been implicated in the cytokine storm that occurs early after BMT and have been shown to be critical for the pathophysiology of acute GVHD.^{83,205–208} In addition to IL-2, several other common γ -chain cytokines (IL-21, IL-7, and IL-15) have been shown to play critical and potentially nonredundant roles in GVHD pathogenesis.²⁰⁹ Type 1 or Tc1/Th1 maturation is recognized as the dominant pattern in acute GVHD.^{210,211} Increased quantities of Th1-associated cytokines, TNF and IFN- γ , in acute GVHD are associated with earlier onset and more severe disease in preclinical models and clinical BMT. Although the dominance of Th1 subsets is well established, Th2 and Th17 subsets are also involved in pathology, and the balance between subsets determines acute GVHD severity, in addition to organ specificity, and the pathogenic or protective effects of any subset cannot be viewed in isolation.^{212,213} Specifically, Th2 differentiation is often seen as opposing Th1 differentiation; however, this subset is also recognized as causing acute GVHD but with predominant pathology in pulmonary, hepatic, and cutaneous tissues,²¹⁴ in contrast to the strong GI association with Th1. Cutaneous pathology also may be generated by Th17 cells; although they are more commonly associated with chronic GVHD, they also have been associated with acute pathology.^{215,216} Recent data have shown that blockade of L-33 binding with the Th2 ST2 receptor during allogeneic-hematopoietic cell transplantation by exogenous ST2-Fc infusions had a marked reduction in GVHD lethality, indicating a role for ST2 as a decoy receptor modulating GVHD.²¹⁷ Th17 differentiation is initiated by IL-6,²¹⁸ and ROR γ t is the defining transcription factor, whereas maintenance and amplification relies on IL-23 and IL-21, respectively. The use of RORC-deficient donor T cells results in attenuated acute GVHD severity and lethality.²¹⁹ Further studies are needed to better define the role of this subset in late acute GVHD versus early chronic GVHD, as well as the relative contribution of IL-17 from CD4 and CD8 T cells to end-organ pathology.

Leukocyte Migration

Donor T cells migrate to lymphoid tissues, recognize alloantigens on either host or donor APCs, and become activated. They then exit the lymphoid tissues and traffic to the target organs and cause tissue damage.²²⁰ The molecular interactions necessary for T-cell migration and the role of lymphoid organs during acute GVHD have recently become the focus of a growing body of research. Chemokines play a critical role in the migration of immune cells to secondary lymphoid organs and target tissues.²²¹ T-lymphocyte production of macrophage inflammatory protein-1- α is critical to the recruitment of CD8⁺ but not CD4⁺ T cells to the liver, lung, and spleen during acute GVHD.²²² Several chemokines such as CCL2-5, CXC-chemokine ligand (CXCL)2, CXCL9-11, CCL17, and CCL27 are overexpressed and might play a critical role in the migration of leukocyte subsets to target organs/liver, spleen, skin, and lungs during acute GVHD.^{220,223} CXC-chemokine receptor (CXCR)3⁺ T and CCR5⁺ T cells cause acute GVHD in the liver and intestine.^{220,224–226} CCR5 expression has also been found to be critical for Treg migration in GVHD.²²⁷ Recent

clinical data from an early phase trial suggests that this may be a viable clinical strategy.²²⁸ In addition to chemokines and their receptors, expression of selectins and integrins and their ligands also regulate the migration of inflammatory cells to target organs.²²¹ For example, interaction between α 4 β 7 integrin and its ligand MadCAM-1 are important for homing of donor T cells to Peyer patches and in the initiation of intestinal GVHD.^{86,229} α L β 2/intercellular adhesion molecule 1 (ICAM1), ICAM2, ICAM3, and α 4 β 1/vascular cell adhesion molecule (VCAM)2 interactions are important for homing to the lung and liver after experimental HCT.²²⁰ The expression of CD62L on donor Tregs is critical for their regulation of acute GVHD, suggesting that their migration in secondary tissues is critical for their regulatory effects.¹²⁵ The migratory requirement of donor T cells to specific lymph nodes (e.g., Peyer patches) for the induction of GVHD might depend on other factors such as the conditioning regimen, inflammatory milieu, etc.^{86,230} Furthermore, FTY720, a pharmacologic sphingosine-1-phosphate receptor agonist, inhibited GVHD in murine but not in canine models of HCT.^{231,232} Thus significant species differences may also factor in the ability of these molecules to regulate GVHD.

Phase 3: Effector Phase

The effector phase that leads to the GVHD target organ damage is a complex cascade of multiple cellular and inflammatory effectors that further modulate each other's responses either simultaneously or successively. Effector mechanisms of acute GVHD can be grouped into cellular and inflammatory effectors. Inflammatory chemokines expressed in inflamed tissues upon stimulation by proinflammatory effectors, such as cytokines, are specialized for the recruitment of effector cells, such as cytotoxic T lymphocytes (CTLs).²³³ Furthermore, the spatiotemporal expression of the cytochemokine gradients might determine not only the severity but also the unusual cluster of GVHD target organs (skin, gut, and liver).^{220,234}

Cellular Effectors

CTLs are the major cellular effectors of GVHD.^{235,236} The principle CTL effector pathways that have been evaluated after allogeneic BMT are the Fas-Fas ligand (FasL), the perforin-granzyme (or granule exocytosis), and the TNFR-like death receptors (DR), such as TNF-related apoptosis-inducing ligand (TRAIL: DR4, 5 ligand) and TNF-like weak inducers of apoptosis (TWEAK: DR3 ligand).^{236–241} The involvement of each of these molecules in GVHD has been tested by using donor cells that are unable to mediate each pathway. Perforin is stored in cytotoxic granules of CTLs and NK cells, together with granzymes and other proteins. Although the exact mechanisms remain unclear, following the recognition of a target cell through the TCR-MHC interaction, perforin is secreted and inserted into the cell-membrane, forming "perforin pores" that allow granzymes to enter the target cells and induce apoptosis through various downstream effector pathways such as caspases.²⁴²

Transplantation of perforin-deficient T cells results in a marked delay in the onset of GVHD in transplants across MiHA disparities only, both MHC and MiHA disparities, and across isolated MHC I or II disparities.^{236,243–247} However, mortality and clinical and histologic signs of GVHD were still induced even in the absence of perforin-dependent killing in these studies, demonstrating that the perforin-granzyme pathway plays little role in target organ damage. A role for the perforin-granzyme pathway for GVHD induction is also evident in studies using donor T-cell subsets. Perforin-deficient or granzyme B-deficient CD8⁺ T cells caused less mortality than wild-type T cells in experimental transplants across a single MHC class I mismatch. This pathway, however, seems to be less important compared with the Fas/FasL pathway in CD4-mediated GVHD.^{246–248} Thus it seems that CD4⁺ CTLs preferentially use the Fas-FasL pathway, whereas CD8⁺ CTLs primarily use the perforin-granzyme pathway.

Fas, a TNF-receptor family member, is expressed by many tissues, including GVHD target organs.²⁴⁹ Its expression can be upregulated by inflammatory cytokines such as IFN- γ and TNF- α during GVHD, and the expression of FasL is also increased on donor T cells, indicating that FasL-mediated cytotoxicity may be a particularly important effector pathway in GVHD.^{236,250} FasL-defective T cells cause less GVHD in the liver, skin, and lymphoid organs.^{245,248,250} The Fas-FasL pathway is particularly important in hepatic GVHD, consistent with the keen sensitivity of hepatocytes to Fas-mediated cytotoxicity in experimental models of murine hepatitis.²³⁶ Fas-deficient recipients are protected from hepatic GVHD, but not from other organ GVHD, and administration of anti-FasL (but not anti-TNF) monoclonal antibodies (MAbs) significantly blocked hepatic GVHD damage occurring in murine models.^{236,251,252} Although the use of FasL-deficient donor T cells or the administration of neutralizing FasL MAbs had no effect on the development of intestinal GVHD in several studies, the Fas-FasL pathway may play a role in this target organ, because intestinal epithelial lymphocytes exhibit increased FasL-mediated killing potential.²⁵³ Elevated serum levels of soluble FasL and Fas have also been observed in at least some patients with acute GVHD.^{254,255}

The use of a perforin-granzyme and FasL cytotoxic double-deficient (cdd) T cells, showed that they were unable to induce lethal GVHD across MHC class I and class II disparities after sublethal irradiation.²⁴⁴ However, when recipients were conditioned with a lethal dose of irradiation, cdd CD4⁺ T cells produced similar mortality to wild-type CD4⁺ T cells.²⁴⁰ These results were confirmed by a recent study demonstrating that GVHD target damage can occur in mice that lack alloantigen expression on the epithelium, preventing direct interaction between CTLs and target cells.²⁴¹

Recently, several additional TNF family apoptosis-inducing receptors/ligands have been identified, including TWEAK, TRAIL, and LT β /LIGHT, all of which have been proposed to play a role in GVHD and GVL responses.^{136,256–262} However, whether these distinct pathways play a more specific role for GVHD mediated by distinct T-cell subsets in certain situations remains unknown. Taken together, experimental data suggest some distinction between the use of different lytic pathways for the specific GVHD target organs and GVL, but the clinical applicability of these observations is as yet largely unknown.

Inflammatory Effectors

Inflammatory cytokines synergize with CTLs resulting in the amplification of local tissue injury and further promotion of an inflammation, which ultimately leads to the observed target tissue destruction in the transplant recipient.²⁶³

The cytokines TNF- α , IL-6, and IL-1 are produced by an abundance of cell types during processes of both innate and adaptive immunity; they often have synergistic, pleiotropic, and redundant effects on both activation and effector phases of GVHD.^{207,219} A critical role for TNF- α in the pathophysiology of acute GVHD was first suggested over 20 years ago because mice transplanted with mixtures of allogeneic BM and T cells developed severe skin, gut, and lung lesions that were associated with high levels of TNF- α messenger RNA (mRNA) in these tissues.²⁶⁴ Target organ damage could be inhibited by infusion of anti-TNF- α MAbs, and mortality could be reduced from 100% to 50% by the administration of the soluble form of the TNF- α receptor (sTNFR), an antagonist of TNF- α .^{79,82,265} TNF-TNFR1 interactions on donor T cells promote alloreactive T-cell responses and TNF-TNFR2 interactions are critical for intestinal GVHD.^{211,259,266} TNF- α also seems to be an important effector molecule in GVHD in skin and lymphoid tissue.^{264,267} In addition, TNF- α might also be involved in hepatic GVHD, probably by enhancing effector cell migration to the liver via the induction of inflammatory chemokines.²⁶⁸ The second major proinflammatory cytokine that appears to play an important role in the effector phase of acute GVHD is IL-1.^{42,263} Secretion of IL-1 appears to occur predominantly during the effector phase of GVHD of the spleen and

skin, two major GVHD target organs.²⁶⁹ A similar increase in mononuclear cell IL-1 mRNA has been shown during clinical acute GVHD. Mice receiving IL-1 displayed a wasting syndrome and increased mortality that appeared to be an accelerated form of disease. By contrast, intraperitoneal administration of IL-1 receptor antagonist (IL-1RA) was able to reverse the development of GVHD in the majority of animals, providing a significant survival advantage to treated animals.²⁷⁰ However, the attempt to use IL-1RA to prevent acute GVHD in a randomized trial was not successful.²⁷¹

As a result of activation during GVHD, macrophages also produce nitric oxide (NO), which contributes to the deleterious effects on GVHD target tissues, particularly immunosuppression.²⁷² NO also inhibits the repair mechanisms of target tissue destruction by inhibiting proliferation of epithelial stem cells in the gut and skin.²⁷³ In humans and rats, the development of GVHD is preceded by an increase in serum levels of NO oxidation products.^{274–276}

IL-6 has also been identified as a critical cytokine that promotes a proinflammatory response during GVHD. Recent data suggest that IL-6 might in fact be the most critical cytokine that increases GVHD severity. It has direct cytopathic effects on the GI tract following allogeneic BMT and likely inhibits the reconstitution of Tregs.^{208,277} It plays a dominant role in mitigating lung injury after allo-BMT.²⁷⁸ Recent clinical trial demonstrated that targeting IL-6 early after transplant, particularly following high-intensity conditioning could mitigate GVHD.

BIOMARKERS OF ACUTE GRAFT-VERSUS-HOST DISEASE

Emerging data from large datasets have identified and validated plasma biomarkers with important prognostic value at the onset of symptoms of acute GVHD. Markers of systemic GVHD include IL-2R α , TNFR1, IL-8, and hepatocyte growth factor.^{1,279} Elafin has been identified as a biomarker specific for skin GVHD, and regenerating islet-derived 3- α (REG3 α) as a biomarker of gastrointestinal GVHD, and ST2 or the soluble IL-33 receptor as a marker of resistance to therapy.^{2–4,280–282}

Recently, the concentrations of three of these plasma biomarkers (TNFR1, ST2, and Reg3 α) were used in the creation of an algorithm that computed the probability of nonrelapse mortality (NRM) for individual patients.^{5,283} The algorithm was developed in a multicenter training set of 328 patients, and two separate multicenter validation sets of 164 and 300 patients, respectively. The investigators identified thresholds that created three distinct Ann Arbor GVHD scores. In all three datasets (training, test, and validation), the cumulative incidence of 6-month NRM significantly increased as the Ann Arbor GVHD score increased: 8% for score 1, 27% for score 2, and 46% for score 3 ($P < .0001$). Conversely, the response to primary GVHD treatment decreased as the GVHD score increased: 86% for score 1, 67% for score 2, and 46% for score 3, $P < .0001$. These findings suggest that biomarker-based scores can be used to guide risk-adapted therapy at the onset of acute GVHD. High-risk patients with a score of 3 are candidates for intensive primary therapy, while low-risk patients with a score of 1 are candidates for rapid tapers of systemic steroid therapy.

Recently the number of Paneth cells in duodenal biopsies for GVHD has been shown to correlate with response to treatment and with long-term survival.^{6,31} The plasma concentration of REG3 α , the clinical severity of GVHD, and the histologic severity at GVHD diagnosis independently predicted lack of response to GVHD therapy 4 weeks following treatment and TRM. Patients who had all three risk factors experienced significantly greater NRM than those with any two of the risk factors (86% versus 66%, $P < .001$). The integration of clinical stage, histologic grade, and biomarkers into a single grading system may permit better risk stratification and rapid identification of patients for whom standard treatment is likely to be insufficient.^{3,281}

These biomarkers may also provide new insights into the biology of GVHD. For example, the IL-22-Reg3 axis protects the epithelial barrier function of the intestinal mucosa. Intestinal stem cells (ISCs)

are principal cellular targets of GVHD in the GI tract, where intestinal flora are critical for amplification of GVHD damage. ISC are protected by antibacterial proteins such as REG3 α secreted by neighboring Paneth cells. Mucosal barrier disruption caused by stem cell dropout and subsequent lack of mucosal regeneration may preferentially allow Paneth cell proteins, including REG3 α , to traverse into the bloodstream. Thus the plasma levels of REG3 α may serve as a “liquid biopsy” and surrogate marker for the cumulative area of these breaches to GI mucosal barrier integrity, a parameter impossible to measure by individual tissue biopsies.

Prevention of Acute Graft-Versus-Host Disease

Elimination of T cells with monoclonal antibodies, immunotoxins, lectins, CD34 columns, or physical techniques are effective at reducing GVHD. A typical unmanipulated marrow transplant entails the infusion of approximately 10^7 T cells per kg of recipient weight. A T-cell dose less than or equal to 10^5 per kg has been associated with complete control of GVHD.⁴¹ More recently, the combination of very high stem cell numbers and less than 3×10^4 CD3 cells per kg allowed haploidentical transplantation without GVHD.²⁸⁴ Presumably host immune cells that survive the initial conditioning are responsible for graft rejection. When the stem cell source contains large numbers of T cells, the GVH reaction further reduces the residual population capable of alloreactivity, thus decreasing graft rejection. To some degree, the higher graft failure rates may be controlled by increasing the intensity of the immunosuppression of the conditioning regimen,^{285,286} or adding back T cells.²⁸⁷ Overall there has been no improvement in survival that can be definitively attributed to T-cell depletion.

Treatment of established GVHD with specific T-cell antibodies has produced mixed results. Although antithymocyte globulin has definite activity in established GVHD, the nonspecific clearance of T cells may result in increased opportunistic infections and no improvement in survival. More specific therapy with the humanized anti-IL-2 receptor antibody, daclizumab^{288,289} or the humanized anti-CD3 antibody, visilizumab^{290,291} are promising, since they offer the potential of selectively removing the activated T cells. However, an increased risk for infection may still be observed.²⁹²

The first generally prescribed GVHD preventive regimen was the administration of intermittent low-dose methotrexate as developed in a dog model by Thomas and Storb.²⁹³ The principle of this approach was to administer a cell cycle-specific chemotherapeutic agent immediately after the transplant, when the T cells have started to divide after exposure to allogeneic antigens. Subsequently, the addition of antithymocyte globulin, prednisone, or both resulted in incremental improvement in the GVHD rate but no improvement in survival.^{294,295} Ultimately, the course of methotrexate was abbreviated and combined with a T-cell activation inhibitor, such as cyclosporine or tacrolimus. The introduction of cyclosporine in the late 1970s was a significant advance in GVHD prevention. A similar agent, tacrolimus, has been shown to provide similar control of GVHD.²⁹⁶ As a single agent, cyclosporine was about as effective as methotrexate.²⁹⁷ However, in combination with methotrexate, there was a significant reduction in the incidence of GVHD and an improvement in survival.²⁹⁸ Subsequent trials of tacrolimus and methotrexate compared with cyclosporine and methotrexate showed no advantage for either combination.²⁹⁶ The addition of prednisone to the conventional two-drug regimen resulted in similar rates of GVHD and no improvement in survival.²⁹⁹

Sirolimus (rapamycin) is a macrocyclic lactone immunosuppressant that is similar in structure to tacrolimus and cyclosporine. All three drugs bind to immunophilins; however, sirolimus complexed with FKBP12 inhibits T-cell proliferation by interfering with signal transduction and cell-cycle progression and can prevent GVHD.³⁰⁰ Because Sirolimus acts through a separate mechanism from the tacrolimus-FKBP complex (and cyclosporine-cyclophilin complex), it may be synergistic with both tacrolimus and cyclosporine. More recently, mycophenolate mofetil (MMF) has been studied. It is the

prodrug of mycophenolic acid (MPA), a selective inhibitor of inosine monophosphate dehydrogenase, an enzyme critical to the de novo synthesis of guanosine nucleotide. Since T lymphocytes are more dependent on such synthesis than myeloid or mucosal cells, MPA preferentially inhibits proliferative responses of T cells.³⁰¹

One hypothesis that flows from the three-step model of GVHD posits that reduction of intestinal colonization with bacteria could prevent GVHD. Animal studies in germ-free environments support this notion; GVHD was not observed until mice were colonized with gram-negative organisms.³⁰² Later, gut decontamination and use of a laminar air flow environment was associated with less GVHD and better survival in patients with severe aplastic anemia.³⁰³ Similarly, studies of intestinal decontamination in patients with malignancies have shown less GVHD in some,^{304,305} but not all studies.³⁰⁶ Finally, another recent approach to GVHD prevention has been the use of nonmyeloablative conditioning transplants. Administration of vorinostat in combination with standard GVHD prophylaxis after related-donor reduced-intensity conditioning hemopoietic stem-cell transplantation reduced cumulative incidence of grade II–IV acute GVHD by day 100 to 22%, lower than the expected incidence of severe acute GVHD.¹⁷² A less intensive preparative regimen decreases the tissue toxicity and subsequent release of cytokines in animal models.^{79,82} Patients generally experience mild toxicity in the initial peritransplant period and develop little or no GVHD, although many develop GVHD later, especially after donor lymphocyte infusions. In fact, the rates of GVHD are often higher than with conventional transplants, and GVHD is associated with a significant portion of the GVL effect.^{307–309}

A recent study has shown that addition of one dose of a humanized anti-IL-6 monoclonal antibody (tocilizumab) in addition to standard cyclosporine methotrexate prophylaxis resulted in only 12% Grade II–IV acute GVHD in 48 patients.^{310,311} An important role for TNF- α in clinical acute GVHD has been suggested by studies demonstrating elevated levels of TNF- α in the serum of patients with acute GVHD and other endothelial complications such as venoocclusive disease.^{312–315} Therapy of GVHD with humanized anti-TNF- α (infliximab)^{316,317} or a dimeric fusion protein consisting of the extracellular ligand-binding portion of the human TNF- α receptor (TNFR) linked to the Fc portion of human immunoglobulin G1 (etanercept)³¹⁸ have shown some promise.^{319,320} The second major proinflammatory cytokine that appears to play an important role in the effector phase of acute GVHD is IL-1. Secretion of IL-1 appears to occur predominantly during the effector phase of GVHD in the spleen and skin, two major GVHD target organs.²⁶⁹ IL-1RA is a naturally occurring pure competitive inhibitor of IL-1 that is produced by monocytes/macrophages and keratinocytes. Of note, the *IL-1RA* gene is polymorphic, and the presence in the donor of the allele that is linked to higher secretion of IL-1RA was associated with less acute GVHD.³²¹ Two-phase I/II trials showed promising data that specific inhibition of IL-1 with either the soluble receptor or IL-1RA could result in remissions in 50% to 60% of patients with steroid-resistant GVHD.^{322,323} However, a subsequent randomized trial of the addition of IL-1RA or placebo to cyclosporine and methotrexate beginning at the time of conditioning and continuing through day 14 after stem cell infusion did not show any protective effect of the drug, despite the attainment of very high plasma levels.^{271,324} Therefore, at least as administered in this study, IL-1 inhibition was insufficient to prevent GVHD in humans. IL-11 was also able to protect the GI tract in animal models and prevent GVHD, but it did not prevent clinical GVHD.³²⁴ Thus not all preclinical strategies successfully translate to new therapies.

