

The background of the cover is a dark, reddish-brown color, featuring a microscopic view of numerous red blood cells. The cells are depicted with a textured, bumpy surface, giving them a three-dimensional appearance. They are scattered across the frame, with some appearing larger and more prominent than others, creating a sense of depth. A semi-transparent dark horizontal band runs across the middle of the cover, serving as a backdrop for the title and authors' names.

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

To the numerous authors who have toiled to create the chapters that constitute this book. Their energy and perseverance are emblematic of their continued commitment to the value of scholarship and education in medicine. The work of each of these authors enhances our knowledge of hematology, which ultimately leads to improved care for patients with blood disorders. To my wife, Nan, and my children, Michael, Judith, Daniel, and Margot, who continue to support my efforts and help me maintain a firm footing in life. To President Barack Obama who has created a country in which I am happy to live and who will always be my role model. To the members of my laboratory and clinical trials groups who make it a pleasure to come to work each day. This edition would not have happened without the continued support of the staff at Elsevier, especially Lucia Gunzel, who has made each edition significantly better and who provides the good cheer that allows us to complete this book. I would also like to acknowledge my colleagues at the Icahn School of Medicine at Mount Sinai School who continue to value the contribution that this book represents. Last, but not least, our loyal readers, who have made this book a success for more than 25 years and continue to value and use it in a manner that enhances their professional pursuits.

Ronald Hoffman, MD

To my wife, Peggy, for your support, inspiration, and partnership; to our children, Tim, Jenny, Julie, and Rob, for your understanding; to our grandchildren for delighting us during this phase of our lives; to my mentors, Art Parde, Arthur Nienhuis, Bernie Forget, and David Nathan, for your support and guidance; to Addy Donnelly and Amy Thorp, for your incredible skill, patience, and good humor throughout this project; and to the many patients and volunteers whose willingness to participate in clinical research made much of the knowledge conveyed by this book possible.

Edward J. Benz, Jr., MD

To my friends and family for their love and support; to my mentors, Eugene M. Berkman and Robert S. Schwartz, who have provided me with invaluable guidance; to my colleagues at the University of Pennsylvania and Harvard, who have helped me develop academic transfusion medicine programs; and to the trainees who make this endeavor enjoyable and worthwhile.

Leslie E. Silberstein, MD

To my family, friends, and all of my present and former colleagues and trainees for their support and encouragement; to all my mentors in hematology who have provided guidance, in particular, Michael Beard and Malcolm Brenner.

Helen E. Heslop, MD

To my wife, Julia, for her love and unwavering support: I would be lost without her; to my children, Daniel and Kyle, for their understanding and encouragement; to Gwen, for extending our family; to my colleagues for providing me with an environment for learning and growth; and to my trainees, for making this all worthwhile.

Jeffrey I. Weitz, MD

To my respected clinical colleagues with appreciation for trusting me with the diagnostic material from their patients; to my esteemed teachers, Jim Vardiman, Diana Variakojis, and from long ago, C. Robert Valeri, for your many lessons focused on things at both ends of the microscope; and to my awesome trainees; it is always a great pleasure to watch you grow to appreciate the serious, yet amazing, nature of our work.

John Anastasi, MD

I wish to express my appreciation to my family. I am grateful for the support, love, and inspiration from Nahla, Youssef, and Farah.

Mohamed E. Salama, MD

Psychosocial Aspects of Hematologic Disorders

Jason Gotlib, MD, MS

Professor of Medicine, Medicine/Hematology, Stanford University School of Medicine, Stanford, California

Eosinophilia, Eosinophil-Associated Diseases, Eosinophil Leukemias, and the Hypereosinophilic Syndromes
Mast Cells and Mastocytosis

Stephen Gottschalk, MD

Professor of Pediatrics, Baylor College of Medicine, Center for Cell and Gene Therapy, Baylor College of Medicine, Texas Children's Hospital, Houston Methodist Hospital, Houston, Texas

Infectious Mononucleosis and Other Epstein-Barr Virus-Associated Diseases

Marianne A. Grant, PhD

Assistant Professor of Medicine, Department of Medicine, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts

The Blood Vessel Wall

Timothy A. Graubert, MD

Director, Hematologic Malignancies, Massachusetts General Hospital Cancer Center; Professor of Medicine, Harvard Medical School, Boston, Massachusetts

Pathobiology of Acute Myeloid Leukemia

Xylina T. Gregg, MD

Hematology and Oncology, Practicing Physician, Utah Cancer Specialists, Salt Lake City, Utah

Red Blood Cell Enzymopathies

John G. Gribben, MD, DSc, FMedSci

Professor of Medical Oncology, Barts Cancer Institute, Queen Mary University of London, London, United Kingdom

Clinical Manifestations, Staging, and Treatment of Follicular Lymphoma

Dawn M. Gross, MD, PhD, FAAHPM

Division of Palliative Medicine, University of California, San Francisco, San Francisco, California

Psychosocial Aspects of Hematologic Disorders

Tanja A. Gruber, MD, PhD

Associate Member of Oncology, St. Jude Children's Research Hospital, Memphis, Tennessee

Acute Myeloid Leukemia in Children

Joan Guitart, MD

Associate Professor, Department of Dermatology, Northwestern University Medical School; Northwestern Memorial Hospital, Chicago, Illinois

T-Cell Lymphomas

Sandeep Gurbuxani, MBBS, PhD

Associate Professor, Department of Pathology, The University of Chicago, Chicago, Illinois

Acute Lymphoblastic Leukemia in Adults

Shiri Gur-Cohen, PhD

Immunology Postdoctoral Fellow, Weizmann Institute of Science, Rehovot, Israel

Interactions Between Hematopoietic Stem and Progenitor Cells and the Bone Marrow: Current Biology of Stem Cell Homing and Mobilization

Alejandro Gutierrez, MD

Assistant Professor of Pediatrics, Division of Hematology/Oncology, Boston Children's Hospital and Dana-Farber Cancer Institute, Harvard Medical School, Boston, Massachusetts

Pathobiology of Acute Lymphoblastic Leukemia

Mehdi Hamadani, MD

Associate Professor of Medicine, Division of Hematology and Oncology, CIBMTR and Medical College of Wisconsin, Milwaukee, Wisconsin

Indications and Outcomes of Allogeneic Hematopoietic Cell Transplantation for Hematologic Malignancies in Adults

Parameswaran N. Hari, MD, MS

Armand Quick William Stapp Professor of Hematology, Division of Hematology Oncology, Medical College of Wisconsin, Milwaukee, Wisconsin

Indications and Outcomes of Allogeneic Hematopoietic Cell Transplantation for Hematologic Malignancies in Adults

John H. Hartwig, MD

Professor, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts

Megakaryocyte and Platelet Structure

Suzanne R. Hayman, MD

Assistant Professor of Medicine, College of Medicine, Cons-Hematology, Mayo Clinic, Rochester, Minnesota

Immunoglobulin Light Chain Amyloidosis (Primary Amyloidosis)

Catherine P.M. Hayward, MD, PhD

Professor of Pathology and Molecular Medicine and Medicine, McMaster University; Hematologist, Division of Hematology and Thromboembolism, Hamilton Health Sciences and St. Joseph's Healthcare; Head, Coagulation, Hamilton Regional Laboratory Medicine Program, Hamilton, Ontario, Canada

Clinical Approach to the Patient with Bleeding or Bruising

Robert P. Hebbel, MD

Regents Professor and Clark Professor, Department of Medicine, Division of Hematology-Oncology-Transplantation, Director, Vascular Biology Center, University of Minnesota Medical School, Minneapolis, Minnesota

Pathobiology of Sickle Cell Disease

Helen E. Heslop, MD

Dan L. Duncan Chair, Professor of Medicine and Pediatrics, Director, Center for Cell and Gene Therapy, Baylor College of Medicine, Houston Methodist Hospital and Texas Children's Hospital, Houston, Texas

Overview and Historical Perspective of Current Cell-Based Therapies Overview and Choice of Donor of Hematopoietic Stem Cell Transplantation

Christopher Hillis, MD

Assistant Professor, Department of Oncology, McMaster University, Hamilton, Ontario, Canada

Hematologic Manifestations of Liver Disease

Christopher D. Hillyer, MD

Professor, Department of Medicine, Weill Cornell Medical College; President and Chief Executive Officer, New York Blood Center, New York, New York

Transfusion of Plasma and Plasma Derivatives: Plasma, Cryoprecipitate, Albumin, and Immunoglobulins

Karin Ho, MD

Assistant Professor of Surgery, Northwestern Medicine, Feinberg School of Medicine, Chicago, Illinois

Disorders of Coagulation in the Neonate

David M. Hockenbery, MD

Full Member, Clinical Research, Fred Hutchinson Cancer Research Center; Professor, Internal Medicine, University of Washington, Seattle, Washington

Cell Death

Ronald Hoffman, MD

Albert A. and Vera G. List Professor of Medicine, Tisch Cancer Institute, Hematology-Oncology Section, Department of Medicine, Icahn School of Medicine at Mount Sinai, New York, New York

Progress in the Classification of Hematopoietic and Lymphoid Neoplasms: Clinical Implications

The Polycythemia Essential Thrombocythemia Primary Myelofibrosis

Kerstin E. Hogg, MBChB, MD, MSc

Assistant Professor, Department of Medicine, McMaster University, Hamilton, Ontario, Canada

Hypercoagulable States

Shernan G. Holtan, MD

Assistant Professor, University of Minnesota, Minneapolis, Minnesota

Complications after Hematopoietic Cell Transplantation

Hans-Peter Horny, MD

Professor, Institute of Pathology, Ludwig Maximilian University of Munich, Munich, Germany

Mast Cells and Mastocytosis

Yen-Michael S. Hsu, MD, PhD

Assistant Professor, Pathology and Laboratory Medicine, Weill Cornell Medical College, New York, New York

Principles of Red Blood Cell Transfusion

Zachary R. Hunter, MA

Department of Pathology and Laboratory Medicine, Boston University School of Medicine, Boston, Massachusetts

Waldenström Macroglobulinemia/Lymphoplasmacytic Lymphoma

James A. Huntington, PhD

Professor, Department of Hematology, University of Cambridge, Cambridge, United Kingdom

Regulatory Mechanisms in Hemostasis

Camelia Iancu-Rubin, PhD

Associate Professor, Medicine, Hematology, and Medical Oncology, Icahn School of Medicine at Mount Sinai, New York, New York

Essential Thrombocythemia

Ali Iqbal, BHSc, MD

Internal Medicine, McMaster University, Hamilton, Ontario, Canada

Hematologic Manifestations of Renal Disease

David E. Isenman, PhD

Professor Emeritus, Departments of Biochemistry and Immunology, University of Toronto, Toronto, Ontario, Canada

Complement and Immunoglobulin Biology Leading to Clinical Translation

Sara J. Israels, MD

Professor, Department of Pediatrics and Child Health, Senior Scientist, Research Institute in Oncology and Hematology, University of Manitoba, Winnipeg, Manitoba, Canada

Molecular Basis of Platelet Function

Joseph E. Italiano, Jr., PhD

Associate Professor of Medicine, Brigham and Women's Hospital; Associate Professor, Harvard Medical School; Assistant Professor, Surgery-Vascular Biology Program, Children's Hospital Boston, Boston, Massachusetts

Megakaryocyte and Platelet Structure

Elaine S. Jaffe, MD

Head, Hematopathology Section, Laboratory of Pathology, National Cancer Institute, Bethesda, Maryland

The Pathologic Basis for the Classification of Non-Hodgkin and Hodgkin Lymphomas

Iqbal H. Jaffer, MBBS, PhD

Resident, Division of Cardiac Surgery, Thrombosis and Atherosclerosis Research Institute, McMaster University, Hamilton, Ontario, Canada

Antithrombotic Drugs

Hematologic Problems in the Surgical Patient: Bleeding and Thrombosis

Sundar Jagannath, MBBS

Professor of Medicine, The Tisch Cancer Institute, Icahn School of Medicine at Mount Sinai, New York, New York

Plasma Cell Neoplasms

Ulrich Jäger, MD

Professor, Department of Medicine I, Head, Division of Hematology and Hemostaseology, Medical University of Vienna, Comprehensive Cancer Center, Vienna, Austria

Autoimmune Hemolytic Anemia

Nitin Jain, MD

Assistant Professor, Department of Leukemia, The University of Texas MD Anderson Cancer Center, Houston, Texas

Acute Lymphoblastic Leukemia in Adults

Paula James, MD, FRCPC

Professor, Department of Medicine, Division of Hematology, Queen's University, Kingston, Ontario, Canada

Structure, Biology, and Genetics of Von Willebrand Factor

Sima Jeha, MD

Director, Leukemia/Lymphoma Developmental Therapeutics, Regional Director, East and Mediterranean Region, International Outreach Program, St. Jude Children's Research Hospital, Memphis, Tennessee

Clinical Manifestations and Treatment of Childhood Acute Lymphoblastic Leukemia

Michael B. Jordan, MD

Professor of Pediatrics, Immunology and Bone Marrow Transplantation and Immune Deficiency, Cincinnati Children's Hospital Medical Center/University of Cincinnati, Cincinnati, Ohio

Histiocytic Disorders

Cassandra D. Josephson, MD

Professor of Pathology and Pediatrics, Director of Clinical Research, Director of Transfusion Medicine Fellowship Program, Department of Pathology, Center for Transfusion and Cellular Therapies, Emory University School of Medicine; Medical Director, Pathology Department, Blood and Tissue Services, Children's Healthcare of Atlanta, Atlanta, Georgia