Therapy for Acute Graft-Versus-Host Disease

Glucocorticoid steroids are the initial therapy for acute GVHD. The mechanisms by which steroids work are multifactorial; they act as lympholytic agents and inhibit the release of inflammatory cytokines such as IL-1, IL-2, IL-6, gamma interferon, and TNF- α . Because of its intravenous availability, methylprednisolone is the steroid most

commonly given for acute GVHD. Various dosing regimens have been used, none of which is clearly superior. High-bolus doses (10–20 mg/kg or 500 mg/m²) have higher initial response rates, but flares on tapering and opportunistic infections are common. Both the Seattle and Minnesota transplant groups have found that treatment with steroids was as effective as, or more effective than, other therapies or combination of therapies, with 20% to 40% of patients having durable long-term responses.^{325,326} Long-term salvage rates for patients who did not respond to steroids were 20% or less; most patients eventually died from infection, acute GVHD, and/or chronic GVHD. More recently, a randomized trial demonstrated that topical therapy with oral budesonide can have prednisone sparing effects and is efficacious in treatment of GI GVHD.³²⁷ Clinically, two types of failure of corticosteroid treatment of acute GVHD can be distinguished: true steroid resistance (i.e., progression of GVHD symptoms and manifestations while patients are receiving full-dose corticosteroid treatment) and steroid dependence (i.e., recurrence [or flare] of GVHD during or after tapering of steroid treatment).³²⁸ In general, the prognosis with true steroid-resistant GVHD is worse than the prognosis of steroid-dependent patients.³²⁸ A comparison of trials dealing with steroid-resistant GVHD is hampered by variable inclusion of both patient groups in many of these trials. A number of agents have been tested, including chemical immunosuppressants such as MMF, antithymocyte globulin (ATG), anti-CD3, anti-T-cell antibodies, and more specific agents directed against activation or adhesion molecules anti-CD25, anti-CD147, or cytokines or extracorporeal photopheresis.^{328,329} To date, there are no randomized trials testing one agent versus the other in this clinical situation. Recent data suggested a role for TNF inhibition when added to steroids in treating GVHD, although a randomized trial failed to demonstrate any difference when compared with the addition of pentostatin or anti-IL2 to steroids and was inferior to the addition of MMF.^{319,330}

Targeted elimination of alloreactive T cells has recently been demonstrated to be a safe and efficacious method to mitigate GVHD. Fusion of human caspase 9 to a modified human FK-binding protein that allowed for dimerization when exposed to a synthetic dimerizing drug led to the rapid death of 90% of alloreactive T cells expressing this construct and mitigated acute GVHD in a pilot trial of five patients following haploidentical BMT.³³¹

Other Supportive Approaches

Infections are the main cause of death in patients with steroid-refractory acute GVHD, and careful surveillance and control of infections is mandatory in patients with acute GVHD. Fungal infections, especially aspergillosis, are the leading complication. Prophylaxis and early aggressive treatment should be facilitated by the introduction of new azoles (voriconazole, posiconazole) or echinocandins (caspofungin, micafungin), which broaden therapeutic efficacy with acceptable toxicity. Other supplementary approaches have been suggested, such as the use of octreotide³³² and oral beclomethasone (or budesonide) to control large volumes of diarrhea.³²⁷

CHRONIC GRAFT-VERSUS-HOST DISEASE

Chronic GVHD was initially defined as a GVHD syndrome presenting more than 100 days after transplantation; its onset occurred either as an extension of acute GVHD (progressive), after a disease-free interval (quiescent), or with no precedent (de novo).^{333,334} Chronic GVHD may be limited or extensive (see Table 108.3). Any grade of acute GVHD increases the probability of chronic GVHD, although no singular pathologic feature of the former predicts the development of the latter. Its incidence ranges from 30% to 60% after transplantation with the bone marrow, although it may be higher after peripheral blood progenitor transplants.³³⁵

As with acute GVHD, the immune system appears to be affected in all patients, who are highly susceptible to bacterial, viral, fungal, and opportunistic infections. Specific abnormalities of cellular

immunity include decreases in the production of antibodies against specific antigens, defects in the number and function of CD4⁺ T cells, and increases in the number of nonspecific suppressor cells, which further diminish lymphocyte responses. Skin changes resembling widespread lichen planus with papulosquamous dermatitis, plaques, desquamation, dyspigmentation, and vitiligo occur in 80% of patients.^{309,336} Destruction of dermal appendages leads to alopecia and onychodysplasia. Severe chronic GVHD of the skin can resemble scleroderma, with induration, joint contractures, atrophy, and chronic skin ulcers. Chronic cholestatic liver disease occurs in 80% of patients and often resembles acute GVHD; it rarely progresses to cirrhosis. Severe mucositis of the mouth and esophagus can result in weight loss and malnutrition. Intestinal involvement, however, is infrequent.^{309,336} Chronic GVHD also produces a sicca syndrome, with atrophy and dryness of mucosal surfaces caused by lymphocytic destruction of exocrine glands, usually affecting the eyes, mouth, airways, skin, and esophagus.^{24,336,337} The hematopoietic system may also be affected, and thrombocytopenia is an unfavorable prognostic factor in patients with chronic GVHD.³⁰⁹ Important predictors of unfavorable outcome are progressive onset, lichenoid skin changes, elevated serum bilirubin level, continued thrombocytopenia, and failure to respond to 9 months of therapy.^{309,338–340} Among patients with none of these risk factors, 70% are expected to survive, compared with less than 20% with two or more of these risk factors.³⁴⁰

Histologic examination of the immune system reveals involution of thymic epithelium, disappearance of Hassall corpuscles, depletion of lymphocytes, and absence of secondary germinal centers in lymph nodes.³³⁷ Pathologic skin findings include epidermal atrophy with changes characteristic of lichen planus and striking inflammation around eccrine units. Sclerosis of the dermis and fibrosis of the hypodermis subsequently develop. GI lesions include localized inflammation of the mucosa and stricture formation in the esophagus and small intestine.³³⁶ Histologic findings in the liver are often similar to those that occur in acute GVHD but are more intense, with chronic changes such as fibrosis and hyalinization of portal triads, obliteration of bile ducts, and hepatocellular cholestasis.³⁰⁹ The endocrine glands of the eyes, mouth, esophagus, and bronchi show destruction focused on centrally draining ducts, with secondary involvement of alveolar components.³³⁷ Findings of bronchiolitis obliterans, similar to those that occur in rejection of lung transplants, are now generally considered a pulmonary manifestation of chronic GVHD, although the pathogenesis of this process remains unclear.³³⁷

Clinical Manifestations of Chronic Graft-Versus-Host Disease

Chronic GVHD can present with a plethora of clinical manifestations. Because of its unpredictable pattern and the late onset, when patients are no longer receiving care at their transplant center, the diagnosis is often delayed or not recognized. The staging of chronic GVHD is summarized in Table 108.4. However, consensus criteria recently developed by the National Institutes of Health (NIH) might soon become the standard for diagnosing and evaluating responses for chronic GVHD.^{341,342}

Dermatologic

Skin involvement in chronic GVHD presents with varied features. Lichenoid chronic GVHD presents as an erythematous, papular rash that resembles lichen planus with no typical distribution pattern.²⁴ Sclerodermatous GVHD may involve the dermis and/or the muscular fascia and clinically resembles systemic sclerosis. The skin is thickened, tight, and fragile, with very poor wound healing. Either hypo or hyperpigmentation may occur. In severe cases the skin may become blistered and ulcerate. Hair changes can include increased brittleness, premature graying, and alopecia. Fingernails and toenails may also be

TABLE 108.4**Commonly Administered Drugs for Graft-Versus-Host Disease Prophylaxis and Treatment**

Drug	Mechanism	Adverse Effects
Corticosteroids	Direct lymphocyte toxicity; suppress proinflammatory cytokines such as TNF- α	Hyperglycemia, acute psychosis, severe myopathy, neuropathy, osteoporosis, cataract development
Methotrexate (MTX)	Antimetabolite: inhibit T-cell proliferation	Significant renal, hepatic, and gastrointestinal toxicities
Cyclosporine A (CSA)	IL-2 suppressor; blocks Ca ²⁺ -dependent signal transduction distal to TCR engagement	Renal and hepatic insufficiency, hypertension, hyperglycemia, headache, nausea and vomiting, hirsutism, gum hypertrophy, seizure with severe toxicity
Tacrolimus (FK506)	IL-2 receptor; blocks Ca ²⁺ -dependent signal transduction distal to TCR engagement	Similar to CSA
Mycophenolate mofetil (MMF)	Inhibits de novo purine synthesis	Body aches, abdominal pain, nausea and vomiting, diarrhea, neutropenia
Sirolimus	mTOR inhibitor	Thrombocytopenia, hyperlipidemia, TTP
Antithymocyte globulin (ATG)	Polyclonal immunoglobulin	Anaphylaxis, serum sickness

IL-2, Interleukin-2; mTOR, mammalian target of rapamycin; TCR, T-cell receptor; TNF- α , tumor necrosis factor- α ; TTP, thrombotic thrombocytopenic purpura.

affected by chronic GVHD. Destruction of sweat glands can cause hyperthermia.³⁴³

Ocular

Ocular GVHD usually presents with xerophthalmia or dry eyes. Irreversible destruction of the lacrimal glands results in dryness, photophobia, and burning. Local therapy with preservative-free tears and ointment or the placement of punctal plugs by an ophthalmologist might be required. Conjunctival GVHD, a rare manifestation of severe chronic GVHD, has a poor prognosis.^{24,343}

Oral

Oral GVHD causes xerostomia and/or food sensitivity.³⁴³ More advanced disease may cause odynophagia caused by esophageal damage and strictures, although esophageal involvement occurs rarely without oral disease. Physical examination may reveal only erythema with a few white plaques, prompting a misdiagnosis of thrush or herpetic infections. Lichenoid changes in advanced disease can cause extensive plaque formation.²⁴

Gastrointestinal

Patients with chronic GVHD have GI complaints that mimic other disease states, including acute GVHD, infection, dysmotility, lactose intolerance, pancreatic insufficiency, and drug-related side effects. In one retrospective review of the intestinal biopsies of patients with chronic GVHD and persistent GI symptoms, a majority of patients had evidence of both acute and chronic GVHD, and only 7% of the patients had isolated chronic GVHD.^{24,336} Thus although chronic GVHD may involve the GI tract alone, it may be difficult to diagnose in those circumstances without concurrent acute GVHD.

Hepatic

Hepatic disease typically presents as cholestasis with elevated serum levels of alkaline phosphatase and bilirubin. Isolated hepatic chronic GVHD has become more common with the increasing use of donor lymphocyte infusions.¹¹ Liver biopsy is required to confirm the diagnosis of chronic hepatic GVHD in patients with no other target organ involvement.

Pulmonary

Bronchiolitis obliterans is a late and serious manifestation of chronic GVHD. Patients typically present with a cough or dyspnea.³⁴³ Severe sclerotic disease of the chest wall may also give rise to similar symptoms with no intrinsic pulmonary disease. Pulmonary function tests demonstrate obstructive physiology and a reduction in DLCO. Chest computed tomography results may be normal or may show hyperinflation with a ground-glass appearance. Overall, patients with bronchiolitis obliterans have minimal response to therapy and a very poor prognosis. Patients with chronic GVHD are also at risk for chronic sinopulmonary infections, but symptoms may be minimal.²⁴

Hematopoietic

Cytopenias in chronic GVHD are common. This may be a result of stromal damage, but autoimmune neutropenia, anemia, and/or thrombocytopenia are also seen. Thrombocytopenia at the time of chronic GVHD diagnosis is associated with poor prognosis. However, thrombocytopenia posttransplant is a poor prognostic factor regardless of GVHD, and eosinophilia is occasionally seen with chronic GVHD.

Immunologic

Chronic GVHD is inherently immunosuppressive. Functional asplenia with an increased susceptibility to encapsulated bacteria is common, and circulating Howell-Jolly bodies can be seen on peripheral blood smear. Patients are also at risk for invasive fungal infections and *Pneumocystis carinii* pneumonia. Hypoglobulinemia is common, and patients with levels below 500 mg/dL should be supplemented with intravenous immunoglobulin.

Musculoskeletal

Fascial involvement in sclerodermatous GVHD is usually associated with skin changes. Fasciitis in joint areas can cause severe restriction of range of motion. Muscle cramps are a common complaint in patients with chronic GVHD, but myositis with elevated muscle enzymes is rare. Many patients with chronic GVHD are on steroid therapy and have low levels of sex hormone posttransplant. Thus avascular necrosis, osteopenia, and osteoporosis are frequent complications.

Although several cases have been described, it is yet to be determined in large studies whether kidneys, which are primary targets in

some animal models of chronic GVHD, are also involved.³⁴⁴ Among the myriad clinical features of chronic GVHD, three definitive signs appear to be risk factors for increased mortality: (1) extensive skin GVHD involving greater than 50% of the body surface area, (2) platelet count of less than 100,000/ μ L, and (3) progressive onset and acute GVHD that continues uninterrupted beyond day 100.³⁴⁵ However, chronic GVHD remains, except in cases with obvious features, a difficult diagnosis; response to therapy is even more difficult to assess. Recent criteria established by the NIH consensus conference might prove to be beneficial in establishing uniform guidelines for diagnosis, treatment, and response.³⁴² The NIH consensus criteria are currently being evaluated.

Differential Diagnosis

The distinction between chronic and acute GVHD has been traditionally based on the time of onset. However, with the advent of low-intensity HCT, that distinction has become less relevant. The NIH working group has, in addition to the two main categories of GVHD, added two subcategories. The broad category of acute GVHD includes (1) classic acute GVHD (maculopapular rash, nausea, vomiting, anorexia, profuse diarrhea, ileus, or cholestatic hepatitis), occurring within 100 days after transplantation or donor leukocyte infusion (DLI), (without diagnostic or distinctive signs of chronic GVHD), and (2) persistent, recurrent, or late acute GVHD: features of classic acute GVHD without diagnostic or distinctive manifestations of chronic GVHD occurring beyond 100 days of transplantation or DLI (often seen after withdrawal of immune suppression). The broad category of chronic GVHD includes (1) classic chronic GVHD without features characteristic of acute GVHD and (2) an overlap syndrome in which features of chronic and acute GVHD appear together. In the absence of histologic or clinical signs or symptoms of chronic GVHD, the persistence, recurrence, or new onset of characteristic skin, GI tract, or liver abnormalities should be classified as acute GVHD regardless of the time after transplantation. With appropriate stratification, patients with persistent, recurrent, or late acute GVHD or overlap syndrome can be included in clinical trials with patients who have chronic GVHD.

CHRONIC GRAFT-VERSUS-HOST DISEASE: PATHOPHYSIOLOGY

The pathophysiology of chronic GVHD is generally much less well understood than that of acute GVHD and has undergone less intensive experimental modeling.²⁴ It is important to recognize that chronic GVHD was originally defined as a temporal rather than a clinical or pathophysiologic entity. The initial clinical reports of chronic GVHD described abnormalities that occurred at least 150 days after stem cell infusion.^{346,347} By convention, day 100 after stem cell infusion is used as an arbitrary divider between acute and chronic GVHD. But some manifestations of acute GVHD occur after day 100, and some manifestations of chronic GVHD may occur before day 100. Thus it is preferable to consider the clinical symptoms and signs per se rather than their timing of onset.

Relatively little is known about the pathophysiology of chronic GVHD. This is in part because of the absence of appropriate animal models that can capture the kinetics and the protean manifestation of chronic GVHD.³⁴⁸ However, recent studies using multiple models that collectively mimic many of the chronic GVHD manifestations have begun to shed light on the complex biology.