Pediatric Transfusion Medicine

Moonjung Jung, MD

Instructor in Clinical Investigation, The Rockefeller University, New York, New York

Neutrophilic Leukocytosis, Neutropenia, Monocytosis, and Monocytopenia

Leo Kager, MD

Associate Professor of Pediatrics, St. Anna Children's Hospital, Department of Pediatrics, Medical University Vienna, Children's Cancer Research Institute, Vienna, Austria

Pharmacogenomics and Hematologic Diseases

Taku Kambayashi, MD, PhD

Associate Professor, Division of Transfusion Medicine and Therapeutic Pathology, Department of Pathology and Laboratory Medicine, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, Pennsylvania

Tolerance and Autoimmunity

Jennifer A. Kanakry, MD

Clinical Head of the Experimental Transplantation and Immunology Branch, National Cancer Institute, National Institutes of Health, Bethesda, Maryland

Virus-Associated Lymphomas

Hagop M. Kantarjian, MD

Chairman, Department of Leukemia, The University of Texas MD Anderson Cancer Center, Houston, Texas

Clinical Manifestations and Treatment of Acute Myeloid Leukemia

Jason Kaplan, MD

Assistant Professor of Medicine (Hematology and Oncology), Northwestern University, Feinberg School of Medicine, Chicago, Illinois

T-Cell Lymphomas

Matthew S. Karafin, MD, MS

Associate Medical Director, BloodCenter of Wisconsin; Assistant Professor, Department of Pathology, Medical College of Wisconsin, Milwaukee, Wisconsin

Transfusion of Plasma and Plasma Derivatives: Plasma, Cryoprecipitate, Albumin, and Immunoglobulins

Aly Karsan, MD

Professor of Pathology and Laboratory Medicine, University of British Columbia; Hematopathologist/Senior Scientist, British Columbia Cancer Agency, Vancouver, British Columbia, Canada
The Blood Vessel Wall

Randal J. Kaufman, PhD

Director, Degenerative Diseases Research, Sanford-Burnham-Prebys Medical Discovery Institute, La Jolla, California
Protein Synthesis, Processing, and Trafficking

Richard M. Kaufman, MD

Medical Director, Adult Transfusion Service, Department of Pathology, Brigham and Women's Hospital; Associate Professor of Pathology, Harvard Medical School, Boston, Massachusetts
Clinical Considerations in Platelet Transfusion Therapy

Frank G. Keller, MD

Associate Professor of Pediatrics, Emory University School of Medicine, Atlanta, Georgia
Hematologic Manifestations of Childhood Illness

Kara M. Kelly, MD

Waldemar J. Kaminski Endowed Chair of Pediatrics, Pediatric Oncology, Roswell Park Cancer Institute, University at Buffalo School of Medicine and Biomedical Sciences, Buffalo, New York
Malignant Lymphomas in Childhood

Craig M. Kessler, MD

Professor of Medicine and Pathology, Department of Medicine, Director, Division of Coagulation, Georgetown University Medical Center, Washington, DC
Inhibitors in Hemophilias

Nigel S. Key, MB, ChB, FRCP

Harold R. Roberts Distinguished Professor, Medicine and Pathology and Laboratory Medicine, Chief, Section of Hematology, Division of Hematology/Oncology, Director, University of North Carolina Hemophilia and Thrombosis Center, Co-Director, Thrombosis and Hemostasis Program, McAllister Heart Institute, University of North Carolina, Chapel Hill, North Carolina
Hematologic Problems in the Surgical Patient: Bleeding and Thrombosis

Alla Keyzner, MD

Assistant Professor of Hematology/Oncology, Icahn School of Medicine at Mount Sinai, New York, New York
Primary Myelofibrosis

Alexander G. Khandoga, MD

Department of Cardiology, German Heart Center Munich, Munich, Germany
Chemokines and Hematopoietic Cell Trafficking

Arati Khanna-Gupta, MSc, PhD

VP, Research and Development (Oncology), MedGenome Labs Pvt. Ltd, Bangalore, India
Granulocytopoiesis and Monocytopoiesis

Eman Khatib-Massalha, MSc, PhD Student

Immunology, Weizmann Institute of Science, Rehovot, Israel
Interactions between Hematopoietic Stem and Progenitor Cells and the Bone Marrow: Current Biology of Stem Cell Homing and Mobilization

Harvey G. Klein, MD

Chief, Transfusion Medicine, National Institutes of Health, Bethesda, Maryland; Adjunct Professor, Departments of Medicine and Pathology, The Johns Hopkins School of Medicine, Baltimore, Maryland
Hemapheresis

Birgit Knoechel, MD, PhD

Assistant Professor of Pediatrics, Harvard Medical School; Department of Pediatric Oncology, Dana-Farber Cancer Institute, Broad Institute of MIT and Harvard, Boston, Massachusetts
Genomic Approaches to Hematology

Orit Kollet, PhD

Immunology, Weizmann Institute, Rehovot, Israel
Interactions Between Hematopoietic Stem and Progenitor Cells and the Bone Marrow: Current Biology of Stem Cell Homing and Mobilization

Barbara A. Konkle, MD

Associate Chief Scientific Officer, Bloodworks Northwest; Professor of Medicine, Hematology, University of Washington, Seattle, Washington
Inhibitors in Hemophilias

Dimitrios P. Kontoyiannis, MD

Frances King Black Endowed Professor, Infectious Diseases, Deputy Head, Division of Internal Medicine, The University of Texas MD Anderson Cancer Center, Houston, Texas
Clinical Approach to Infections in the Compromised Host

John Koreth, MBBS, DPhil

Associate Professor, Harvard Medical School, Department of Medical Oncology, Dana-Farber Cancer Institute, Boston, Massachusetts
Allogeneic Hematopoietic Stem Cell Transplantation for Acute Myeloid Leukemia and Myelodysplastic Syndrome in Adults

Gary A. Koretzky, MD, PhD

Francis C. Wood Professor of Medicine, Division of Rheumatology, Abramson Family Cancer Research Institute, University of Pennsylvania, Philadelphia, Pennsylvania
T-Cell Immunity

Dipak Kotecha, MD, PhD

Clinician Scientist in Cardiovascular Medicine, Institute of Cardiovascular Sciences, University of Alabama at Birmingham, Birmingham, Alabama; Adjunct Research Fellow, Monash Centre of Cardiovascular Research and Education, Monash University, Melbourne, Australia
Atrial Fibrillation

Marina Kremyanskaya, MD, PhD

Assistant Professor, The Tisch Cancer Institute, Icahn School of Medicine at Mount Sinai, New York, New York
The Polycythemias
Essential Thrombocythemia
Primary Myelofibrosis

Anju Kumari, PhD

Postdoctoral Fellow, Department of Immunology, Weizmann Institute of Science, Rehovot, Israel
Interactions Between Hematopoietic Stem and Progenitor Cells and the Bone Marrow: Current Biology of Stem Cell Homing and Mobilization

Timothy M. Kuzel, MD, FACP

Professor of Medicine, Chief, Division of Hematology, Department of Internal Medicine, Rush University Medical Center, Chicago, Illinois
T-Cell Lymphomas

Ralf Küppers, MD

Professor, Institute of Cell Biology (Cancer Research), University of Duisburg-Essen Medical School, Essen, Germany
Origin of Hodgkin Lymphoma

Martha Q. Lacy, MD

Professor of Medicine, Myeloma, Amyloidosis, Dysproteinemia Group, Mayo Clinic, Rochester, Minnesota
Immunoglobulin Light Chain Amyloidosis (Primary Amyloidosis)

Elana Ladas, PhD, RD

Assistant Professor of Nutrition, Columbia University, New York, New York

Integrative Therapies in Patients with Hematologic Diseases

Wendy Landier, PhD, CRNP

Associate Professor, Department of Pediatrics, Division of Pediatric Hematology/Oncology, Institute for Cancer Survivorship and Outcomes, School of Medicine, University of Alabama at Birmingham, Birmingham, Alabama

Late Complications of Hematologic Diseases and Their Therapies

Kfir Lapid, PhD

Postdoctoral Fellow, University of Texas Southwestern, Dallas, Texas

Interactions Between Hematopoietic Stem and Progenitor Cells and the Bone Marrow: Current Biology of Stem Cell Homing and Mobilization

Tsvee Lapidot, PhD

Professor, Incumbent of the Edith Aronoff Stein Professorial Chair in Stem Cell Research, Department of Immunology, Weizmann Institute of Science, Rehovot, Israel

Interactions Between Hematopoietic Stem and Progenitor Cells and the Bone Marrow: Current Biology of Stem Cell Homing and Mobilization

Peter J. Larson, BS, MD

Director, Global Clinical Strategy, Biological Products, Research Triangle Park, North Carolina

Transfusion Therapy for Coagulation Factor Deficiencies

Marcel Levi, MD, PhD

Professor of Medicine, University College London Hospitals, University College London, London, United Kingdom

Disseminated Intravascular Coagulation

Russell E. Lewis, PharmD

Associate Professor, Infectious Diseases, Department of Medical and Surgical Sciences, University of Bologna, Bologna, Italy

Clinical Approach to Infections in the Compromised Host

Howard A. Liebman, MA, MD

Professor of Medicine and Pathology, Department of Medicine, Hematology, Keck School of Medicine, University of Southern California, Los Angeles, California

Hematologic Manifestations of HIV/AIDS

David Lillicrap, MD, FRCPC

Professor of Pathology and Molecular Medicine, Queen's University, Kingston, Ontario, Canada

Hemophilia A and B

Wendy Lim, MD, MSc, FRCPC

Associate Professor of Medicine, McMaster University, Hamilton, Ontario, Canada

Venous Thromboembolism

Hematologic Manifestations of Liver Disease

Judith C. Lin, MD

Assistant Professor of Hematology-Oncology, Mount Sinai Hospital, New York, New York

Approach to Anemia in the Adult and Child

Robert Lindblad, MD, FACEP

Chief Medical Officer and Director of Safety and Regulatory Affairs, The EMMES Corporation, Rockville, Maryland

Investigational New Drug-Enabling Processes for Cell-Based Therapies

Gregory Y.H. Lip, MD, FRCP, FACC, FESC

Professor of Cardiovascular Medicine, Institute of Cardiovascular Sciences, University of Birmingham, Birmingham, United Kingdom

Atrial Fibrillation

Jane A. Little, MD

Associate Professor in Hematology/Oncology, Department of Medicine, Case Western Reserve School of Medicine, Cleveland, Ohio

Anemia of Chronic Diseases

Jens G. Lohr, MD, PhD

Assistant Professor of Medicine, Harvard Medical School; Department of Medical Oncology, Dana-Farber Cancer Institute; Department of Medicine, Brigham and Women's Hospital, Broad Institute of MIT and Harvard, Boston, Massachusetts

Genomic Approaches to Hematology

José A. López, MD

Chief Scientific Officer, Research Institute, Bloodworks Northwest; Professor of Medicine and Biochemistry, University of Washington, Seattle, Washington

Acquired Disorders of Platelet Function

Francis W. Luscinskas, PhD

Professor of Pathology, Brigham and Women's Hospital, Boston, Massachusetts

Cell Adhesion

Jaroslav P. Maciejewski, MD, PhD

Chairman and Professor of Medicine, Department of Translational Hematology and Oncology Research, Taussig Cancer Center, Cleveland Clinic, Cleveland, Ohio

Aplastic Anemia

Acquired Disorders of Red Cell, White Cell, and Platelet Production

Navneet S. Majhail, MD, MS

Director, Blood and Marrow Transplant Program, Cleveland Clinic; Professor, Cleveland Clinic Lerner College of Medicine, Cleveland, Ohio

Complications After Hematopoietic Cell Transplantation

Olivier Manches, PhD

Research Assistant, Division of Hematology and Oncology, Tisch Cancer Institute, Mount Sinai, New York, New York

Dendritic Cell Biology

Robert J. Mandle, PhD

President, Biosciences Research Associates, Inc., Cambridge, Massachusetts

Complement and Immunoglobulin Biology Leading to Clinical Translation

Kenneth G. Mann, PhD

Professor Emeritus, Biochemistry and Medicine, College of Medicine, University of Vermont, Burlington, Vermont; Chairman, Haematologic Technologies Inc., Essex Junction, Vermont

Molecular Basis of Blood Coagulation

Catherine S. Manno, MD

Pat and John Rosenwald Professor and Chair, Department of Pediatrics, New York University School of Medicine, New York, New York

Transfusion Therapy for Coagulation Factor Deficiencies

Andrea N. Marcogliese, MD

Associate Professor, Pathology & Immunology and Pediatrics, Section of Hematology Oncology, Baylor College of Medicine, Houston, Texas

Resources for the Hematologist: Interpretive Comments and Selected Reference Values for Neonatal, Pediatric, and Adult Populations

Guglielmo Mariani, MD

Faculty of Science and Technology, University of Westminster, London, United Kingdom

Inhibitors in Hemophilias

Francesco M. Marincola, MD

Chief Research Officer, Research Branch, Sidra Medical and Research Center; Professor of Medicine, Weill Cornell Medical College, Doha, Qatar

Human Leukocyte Antigen and Human Neutrophil Antigen Systems

John Mascarenhas, MD

Associate Professor of Medicine, The Tisch Cancer Institute, Icahn School of Medicine at Mount Sinai, New York, New York