T cells: Based on certain clinical features chronic GVHD has been considered to be an autoimmune disease, with some experimental data suggesting that chronic GVHD results from defective central negative selection, which leads to the generation of autoreactive clones that escape tolerogenic mechanisms operating in the periphery.^{349,350} The autoreactive cells of chronic GVHD are associated with a damaged thymus, which can be injured by several mechanisms,

including acute GVHD, the conditioning regimen, or age-related involution and atrophy. In chronic GVHD the ability of the thymus to delete autoreactive T cells (negative selection) and to induce tolerance is impaired.^{24,351,352} Chronic GVHD could also be a product of T cells that have undergone relatively chronic antigen stimulation as a result of the presence of inexhaustible and ubiquitous MiHA antigens. Allo-T cells under circumstances of chronic MiHA antigen stimulation can induce syndromes resembling those induced by the chronic antigen stimulation in autoimmune diseases. This concept is also consistent with the proposal of acute GVHD as a risk factor for chronic GVHD. The antigens targeted in chronic GVHD could be the same dominant ones targeted in acute GVHD, but the reactive T cells could be different; for example, they may secrete TGF- β . Recent data have shown that the balance between Treg and conventional T-cells is critical for chronic GVHD.¹⁷¹

Cytokines: TGF- β has been implicated in the development of fibrosis and chronic GVHD.¹⁸⁰ IL-17 and subsequent T-cell differentiation along the Th17 pathway have recently been strongly associated with cGVHD. IL-17 was shown more recently to result in colony stimulating factor (CSF)1-dependent macrophage accumulation in skin and lung, which drives tissue fibrosis.³⁵³ Systemic IL-17 levels increase late after clinical BMT, at a time when chronic GVHD develops.³¹¹ Inhibition of Th17 differentiation and CSF1 appear to be relevant to the development of chronic GVHD.

IL-2 is critical for Treg homeostasis. Recent data have shown that Treg: conventional T-cell balance is critical for chronic GVHD.¹⁷¹ In addition, inhibition of terminal cytokines involved in fibrosis, such as TGF- β and IL-13, represent additional targets; however, TGF- β inhibition may be problematic given its important role in Treg homeostasis.

B cells: In some patient subsets, responses to rituximab, presence of MiHA-specific antibodies, and the presence of chronic GVHD after T-cell depletion (TCD) allo-BMT would indicate that in addition to donor T cells, donor B cells might be a direct effector or might have a role in priming T cells as APCs.^{354,355} Murine models demonstrated a pathogenic role for donor B cells and allo-antibody production in causing experimental chronic GVHD. It is also clear that T follicular helper (T_{FH}) cells and IL-21 play important roles in the development of chronic GVHD via the stimulation of germinal center B cells and alloantibody generation.³⁵⁶ Two tyrosine kinases expressed in the hepatocellular carcinoma (TEC) family of kinases, IL-2-inducible kinase (ITK) and Bruton tyrosine kinase (BTK), share close homology and play critical roles in both T-cell and B-cell function. ITK helps to drive T-cell activation and differentiation while BTK is essential for B-cell receptor signaling. In mouse studies treatment with ibrutinib, an ITK and BTK inhibitor, reversed lung pathology and pulmonary dysfunction in mice with established chronic GVHD in a model dependent on cooperation between T_{FH} and germinal center B cells; additionally, ibrutinib reduced the progression of sclerodermatous chronic GVHD in mice.³⁵⁷ Targeting syk in B cells has been shown to mitigate chronic GVHD in several models. Syk deletion in vivo was effective in treating established chronic GVHD, as was a small-molecule inhibitor of Syk, fostamatinib, which normalized germinal center formation and decreased activated CD80/86(+) dendritic cells.³⁵⁸ In multiple distinct models of sclerodermatous chronic GVHD, clinical and pathologic disease manifestations were not eliminated when mice were therapeutically treated with fostamatinib, though both clinical and immunologic effects could be observed in one of these scleroderma models.

BIOMARKERS OF ACUTE GRAFT-VERSUS-HOST DISEASE

Less progress has been made with biomarkers for chronic GVHD than for acute GVHD; nevertheless, several are beginning to emerge. CXCL9 has been identified and validated in several hundred patients from at least two HCT centers.^{7,359} Other biomarkers with potential utility include soluble B-cell activation factor (sBAFF), anti-dsDNA antibody, soluble IL-2 receptor alpha (sIL-2R α), and soluble CD13

(sCD13); sBAFF and anti-dsDNA also may be elevated in patients with late-onset chronic GVHD, but these biomarkers need to be validated in much larger cohorts before definitive conclusions can be drawn.

THERAPY FOR CHRONIC GRAFT-VERSUS-HOST DISEASE

Chronic GVHD has a major impact on both quality of life and survival, frequently involves multiple organs, and necessitates prolonged immunosuppressive therapy.³⁶⁰ One report noted that 15% of cancer-free patients were still receiving immunosuppressive therapy after 7 years.³⁶¹ The more severe forms of chronic GVHD are clearly associated with a lower disease-free survival. Thus the potential benefit of a GVL effect is shadowed by significant treatment-related mortality.³⁶¹

Current therapies for chronic GVHD are of limited efficacy, and there is no long-term satisfactory regimen for patients who do not respond to front-line steroid-based therapy. Indeed, no medication has been approved by the Food and Drug Administration for use in chronic GVHD. The lack of standardized response criteria to measure therapeutic efficacy poses a major obstacle to pursuing therapeutic trials in chronic GVHD. Overall survival and/or discontinuation of systemic immunosuppression are accepted long-term endpoints in chronic GVHD trials. The recent NIH-sponsored consensus project provided, for the first time, a set of standardized measures and definitions to use as response criteria in chronic GVHD.^{341,342} Nonetheless, these recommendations are yet to be tested and validated in prospective studies. The NIH consensus conference has defined response measures that are classified in two main groups: clinician-assessed and patient-reported (Table 108.5).³⁴⁸

The prevention of acute GVHD has not consistently resulted in a lower incidence of chronic GVHD. A clear example is the use of reduced-intensity transplants, consistently associated with a lower incidence of acute GVHD but with no major impact on chronic GVHD.^{362,363} The extended use of GVHD prophylaxis with cyclosporine, or variations in the cyclosporine dosage used, showed no beneficial effects on the incidence of chronic GVHD.^{360,364} The addition of thalidomide to cyclosporine and methotrexate prophylaxis, the administration of intravenous immunoglobulin, and early treatment based on biopsy findings of subclinical GVHD in an attempt to preemptively treat chronic GVHD were unsuccessful.³⁶⁰ A randomized placebo-controlled study in Europe showed that the addition of ATG Fresenius resulted in a significant reduction in the severity and incidence of chronic GVHD.^{8,365}

The most commonly used therapies to treat chronic GVHD are cyclosporine A (CSA) and prednisone. Sullivan and colleagues³⁶⁶ reported that prednisone alone is superior to prednisone plus azathioprine for primary treatment of patients with chronic GVHD.

However, in patients classified as high-risk on the basis of platelet counts below 100,000/ μ L, treatment with prednisone alone resulted in only 26% 5-year survival. When a similar group of patients was treated with alternating-day CSA and prednisone, 5-year survival exceeded 50%.³⁶⁷ A randomized study of patients with extensive GVHD found no difference when prednisone alone was compared with prednisone plus CSA.²⁴ For chronic GVHD that recurs or fails to respond to initial therapy, there is no standard treatment. A small recent study has shown that an 8 week administration of low dose, subcutaneous IL-2 ameliorated several manifestations of chronic GVHD that was resistant to steroids, particularly in the skin.^{9,368} This improvement was associated with an increase in Tregs. This increase was caused by enhanced, proliferation, thymic export and resistance to apoptosis.^{10,171} Randomized clinical trials of this approach are currently being conducted. Other experimental therapies include psoralen plus ultraviolet light A, MMF, thalidomide, total lymphoid irradiation, Plaquenil, extracorporeal photopheresis, pentostatin, and acetrelin.³³⁸ (see Table 108.4, for list of the commonly used GVHD drugs and their side effects.)

Transfusion-Associated Graft-Versus-Host Disease

Most blood products administered to immunocompromised patients are now irradiated or at least leukocyte-depleted to avoid the transfusion of viable alloreactive T cells. With most homologous blood products, the MHC incompatibility between donor and recipient results in rapid clearance of transfused T cells by the recipient's immune system. However, occasionally, transfusions from donors who are homozygous for one of the recipient's MHC haplotypes are not recognized as foreign by the recipient.^{369–371} These cells can survive, "engraft," and mount an immunologic attack against the unshared haplotype in the patient, resulting in transfusion-induced GVHD.³⁷¹ Transfusion-associated GVHD differs from GVHD occurring after transplantation in terms of kinetics and manifestations (i.e., with transfusion-associated GVHD, the recipient marrow is a major target).³⁷⁰ Since the number of stem cells in the offending blood product is inadequate, there is no hemopoietic recovery from donor cells. This syndrome is generally fatal as a result of refractory pancytopenia and/or other organ involvement.

GRAFT-VERSUS-LEUKEMIA RESPONSES

The GVL response after allogeneic HCT results from the immunologic attack of the host tissue and, by extension, the leukemia (i.e., the tumor). This response represents a potent form of immunotherapy that circumvents some of the "immunoediting" mechanisms used by tumor cells to develop in the hosts. The power of the alloimmune response to eliminate malignancy was first reported more than 50 years ago in experimental models by Barnes et al.¹ However, GVL as its own entity and its close association with GVHD were not established until another 15 years later.³⁷² GVL responses demonstrate the clearest and arguably to date, the most potent demonstration of the power to harness the immune system to eradicate malignant diseases. The critical and direct evidence of GVL effect in clinical transplantation has been provided by the use of DLI to treat relapses after allogeneic HCT.^{373–375} Kolb and colleagues first reported three patients with relapsed chronic myeloid leukemia (CML) who achieved complete cytogenetic remission after treatment with IFN- α and DLI from the original donors.³⁷⁶ Subsequently, these findings have been confirmed in several reports.^{377–379}

The most recent and dramatic effect of the GVL effect has been demonstrated using genetic engineering to create tumor antigen-specific T cells (CAR T-cell therapy). Most discussion below is geared towards biology of GVL responses after allo-BMT. The mechanisms of GVL responses after CAR T-cell therapy while seemingly evident (antigen-specific T cells eliminating leukemia and other cells expressing the antigen), the mechanisms for failure and complications are just being explored.

TABLE 108.5 National Institutes of Health Chronic Graft-Versus-Host Disease Measures

Measure	Clinician-Assessed	Patient-Reported
Chronic GVHD Specific Core Measures		
Signs	Organ-specific measures	Not applicable
Symptoms	Clinician-assessed symptoms	Patient-reported symptoms
Global rating	Mild, moderate, or severe 0–10 severity scale 7-point change scale	Mild, moderate, or severe 0–10 severity scale 7-point change scale
Chronic GVHD Nonspecific Ancillary Measures		
Function	Grip strength 2-minute walk time	Patient-reported function
Quality of life	—	Patient-reported health-related quality of life

GVHD, Graft-versus-host disease.

Clinical Features of Graft-Versus-Leukemia

Clinical evidence that the donor graft mediates an important anti-leukemic effect comes from higher relapse rates for recipients of syngeneic stem cells than for recipients of HLA-matched sibling grafts.³⁸⁰ These findings have also been confirmed in a multicenter analysis of HCT recipients with acute myelogenous leukemia (AML) in first remission and subsequent retrospective analyses by the International Bone Marrow Transplant Registry (IBMTR).^{381–383} The second IBMTR analysis also showed that the magnitude of this GVL effect is greater for patients with CML and AML and not statistically significant for patients with acute lymphoblastic leukemia (ALL) in first remission.^{384,385}

Several case reports of patients with relapse of leukemia after allogeneic HCT noted remissions of the malignancy either after abrupt withdrawal of immunosuppression or during a flare of acute GVHD.^{386–389} Patients who develop GVHD after allogeneic HCT experience relapse less frequently than similar patients who do not develop clinical disease. GVHD is protective against relapse both for HCT recipients with advanced leukemia^{390–392} and for patients who receive transplants in earlier stages of malignancy.³⁹³ Additional analyses also suggest that the magnitude of the GVL effect appears to be disease and stage-specific.^{392–394} Initial reports suggested that chronic GVHD was most protective against relapse,³⁹² but other analyses demonstrate that acute GVHD is also protective.³⁹³ Based on these reports, newer trials of immunotherapy are designed to include cessation of immunosuppressive therapy (without taper) to induce a GVL reaction for patients whose malignancy has relapsed after HCT. Furthermore, Childs and colleagues demonstrated that the graft-versus-tumor (GVT) effect also plays an important role in inducing remissions from a nonhematologic malignancy, renal cell carcinoma.³⁹⁵

Another line of clinical evidence regarding the GVL effect of allogeneic HCT and its tight linkage to GVHD comes from the studies using T-cell depletion of the donor graft. Donor T cells included in the stem cell graft are critical for acute GVHD, and T-cell depletion by various strategies is one of the most successful means of reducing the incidence and severity of GVHD after allogeneic HCT.^{26,396–401} Unfortunately, although T-cell depletion results in less treatment-related morbidity and mortality, improved overall survival rates have not been reliably demonstrated. This failure is caused in large part by a reciprocal increase in the subsequent relapse rate after T-cell depletion, as well as to graft failure and other complications.^{394,402,403} T-cell depletion increases relapse rates particularly in CML.^{393,394,404} This observation provides further strong, albeit indirect, evidence that allogeneic donor T cells are important mediators not only of GVHD, but also of the GVL properties of the allogeneic stem cell graft. Finally, the most compelling evidence of donor T cells in mediating GVL comes from the observations made from donor lymphocyte infusions (discussed later). The induction of GVL is a complex process.

Genetic Basis

The immunotherapeutic effect that occurs in the allo-BMT setting is primarily mediated by allogeneic donor T or NK cells directed against the alloantigens shared by the recipient tumor and target tissues and/or tumor-specific antigens (TSAs) that have the advantage of not being subjected to tolerance mechanisms by the host tumor.^{56,405,406} Understanding of the exquisite specificity of T-cell responses led to attempts to identify specific antigens that are responsible for the GVL effect. Much of the focus has been on the identification of (1) certain oncogenic viral proteins (because these are absent in normal cells but expressed by transformed tumor cells [certain Epstein-Barr virus peptides such as Epstein-Barr virus nuclear antigen-1, latent membrane protein {LMP}-1, LMP, LCL]), (2) antigens that are expressed in a tissue-specific fashion (melanoma specific proteins), and (3) proteins that are overexpressed in tumors (WT1, proteinase 3, survivin, telomerase reverse transcriptase, CYPB1, and human epidermal growth factor receptor 2/neu).^{53,56}

Although these antigens are specific, most T-cell responses to these antigens are limited because of the poor immunogenicity of these proteins, expression on normal cells, defects in the processing or presentation of tumor antigens, or production of factors that disable T-cell responses. Thus clinical attempts to obtain high specificity of T-cell responses have been offset with difficulties in obtaining enough sensitivity and vice versa. Furthermore, given the current concepts of stem cell origins of leukemia and cancers, identification of the immunogenic proteins that are specifically expressed in the malignant stem cells and harnessing T-cell responses to those antigens will be needed for the optimal GVL effect to cure malignancy.^{407,408}

In contrast to the TSAs or tumor-associated antigens (TAAs) discussed earlier, alloantigens are not subjected to tolerance mechanisms. Vaccination strategies with autologous T cells using TAAs or TSAs have yielded disappointing clinical antitumor responses.⁴⁰⁹ By contrast, allogeneic HCT has met with remarkable GVL responses perhaps owing to recognition of minor alloantigens in addition to the TAAs.⁴¹⁰ This concept has been demonstrated by recent murine studies, which showed that alloantigen on the tumor cells is required for GVL responses and that the principal targets of GVL are the immunodominant allogeneic MiHAs rather than the TAAs.^{60,91} Thus T cells specific for MiHA antigens could provide for a potent GVL effect. Significant progress has been made in the identification of MiHAs that are specifically expressed in the host hematopoietic tissues and therefore might allow for a GVL response without causing GVHD.⁵³ Together, these results suggest that in addition to tumor-specific proteins, expression of alloantigens and cognate interactions between donor T cells and the tumor tissues are required for the effective induction of the majority of GVL responses. However, T cells specific for some MiHAs are also responsible for GVHD, and a means of consistently separating the beneficial GVL effect from GVHD has not yet been clinically achieved.

Killer-Cell Immunoglobulin-Like Receptor Polymorphisms

The two competing models described earlier, the “mismatched ligand” and the “missing ligand” models for HLA-KIR allorecognition, have been supported by clinical observations of GVL responses in different patient and transplant populations.^{65,66} The former model has been shown to separate GVL and GVHD responses in the context of TCD haploidentical HCT for AML.^{46,67} Even though this model is supported by elegant laboratory studies, it was found to be invalid for ALL and also for AML after unrelated donor HCT with immunosuppression.⁶⁷ Recent retrospective clinical data suggest that GVHD and GVL can be separated by the “missing ligand” model in CML/AML and myelodysplastic syndrome patients after TCD HLA identical sibling HCT.^{46,66,69} Further validation of either models by clinical prospective studies and a better understanding of the balance between the inhibitory and activating receptor-ligand interaction of the NK cells are needed to adequately exploit the interface between HLA-KIR genetics to separate GVHD from GVL (see [Chapter 102](#)).^{64,411}

Chimeric Antigen Receptor T Cells and Cytokine Release Syndrome

Infusion of unselected CD19 specific CAR T cells is associated with a massive cytokine storm that causes severe toxicity, known as cytokine release syndrome (CRS). CRS is a nonantigen-specific toxicity that occurs as a result of high-level immune activation.^{412,413} The magnitude of immune activation typically required to mediate clinical benefit using modern immunotherapies exceeds the levels of immune activation that occur in more natural settings. The symptomatology and severity associated with CRS varies greatly and many features of CRS mimic infection. Thus fever is a hallmark, at times temperatures exceeding 40.0°C. Other features, some potentially life

threatening, include adult respiratory distress syndrome, fluid retention, neurologic toxicity, cardiac, renal and/or hepatic failure, and disseminated intravascular coagulation. Some of these, particularly lung and cardiac dysfunction, can be rapid onset and severe, but are typically reversible. Neurologic symptoms occurring in the context of CRS are varied and may occur coincident with other symptoms of CRS or may arise when the other symptoms of CRS are resolving.⁴¹⁴ Magnetic resonance imaging often reveals no abnormalities. IL-6 appears to be the most relevant cytokine in CRS, although likely not the only cytokine involved. CRS may also be associated with findings of macrophage activation syndrome/hemophagocytic lymphohistiocytosis.⁴¹⁴ In addition, rapid turnover of underlying leukemia/tumor might lead to tumor lysis syndrome that may coincide or contribute to the severity of CRS. Appropriate supportive care, steroids, and anti-IL-6, tocilizumab remain the current mainstay for management of CRS. Furthermore, whether CRS severity is dependent on the type of T cell being engineered (central versus effector versus naive versus bulk), or the type of vector and/or antigen being targeted remains unknown.