The Polycythemias

Essential Thrombocythemia

Primary Myelofibrosis

Steffen Massberg, MD

Professor of Cardiology, German Heart Center Munich, Technical University of Munich, Munich, Germany

Chemokines and Hematopoietic Cell Trafficking

Rodger P. McEver, MD

Member and Chair, Cardiovascular Biology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, Oklahoma

Cell Adhesion

Emer McGrath, MB, PhD

Brigham and Women's Hospital, Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts

Stroke

Matthew S. McKinney, MD

Instructor in Medicine, Department of Medicine, Division of Hematologic Malignancies, Duke University School of Medicine, Durham, North Carolina

Origin of Non-Hodgkin Lymphoma

Rohtesh S. Mehta, MD, MPH, MS

Assistant Professor of Medicine, Stem Cell Transplantation and Cellular Therapy, The University of Texas MD Anderson Cancer Center, Houston, Texas

Unrelated Donor Cord Blood Transplantation for Hematologic Malignancies

William C. Mentzer, MD

Professor Emeritus, Pediatrics, University of California, San Francisco, San Francisco, California

Extrinsic Nonimmune Hemolytic Anemias

Giampaolo Merlini, MD

Director, Amyloidosis Research and Treatment Center, Foundation IRCCS Policlinico San Matteo, Department of Molecular Medicine, University of Pavia, Pavia, Italy

Waldenström Macroglobulinemia/Lymphoplasmacytic Lymphoma

Reid Merryman, MD

Clinical Fellow, Dana-Farber/Partners CancerCare Hematology/Oncology Fellowship Program, Boston, Massachusetts

Immune Checkpoint Blockade in Hematologic Malignancies

Marc Michel, MD

Department of Internal Medicine, National Referral Center for Adult Immune Cytopenias, Henri Mondor University Hospital, Assistance Publique Hôpitaux de Paris, Creteil, France

Autoimmune Hemolytic Anemia

Anna Rita Migliaccio, PhD

Professor, The Tisch Cancer Institute, Icahn School of Medicine at Mount Sinai, New York, New York; Professor of Biological and Neurological Sciences, Alma Mater University, Bologna, Italy

Biology of Erythropoiesis, Erythroid Differentiation, and Maturation

Jeffrey S. Miller, MD

Professor of Medicine, Division of Hematology, Oncology, and Transplantation, University of Minnesota, Minneapolis, Minnesota

Natural Killer Cell-Based Therapies

Martha P. Mims, MD, PhD

Professor and Chief, Section of Hematology Oncology, Internal Medicine, Baylor College of Medicine, Houston, Texas

Lymphocytosis, Lymphocytopenia, Hypergammaglobulinemia, and Hypogammaglobulinemia

Traci Heath Mondoro, PhD

Alternate Representative Branch Chief, NHLBI Translational Blood Science and Resources Branch, Division of Blood Diseases and Resources, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland

Investigational New Drug-Enabling Processes for Cell-Based Therapies

Paul Moorehead, MD

Section of Pediatric Hematology/Oncology, Janeway Children's Health and Rehabilitation Centre; Clinical Assistant Professor, Discipline of Pediatrics, Faculty of Medicine, Memorial University, St. John's, Newfoundland and Labrador, Canada

Hemophilia A and B

Luciana R. Muniz, MD

PhD Student, Icahn School of Medicine at Mount Sinai, Division of Hematology and Oncology, Tisch Cancer Institute, New York, New York

Dendritic Cell Biology

Nikhil C. Munshi, MD

Associate Director, Jerome Lipper Multiple Myeloma Center, Dana-Farber Cancer Institute; Physician, Hematology/Oncology and Medicine, Boston VA Healthcare System; Associate Professor of Medicine, Harvard Medical School, Boston, Massachusetts

Plasma Cell Neoplasms

Vesna Najfeld, PhD

Professor of Pathology and Medicine, Director, Tumor CytoGenomic Laboratory, Icahn School of Medicine at Mount Sinai, New York, New York

Conventional and Molecular Cytogenomic Basis of Hematologic Malignancies

The Polycythemias

Essential Thrombocythemia

Primary Myelofibrosis

Lalitha Nayak, MD

Assistant Professor in Hematology and Oncology Medicine, Case Western Reserve University School of Medicine, Cleveland, Ohio

Anemia of Chronic Diseases

Ishac Nazy, PhD

Associate Professor of Medicine, Michael G. DeGroote School of Medicine, McMaster University, Hamilton, Ontario, Canada

Diseases of Platelet Number: Immune Thrombocytopenia, Neonatal Alloimmune Thrombocytopenia, and Posttransfusion Purpura

Anne T. Neff, MD

Professor of Medicine, Cleveland Clinic Lerner College of Medicine; Staff Physician, Cleveland Clinic Foundation, Cleveland, Ohio

Rare Coagulation Factor Deficiencies

Paul M. Ness, MD

Director, Transfusion Medicine, The Johns Hopkins Hospital; Professor of Pathology and Medicine, The Johns Hopkins University School of Medicine, Baltimore, Maryland

Principles of Red Blood Cell Transfusion

Luigi D. Notarangelo, MD

Director, Research and Molecular Diagnosis Program on Primary Immunodeficiencies, Professor of Pediatrics and Pathology, Children's Hospital, Harvard Medical School, Boston, Massachusetts

Congenital Disorders of Lymphocyte Function

Sarah H. O'Brien, MD, MSc

Associate Professor of Medicine, The Ohio State University, Pediatric Hematology/Oncology, Pediatrics, Investigator, Center for Innovation in Pediatric Practice Research, Nationwide Children's Hospital, Columbus, Ohio

Hematologic Manifestations of Childhood Illness

Owen A. O'Connor, MD, PhD

Associate Professor of Medicine, Director, Lymphoid Development and Malignancy Program, Herbert Irving Comprehensive Cancer Center, Columbia University; Chief, Lymphoma Service, College of Physicians and Surgeons, Presbyterian Hospital, Columbia University Medical Center, New York, New York

T-Cell Lymphomas

Martin O'Donnell, MD, PhD

Associate Clinical Professor, Divisions of General Internal Medicine and Hematology and Thromboembolism, Department of Medicine, McMaster University, Hamilton, Ontario, Canada

Stroke

Amanda Olson, MD

Assistant Professor, Stem Cell Transplantation and Cellular Therapy, The University of Texas MD Anderson Cancer Center, Houston, Texas

Unrelated Donor Cord Blood Transplantation for Hematologic Malignancies

Stuart H. Orkin, MD

David G. Nathan Professor of Pediatrics, Dana-Farber/Boston Children's Cancer and Blood Disorders Center, Howard Hughes Medical Institute, Harvard Medical School, Boston, Massachusetts

Hematopoietic Stem Cell Biology

Menaka Pai, BSc, MSc, MD, FRCPC

Associate Professor of Medicine and Associate Member of Pathology and Molecular Medicine, McMaster University; Consultant Hematologist, Hamilton Regional Laboratory Medicine Program, Hamilton, Ontario, Canada

Laboratory Evaluation of Hemostatic and Thrombotic Disorders

Sung-Yun Pai, MD

Associate Professor of Pediatrics, Department of Medicine, Children's Hospital Boston; Department of Pediatric Oncology, Dana-Farber Cancer Institute, Boston, Massachusetts

Congenital Disorders of Lymphocyte Function

Michael Paidas, MD

Professor of Obstetrics, Gynecology, and Reproductive Sciences, Yale University, New Haven, Connecticut

Hematologic Changes in Pregnancy

Sandhya R. Panch, MD, MPH

Staff Clinician, Cell Therapy Section, Department of Transfusion Medicine, National Institutes of Health, Bethesda, Maryland

Hemapheresis

Reena L. Pande, MD, MSc

Associate Physician, Cardiovascular Division, Brigham and Women's Hospital, Boston, Massachusetts

Peripheral Artery Disease

Thalia Papayannopoulou, MD

Professor of Medicine, Division of Hematology, University of Washington, Seattle, Washington

Biology of Erythropoiesis, Erythroid Differentiation, and Maturation

Rahul Parikh, MD

Radiation Oncologist, Rutgers Cancer Institute of New Jersey, New Brunswick, New Jersey

Hodgkin Lymphoma: Clinical Manifestations, Staging, and Therapy

Effie W. Petersdorf, MD

Professor of Medicine, University of Washington; Member, Fred Hutchinson Cancer Research Center, Seattle, Washington

Unrelated Donor Hematopoietic Cell Transplantation

Shane E. Peterson, MD

Attending Physician, Emergency Medicine, Mount Sinai Health System, New York, New York

Pain Management and Antiemetic Therapy in Hematologic Disorders

Stefania Pittaluga, MD, PhD

Staff Clinician, Hematopathology Section, Laboratory of Pathology, Center for Cancer Research, National Cancer Institute, Bethesda, Maryland

The Pathologic Basis for the Classification of Non-Hodgkin and Hodgkin Lymphomas

Doris M. Ponce, MD

Assistant Professor of Medicine, Adult Bone Marrow Transplantation, Memorial Sloan-Kettering Cancer Center, New York, New York

Unrelated Donor Cord Blood Transplantation for Hematologic Malignancies

Laura Popolo, PhD

Professor, Department of Biosciences, University of Milan, Milan, Italy

Protein Synthesis, Processing, and Trafficking

Josef T. Prchal, MD

Professor, Division of Hematology and Hematologic Malignancies, Department of Internal Medicine, University of Utah, Salt Lake City, Utah

Red Blood Cell Enzymopathies

Ching-Hon Pui, MD

Member, Chair, Department of Oncology, Co-Leader, Hematological Malignancies Program; Fahad Nassar Al-Rashid Chair of Leukemia Research, American Cancer Society; Professor, St. Jude Children's Research Hospital, Memphis, Tennessee

Clinical Manifestations and Treatment of Childhood Acute Lymphoblastic Leukemia

Pere Puigserver, PhD

Professor of Cell Biology, Dana-Farber Cancer Institute; Associate Professor of Cell Biology, Harvard Medical School, Boston, Massachusetts

Signaling Transduction and Metabolomics

Janusz Rak, MD, PhD

Jack Cole Chair in Pediatric Hematology/Oncology, Professor, Department of Pediatrics, McGill University, The Research Institute of the McGill University Health Centre, Montreal Children's Hospital, Montreal, Quebec, Canada

Vascular Growth in Health and Disease

Carlos A. Ramos, MD

Associate Professor, Department of Medicine, Hematology-Oncology Section, Baylor College of Medicine; Center for Cell and Gene Therapy, Baylor College of Medicine, Houston Methodist Hospital and Texas Children's Hospital, Houston, Texas

Marginal Zone Lymphomas (Extranodal/MALT, Splenic, and Nodal)

Jacob H. Rand, MD

Professor, Department of Pathology and Laboratory Medicine, Weill Cornell Medical College, New York, New York

The Antiphospholipid Syndrome

Margaret L. Rand, PhD

Professor, Departments of Laboratory Medicine & Pathobiology, Biochemistry, and Paediatrics, University of Toronto; Senior Associate Scientist, Translation Medicine, Research Institute; Associate Scientific Staff, Division of Haematology/Oncology, The Hospital for Sick Children, Toronto, Ontario, Canada

Molecular Basis of Platelet Function

Dinesh S. Rao, MD, PhD

Assistant Professor of Pathology and Laboratory Medicine, David Geffen School of Medicine at University of California, Los Angeles, Los Angeles, California

Overview and Compartmentalization of the Immune System

Farhad Ravandi, MD

Professor of Medicine, Leukemia, The University of Texas MD Anderson Cancer Center, Houston, Texas

Hairy Cell Leukemia

David J. Rawlings, MD

Director, Center for Immunity and Immunotherapies, Seattle Children's Research Institute; Chief, Division of Immunology, Department of Pediatrics, University of Washington School of Medicine, Seattle, Washington

B-Cell Development

Pavan Reddy, MD

Associate Division Chief, Hematology and Oncology, Co-Director, Hematologic Malignancies and Bone Marrow Transplant Program, University of Michigan Cancer Center, Ann Arbor, Michigan

Graft-versus-Host Disease and Graft-versus-Leukemia Responses

Mark T. Reding, MD

Associate Professor of Medicine, Division of Hematology, Oncology, and Transplantation, Director, Center for Bleeding and Clotting Disorders, University of Minnesota Medical Center, Minneapolis, Minnesota

Hematologic Problems in the Surgical Patient: Bleeding and Thrombosis

Andreas Reiter, MD

Faculty of Medicine in Mannheim, Department of Hematology and Oncology, University of Heidelberg, Mannheim, Germany

Eosinophilia, Eosinophil-Associated Diseases, Eosinophil Leukemias, and the Hypereosinophilic Syndromes

Lawrence Rice, MD

Professor of Medicine, Weill Cornell Medical College; Chief of Hematology, Department of Medicine, Houston Methodist Hospital, Houston, Texas

Neutrophilic Leukocytosis, Neutropenia, Monocytosis, and Monocytopenia

Matthew J. Riese, MD, PhD

Assistant Professor, Division of Hematology/Oncology, Department of Medicine, Medical College of Wisconsin; Associate Investigator, Blood Research Institute, BloodCenter of Wisconsin, Milwaukee, Wisconsin

T-Cell Immunity

Arthur Kim Ritchey, MD

Professor of Pediatrics, Vice-Chair for International Affairs, Pediatrics, University of Pittsburgh School of Medicine, Pediatric Hematology/Oncology, Children's Hospital of Pittsburgh of UPMC, Pittsburgh, Pennsylvania