Immunobiology of Graft-Versus-Leukemia Responses

Given the tight association of clinical GVHD and GVL, as well as the common biologic principles governing these responses after allogeneic HCT, it is important to discuss the similarities and distinctions between them in the context of the three cellular phases of GVHD.⁴¹⁵

Phase 1: Activation of Antigen-Presenting Cells

The concept that tumor eradication after allogeneic HCT might not require toxic chemoradiotherapy and could be achieved primarily by the immunotherapeutic effect from the GVL responses has led to the clinical development of nonmyeloablative HCT for hematologic and nonhematologic malignancies.⁴¹⁶ Phase 1 is characterized by the development of the cytokine storm-generated danger signals from the conditioning regimen and the subsequent activation of APCs.⁴¹⁵ Experimental data suggested that the reduction in conditioning would attenuate the cytokine storm, lead to the development of mixed donor-host chimerism, and confine the GVH response primarily to secondary lymphoid organs, thus cause less severe GVHD without impairing GVL responses.^{417–419} However, nonmyeloablative HCT has delayed the kinetics but did not reduce the overall incidence of GVHD and a significant number of patients either failed to respond or relapsed.²¹ Furthermore, recent murine and human studies have suggested that homeostatic expansion of T cells in a lymphopenic environment induced by conditioning (as opposed to mere immunosuppression) improves the antitumor efficacy of adoptively transferred syngeneic or autologous T cells by increasing the availability of space, enhancing the memory responses, and reducing the competition for homeostatic cytokines (such as IL-7 and IL-15) for transferred T cells while eliminating regulatory T cells.^{420–422} Thus low-intensity HCT clearly demonstrates the principle of the GVL effect, but the roles of the cytokine storm and homeostatic expansion of allogeneic T cells in shaping the intensity of GVL responses are not known.

Host and donor APCs are critical for the induction and severity of GVHD.⁷ Activation of APCs is the key step in phase 1 of GVHD.⁴¹⁵ Significant progress has been made in understanding the role of APCs in GVL. Recent experimental evidence has demonstrated a crucial role for professional host APCs in the induction of GVL responses mediated by donor T cells, even when the tumor cells showed some features of APCs.^{91,423} Tumors that merely express costimulatory molecules may still be unable to stimulate an effective immune response because of their various “immunoediting” processes that cause ineffective antigen presentation.⁴²⁴ However, when the tumor cell itself functions as a professional APC, as with CML, it can generate an effective GVL response.^{425,426} By contrast, cancers such as acute leukemias that seldom differentiate into APCs generate poor GVL

responses. Data also demonstrated that given sufficient time and a low tumor burden, cross-presentation of TAAs and/or alloantigens by professional donor APCs can occur and may promote or sustain GVL responses by maintaining or expanding alloreactive T cells after initial priming on host APCs.^{91,426} This concept is consistent with clinical GVL responses in CML in which the final stage of a GVL response to CML may be the result of donor T cells responding not directly to the small number of CML stem cells or progenitors (which would be undifferentiated and therefore poor APCs) but to tumor antigens cross-presented on professional donor APCs. Emerging data suggest that enhancing such cross-presentation is sufficient to elicit effective GVL responses against acute or advanced leukemia. These data, however, suggest that GVL responses generated after low-intensity conditioning may not be as robust as those after full intensity HCT and highlight the need for a clearer understanding of the effects of the cytokine storm and lymphopenia generated danger signals on the activation of APCs in mediating GVL.

Recent data showed that APC subsets could potentially be modulated to enhance the GVL effect without aggravating GVHD. Host-derived CD8 α^+ DCs were shown to be required for the induction of optimal GVT responses when Batf3 deficient mice were used as recipients in experimental allo-HCT.¹⁰⁹ TLR3 stimulation via poly I:C in host CD8 α^+ DCs, enhanced GVL responses without exacerbating GVHD. However, cellular processes of regulating GVL responses in host APCs still remain unclear. The molecular mechanisms underpinning the role of host APC subsets in GVL are just now being deciphered. It has been observed that absence of Ikaros in host hematopoietic APCs exacerbates GVHD, but without concomitantly enhancing GVT responses in multiple models.⁴²⁷ The role of donor-derived DCs in mediating GVL is also being explored. Initial reports regarding this association demonstrated that donor APCs are not required for GVL responses, but play an indispensable role in GVHD in a MHC-matched, MiHA-mismatched BMT model. In order to present host TSAs, via donor APCs, to donor CD8 $^+$ T cells, donor APCs must have the capacity for cross-presentation as they do not express both endogenous alloantigens and TSAs.⁴²⁸ Furthermore, additional studies are needed to determine which specific subsets of donor APCs play a critical role in enhancing GVT responses. Reports suggest that donor CD11b $^+$ APCs within the BM grafts consist mostly of pDC progenitors (pre-pDCs) and enhance the GVL activity of donor T cells by promoting differentiation into Th1/type 1 CTLs. Pre-pDCs also regulate GVH and GVT responses altering the balance between donor Tregs and inflammatory T cells by inducing indoleamine 2,3-dioxygenase synthesis.⁴²⁸

Phase 2: Donor T-Cell Activation

The core of GVL responses, as with GVHD, is also dependent on the activation of appropriate numbers of T cells. The “second” signals from professional APCs (or certain tumor cells that function as effective APCs) are critical for generating an effective GVL response.²³⁰ Several of the costimulatory pathways that modulate GVHD have also been evaluated in mediating GVL responses. Blockade of CD28 costimulation preserved GVL responses but reduced GVHD in murine studies.⁴²⁹ However, when the tumor cells also expressed B7 molecules, such blockade reduced the GVL responses.⁴²⁵ Ex vivo blockade of CD40-CD40L interaction has been shown to reduce GVHD by generating Tregs but still preserve GVL. By contrast, blockade of the 4-1BB pathway reduced both GVHD and GVL.¹⁴⁰ The other costimulatory molecules (OX40 and ICOS) and the inhibitory molecules (CTLA-4 and PD-1) also modulate antitumor responses.^{141,142} A better understanding of the context (i.e., low intensity or DLI) and the hierarchy of timing, duration, and extent of costimulatory requirements of donor T-cell subsets might allow for balancing the intensity of GVL and GVHD responses. Clinical and experimental evidence suggest that donor T-cell numbers correlate with the severity of GVHD and GVL responses. TCD grafts had reduced GVHD but increased disease relapse, suggesting a role for

T-cell numbers in GVL responses as well.⁴³⁰ Clinical attempts to separate GVHD and GVL by regulating allogeneic T-cell dose have met with limited success. For example, administration of 1×10^5 T cells/kg after HLA-matched sibling transplantation did not mediate GVL effects and yet was associated with a measurable incidence of GVHD. Thus infusion of the correct numbers of donor T-cell effectors is crucial for GVL responses.⁴³⁰ This has been demonstrated by durable responses that are observed in CML and other malignancies after DLI (see later), despite the experimental evidence that host APCs stimulate a stronger GVL response than do donor APCs.^{91,426} This could be because, clinically, DLI is almost always given without immunosuppression to an individual who has not developed GVHD either from the chemical immunosuppression or physical removal of donor T cells from the allograft. This lack of immunosuppression after DLI increases the likelihood of a GVH response, and DLI is almost always associated with clinical GVHD. The delivery of additional allogeneic effector cells in DLI also increases the effector:target ratio compared with the time of initial HCT. The latter is also clinically demonstrated by a more effective GVL response to DLI against minimal residual disease (BCR-ABL positivity by PCR) compared with the response against high leukemic burden (e.g., blast crisis) in CML patients.⁴²⁶ Thus DLI provides the proof, in principle, for the concepts that sufficient T-cell numbers and appropriate antigen presentation are required for both GVHD and an effective GVL response.

T-Cell Subsets

Most experimental studies have implicated donor CD8⁺ T cells as the primary mediators of GVL, but there are no clinical data for CD8⁺-mediated GVL responses in the absence of CD4⁺ T cells.^{56,236,426} Moreover, some clinical data suggest a role for greater CD4-mediated GVL responses without an increase in GVHD after allogeneic HCT and DLI.^{423,431–434} But it is unclear whether CD4⁺ T-cell initiated GVL responses occur in the absence of generation of MiHA specific CD8⁺ T cells. Given the critical requirement of alloantigens for most GVL responses, the specific requirement of CD4 and/or CD8 T cells for GVL and GVHD is likely to be determined by the expression of the relevant immunodominant MiHAs and/or TAAs. Therefore it is unlikely that GVHD and GVL responses can be separated under all circumstances merely by depletion of either subset of alloreactive T cells. However, experimental data suggest it might be possible to separate GVHD and GVL when certain donor T-cell subsets are either depleted or infused (DLI) at an appropriate interval after transplant.⁴²³ But the optimal time interval, if any, after clinical HCT is yet to be determined.

Because of recent identification and understanding of the role of various T-cell subsets in mediating immune responses, depletion of specific T-cell subsets to separate GVHD and GVL remains an area of active investigation. For example, recent experimental data suggest that CD62L expressing naive T cells home to secondary lymph nodes and are critical for initiating GVHD.¹⁵¹ By contrast, CD62L-negative effector memory T cells with enhanced reactivity to recall antigens mediated GVL responses with minimal GVHD.¹⁵¹ An important caveat to these data is the fact that the lack of a priori knowledge of the repertoire of human memory T cells would make it difficult to predict whether these cells might cross-react only with TAAs or with the recipient's alloantigens. Using CD62L status alone as a determinant of GVHD potential can also have other unintended consequences; recent studies have demonstrated that its expression is critical for the regulation of GVHD by Tregs (see later). Moreover, it is not known whether the behavior of human memory T cells parallels that of murine memory T cells in their migratory, functional, and cytolytic capabilities. Although Tregs reduce antitumor immunity in murine models and in human subjects, experimental data suggest that administration of donor-type Tregs, either at the time of HCT or when delayed, reduced GVHD but preserved CD8⁺-mediated perforin-dependent GVL responses.^{435,436} Similar preservation of experimental GVL was also observed by harnessing donor NKT cell function with granulocyte colony stimulating factor analogues.^{178,179} However, it remains unclear whether these observations are valid after

clinical HCT when the GVL responses might not be entirely dependent on CD8 T cells.

T-Cell Migration

It is conceivable that manipulation of these interactions to focus the alloimmune response to lymphohematopoietic tissues would enhance GVL responses but not GVHD. For example, blockade of the CCR9 ligand TECK or CCR5 and CCL17 may prevent the migration of donor T cells to GI tract and skin respectively, but preserve GVL.²²⁰ Pharmacologic manipulation with the immunosuppressive agent FTY720 has recently provided the proof in principle for this approach.²³¹ Given the redundancy, strategies to modulate the chemokine biology for separation of GVHD and GVL will require greater understanding of these networks in modulating the migration not only of specific T-cell subsets but also of the other immune cells in the context of different conditioning regimens.

Phase 3: Effector Phase of Graft-Versus-Leukemia

The effector arm of GVL is also characterized primarily by the antigen-specific cellular components and less by the inflammatory components of alloresponse. Experimental data demonstrate that neutralization of IL-1 α reduced GVHD but preserved GVL.²⁶⁹ By contrast, donor TNF- α secretion contributes to both GVHD and GVL effects, and in some cases, antagonism of TNF- α reduced GVHD and GVL responses.^{437–439} Nonetheless, antagonism of non-specific inflammatory effectors (such as either IL-1 or TNF- α) appears to regulate GVHD to a greater extent than GVL responses after experimental allogeneic HCT.⁴³⁹

Several lines of experimental and clinical data demonstrate that antigen-specific donor T-cell subsets and NK cells are the key effectors of GVL.⁵⁶ The cytotoxic pathways that are operative in the NK and T cell-mediated antitumor responses have been well characterized.⁵⁶ Fas ligand-mediated CTL of tumor targets is used by both NK and T (mostly Th1) cells, but most murine experiments with FasL-deficient donor T cells suggested that FasL is a key effector molecule for causing GVHD but not GVL.²³⁶ However, one study found that FasL is required for CD4⁺-mediated GVL against myeloid leukemia.^{440,441} By contrast, even though perforin-mediated CTL pathways are also used by T (mostly Th2) and NK cells, experimental data with perforin-deficient donor T cells demonstrated a loss of GVL with a diminution in the severity of GVHD.²³⁶ In some other experimental models, perforin was required only for GVL but not for GVHD.²³⁶ Recent data showed that TRAIL-mediated CTL had no effect on GVHD severity but was required for optimal GVL.²⁵⁷ Therefore strategies that increase donor T cell TRAIL expression or enhance the susceptibility of tumors to TRAIL-mediated CTL (such as histone deacetylase inhibitors) may promote a robust GVL effect without exacerbating GVHD.^{442–444} Thus significant progress has been made in recent understanding of the CTL pathways used by donor T cells for GVL responses, but the role and context of use of these pathways by donor NK and NKT cells after allogeneic HCT are not known.

It is likely that effector cells responsible for the GVL and GVHD effects of HCT will similarly be responsible for the GVL effect associated with DLI, although this assumption has not been formally proven. The administration of select subsets of donor mononuclear cell fractions is the ideal setting in which to dissect the cellular mechanisms responsible for GVL induction and strategies that delay the infusion of these various cellular subsets will help define the mechanisms and enhance the efficacy of DLI.

Immunobiology of Cytokine Release Syndrome After Chimeric Antigen Receptor T-Cell Therapy

CRS has been typically reported with mAb infusions, such as anti-CD3 (OKT3), and the CD28 superagonist etc.^{445,446} In recent years it has been increasingly appreciated as the major acute toxicity from infusion of CAR T cells and bispecific antibodies for leukemia.^{447,448}

It is characterized by an acute (days, depending on the inducing agent) and intense inflammatory response wherein the majority of the infused CAR T cells along with other immune cells such as NK cells, monocyte-macrophages, and dendritic cells become activated and release inflammatory cytokines.^{449,450} Much remains to be understood about the biology of CRS following CAR T-cell therapy. However, it appears that the incidence and severity of the syndrome is greater in patients with large tumor burdens, presumably because of higher levels of T-cell expansion and activation.⁴¹⁴ However, as yet, no clear relationship between the cell infusion dose and the incidence/severity of CRS has been observed. It is associated with a massive proinflammatory cytokine storm with elevated IFN- γ , IL-6, TNF- α , IL-2, granulocyte-macrophage colony-stimulating factor and IL-5.⁴¹⁴ Amongst these cytokines, it appears that in many instances IL-6 may be the most critical cytokine and its effects are likely from trans-signaling. The source of IL-6 and mechanisms remain unknown. The biology behind the incidence of neurotoxicities remains unclear. It is also unknown whether CRS is required for eventual clinical response and/or if mitigating it blunts response rates. Furthermore, whether CRS is reduced when selected T cells (central memory subset) are engineered with CARs instead of using bulk T cells remains an open question. The relationship of CRS with the type of vectors or other methodologic aspects also remains unknown.

Several other critical mechanisms for enhancing the efficacy of CAR T cells or for mitigating their toxicities remain to be understood. The data on whether other targets (instead of CD19) can be as effective remain to be explored. The role of costimulatory domains in promoting efficacy, toxicity or exhaustion remains largely unknown. Recent experimental observations suggest that CARs against non-CD19 targets may be more susceptible to exhaustion and in these cells CD28 costimulation augments, whereas 4-1BB costimulation reduces, exhaustion induced by persistent CAR signaling.⁴⁵¹ Thus much remains to be understood with regards to the immunobiology of CRS, and CAR T-cell therapy.

FUTURE DIRECTIONS

Complications of HCT, particularly GVHD, remain major barriers to the wider application of allogeneic HCT for a variety of diseases. Recent advances in the biology of genetic polymorphisms, the chemocytokine networks, several novel cellular subsets including regulatory T cells, and the direct mediators of cellular cytotoxicity have led to improved understanding of this complex disease process. Animal studies show that modulation of several mediators of the complex GVHD cascade may be able to reduce the undesirable inflammatory aspects of GVHD while preserving the benefits of GVL. However, most of the laboratory observations remain to be studied in well-controlled clinical trials. Multiple cellular effectors may be involved in GVL, although donor T-cell recognition of host antigens is an important element of this process. Cellular immunotherapy such as DLI offers a strategy for separating GVHD and the GVL effect. Both experimental and clinical data suggest that posttransplantation cellular immunotherapy can be performed relatively safely and effectively, and optimization of patient selection, cell dose, and timing of administration may all serve to limit toxicity and enhance the potential GVL effects.

COMPLICATIONS AFTER HEMATOPOIETIC CELL TRANSPLANTATION

Shernan G. Holtan, Navneet S. Majhail, and Daniel J. Weisdorf

The high-dose therapy used in hematopoietic cell transplantation (HCT) results in toxicities induced directly by the treatment and secondarily by the prolonged immunodeficiency and extended recovery process. Identification of risk factors for particular complications allows the design of risk-specific supportive care regimens that may reduce the morbidity and mortality accompanying transplantation. HCT-related complications can be broadly classified into infections, early noninfectious complications (within 3 months of HCT), late noninfectious complications (after 3 months of HCT), and graft-versus-host disease (GVHD) (Table 109.1).

INFECTIONS

Infections are among the most frequent causes of nonrelapse mortality in HCT recipients and cause significant morbidity, both in the early and late transplant period (Table 109.2). Immune defects occurring in the posttransplant period can be divided into predictable phases based on time from engraftment (sustained absolute neutrophil count $>500/\mu\text{L}$), with characteristic infections in each phase (Fig. 109.1). Antimicrobial prophylaxis regimens tailored to address the risk of specific infections during these time periods are effective in limiting the incidence of posttransplant opportunistic infections (Table 109.3). Evidence-based guidelines for preventing infectious complications in HCT recipients have been published and can be used as a reference for determining infection risk and assigning antimicrobial prophylaxis for individual patients.¹

Engraftment generally occurs within 7–14 days in autologous and 10–28 days in allogeneic HCT recipients. Recipients of grafts from unrelated donors (URD) or umbilical cord blood (UCB) tend to engraft later compared with sibling donors; marrow grafts recover a bit more slowly than filgrastim-mobilized peripheral blood stem cell (PBSC) grafts. Importantly, up to 5% of URDs (or potentially greater if human leukocyte antigen [HLA]-mismatched) and approximately 10% of UCB grafts may fail to engraft leading to prolonged neutropenia and extended transfusion dependence. In addition to neutropenia, the main risk factors for infection during this preengraftment phase are disruption of mucocutaneous barriers and indwelling venous catheters. Bacterial infections can occur in up to 30% of transplant recipients during this initial period and usually arise from normal flora of the skin (coagulase-negative *Staphylococcus*), oropharynx, and gastrointestinal tract (*Streptococcus viridans*, *Enterococcus* spp. and enteric gram-negative bacilli). Colonizing yeasts or inhaled airborne molds also invade because of neutropenia and disruption of normal host flora and can lead to systemic mycotic infections (most often candida or aspergillus spp.) in 10% to 15% of patients. Reactivation of latent herpes viruses (herpes simplex, cytomegalovirus [CMV] or human herpesvirus [HHV]-6 can occur, but may be contained by antiviral prophylaxis.

The predominant immunologic defects seen in the early and late postengraftment period are impairments of cellular and humoral immune systems. This underlying severe immune dysfunction is enhanced and prolonged by acute and chronic GVHD and by corticosteroids and the immunosuppressive agents used for GVHD prevention and treatment. The incidence of late opportunistic infections is much lower in autologous HCT recipients because of faster immune

reconstitution and the lack of immunosuppressive drug therapy. Immune reconstitution can take up to 2 years to fully recover in allogeneic HCT recipients and may be incomplete because of ongoing GVHD. Patients with chronic GVHD can be functionally asplenic and be at risk for infections by encapsulated bacteria including pneumococcus or *H. influenza*. In addition, chronic GVHD patients on long-term immunosuppression remain susceptible to fungi (*Aspergillus* spp., *Candida* spp. and *Pneumocystis jiroveci*) and viruses including CMV and varicella zoster virus (VZV). Additional factors that can delay immune reconstitution include donor-recipient HLA disparity, with depletion of T cells either through ex vivo graft manipulation or in vivo with antithymocyte globulin (ATG) or alemtuzumab. URDs and possibly UCB as a graft source may also augment infection risks.^{2,3} Antimicrobial prophylaxis should continue beyond the initial post-transplant period, typically for at least 3–6 months after cessation of all immunosuppression, especially in patients being treated for chronic GVHD. Some centers use total T cell (CD3+) and particularly CD4 cell levels as surrogate markers of T-cell recovery and to guide decisions regarding the intensity and duration of infection surveillance and antimicrobial prophylaxis. Supplemental intravenous immunoglobulin (IVIg) has been considered for patients with persistent hypogammaglobulinemia (immunoglobulin G [IgG] levels <400 mg/dL), but its prophylactic use is costly, does not prolong survival or prevent late infections, and may impair humoral immune reconstitution. Patients with GVHD and those with indwelling venous access undergoing endoscopy or dental procedures should receive antibiotics for endocarditis prophylaxis. Published guidelines are available for immunization of HCT survivors (Table 109.4).¹

Based on the type and dose of conditioning chemotherapy and radiation, recipients of nonmyeloablative or reduced-intensity conditioning (NMA/RIC) regimens can exhibit varying degrees of myelosuppression.⁴ The incidence of bacterial infections is lower in NMA/RIC recipients because of the shorter duration of posttransplant neutropenia. However, the degree of lymphodepletion tends to be comparable with that seen with myeloablative regimens and the risks of invasive aspergillosis and CMV reactivation remain unchanged.

Among UCB HCT recipients, neutrophil engraftment and immune reconstitution can be delayed and a higher incidence of bacterial and viral infections in the early posttransplant period has been reported. Overall, the risk of serious infections among children receiving UCB grafts is comparable with that of URD marrow and is lower than that of a T-cell depleted graft source.² Among adult UCB HCT recipients, the incidence of infections is higher in the early posttransplant period; however, infections do not compromise the risks of overall and nonrelapse mortality compared with URD HCT.²

The approach to managing posttransplant infections is generally similar to that for infections in patients with cancer, especially acute leukemia (Chapter 89). However, certain infections, particularly caused by viruses and fungi, are more common in the HCT population and are discussed in further detail here.

Febrile Neutropenia

A large proportion of patients develop fever in the early posttransplantation period though an infectious pathogen is identified in only

TABLE 109.1 Major Complications of Hematopoietic Cell Transplantation

	Complication	Incidence (%)
Infections	Bacterial infections	
	Gram-positive bacteremia	20–30
	Gram-negative bacteremia	5–10
	Viral infections	
	Cytomegalovirus	5–40 in high risk patients ^a
	Herpes simplex virus	5–10 in seropositive patients
	Varicella-zoster virus	10–50 in seropositive patients
	Respiratory viruses	10–20
	Fungal infections	
	<i>Candida</i>	5–10
	<i>Aspergillus</i> and other molds	5–15
	<i>Pneumocystis jirovecii</i>	<1
	Other infections	
	<i>Toxoplasma gondii</i>	2–7 in seropositive patients
Early noninfectious	Regimen-related toxicity	
Complications	Mucositis	60–75
(0–3 months)	Hemorrhagic cystitis	5–10
	Venoocclusive disease	5–40
	Pneumonitis	10–20
	Alveolar hemorrhage	5–10
	Graft failure	2–10
	Adverse drug reactions	Common
Late noninfectious	Organ specific late effects	
Complications	Cataracts	25–40
(>3 months)	Hypothyroidism	30–50
	Sterility/hypogonadism	50–90
	Growth disturbances	30–50 in prepubertal children
	Osteoporosis/avascular necrosis	5–20
	Malignant relapse	Variable
	Second cancers	2–12
Graft-versus-host disease	Acute	20–50 with related, 40–90 with unrelated donors, 20–50 with UCB
	Chronic	20–40 with related, 40–70 with unrelated donors, 20–40 with UCB

^aCMV-seropositive HCT recipients or CMV-seronegative recipients with a CMV-seropositive donor.
UCB, umbilical cord blood.

50% of patients. Fever may also be caused by tissue inflammation (oropharyngeal or enteric mucositis), transfusions, amphotericin (now used infrequently in the era of mold-active azoles), or other drug fever. Bacterial infections caused by aerobic bacteria such as coagulase-negative *Staphylococci*, *Viridans streptococci* and enteric gram-negative bacilli are the primary concern during this neutropenic phase, although there is also an ongoing risk of infections with yeasts.

Prophylactic strategies can include suppressive antimicrobials, directed against aerobic, particularly enteric bacteria and fungi.

Empiric therapy with broad spectrum antibiotics is usually started at fever onset along with appropriate clinical and microbiologic evaluation. The choice of antibiotics depends on prior and current antibiotic usage modified by local resistance patterns and can be based on recommendations available for the treatment of febrile neutropenia in cancer patients.⁵ Among patients with persistent febrile neutropenia, that is fever without an identified focus that continues despite 3–5 days of appropriate broad-spectrum antibiotics, invasive fungal infections should be considered.⁶ Initiating empiric antifungal therapy with mold-active agents such as voriconazole, an echinocandin or amphotericin is generally recommended at this stage. The choice of agent is dependent on prior exposure to antimold agents for prophylaxis where resistant species (e.g., zygomycetes) may emerge. Empiric mold specific therapy can be started earlier in patients who have experienced prolonged periods of neutropenia pre-HCT (e.g., patients with myelodysplastic syndromes [MDSs]). Repeated vigorous investigation to identify sources of infection (e.g., with computed tomography [CT] scan of the chest and sinuses), even for fever recurring after initial defervescence, is essential. Although administration of myeloid growth factors (granulocyte colony-stimulating factor [G-CSF] or granulocyte-macrophage CSF [GM-CSF]) reduces the duration of neutropenia and accelerates engraftment, they have not been demonstrated to reduce mortality from early posttransplant infections. Granulocyte infusions are applied rarely for life-threatening infections during the preengraftment phase. Novel cellular therapies, such as third-party expanded myeloid progenitor cells are currently being studied for their role in providing protection from severe infections before engraftment.

Cytomegalovirus Infection

Epidemiology and Risk Factors

Despite the introduction of effective antiviral therapies, CMV infection continues to be a major cause of infection-related morbidity and mortality in HCT recipients.⁷ The risk of CMV reactivation spans both the early and late transplant period, especially in patients with GVHD on prolonged immunosuppression. Although the incidence of early CMV disease with organ involvement has declined to 3% to 6% with the use of empiric antiviral drug therapy directed by routine surveillance with CMV DNA polymerase chain reaction (PCR) or antigenemia testing, late onset CMV infection is still seen in up to 20% to 40% of patients.⁷

Seropositivity of the recipient is the most important risk factor for CMV infection in HCT recipients, and reactivation of latent virus is the most important mechanism resulting in CMV disease. Nearly all CMV infections (<5%) in seronegative recipients are the result of exogenous exposure (primary CMV infection), either from a seropositive stem cell donor or from cellular blood products collected from CMV seropositive donors. The possibility of false negative serology pre-HCT should also be considered in patients with early CMV reactivation. CMV infection and especially end-organ CMV disease is also more frequent following allogeneic HCT, with CMV infections occurring in less than 5% of autograft recipients. However, autologous HCT recipients who have previously received T-cell suppressive therapies (e.g., fludarabine, alemtuzumab) can be at high-risk for CMV infection. Among patients undergoing allogeneic transplantation, the risk may be greater with URD compared with related donors. Although the prevalence of donor seropositivity is nearly zero in UCB grafts, the risk of posttransplant CMV infection may be similar as recipient CMV status is still the predominant risk factor for infection although the CMV naive UCB graft confers no latent protective immunity against CMV.⁸ Other factors that delay immune reconstitution may also increase the risk for CMV infection, including older recipient age, greater donor-recipient HLA mismatch, acute and chronic GVHD, and need for prolonged immunosuppression, especially with high-dose corticosteroids. CMV

TABLE
109.2

Common Infections in Hematopoietic Cell Transplant Recipients

Pathogen	Risk Period After HCT	Risk Factors	Common Clinical Syndromes	Treatment
Gram-positive cocci	1–4 wk	Neutropenia Mucositis Central venous catheters Skin breakdown	Bacteremia	Antibiotics based on susceptibility testing
<i>Enterobacteriaceae</i> spp.	1–4 wk	Neutropenia Skin breakdown GI mucosal breakdown	Bacteremia	Antibiotics based on susceptibility testing

CMV, cytomegalovirus; EBV, Epstein-Barr virus; GI, gastrointestinal tract; GVHD, graft-versus-host disease; HCT, hematopoietic cell transplantation; HLA, human leukocyte antigen; HSV, herpes simplex virus; PTLD, posttransplant lymphoproliferative disorder; TMP-SMX, trimethoprim-sulfamethoxazole; VZV, varicella-zoster virus.

TABLE
109.3

Recommended Antimicrobial Prophylaxis Against Common Infections

Pathogen	Preventing Early Disease (0–100 days after HCT)	Preventing Late Disease (>100 days after HCT)
Bacterial infections	No specific recommendations ^a	Antibiotics (based on local resistance patterns) to prevent infections caused by encapsulated bacteria (<i>S. pneumoniae</i> , <i>H. influenzae</i> , and <i>N. meningitidis</i>) in patients on chronic immunosuppression
CMV	Prophylaxis or preemptive treatment with ganciclovir or valganciclovir in high risk patients ^b	Preemptive treatment with ganciclovir or valganciclovir in high-risk patients ^b
HSV	Acyclovir in seropositive patients	Acyclovir in patients with recurrent HSV infections
Yeast infections	Fluconazole	Fluconazole in patients on chronic immunosuppression
Mold infections	No specific recommendations ^c	No specific recommendations ^a
<i>Pneumocystis jirovecii</i>	Trimethoprim-sulfamethoxazole (preferred) or dapsone or pentamidine	Trimethoprim-sulfamethoxazole (preferred) or dapsone or pentamidine in patients on chronic immunosuppression
Respiratory viruses	Isolation; masks; hand-washing Vaccination of household contacts	Vaccination of patient and household contacts

^aLimited data exist favoring fluoroquinolones such as levofloxacin. No impact on infection-related mortality.

^bCMV-seropositive HCT recipients or CMV-seronegative recipients with a CMV-seropositive donor.

^cLimited data available. Prospective testing of voriconazole and posaconazole suggests possible benefit as prophylaxis. No impact on mold-related mortality. CMV, cytomegalovirus; HCT, hematopoietic cell transplantation; HSV, herpes simplex virus.

Fig. 109.1 COMMON INFECTIONS IN HCT RECIPIENTS. GVHD, Graft-versus-host disease.

TABLE 109.4 Recommended Vaccinations for Hematopoietic Cell Transplant Recipients

Vaccine ^a	Time Post-HCT to Initiate Vaccine (months)	No. of Doses ^b
Pneumococcal conjugate (PCV)	3–6	2–3 ^c
Tetanus, diphtheria, acellular pertussis ^d	6–12	3
<i>Haemophilus influenzae</i> conjugate	6–12	3
Inactivated polio	6–12	3
Recombinant hepatitis B	6–12	3
Inactivated influenza	4–6	1–2 yearly ^e
Measles-mumps-rubella (live)	24	1–2 ^f
Varicella zoster	24	1 ^f

^aVaccinations are deferred in patients with chronic GVHD until discontinuation of immunosuppression.

^bA minimum of 1 month interval between doses is suggested.

^cFollowing the primary series of three PCV doses, a dose of the 23-valent polysaccharide pneumococcal vaccine (PPSV23) to broaden the immune response might be given. For patients with chronic GVHD who are likely to respond poorly to PPSV23, a fourth dose of the PCV should be considered instead of PPSV23.

^dDiphtheria tetanus pertussis vaccine (DTaP) is preferred, however, Tdap can be used if DTaP is not available.

^eFor children <9 years of age, two doses are recommended yearly between transplant and 9 years of age.

^fNot recommended <24 months post-HCT, in patients with active GVHD and in patients on immune suppression. In children, two doses of MMR are favored. Lower viral dose vaccines (varicella vaccine, live [varivax], not zoster vaccine, live [zostavax]) may be preferred as potentially safer.

GVHD, Graft-versus-host disease; MMR, major molecular response; PPSV23, 23-valent; pneumococcal polysaccharide vaccine; Tdap, tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine.

reactivation posttransplantation has been recently associated with natural killer (NK) cell maturation toward an innate memory-cell phenotype that may contribute to both infection control and possibly to reduced cancer relapse after allogeneic HCT.⁹

Clinical Presentation and Diagnosis

The most common manifestation of CMV infection is asymptomatic reactivation noted by screening antigenemia or DNA PCR testing. CMV organ infection and disease are most often pneumonia and enteritis. CMV is the most common specific cause of interstitial pneumonitis and is responsible for up to 50% of all cases. Infection at other sites such as retinitis, hepatitis and central nervous system disease are less common and are usually seen in late-onset or persisting CMV infection. Indirect effects of CMV infection may include increased risks of graft rejection plus bacterial and fungal superinfection. The presence of posttransplant CMV viremia is a strong predictor of subsequent clinical CMV disease. CMV pneumonia develops in 60% of patients with untreated asymptomatic viremia, and treatment of viremia can reduce the incidence of CMV pneumonia to less than 5%. Although autologous HCT recipients have a lower risk of developing CMV infection, the severity of infection (e.g., pneumonia), if it develops, is similar to that observed in recipients of allogeneic HCT.

The diagnosis of CMV can be made either by demonstration of characteristic cytology or cytopathic effects in tissue culture or by the use of more sensitive molecular methods that detect viral proteins or DNA. Commonly used molecular assays include CMV DNA detection methods, and the pp65 antigenemia assay. Detection of the CMV pp65 antigen in leukocytes has been the commonly used method for CMV surveillance after HCT, but is ineffective during early post-HCT leukopenia. However, direct detection of CMV DNA either by PCR or DNA hybrid capture assay is the most sensitive method to detect CMV. Furthermore,

plasma CMV DNA PCR, though not as sensitive as whole blood PCR, can be a valuable tool to monitor CMV during periods of neutropenia when CMV antigenemia testing is unreliable. In addition, quantitative real-time PCR assays allow estimation of viral load which can assist in determining need for therapy and risk of disease progression and in monitoring response among patients receiving anti-CMV treatment. Viral cultures of urine, saliva, blood or bronchioalveolar lavage (BAL), using either rapid shell-vial or routine culture techniques, have limited clinical utility since they are less sensitive than antigen or DNA detection techniques and take much longer to report. Shell-vial cultures of CMV from BAL fluid are less specific for CMV pneumonia and can be positive in asymptomatic seropositive patients without pneumonia who are shedding CMV in oral or respiratory secretions. Despite this lack of specificity, even in asymptomatic patients, finding CMV in BAL fluid is a strong predictor for the development of subsequent CMV pneumonia, and treatment should be initiated.

Prevention and Treatment

For seronegative recipients, the use of seronegative donors and CMV-safe blood products is the mainstay of prevention of CMV disease (Box 109.1). For high-risk patients (seropositive recipients or seropositive donors for seronegative recipients), two general strategies can be used, both of which have been effective in reducing early CMV infection rates to less than 10%.⁷ The first is the “preemptive” approach, which involves prompt treatment of early CMV viremia with ganciclovir, valganciclovir, or foscarnet before it can lead to clinical disease. The second is the “general prophylaxis” approach, in which all at-risk patients are treated with antiviral prophylaxis. The former approach requires availability and frequent scheduled application of reliable and rapid early diagnostic tests. The latter approach can reduce the rate of early CMV infection, but does not impact mortality or the risk for late CMV infection and is associated with a higher incidence of ganciclovir-induced myelosuppression. Both approaches require aggressive surveillance to allow prompt detection of infection. High-dose acyclovir or valacyclovir, although not as effective as ganciclovir, also reduces the incidence of CMV viremia, but continued surveillance for CMV is still required with prompt initiation of preemptive therapy with ganciclovir or foscarnet when viremia develops. Unlike ganciclovir, which has to be administered intravenously, its prodrug valganciclovir, has excellent oral bioavailability and is often used for prophylaxis and preemptive therapy of CMV infection among HCT recipients. Since autologous HCT recipients have a lower risk of CMV disease, the preemptive approach to preventing CMV infection is usually sufficient. Surveillance for CMV is continued weekly until at least day 100 posttransplant for high-risk patients and is continued longer in patients with chronic GVHD on high-dose immunosuppression.

CMV disease, especially pneumonia, must be diagnosed and treated promptly as it remains associated with very high rates of mortality. The combined use of ganciclovir and IVIg has been the most successful treatment for CMV pneumonia, with resolution in 50% to 75% of nonventilator dependent patients. Prolonged therapy (>2 months) with the combination is indicated because shorter treatment regimens have been associated with recurrence of CMV pneumonia. Foscarnet can be effective in clinical settings in which ganciclovir fails or is associated with excess toxicity, usually myelosuppression. Although treatment is generally similar, with ganciclovir or foscarnet plus immunoglobulin, CMV enteritis, hepatitis, and retinitis are variably responsive. Valganciclovir may be considered for treatment of mild to moderate CMV organ disease, although more prolonged administration may be required.¹⁰ Adoptive cellular therapies (using approaches to enhance NK or infuse CMV-specific T cells) are also being explored. Although rare, CMV antiviral resistance can occur and ganciclovir or foscarnet can be used as alternative drugs for second-line therapy. Cidofovir can be considered when disease progresses despite treatment with ganciclovir and foscarnet and a

BOX 109.1 Approach to Prevention and Treatment of Cytomegalovirus Infection

Prevention

1. Seronegative recipient with seronegative donor (allogeneic and autologous): Transfuse only cytomegalovirus (CMV) safe blood products. Leukocyte depletion by filtration and blood from CMV-seronegative donors are clinically equivalent alternatives.
2. Seronegative recipient with seropositive donor (allogeneic): Deliver only CMV-safe blood products (seronegative or leukocyte depleted), but administer chemoprophylaxis as well to prevent reactivation of donor-derived and transmitted latent virus.
3. Seropositive recipients: Prophylaxis with acyclovir appears to be somewhat useful. Use of immunoglobulin may be beneficial. There is no proven role for seronegative blood products. Ganciclovir is highly effective when given prophylactically, but is myelosuppressive. Patients who must interrupt the course of ganciclovir because of leukopenia are at risk for development of CMV reactivation and disease. Ganciclovir (or valganciclovir) is the current best prophylaxis in high-risk patients, but is not indicated for autologous recipients. Intensive surveillance and early preemptive therapy may be equivalently effective.
4. All patients need periodic (weekly) monitoring for CMV antigenemia or CMV DNA polymerase chain reaction for 8–12 weeks posttransplantation. Longer duration (beyond 12 weeks) surveillance is appropriate for allograft recipients, especially those with graft-versus-host disease.