Hematologic Manifestations of Childhood Illness

David J. Roberts, MBChB, D Phil

Consultant Haematologist, National Health Service Blood and Transplant, John Radcliffe Hospital; Professor of Haematology, Nuffield Department of Clinical Laboratory Sciences, University of Oxford, Oxford, United Kingdom

Hematologic Aspects of Parasitic Diseases

Elizabeth Roman, MD

Assistant Professor of Pediatrics, New York University School of Medicine, New York, New York

Transfusion Therapy for Coagulation Factor Deficiencies

Cliona M. Rooney, PhD

Professor of Pediatrics, Section of Hematology-Oncology, Department of Molecular Virology and Microbiology, Department of Pathology and Immunology, Baylor College of Medicine, Houston, Texas

Infectious Mononucleosis and Other Epstein-Barr Virus-Associated Diseases

Steven T. Rosen, MD

Provost and Chief Scientific Officer, City of Hope Medical Center, Duarte, California

T-Cell Lymphomas

David S. Rosenthal, MD

Professor of Medicine, Emeritus, Harvard Medical School; Past Medical Director, Leonard P. Zakim Center for Integrative Therapies, Dana-Farber Cancer Institute, Boston, Massachusetts

Integrative Therapies in Patients with Hematologic Diseases

Marlies P. Rossmann, MD, PhD

Stem Cell Program and Division of Hematology/Oncology, Children's Hospital Boston, Howard Hughes Medical Institute and Harvard Medical School; Department of Medical Oncology and Department of Pediatric Oncology, Dana-Farber Cancer Institute, Harvard Medical School, Boston, Massachusetts; Department of Stem Cell and Regenerative Biology and Harvard Stem Cell Institute, Harvard University, Cambridge, Massachusetts

Hematopoietic Stem Cell Biology

Antal Rot, MD

Professor, Chair of Biomedical Sciences, The University of York, Heslington, York, United Kingdom

Chemokines and Hematopoietic Cell Trafficking

Scott D. Rowley, MD

Member, Adult Blood and Marrow Transplantation Program, John Theurer Cancer Center, Hackensack University Medical Center, Hackensack, New Jersey; Director, Bone Marrow and Stem Cell Transplant Program, Lombardi Comprehensive Cancer Center, MedStar Georgetown University Hospital, Washington, DC; Professor of Medicine, Georgetown University School of Medicine, Washington, DC

Practical Aspects of Hematologic Stem Cell Harvesting and Mobilization

PREFACE

This is the seventh edition of *Hematology: Basic Principles and Practice*. This textbook has, over the last 30 years, become a staple for many students of hematology. It is our intent that this seventh edition continue to fill this role. The goal of this venture has always been, and continues to be, the creation of a volume of information that summarizes the overall body of knowledge known as hematology. In this time of online publishing and rapid publication, as well as the availability of numerous search engines that provide algorithms to assist with patient care, the value of *Hematology: Basic Principles and Practice* to our readership is even greater than in the past. Currently, there is a trend to use content-lite vehicles that provide condensed forms of information to the hematology community. From our perspective, this bullet point–directed strategy of education dealing with complex science and medicine represents a serious misstep that ultimately diminishes the hematology community’s opportunity to achieve excellence in research and patient care. This edition provides a compilation of chapters that summarizes an in depth analysis of hematology. These chapters have been created by luminaries in their respective fields and have been critically evaluated by the editorial team. We all understand that the medical literature changes by the hour, but practice-changing advances are relatively few. These chapters provide a solid foundation with which the readership can assess the significance of the most recent advances in hematology. From these carefully crafted and edited chapters the readership can *rapidly* gain access to a comprehensive body of knowledge that will serve as a platform to better appreciate the rapidly evolving literature in hematology science and practice. Cryptic summaries of complex issues that underlie hematology cannot be critically evaluated with a series of bullet points. Medicine and science are more nuanced and require a commitment by the target audience to appreciate where a particular field is and where it is going. Of course, the use of this textbook requires an initial time commitment on the part of the reader that ultimately will lead to significant rewards. In the long run the examination of these chapters is an investment in your intellectual development and educational pursuits. To some, this approach might be considered “old school,” but we believe it really shows prudence and respect for this incredibly challenging field. It makes hematology challenging and exciting again. The editorial team for the sixth edition has remained intact and includes Drs. Ronald Hoffman, Edward Benz, Leslie Silberstein, Helen Heslop, Jeffrey Weitz, and John Anastasi. For this seventh edition, Dr. Mohammed Salama has joined our team. Dr. Salama is Professor of Pathology and Chief of

Hematopathology at the University of Utah School of Medicine. He has helped to improve the quality of the photomicrographs that play a prominent role in many of our chapters. Additionally, Dr. Salama has developed a virtual microscopy system that will allow the readers to better examine relevant histopathology of a number of blood disorders. We believe this system will be useful to our readership in order to better appreciate the critical aspects of hemato-pathology needed to practice modern hematology. Dr. Syed Abutalib has also joined our group and will serve as the editor responsible for monthly updates. Dr. Abutalib is a hematologist and medical oncologist at the Midwestern Regional Medical Center in Zion, Illinois. Syed is in clinical practice and a full-time clinician. He has an intense interest and extensive track record in medical education. Our editorial team felt that a full-time practitioner would be best suited to determine which updates would be of greatest importance to our readership. Several updates will be provided monthly to the readership, and these will be vetted by the other editors working with Dr. Abutalib. These efforts will provide a path by which we can continue to expand and improve the content provided within the text after the time of publication. With this mechanism in place we have become a book that can change and evolve over time. Please utilize these updates to better evaluate the the massive wave of new information that we all encounter.

After the completion of this seventh edition we still feel this book is a work in progress. We are still seeking and considering the best ways to provide timely information to our readership, and we remain humbled by the complexity of this task in this age of rapid communication. We will continue to modify this book and have enjoyed the challenges we have encountered in its preparation. Over the years, we have added additional members to our editorial team to create a book that we can be proud of and that we have certainty will be of use to our readership. We hope that this seventh edition meets our joint expectations and the growing needs of our readership.

	76	Origins of Non-Hodgkin Lymphomas	Follicular Lymphoma
	79	Clinical Manifestations and Treatment of Indolent Lymphomas: Marginal Zone Lymphomas (Extranodal/MALT, Splenic, and Nodal)	Splenic Marginal Zone Lymphoma
	81	Mantle Cell Lymphoma	Mantle Cell Lymphoma
	82	Diagnosis and Treatment of Diffuse Large B-Cell Lymphoma and Burkitt Lymphoma	Burkitt Lymphoma
	82	Diagnosis and Treatment of Diffuse Large B-Cell Lymphoma and Burkitt Lymphoma	T Cell Rich B Cell Lymphoma
	83	Virus-Related Lymphomas	Plasmablastic Lymphoma Oral Cavity, HIV+

The background of the page features a light blue illustration of a cell membrane at the top and bottom, composed of a phospholipid bilayer. In the center, a DNA double helix is depicted, with several clusters of small circles representing nucleosomes or other molecular structures. The overall design is clean and scientific.