Treatment

1. Asymptomatic infections (allogeneic and autologous): Ganciclovir or valganciclovir treatment of asymptomatic infection detected in blood or bronchioalveolar lavage (BAL), by either molecular detection or antigenic methods, is recommended to prevent the development of CMV pneumonia. Intensive induction treatment (2 weeks) followed by a maintenance phase of 5+ days/week therapy for an additional 4–8 weeks is necessary.
2. CMV pneumonia: Ganciclovir in combination with immunoglobulin is recommended. This should be instituted promptly. Once the disease has progressed to cause respiratory failure and ventilator dependence, survival is limited.

No Treatment

1. Empiric CMV therapy for interstitial pneumonitis is not indicated in seronegative recipients with seronegative graft and blood donors. Diagnostic evidence of CMV infection should be obtained.
2. Empiric CMV therapy for interstitial pneumonitis is also not indicated in patients whose BAL is negative for CMV by direct staining and molecular testing. However, BAL CMV studies have a small (<5%) false-negative rate, and close follow up and monitoring is still required.
3. Asymptomatic CMV viruria does not require therapy, but does need close follow up and serial blood viral testing for surveillance of systemic disease.

liposomal formulation of cidofovir with good oral bioavailability (CMX-001, brincidofovir) is being studied in prophylaxis and treatment of CMV infections in HCT.

Other Latent Viral Infections

Primary and reactivation infections of other herpesviruses can occur after transplantation. Herpes simplex virus (HSV) infection is uncommon with the use of acyclovir or valacyclovir prophylaxis in seropositive patients. Acyclovir-resistant HSV infection can occur in patients given low-dose prophylaxis or intermittent treatment and in recipients of T-cell depleted grafts. Foscarnet is the drug of choice for resistant disease with cidofovir reserved as an alternative agent. VZV reactivation can occur in 30% to 50% of HCT recipients with previous exposure to VZV, and can be effectively delayed and possibly prevented by acyclovir prophylaxis. Acyclovir prophylaxis has been suggested for the 6–12 months after transplantation for VZV seropositive autologous and allogeneic HCT recipients; patients with

chronic GVHD need to continue prophylaxis for the duration of their immunosuppression.¹

Human polyomavirus type I, also known as BK virus, can cause hemorrhagic cystitis in the early posttransplant period. Urine PCR can identify BK virus and distinguish it from hemorrhagic cystitis caused by other infections (e.g., adenovirus) and urotoxic agents (e.g., cyclophosphamide). Quinolone antibiotics suppress BK virus replication in vivo and in vitro and may have a role as prophylaxis in patients at high risk for hemorrhagic cystitis.¹ Along with bladder irrigation or forced polyuria intravesical or intravenous cidofovir has been used for the treatment of BK virus hemorrhagic cystitis.¹ Rarely, BK virus encephalitis has been described postallogeic HCT. Another polyoma virus, John Cunningham virus, can reactivate in immunocompromised HCT recipients and lead progressive multifocal leukoencephalopathy, a fatal demyelinating disease of the central nervous system. Severe immune deficiency is the primary risk factor for these opportunistic infections, and treatment is primarily supportive and aimed at an improving immune function, if possible.

HHV-6 can also reactivate from latency post-HCT, with incidence ranging from 20% in recipients of grafts from matched sibling donors, 46% in URDs, and 69% of recipients of UCB grafts, at a median of 23 days after HCT.¹¹ Although reactivation is common, routine surveillance is not necessary. Rather, preemptive treatment of a high viral load (>25,000 copies) with ganciclovir or foscarnet, in the presence of symptoms (headache, mental status changes, unexplained fever and/or rash, delayed engraftment or marrow suppression) should be considered. Reactivation of HHV-6 is common and is rarely associated with poor post-HCT outcomes.

Acquired Viral Infections

HCT recipients can be prone to community-acquired respiratory viral (CRV) infections with influenza, parainfluenza, and respiratory syncytial virus (RSV). As upper respiratory infections can progress to more serious lower respiratory infections and certain CRVs can be treated, appropriate diagnostic testing (e.g., nasopharyngeal swabs) should be considered to identify the virus if possible. Zanamivir or oseltamivir can be used for chemoprophylaxis and prompt treatment of influenza. Aerosolized and possibly oral ribavirin can be considered in patients with RSV infection, especially if they are early posttransplantation or have lower respiratory tract involvement.

Adenovirus infections can occasionally occur after allogeneic HCT, especially among recipients of T-cell depleted or mismatched grafts and in patients with GVHD. Novel antivirals are needed to treat respiratory viral infections in HCT recipients. An inhaled antiviral, DAS181, cleaves sialic acid-containing receptors on the surface of host respiratory epithelial cells, thus preventing influenza and parainfluenza attachment to and infection of respiratory cells, is currently undergoing clinical study.¹²

Fungal Infections

Invasive fungal infections are among the leading causes of mortality in HCT recipients. The vast majority of fungal infections in this setting are caused by yeasts (*Candida* spp.) or molds (*Aspergillus* spp.).

Candida Infections

Candida albicans has been the leading cause of yeast infections in HCT recipients, but the current widespread use of azole prophylaxis in the early transplant period has reduced the overall incidence, but led to the emergence of a variety of non-*albicans* species, such as *Candida tropicalis*, *Candida krusei* and *Candida glabrata*, as important pathogens.¹³ These yeasts are normal inhabitants of the skin, oral and gastrointestinal mucosa which overgrow as normal commensal flora are disrupted by broad-spectrum antibacterials. Breakdown of these mucosal surfaces caused by radiation and chemotherapy, compounded

by neutropenia in the preengraftment period, can greatly increase the risk of invasion and systemic yeast infections. Presence of indwelling central venous catheters and alteration of normal surface flora arising from antibiotics are additional risk factors for *Candida* infections.¹

Clinical manifestations can range from localized mucocutaneous to disseminated deep-tissue infection. A high index of suspicion is needed for the diagnosis of *Candida* infections, especially in patients with persistent febrile neutropenia, since blood cultures are usually not very sensitive for isolation and identification of *Candida* spp. Oral and esophageal candidiasis frequently occurs in the early posttransplant period and should be treated aggressively as these can serve as portals for subsequent systemic infection. Venous catheter infections can be difficult to eradicate with antifungal agents alone and necessitate removal of the central line. Patients with candidemia are also at risk for endovascular infections such as endocarditis, thrombophlebitis or endophthalmitis. Hepatosplenic candidiasis is the most common manifestation of disseminated candidiasis, although it is increasingly rare with widespread use of effective anticandida azoles and echinocandins. Specific signs or symptoms related to organ involvement may be absent and the diagnosis frequently has to be made by abdominal CT scan imaging.

Prophylaxis with fluconazole is recommended in the preengraftment and early postengraftment periods, especially among allogeneic HCT recipients.^{1,14,15} In patients who are at high-risk for mold infections, caspofungin, micafungin, voriconazole, or posaconazole can be considered as they have antimold activity. *Candida krusei* and *Candida glabrata* are intrinsically resistant to fluconazole and other agents (e.g., posaconazole, voriconazole, or micafungin) should be preferred for prophylaxis in patients colonized with fluconazole-resistant *Candida* species. Itraconazole is another active agent, but its use is limited by its tolerability, absorption, and toxicities. Cross-resistance to azoles can occur among *Candida* species. Antifungal agents for treatment of suspected or known invasive candidiasis include voriconazole or posaconazole, echinocandins or an amphotericin formulation, especially when infection occurs in the setting of ongoing fluconazole prophylaxis.¹⁵

Aspergillus Infections

Most mold infections in HCT recipients are caused by *Aspergillus fumigatus*, *Aspergillus flavus*, and *Aspergillus niger*, which gain entry through breakdown of mucosal surfaces in the nasal passages, sinuses, and the lower respiratory tract. *Aspergillus* infections can occur early after HCT (during the neutropenic phase) or later, especially complicating the immunosuppression associated with acute or chronic GVHD. Risk factors for *Aspergillus* infections include allogeneic (more than autologous) HCT, prolonged neutropenia, and GVHD.¹⁶ Transplantation for diseases that cause extended neutropenia or neutrophil dysfunction pretransplantation (e.g., aplastic anemia and MDS, Fanconi anemia, or chronic granulomatous disease) also increases the risk. Prior history of *Aspergillus* infection has also been observed to be a risk factor for recrudescence after HCT.

Aspergillus occurring in the posttransplant setting can be difficult to diagnose pre-mortem. Hence, a high index of suspicion and an aggressive approach is required to establish its diagnosis and initiate therapy. Since the nasal passages and tracheobronchial tree are the most common portals of entry for *Aspergillus* spp., these two sites are also the most common sites of infection. Sinusitis is frequently symptomatic and more advanced disease can be associated with erosion, vascular invasion and necrosis of surrounding structures. Pulmonary manifestations typically include nodular infiltrates, usually distributed along the lung periphery, with pleuritic pain or cough as an initial symptom. Frank consolidation (with a halo sign on CT scan) or cavitary lesions can be seen in more advanced stages of pulmonary involvement. *Aspergillus* has angioinvasive properties and can present with hemoptysis or with intravascular dissemination to the skin or brain.

Blood cultures have a very low sensitivity in detecting *Aspergillus* and diagnosis has to rely on demonstration of typical fungal

morphology on culture or histopathology or on tests to detect fungal components or nucleic acids. Nasal and bronchial washings for *Aspergillus* also may not be sensitive and lung biopsy may be required to obtain a definitive diagnosis. The galactomannan assay is an enzyme-linked immunosorbent assay to detect the *Aspergillus* cell wall glycoprotein; it has a high specificity, but low sensitivity for diagnosing invasive aspergillosis and has not been reproducible in well-designed trials. Similarly, testing for β -D-glucan has modest clinical utility, but low sensitivity. Molecular methods for diagnosis, including PCR for *Aspergillus* DNA, are also undergoing development. More invasive evaluations (e.g., fine needle aspiration or biopsy) are often needed to confirm the presence of *Aspergillus* in suspicious lesions identified on clinical exam or imaging studies.

The use of high-efficiency air filters has reduced the nosocomial acquisition of *Aspergillus*, at least during the early neutropenic phase when isolation measures are used. The optimal pharmacologic strategy for primary prophylaxis against aspergillosis in HCT recipients is not well defined. Posaconazole has been shown to be effective for prophylaxis in HCT recipients with GVHD. A large randomized trial showed no difference in fungal-free survival between voriconazole and fluconazole in HCT recipients at low risk for disease progression or early HCT mortality, although there was a trend towards fewer *Aspergillus* infections and less empiric antifungal use in voriconazole recipients.¹⁷ Inhaled or low dose intravenous amphotericin has not been effective for primary prophylaxis. In patients with a previous history of invasive aspergillosis, secondary prophylaxis with a mold-specific azole (e.g., oral voriconazole or posaconazole) or parenteral echinocandins or an amphotericin preparation is recommended, possibly for the duration of intensive immunosuppression. Therapy with a mold-specific azole, an echinocandin, or an amphotericin preparation should be initiated in patients with invasive aspergillosis or in high-risk patients with persistent febrile neutropenia.¹⁸ Azoles and echinocandins have a more favorable side effect profile compared with amphotericin formulations. Patients with disease progressing on a single antimold drug might need combination therapy with two antimold agents. The role of adjunctive measures such as cytokine growth factors, immunoglobulin infusion, or granulocyte transfusion remains undefined.

Other molds including fusarium, alternaria or the zygomycetes may present similarly and might be difficult to distinguish on tissue biopsy.¹⁹ Aggressive antifungal therapy is required for their management and may require multidrug therapy. Granulocyte transfusions may be an important adjunct for treatment of invasive fungal infections during neutropenia, but formal studies have not demonstrated improvements in survival.^{20,21}

EARLY NONINFECTIOUS COMPLICATIONS

High-dose chemotherapy and radiation regimens are used before transplantation for their antineoplastic and immunosuppressive effects. However, these treatments can damage host tissue, resulting in significant morbidity. Early HCT-associated complications can frequently simulate infections or be compounded by concurrent infections. In addition, because epithelial tissue repair may be delayed by ongoing neutropenia and local microinvasive infection, delay in hematopoietic engraftment can exaggerate and prolong these toxicities.

Graft Failure

Failure to establish hematologic engraftment (primary graft failure) and loss of an established graft (late graft failure) are serious, though uncommon complications of both autologous and allogeneic HCT. Delayed or poor graft function can exaggerate and prolong the risks of infection and can increase the risk of peritransplant mortality. Graft failure can occur if insufficient hematopoietic progenitors are infused. A minimum of approximately 2×10^4 colony-forming cells from marrow per kilogram (kg) recipient weight are needed to

establish autologous engraftment. This is accomplished by infusing approximately 1×10^8 autologous marrow mononuclear cells/kg. Most investigators recommend infusion of a minimum of at least 2×10^8 marrow mononuclear cells/kg to ensure establishment of an allogeneic graft. UCB derived hematopoietic grafts can engraft with a lower number of cells. Stem cells and progenitors can be damaged by cryopreservation or by ex vivo purging, and additional cells are required if intensive purging, especially with alkylators, is performed though currently this approach to autograft preparation is uncommon. Selection of CD34+ cells as a technique for tumor cell depletion does not compromise engraftment, unless the quantitative cell losses through selection are excessive.

The use of hematopoietic stem cells and progenitors harvested from the blood by apheresis instead of the bone marrow has become widely prevalent, both for autologous and allogeneic HCT. Autologous peripheral blood hematopoietic cell grafts (PBSC) are collected after mobilization of marrow-derived progenitors into the blood by cytokine (G-CSF or GM-CSF) therapy or during recovery from myelosuppressive chemotherapy, often in combination with growth factors (Chapter 97). Progenitor content of blood or marrow grafts is assayed by quantitation of mononuclear cells expressing the hematopoietic progenitor-associated surface marker CD34. Peripheral graft mobilization can be further enriched by the use of plerixafor, an inhibitor of CXCR4-chemokine receptor 4 that releases cells from the marrow. Allogeneic grafts are mobilized from healthy donors using growth factors alone, nearly exclusively using G-CSF though clinical trials with plerixafor are ongoing.

Graft failure is uncommon if $>2 \times 10^6$ CD34+ cells/kg or more are collected, cryopreserved, and later infused as an autologous graft though guidelines often target $>5 \times 10^6$ /kg for prompt neutrophil and platelet recovery. The minimum CD34 content for an allogeneic graft is less well defined, but more than 5×10^6 CD34+ cells/kg is frequently cited as a target collection for an allogeneic donor allograft. Mobilized PBSC grafts yield satisfactory and more rapid trilineage hematopoietic recovery than grafts from marrow-derived cells. Similar to marrow grafting, late graft failure is possible, but unlikely ($<5\%$) after transplantation using PBSC. Infusion of a sufficient graft cell dose (nucleated or CD34+ cells) may be the most important controllable factor to limit the risk of graft failure.

Recipient myelofibrosis or splenomegaly can interfere with engraftment. Splenomegaly can delay hematologic recovery, presumably because both progenitors and mature blood cells are sequestered in the spleen and may particularly prolong dependence on platelet transfusions. The presence of moderate severe myelofibrosis also delays engraftment, perhaps because of faulty homing of stem cells in the marrow microenvironment.

Posttransplantation therapy can jeopardize engraftment. Graft failure or poor graft function has been associated with use of methotrexate, ATG, acyclovir, ganciclovir, trimethoprim-sulfamethoxazole (TMP-SMX), and mycophenolate mofetil (MMF). Posttransplant complications such as CMV, HHV-6 or fungal infections, and acute and chronic GVHD can also compromise successful engraftment.

Allogeneic HCT, especially using unrelated or mismatched donors, poses unique engraftment problems. Transplants between siblings completely matched at *HLA-A*, *HLA-B*, and *HLA-DR* loci are rarely (1%–3%) associated with graft failure; however, the probability of graft failure in the related-donor transplantation setting increases to near 10% with greater degrees of donor-recipient HLA incompatibility. This may be overcome by the promising use of post-HCT cyclophosphamide to deplete alloreactive host and particularly donor cells.²² The problem is more frequently observed, although still $<5\%$ in the volunteer adult URD setting, where primary or secondary graft failure may occur even after transplantation from donors well matched at the *HLA-A*, *HLA-B*, *HLA-C*, and *HLA-DR* loci. In some cases, failure of URD stem cells to engraft may result from reactivity against other important histocompatibility determinants, including *HLA-C* or donor-specific antibodies against *HLA* class I or class II molecules.²³ Early failure of an allogeneic graft can be accompanied by emergence of cytotoxic T-lymphocytes of host origin, presumably representing immune-mediated graft rejection. This may be blunted by effective

host immunosuppression by the conditioning regimen and peritransplant immunoprophylaxis. T-lymphocyte depletion of donor marrow performed as GVHD prophylaxis can also adversely affect engraftment, even from matched sibling donors. Ex vivo marrow manipulation can deplete stem cells. T-cell depletion can also render the graft immunoincompetent and functionally less capable of preventing graft rejection.

Compared with related or URD allografts, time to neutrophil recovery is significantly delayed in patients receiving UCB grafts. In addition, the overall incidence of graft failure is somewhat greater, currently 5% to 15% with present selection strategies. The most critical determinants of engraftment following UCB transplantation are both HLA matching and cell dose, and units with a total nucleated cell dose of at least 2.5×10^7 cells/kg or more have a greater probability of successful engraftment. Since each UCB unit has a limited number of hematopoietic stem and progenitor cells, methods to overcome this limitation of cell dose are being investigated. These include transplantation using multiple UCB units, ex vivo expansion to increase the number of progenitor cells, and approaches to improve homing including intrabone marrow injection of the graft or preincubation with prostaglandins. Increasing overall cell dose and the added antihost immunologic response with transplantation of two UCB units has increased the chances of successful engraftment, especially in adults.

The use of recombinant G-CSF or GM-CSF, which stimulate myelopoiesis, has improved the treatment of graft failure. Improvement in myelopoiesis can be seen in 50% to 60% patients with poor graft function within 14–21 days after initiation of growth factor therapy. Myeloid growth factor therapy can increase peripheral blood leukocyte recovery, but has little effect on platelet reconstitution. Recombinant human thrombopoietin receptor agonists are now available, although their efficacy and safety profile in HCT recipients is currently being studied. Limited experience suggests the value of recombinant erythropoietin in reducing red blood cell transfusion needs.

A second stem cell infusion can be useful if graft failure occurs. In the case of a failed autograft, infusion of previously harvested and frozen marrow or blood cells frequently reestablishes functional hematopoiesis and hematologic improvement. In the case of graft failure after related-donor transplantation, a second infusion of donor marrow or cytokine-mobilized PBSC may allow successful engraftment. Sometimes, because of the presumption of immune-mediated rejection, reconditioning with reduced doses of cytotoxic agents or further immunosuppression with ATG, corticosteroids, or cyclosporine is used to prepare the recipient for a second infusion.

The treatment of graft failure after URD transplantation poses special problems. URDs may not be available for a second marrow harvest or blood stem cell apheresis. In experimental settings where graft failure risks are high, it may be prudent to store autologous stem cells from patients undergoing URD transplantation, although this is rarely done. The original donor is not available in recipients of unrelated UCB grafts and the only treatment option for graft failure in this setting is a second transplant using cells from a different UCB or volunteer adult donor (related or unrelated) second allograft, or reinfusion of autologous backup cells, if available. Because of variability in the circumstances and donor options available, there are few clear data on the outcomes of second allografts in these situations.²⁴

Sinusoidal Obstruction Syndrome

Sinusoidal obstruction syndrome (SOS), also known as hepatic venoocclusive disease, is a serious liver disorder characterized by jaundice, ascites, fluid retention, and hepatomegaly that complicates up to 5% to 50% of HCT's.²⁵ The varying reported incidence is based upon stringency of the definition of the clinical diagnosis (Box 109.2). The primary initiating event is thought to be portal hypertension caused by inflammatory and edematous obstruction of hepatic sinusoids and venules, which secondarily leads to damage to surrounding centrilobular hepatocytes. Chemotherapy and total body irradiation

BOX 109.2 Sinusoidal Obstruction Syndrome

Diagnostic Criteria for Sinusoidal Obstruction Syndrome (SOS)

Bilirubin ≥ 2 mg/dL before day 21 post-HCT and at least two of the following: (1) hepatomegaly or right upper quadrant pain, (2) ascites, or (3) weight gain $>5\%$ over baseline.

SOS is a clinical diagnosis; liver ultrasound with Doppler studies or liver biopsy can support or confirm the diagnosis.

Risk Factors

Pretransplant Factors

- Prior hepatic inflammatory disease (e.g., chronic hepatitis B or C, nonalcoholic steatohepatitis, alcoholic hepatitis)
- Prior hepatic fibrotic disease (e.g., cirrhosis)
- Extensive pre-HCT chemotherapy
- Prior exposure to gemtuzumab ozogamicin
- Prior liver irradiation

Transplant-Related Factors

- Conditioning regimen (e.g., myeloablative total body irradiation or busulfan-based regimens)
- Exposure to other agents (e.g., sirolimus, itraconazole)

Prognostic Factors

Adverse prognostic factors include: development of multiorgan failure, rapid increase in weight, rapid increase in bilirubin.

Treatment

For $>70\%$ of patients, SOS will recover spontaneously with supportive care. However, mortality rates are $>80\%$ for patients with severe SOS. Treatment options, especially for patients with more severe SOS, includes:

Pharmacologic

- Ursodeoxycholic acid (prophylaxis)
- Defibrotide (investigational—prophylaxis and treatment)
- Low-dose heparin and low-molecular-weight heparin (prophylaxis)
- Tissue plasminogen activator (investigational – prophylaxis and treatment)
- Antithrombin III (investigational—prophylaxis and treatment)

Nonpharmacologic

- Supportive care with management of multiorgan failure
- Transjugular intrahepatic portosystemic shunt
- Liver transplantation

(TBI) used in pretransplant conditioning regimens produce sinusoidal endothelial injury. Subsequent deposition of fibronectin and factor VIII/von Willebrand factor at the site of damaged endothelium can lead to activation of the coagulation system and subsequent sinusoidal obstruction. Such changes are often associated with depressed plasma protein C levels and other signs of procoagulant activity, including lower antithrombin III levels and elevated factor VIII and fibrinogen levels. Cytokines such as tumor necrosis factor (TNF)- α and alterations in the levels of nitric oxide and matrix metalloproteinases may also have a role in its pathogenesis.

Risk factors associated with the development of SOS include history of pretransplant hepatitis or liver injury, intensive preparative regimens, increased TBI dose and dose rate and increased busulfan dose. SOS may also be more frequent after mismatched related or URD transplantation. Prior therapy with gemtuzumab ozogamicin also increases the risk of posttransplant SOS. Sirolimus has also been shown to increase the risks of SOS after myeloablative allogeneic HCT, particularly using busulfan-based regimens.

Signs of SOS usually occur within 2–4 weeks after hematopoietic graft infusion, but may be recognized much sooner, even during administration of an intensive preparative regimen. Clinical evidence of venoocclusive disease includes hyperbilirubinemia, tender hepatomegaly, ascites, and weight gain.²⁵ More advanced stages can be associated with encephalopathy along with renal, pulmonary, and multiorgan failure. The diagnosis of SOS is primarily based on

clinical criteria that include presence of jaundice, plus either hepatomegaly, weight gain, and/or ascites within 2–3 weeks of stem cell infusion. However, other causes of hyperbilirubinemia and weight gain early after transplantation (e.g., drugs, hepatitis, capillary leak, cardiac failure, volume overload) can complicate the differential diagnosis, particularly for milder or less abrupt presentations of these symptoms. Percutaneous or transabdominal needle biopsy of the liver is hazardous in severely thrombocytopenic transplant recipients and should be avoided. Transvenous biopsies may provide sufficient histologic material for diagnosis and may allow determination of hepatic wedge pressure product (greater than 10 mm is associated with SOS), but may be associated with hemorrhagic complications as well. Ultrasonographic Doppler flow studies demonstrating reversal of portal flow or a higher portal vein resistive index have been suggested as a noninvasive means of confirming the diagnosis, but their validity has recently been questioned. SOS can be graded from mild to severe depending on the degree of hyperbilirubinemia and weight gain. Severe SOS is almost universally fatal within several weeks of onset.

Effective methods for prevention and treatment of SOS have not been defined. Limited understanding of the cellular and microvascular pathophysiology of SOS has confounded development of more rational approaches to its prevention and treatment. Possible approaches include preventive therapy with low-dose heparin, prostaglandin E, pentoxifylline (a TNF- α blocking agent), although none has proved effective in carefully performed prospective trials. Post-HCT hepatic injury including SOS has become less frequent with widespread and prolonged administration of ursodiol as a choleretic and hepatic protectant. Recombinant tissue plasminogen factor has been used successfully to treat established SOS, however, thrombolytics are associated with substantially increased risk of hemorrhage. Transjugular intrahepatic portosystemic shunts have also been used with some success. Early experience with defibrotide, a single-stranded

polyribonucleotide with fibrinolytic, antithrombotic, and antiischemic properties, has been favorable with 30% to 40% of patients with severe SOS achieving complete resolution and improvement in survival.²⁶ Its efficacy in the prophylaxis and management of severe SOS is currently being investigated in larger clinical trials.

Interstitial Pneumonitis

Interstitial pneumonitis is a common and frequently fatal complication, affecting up to 35% of allogeneic transplant recipients, although recent advances in supportive care have substantially reduced this risk. Interstitial pneumonitis is notably less common after autografting. It is characterized by diffuse, interstitial inflammation accompanied by hypoxemia, dyspnea, and nonproductive cough, sometimes with fever. Risk factors associated with the development of interstitial pneumonitis include use of methotrexate for GVHD prophylaxis, older age at transplant, severe GVHD, interval from diagnosis of hematologic disease to HCT of 6 months or greater, poor pretransplant performance status and use of higher TBI dose rate (>4 cGy/min). Remarkably, in one study, the reported risk of interstitial pneumonitis was 8% when none of these risk factors were present, compared with 94% when all six factors were present. It has been hypothesized that URD transplantation is more immunosuppressive and thus associated with more severe opportunistic infections and greater risk of interstitial pneumonitis, but this has not been rigorously investigated.

The course of interstitial pneumonitis is often catastrophic, manifesting with rapidly progressive tachypnea, hypoxemia, and hemodynamic compromise. Therefore, therapeutic intervention must frequently occur before the return of definitive results of diagnostic tests and must be initiated based on the assessment of clinical risk factors and the underlying clinical setting (Box 109.3).

BOX 109.3 Approach to Interstitial Pneumonitis

The presentation of interstitial pneumonitis after hematopoietic cell transplantation (HCT) should be considered an urgent medical situation and empiric broad-spectrum therapy must be initiated early. The choice of therapy is influenced by the following:

1. Timing: Within the first 3 weeks after HCT, interstitial pneumonitis is more likely to be idiopathic (including diffuse alveolar hemorrhage) or fungal than caused by cytomegalovirus (CMV) infection. Beyond 6 weeks, idiopathic pneumonitis is unusual and the cause is more likely infectious. *Pneumocystis jirovecii* pneumonia is rare beyond 1 year after transplantation except in patients with ongoing chronic graft-versus-host disease. Respiratory syncytial virus (RSV) infections are seasonal (fall and winter), and community outbreaks can be prevalent. Influenza is also seasonal, whereas parainfluenza can occur year round.
2. CMV serology and prophylaxis: If a seronegative recipient has received a seronegative graft and noninfective (seronegative or leukocyte-depleted) blood, CMV pneumonia is unusual. Seropositive recipients are at higher risk, although with ganciclovir or other antiviral prophylaxis, the risk is markedly reduced. Other prophylactic regimens for CMV, such as acyclovir or intravenous immunoglobulin, have still been associated with significant risk for serious CMV infection in the seropositive recipient. Serial negative testing for CMV antigenemia or DNA-polymerase chain reaction makes CMV pneumonitis less likely.
3. Prolonged neutropenia: This factor is associated with infectious causes, particularly with fungal pneumonias.
4. Type of transplant: Diffuse alveolar hemorrhage is less frequently seen in patients undergoing autologous HCT. CMV pneumonia is unusual (2%–3%) in autologous recipients, but it still has a high case fatality rate. All infectious causes are more common after allogeneic HCT. More intensive conditioning regimens (e.g., higher total body irradiation, carmustine) are associated with greater risks of pneumonitis.
5. Compliance and prophylaxis: A thorough assessment of what prophylaxis the patient has actually been receiving (e.g., trimethoprim-sulfamethoxazole, penicillin, CMV prophylaxis, transfusions outside the transplant center) is critical to assess risk.
6. Chest radiograph: The pattern and distribution of the infiltrate may narrow the differential diagnosis. Cardiac enlargement or pleural effusions may suggest pulmonary edema. A chest computed tomography scan is useful, especially if nodularity, pleural involvement, or cavitary lesions (possibly fungal) are suspected.
7. Epidemiology: Identification of the causes of other recent cases can be most helpful with infections that are horizontally transmitted (e.g., RSV) or have common environmental risk factors (e.g., *Aspergillus* infection associated with construction).
8. Bronchoalveolar lavage (BAL): This can be extremely useful to establish a specific diagnosis or to exclude others. CMV rarely causes pneumonia without positive BAL findings (either direct staining of CMV-associated antigens in BAL cells or DNA-PCR). BAL also usually detects RSV, *Pneumocystis jirovecii* and other respiratory viruses, though not as rapidly, but is required to identify alveolar hemorrhage. It is less sensitive for diagnosis of fungal pneumonias. Galactomannan or β -D-glucan studies of serum or BAL may indicate fungal pneumonia, but are insensitive.
9. Lung biopsy: Although this is the gold standard for definitive diagnosis of most of the possible causes of interstitial pneumonitis, it can often be avoided through the use of clinical diagnostic measures listed. It may be necessary for the definitive diagnosis of fungal pneumonias, pulmonary changes associated with chronic graft-versus-host disease (bronchiolitis obliterans), or idiopathic interstitial pneumonitis. Either bronchoscopic(transbronchial), open surgical or video-assisted thoracoscopic can be used. Transbronchial biopsies are insufficient for other than very diffuse processes and carry risks of bleeding and/or pneumothorax. The surgical approaches are more invasive, but more often definitive.
10. Ventilator therapy: Progressive respiratory failure after HCT is rarely reversible, especially in adults. Although aggressive diagnostic and therapeutic measures are essential, some centers offer patients and their families the option of foregoing mechanical ventilatory support if survival is not expected. Preliminary discussion of this possible complication in pretransplant patient counseling can facilitate decision-making if respiratory failure does occur.

Infectious Causes of Interstitial Pneumonitis

Infections are the most common cause of interstitial pneumonitis in HCT recipients. CMV and *Aspergillus* are the most common infections associated with interstitial pneumonitis and have been discussed earlier. Other important, though relatively uncommon infections to consider are *Pneumocystis jirovecii*, RSV and similar respiratory viruses.

Pneumonitis caused by *Pneumocystis* has a typical bilateral distribution with a 'butterfly' pattern on chest radiograph and prominent hypoxemia, and rarely causes pleural effusions. The previously reported 5% to 15% risk of *Pneumocystis* pneumonia has been largely eliminated by routine use of prophylaxis with TMP-SMX (first choice), dapsone, atovaquone, or inhaled pentamidine. Prophylaxis with TMP-SMX virtually eliminates *Pneumocystis* pneumonia from the differential diagnosis, but only if patient compliance with therapy is certain. Diagnosis requires cytologic evaluation of silver-stained preparations of BAL cells or sputum, although transbronchial lung biopsy may slightly increase the diagnostic yield of a bronchoscopic examination. *Pneumocystis* pneumonia is effectively treated with high dose TMP-SMX or parenteral pentamidine. Prophylaxis against *Pneumocystis* pneumonia should be continued through the period of immunosuppression (6 months to 1 year posttransplantation) and for the duration of any therapy for chronic GVHD.

RSV is a potentially fatal cause of interstitial pneumonitis and typically occurs in the fall and winter months. RSV should be suspected if the patient presents a history of rhinorrhea and if RSV has been frequently recognized in the community or in the hospital. Diagnosis can be made by rapid antigen or PCR testing on nasal washings or BAL specimens. Because of the possibility of horizontal transmission, patients with RSV should be isolated. Inhaled and sometimes oral ribavirin is used for treatment of RSV-associated pneumonia. Other community acquired viruses, such as parainfluenza or influenza can also cause interstitial pneumonitis in the transplant recipient. Their presentation is clinically indistinguishable from RSV though parainfluenza pneumonitis is not seasonal and may be seen year round. Yearly influenza vaccination for HCT recipients and especially their household contacts may be effective in reducing risks of this infection.

Noninfectious Causes of Interstitial Pneumonitis

Idiopathic Interstitial Pneumonitis

Idiopathic interstitial pneumonitis is a diagnosis of exclusion based on typical findings and ruling out infectious causes. Its timing is somewhat earlier than other causes of interstitial pneumonitis, typically occurring within the first 2–7 weeks after HCT. The recognized risk factors for idiopathic interstitial pneumonitis include older age at transplant, extensive pretransplant chemotherapy, high-dose cyclophosphamide, TBI (higher total dose and dose rate), blood transfusions, administration of methotrexate and GVHD.²⁷

The observation that idiopathic interstitial pneumonitis is as frequent among syngeneic as among allogeneic recipients and has an equally high incidence in T-cell depleted grafts, suggests that immunosuppression is less of a risk factor for idiopathic interstitial pneumonitis than it is for infectious interstitial pneumonitis. Clinical observations support a toxic cause for idiopathic interstitial pneumonitis, and radiation-induced lung damage appears to be the major contributor, especially the use of high-dose TBI. Effective therapy has not been established, although high-dose corticosteroids are often administered. Inflammatory cytokines, including interleukin (IL)-1 and TNF- α , have been implicated in lung injury. Etanercept, a TNF- α binding protein has been reported to improve lung function in patients with idiopathic interstitial pneumonitis, particularly if administered before the need for mechanic ventilation. Its use was not confirmed to be better than placebo when used in

combination with corticosteroids in a recent, though small, multicenter trial.^{28,29}

Diffuse Alveolar Hemorrhage

Alveolar hemorrhage is a clinical syndrome of acute onset of pulmonary infiltrates and hypoxemia with a progressively bloodier BAL on bronchoscopy.³⁰ Alveolar hemorrhage arising from noninfectious causes has been called diffuse alveolar hemorrhage, but it is often difficult to distinguish it from infection-associated pulmonary hemorrhage, especially in the early posttransplant period.³⁰ The reported incidence of diffuse alveolar hemorrhage ranges from 2% to 5% in autologous and 5% to 10% in allogeneic HCT recipients. Its pathogenesis is not known, but it most likely develops as result of a complex interaction of a variety of factors, including alveolar injury from radiation and chemotherapy, inflammatory damage caused by neutrophils and cytokines, and underlying infections. Older age at transplant, use of an allogeneic donor source, and GVHD are risk factors for this syndrome. The risk is similar with NMA and myeloablative conditioning regimens.³¹ Onset typically occurs within the first 3 months of transplantation with dyspnea, hypoxia, and cough, although late-onset alveolar hemorrhage is also possible. Hemoptysis is usually absent and bronchoscopy with BAL is required to confirm the diagnosis and to exclude infectious etiologies. This syndrome is very serious and the majority of patients develop respiratory failure with mortality rates of more than 70%. Hemorrhage occurring in the periengraftment period is associated with a better outcome compared with later-onset hemorrhage. Treatment includes correction of any coagulopathy and aggressive ventilatory support. High-dose corticosteroids have been used for its management, but their efficacy has not been clearly proven. Small case series have reported the successful use of recombinant factor VIIa and aminocaproic acid, but their efficacy needs to be confirmed in clinical trials. Cytokine antagonists (e.g., etanercept) might have a therapeutic role that is being investigated in clinical trials.

LATE NONINFECTIOUS COMPLICATIONS

Improvements in transplantation techniques and supportive care have led to an increasing number of long-term HCT survivors. Among HCT recipients who remain disease-free through 2–5 years posttransplantation, the probability of survival over the following 10–20 years is more than 80%.^{32,33} These survivors remain at risk for late transplant associated complications, which can include specific organ dysfunction, second cancers, infections because of ongoing immunodeficiency, functional impairments, and compromise in the quality of life (QOL; Table 109.5).³⁴ Guidelines for screening and prevention of late effects in HCT survivors have been published.^{4,35} In addition, following general population guidelines for screening and prevention of cancers and chronic diseases and promoting a generally healthy lifestyle is recommended for all HCT survivors.

Organ-Specific Late Effects

A multitude of pre-, peri-, and post-HCT factors determine a patient's overall risk for developing specific late complications. Risk factors include age at the time of HCT, gender, and lifestyle factors such as tobacco and alcohol use. In addition, patients may have preexisting comorbidities such as chronic renal insufficiency or cardiovascular disease that can be exacerbated by chemotherapy, radiation, and other medications they receive to treat their malignancy and during HCT. Exposure to chemotherapy and radiation as part of initial treatment of underlying hematologic disorder or as part of the conditioning regimen given before HCT also can contribute to organ-specific complications. Allogeneic HCT recipients who develop chronic GVHD may require long-term treatment with glucocorticoids, calcineurin inhibitors (e.g., cyclosporine or tacrolimus), or other immunosuppressive agents and can be prone to developing medication-related side effects, infections

TABLE 109.5 Selected Late Complications of Hematopoietic Cell Transplantation

Complication	Risk Factors	Monitoring and Prevention
Endocrine		
<i>Hypothyroidism</i>	TBI/radiation	Periodic assessment of thyroid and gonadal function
<i>Hypogonadism</i> <i>Growth retardation</i>	Chronic GVHD Chemotherapy

<i>Osteoporosis</i> <i>Avascular necrosis</i> Second cancers	TBI/radiation Corticosteroids TBI/radiation Chemotherapy Chronic GVHD	Periodic bone densitometry Periodic cancer screening

GVHD, Graft-versus-host disease; TBI, total body irradiation.

and second malignancies, especially those associated with chronic immunodeficiency.

Although any organ system can be involved, certain organs have a greater predilection for late-onset problems post-HCT. Cataracts develop in more than one-third of patients by 5-years posttransplantation and often require surgical therapy. Hypothyroidism can be seen in up to 50% and hypogonadism in up to 90% of HCT survivors. The majority of HCT survivors become permanently sterile, although HCT without TBI can be fertility-sparing in nearly one-third of men and women. Prepubertal children may retain fertility, although secondary sexual development may be delayed. Up to 50% of children undergoing HCT also develop growth retardation. Musculoskeletal complications including osteoporosis and avascular necrosis of weight-bearing joints can be particularly debilitating. An increased incidence of cardiovascular events and diabetes has also been reported. The risk for most organ-specific late complications continues to

increase with time and continued surveillance for these problems indicated in all HCT survivors.

Second Cancers

Secondary cancers are a rare, but devastating complication of HCT. They account for 5% to 10% of deaths among greater than 2 year survivors. These malignancies can be broadly categorized as post-transplant lymphoproliferative disorders (PTLD), hematologic malignancies, and solid cancers.^{36,37}

PTLD comprise a heterogeneous group of lymphoid proliferations, primarily involving B-lymphocytes that develop as a result of uncontrolled Epstein-Barr virus (EBV) infection. (Chapter 54) They occur almost exclusively in allogeneic HCT recipients, with an overall incidence of 1% to 2%. They typically manifest soon after transplantation with more than 80% of cases diagnosed within the first year. Since T cells play an important role in preventing proliferation of EBV-infected lymphocytes, removal of T cells from the hematopoietic graft or anti-T-cell serotherapy with ATG or alemtuzumab are strong risk factors for PTLD. A greater degree of immunosuppression, such as that resulting from GVHD and use of grafts from unrelated or HLA-mismatched donors, also increases the risk for PTLD. Treatment of PTLD is often challenging, and available treatments are not very effective. Withdrawal of immunosuppression is usually attempted first, but can be difficult in patients with active GVHD. Treatment options include anti-CD20 monoclonal antibody rituximab, antiviral therapy with acyclovir or ganciclovir, multiagent chemotherapy, or infusion of EBV-specific cytotoxic T lymphocytes. Since PTLD is associated with high mortality rates, active surveillance for EBV reactivation in high-risk settings and initiation of preemptive therapy, often with rituximab, is important.

Secondary MDS and acute myeloid leukemia (AML) can be seen in 5% to 15% of autologous HCT recipients, but is extremely rare among allogeneic HCT recipients. They usually occur following a latency period of 2–5 years.³⁶ Bone marrow evaluation can show cytogenetic abnormalities characteristic of other treatment-induced AML/MDS (e.g., balanced translocations to 11q23, monosomy of 5q and 7q or multiple, complex chromosomal aberrations). Risk factors for secondary MDS/AML include older age at transplant, the type, intensity and duration of pre-HCT chemotherapy (especially alkylating agents), and use of TBI. Outcomes are very poor and long-term survival rates are less than 20%, sometimes following a second allograft for this new malignancy.

Secondary solid cancers have a latency period of 3–5 years following HCT. Subsequently, their incidence continues to rise with time and is higher than what may be expected in age- and gender-matched general populations. Their cumulative incidence ranges from 1% to 2% at five years, 2% to 6% at 10 years, and 4% to 15% at 15 years posttransplantation.³⁶ Younger age at transplantation, use of TBI and chronic GVHD are important risk factors for solid cancers. Solid cancers at variety of sites have been reported, including cancers of the head and neck, liver, brain and nervous system, thyroid, and bone and connective tissue. Since there is no plateau in the incidence of secondary solid cancers after HCT, their overall risk has not been completely realized, and longer follow up than what is currently available is needed before the true magnitude of risk will become apparent. Lifelong cancer screening is recommended for all HCT survivors according to established guidelines (Table 109.6).^{4,35}

Quality of Life After Transplantation

Despite the early morbidity associated with HCT, the majority of transplant survivors attain high levels of physical and psychologic QOL and return to full-time employment by 3–5 years posttransplant. However, up to 20% to 40% of long-term survivors continue to have functional, psychological, and cognitive impairments years after HCT.^{38,39} The major risk factors for compromised QOL are older age and advanced disease at transplantation, chronic GVHD

TABLE 109.6 Screening Guidelines for Common Cancers After Hematopoietic Cell Transplantation

Site	Screening Recommendations
Breast	Mammogram annually starting at age 40 years; in women who have received ≥ 20 Gy to the chest region begin at age 25 years or 8 years after radiation, whichever is later
Cervix	Pap smear every year (for regular Pap test) or every 2 years (for liquid-based Pap test); may screen every 2–3 years after 30 years of age if patient has three consecutive normal tests
Colorectal	Beginning at age 50 years, fecal occult blood annually and/or flexible sigmoidoscopy every 5 years, or double contrast barium enema every 5 years, or colonoscopy every 10 years; certain high-risk groups (e.g., patients with inflammatory bowel disease) may need earlier initiation and more frequent screening
Lung	Yearly pulmonary exam with imaging as appropriate
Oral	Yearly oral cavity exam
Thyroid	Yearly thyroid exam
Skin	Yearly skin exam

Pap, Papanicolaou.

and presence of medical late effects. Although chronic GVHD is a strong predictor of poor QOL, the overall health and functional status improves with resolution of GVHD and eventually reaches a level comparable with that seen in patients with no history of chronic GVHD. Gender specific differences in QOL have also been observed with females more likely to report impairments in psychologic and sexual domains. Cognitive deficits, particularly involving executive function, memory and motor skills, have been reported in 30% to 60% of HCT survivors. The risk of developing these neuropsychological sequelae is increased in patients receiving transplantation at an older age, although a recent prospective study did not identify any association of cognitive deficit with intensity of conditioning, cyclosporine, length of inpatient stay, or the development of GVHD.⁴⁰

GRAFT-VERSUS-HOST DISEASE

GVHD is a clinicopathologic syndrome initiated by T cell–mediated alloreactivity that commonly occurs as a complication of allogeneic HCT and leads to significant morbidity and mortality (also see [Chapter 108](#)). It is usually classified as acute GVHD or chronic GVHD. Acute GVHD may be further characterized as classic acute GVHD (onset ≤ 100 days) and persistent, recurrent or late-onset acute GVHD (onset >100 days). In the absence of clinical features characteristic of acute GVHD, chronic GVHD is called classic chronic GVHD. When features of both acute and chronic GVHD appear together, it is classified as overlap syndrome, based upon a consensus conference proposed definition. Recent revisions lend lesser support for maintaining this overlap syndrome as an independent category.⁴¹

Current understanding of the pathogenesis of GVHD suggests that alloreactive donor T-lymphocytes recognize histocompatibility antigens on host cells and initiate secondary inflammatory injury, leading to the clinical symptoms of GVHD.⁴² This alloreactive response can be initiated or accelerated by conditioning regimen-induced tissue injury with release of proinflammatory cytokines, primarily IL-1 and TNF- α . GVHD is more frequent and more severe in recipients of partially matched transplants, suggesting that major histocompatibility complex encoded molecules may be the prime antigenic targets initiating the alloreactive T-cell response. Minor histocompatibility antigens also play an important role in its pathogenesis, especially in HLA-identical sibling donor grafts. Activated donor-derived T-cells produce IL-2 and interferon- γ , expand and

differentiate into effector cells and recruit mononuclear phagocytes and neutrophils and possibly NK cells which ultimately yield host tissue destruction, primarily through apoptosis. T-cell depletion of the graft reduces the risk of acute and chronic GVHD, albeit at the cost of increasing risks of disease relapse caused by blunting of the graft-versus-tumor response. Alternative mechanisms may also be involved in the pathogenesis of chronic GVHD including autoreactivity, loss of self-tolerance and B-cell dysregulation.⁴²

Acute Graft-Versus-Host Disease

Risk Factors and Clinical Features

Up to 50% of patients receiving HLA-identical sibling-donor and up to 90% of patients receiving URD HCT develop acute GVHD. Donor-recipient HLA disparity is the most important risk factor for acute GVHD. Additional risk factors include increasing recipient and donor age, use of alloimmunized donors such as parous women, and HCT from unrelated instead of sibling donors. Among recipients of UCB, acute GVHD occurs in 20% to 60% of patients; incidence of acute GVHD, though of only moderate severity, may be higher among recipients of double UCB transplantation.⁴³

Skin, liver, and gastrointestinal tract are the most common sites of GVHD. Acute GVHD of the skin is characterized by a maculopapular rash that, when severe, can lead to bullae or even resemble toxic epidermal necrolysis. Hepatic involvement manifests as cholestatic hepatitis with marked elevation of serum bilirubin and alkaline phosphatase, but usually only mild transaminase alterations. In the intestine, upper gastrointestinal tract GVHD can produce nausea, vomiting and anorexia, whereas small bowel and colon GVHD produces large volume secretory diarrhea. The diagnosis is clinical but frequently requires histologic confirmation to distinguish it from other frequent toxicities in the early posttransplantation period (e.g., hypersensitivity drug rash, drug-induced cholestasis, SOS, or infectious enteritis). The histologic hallmark of acute GVHD is apoptosis of the proliferative and regenerative cell layer of the epidermis, intestinal or biliary epithelium.

Acute GVHD is graded according to organs involved (skin, liver or gastrointestinal tract) and the extent (stage) of each organ involvement. Mild to moderate (grade I or II) GVHD is characterized by limited organ involvement and carries an excellent prognosis. Severe (grade III or IV) GVHD has extensive multiorgan involvement with significant morbidity and poor survival, commonly evolves to chronic GVHD and is associated with an increased risk of secondary opportunistic infections.

Prophylaxis of Graft-Versus-Host Disease

The most effective techniques for GVHD prevention have involved ex vivo depletion of donor T-lymphocytes, most often coupling immunologic recognition (monoclonal anti-T-cell antibodies) with depletion techniques (immunomagnetic beads, complement cytotoxicity or toxin immunoconjugates). Immunomagnetic selection of CD34+ cells from the graft (negatively selecting out T cells) has been used more widely in recent years.⁴⁴ Although vigorous T-cell depletion prevents acute GVHD, it also may increase the risks of graft failure and neoplastic relapse after transplantation.

Pharmacologic immunosuppression administered in the first several months after transplantation can prevent or blunt the initiating T-cell recognition and proliferative response that triggers GVHD and can allow development of immune system tolerance and complete lymphohematopoietic chimerism. Methotrexate, corticosteroids, ATG, cyclosporine, tacrolimus, MMF and sirolimus have been used for prophylaxis of GVHD and have successfully reduced both the frequency and the severity of clinical GVHD.⁴⁵ Despite the potential role of inflammatory cytokines in initiation and amplification of GVHD, clinical blockade of IL-1, IL-2, or TNF- α has not been effective in GVHD prophylaxis. Current therapies being tested in

addition to the backbone of calcineurin inhibitors in multicenter trials include posttransplant cyclophosphamide (to lyse proliferating alloreactive donor T cells), bortezomib, and maraviroc (inhibits lymphocyte chemotaxis, but not function).

Treatment of Acute Graft-Versus-Host Disease

Therapy for acute GVHD requires both immunosuppression to blunt the T-cell–induced tissue injury and appropriate supportive care. Corticosteroids are the mainstay of initial therapy for acute GVHD. GVHD involving limited areas of the skin can be treated with topical corticosteroids alone. Oral beclomethasone can be used to treat early stage GVHD of the upper gastrointestinal tract. Corticosteroids (2 mg/kg per day prednisone) are initial therapy for more advanced GVHD and yield response rates of approximately 50%. No regimen has shown a consistent increase in response rates or improvement in survival compared with corticosteroids alone. In a recent large randomized phase II trial comparing corticosteroids with MMF, pentostatin, etanercept or denileukin diftitox, efficacy and toxicity data suggested the combination of MMF and corticosteroids to be most promising.⁴⁶ This combination was not superior to corticosteroids alone in the follow-up randomized phase III trial, however.⁴⁷ Other investigational therapies include inhibitors of lymphocyte homing to intestinal tissues and infusion of mesenchymal stem cells. Prognosis is poor for patients with steroid-resistant disease, which is GVHD that does not respond to initial therapy with corticosteroids. Up to 10% to 40% of patients will respond to salvage therapy with ATG or other drugs such as sirolimus, tacrolimus, MMF, pentostatin or cyclosporine, either as single agents or in combination. Monoclonal antibodies and immunotoxins directed against T-cells or inflammatory cytokines have been investigated, although their effectiveness has not been demonstrated outside of small case series. Specific agents with reported activity in steroid-refractory acute GVHD include pentostatin, etanercept and infliximab (TNF- α receptor blockers), dacluzimab and denileukin diftitox (IL-2 receptor inhibitors), and visilizumab (anti-CD3 antibody). Extracorporeal photochemotherapy has also been reported to have some efficacy in steroid-refractory acute GVHD. In addition to effective immunosuppression, successful management of acute GVHD involves attention to supportive care, particularly skin care, nutrition and limitation of polypharmacy-associated drug interactions. Infections are a leading cause of death in patients with GVHD and attention should be paid to infection surveillance and prophylaxis.

Chronic Graft-Versus-Host Disease

Risk Factors and Clinical Features

Chronic GVHD is a complex syndrome in recipients of allogeneic HCT that occurs later, typically between 3–7 months posttransplant, although it can also begin before 3 months and even beyond 2 years. Its incidence ranges from 30% to 50% in HLA-matched sibling donor transplants to 50% to 70% in HLA-matched URD transplants and it is the leading cause of nonrelapse late mortality in allogeneic HCT survivors. Recipients of UCB grafts have lower risks compared with matched adult URD HCT and comparable or even lower than matched related donor HCT recipients. Chronic GVHD occurs most frequently in patients with preceding acute GVHD, but can also manifest de novo without any preceding acute GVHD. The distinction between classic chronic GVHD and overlap syndrome requires attention to clinical symptoms and signs which are characteristic and thus diagnostic of chronic GVHD.

Acute GVHD is the most important risk factor for development of subsequent chronic GVHD. Use of mismatched or URDs and transplantation using peripheral blood derived hematopoietic stem cells instead of bone marrow also increases its risk. Other reported risk factors for chronic GVHD include older recipient age, use of a female donor, CMV seropositivity, high graft CD34+ cell count, and

TABLE 109.7 Common Clinical Manifestations of Chronic Graft-Versus-Host Disease

Organ System	Clinical Manifestations
Cutaneous	Poikiloderma, lichen planus, dermal sclerosis, morphea-like features, hypopigmentation or hyperpigmentation, ichthyosis, nail dystrophy, onycholysis
Ocular	Keratoconjunctivitis sicca, conjunctivitis, corneal ulcerations
Oral	Lichen planus, hyperkeratotic plaques, xerostomia, mucosal atrophy, ulcers, restriction of mouth opening from sclerosis
Pulmonary	Bronchiolitis obliterans, bronchiolitis obliterans-organizing pneumonia
Gastrointestinal	Esophageal web and strictures, malabsorption syndrome, exocrine pancreatic insufficiency
Hepatic	Cholestasis
Genitourinary	Vaginal stenosis or scarring, lichen planus
Musculoskeletal	Fasciitis, joint contractures from sclerosis, myositis or polymyositis, arthritis
Hematopoietic	Thrombocytopenia, eosinophilia, lymphopenia, hemolytic anemia, hypogammaglobulinemia

treatment with donor lymphocyte infusion. Similar to acute GVHD, in vitro or in vivo T-cell depletion of the graft can reduce the incidence of chronic GVHD.

Chronic GVHD can affect any organ system; however, certain pathognomonic clinical signs and symptoms have to be present to establish the diagnosis (Table 109.7).⁴⁸ Other clinical manifestations, though not diagnostic of chronic GVHD, can be characteristic, though may be seen in acute GVHD as well. Additional investigations including biopsies might be needed to verify the diagnosis and to rule out other etiologies, such as infections, drug effects and malignancies. The skin, mouth, eyes, and liver are the most commonly involved sites of chronic GVHD. The cutaneous manifestations resemble autoimmune disease and can include poikiloderma, lichen planus-like eruptions or scleroderma (sclerosis). An inflammatory dermatitis can progress to severe dermal and periarticular fibrosis with loss of skin appendages (hair and sweat glands) as well as significant skin tightness, fasciitis and loss of joint flexibility. Additional manifestations include dry eyes and dry mouth, which can resemble Sjögren syndrome clinically and histologically; enteritis with anorexia, early satiety, malabsorption, weight loss and failure to thrive, or esophageal dysmotility or stricture; and cholestatic (or sometimes hepatic) jaundice. Pulmonary involvement in the form of bronchiolitis obliterans is an uncommon manifestation, but can be particularly debilitating and dangerous. In addition, the profound immune dysfunction associated with chronic GVHD because of hypogammaglobulinemia, impaired cellular immunity and functional asplenia, greatly increases the risk of secondary infections from bacteria, viruses and fungi. After the onset of chronic GVHD, 25% to 40% of patients die within 2 years, often of infections.

Chronic GVHD can be classified as mild, moderate, or severe depending on the number of organs involved and the degree of individual organ involvement. In general, factors associated with an adverse prognosis include thrombocytopenia, progressive onset from acute GVHD, poor performance status, lack of response to initial therapy and extensive skin or lung involvement.

Treatment of Chronic Graft-Versus-Host Disease

Although acute GVHD is one of the strongest predictors for chronic GVHD, strategies to limit acute GVHD such as prolonging or

intensifying initial immunosuppression have not been consistently effective in preventing subsequent chronic GVHD. As with acute GVHD, the specific immunosuppressive therapy for chronic GVHD is most often corticosteroids, usually in combination with cyclosporine. The ongoing and long lasting nature of the syndrome demands that reduced doses and, if possible, alternate day steroid therapy be used to minimize chronic complications of prolonged corticosteroid therapy. Typical corticosteroid regimens start with daily prednisone 1 mg/kg per day and responding patients are tapered down to 0.5–1 mg/kg every other day and continued on this dose for 6–9 months beyond any active GVHD symptoms, followed by a slow withdrawal of immunosuppression. Longer therapy may be required for some patients, and early withdrawal of therapy has been frequently accompanied by flares of chronic GVHD. Salvage therapies including high-dose corticosteroids, sirolimus, tacrolimus, MMF, thalidomide, azathioprine, and hydroxychloroquine have been tried with limited response rates. Newer approaches currently being investigated as potential therapies for chronic GVHD include modulation of T-cell function, B-cell depletion, induction of immune tolerance and cytokine blockade. Small uncontrolled studies have reported the use of pentostatin, alemtuzumab and ATG to inhibit T-cell function and rituximab to eliminate B-cells with response rates of 30% to 50%. T-cell immunomodulation using extracorporeal photopheresis has been shown to have some activity, especially in sclerotic cutaneous chronic GVHD. Preliminary studies using daclizumab, etanercept, and infliximab for blockade of the cytokine-mediated inflammatory response have also shown short-term responses. The treatment of chronic GVHD demands particular attention to prophylaxis and aggressive therapy of secondary opportunistic infections. Most successful strategies for treating chronic GVHD incorporate long-term reduced-dose immunosuppressive therapy, aggressive antimicrobial prophylaxis and supportive care. Strategies favoring development of donor-derived regulatory T cells which may facilitate the development of immunologic tolerance including avoidance of calcineurin inhibitors (cyclosporine or tacrolimus) or photopheresis are being studied.