PART
I

**MOLECULAR AND CELLULAR
BASIS OF HEMATOLOGY**

This page intentionally left blank

ANATOMY AND PHYSIOLOGY OF THE GENE

Andrew J. Wagner, Nancy Berliner, and Edward J. Benz, Jr.

Normal blood cells have limited life spans; they must be replenished in precise numbers by a continuously renewing population of progenitor cells. Homeostasis of the blood requires that proliferation of these cells be efficient yet strictly constrained. Many distinctive types of mature blood cells must arise from these progenitors by a controlled process of commitment to, and execution of, complex programs of differentiation. Thus, developing red blood cells must produce large quantities of hemoglobin but not the myeloperoxidase characteristic of granulocytes, the immunoglobulins characteristic of lymphocytes, or the fibrinogen receptors characteristic of platelets. Similarly, the maintenance of normal amounts of coagulant and anticoagulant proteins in the circulation requires exquisitely regulated production, destruction, and interaction of the components. Understanding the basic biologic principles underlying cell growth, differentiation, and protein biosynthesis requires a thorough knowledge of the structure and regulated expression of genes because the gene is now known to be the fundamental unit by which biologic information is stored, transmitted, and expressed in a regulated fashion.

Genes were originally characterized as mathematical units of inheritance. They are now known to consist of molecules of deoxyribonucleic acid (DNA). By virtue of their ability to store information in the form of nucleotide sequences, to transmit it by means of semiconservative replication to daughter cells during mitosis and meiosis, and to express it by directing the incorporation of amino acids into proteins, DNA molecules are the chemical transducers of genetic information flow. Efforts to understand the biochemical means by which this transduction is accomplished have given rise to the discipline of molecular genetics.

THE GENETIC VIEW OF THE BIOSPHERE: THE CENTRAL DOGMA OF MOLECULAR BIOLOGY

The fundamental premise of the molecular biologist is that the magnificent diversity encountered in nature is ultimately governed by genes. The capacity of genes to exert this control is in turn determined by relatively simple stereochemical rules, first appreciated by Watson and Crick in the 1950s. These rules constrain the types of interactions that can occur between two molecules of DNA or ribonucleic acid (RNA).

DNA and RNA are linear polymers consisting of four types of nucleotide subunits. Proteins are linear unbranched polymers consisting of 21 types of amino acid subunits. Each amino acid is distinguished from the others by the chemical nature of its side chain, the moiety not involved in forming the peptide bond links of the chain. The properties of cells, tissues, and organisms depend largely on the aggregate structures and properties of their proteins. The central dogma of molecular biology states that genes control these properties by controlling the structures of proteins, the timing and amount of their production, and the coordination of their synthesis with that of other proteins. The information needed to achieve these ends is transmitted by a class of nucleic acid molecules called RNA. Genetic information thus flows in the direction DNA $\rightarrow$ RNA $\rightarrow$ protein. This central dogma provides, in principle, a universal approach for investigating the biologic properties and behavior of any given cell, tissue, or organism by study of the controlling genes. Methods permitting direct manipulation of DNA sequences should then be

universally applicable to the study of all living entities. Indeed, the power of the molecular genetic approach lies in the universality of its utility.

One exception to the central dogma of molecular biology that is especially relevant to hematologists is the storage of genetic information in RNA molecules in certain viruses, notably the retroviruses associated with T-cell leukemia and lymphoma, and the human immunodeficiency virus. When retroviruses enter the cell, the RNA genome is copied into a DNA replica by an enzyme called *reverse transcriptase*. This DNA representation of the viral genome is then expressed according to the rules of the central dogma. Retroviruses thus represent a variation on the theme rather than a true exception to or violation of the rules.

ANATOMY AND PHYSIOLOGY OF GENES

DNA Structure

DNA molecules are extremely long, unbranched polymers of nucleotide subunits. Each nucleotide contains a sugar moiety called deoxyribose, a phosphate group attached to the 5' carbon position, and a purine or pyrimidine base attached to the 1' position (Fig. 1.1). The linkages in the chain are formed by phosphodiester bonds between the 5' position of each sugar residue and the 3' position of the adjacent residue in the chain (see Fig. 1.1). The sugar-phosphate links form the backbone of the polymer, from which the purine or pyrimidine bases project perpendicularly.

The haploid human genome consists of 23 long, double-stranded DNA molecules tightly complexed with histones and other nuclear proteins to form compact linear structures called *chromosomes*. The genome contains 3 billion nucleotides; each chromosome is thus 50 to 200 million bases in length. The individual genes are aligned along each chromosome. The human genome contains about 30,000 genes. Blood cells, similar to most somatic cells, are diploid. That is, each chromosome is present in two copies, so there are 46 chromosomes consisting of approximately 6 billion base pairs (bp) of DNA.

The four nucleotide bases in DNA are the purines (adenosine and guanosine) and the pyrimidines (thymine and cytosine). The basic chemical configuration of the other nucleic acid found in cells, RNA, is quite similar, except that the sugar is ribose (having a hydroxyl group attached to the 2' carbon rather than the hydrogen found in deoxyribose) and the pyrimidine base uracil is used in place of thymine. The bases are commonly referred to by a shorthand notation: the letters A, C, T, G, and U are used to refer to adenosine, cytosine, thymine, guanosine, and uracil, respectively.

The ends of DNA and RNA strands are chemically distinct because of the 3' $\rightarrow$ 5' phosphodiester bond linkage that ties adjacent bases together (see Fig. 1.1). One end of the strand (the 3' end) has an unlinked (free at the 3' carbon) sugar position and the other (the 5' end) has a free 5' position. There is thus a polarity to the sequence of bases in a DNA strand: the same sequence of bases read in a 3' $\rightarrow$ 5' direction carries a different meaning than if read in a 5' $\rightarrow$ 3' direction. Cellular enzymes can thus distinguish one end of a nucleic acid from the other; most enzymes that "read" the DNA sequence tend to do so only in one direction (3' $\rightarrow$ 5' or 5' $\rightarrow$ 3' but not

Fig. 1.1 STRUCTURE, BASE PAIRING, POLARITY, AND TEMPLATE PROPERTIES OF DNA. (A) Structures of the four nitrogenous bases projecting from sugar phosphate backbones. The hydrogen bonds between them form base pairs holding complementary strands of DNA together. Note that whereas A–T and T–A base pairs have only two hydrogen bonds, C–G and G–C pairs have three. (B) The double helical structure of DNA results from base pairing of strands to form a double-stranded molecule with the backbones on the outside and the hydrogen-bonded bases stacked in the middle. Also shown schematically is the separation (unwinding) of a region of the helix by mRNA polymerase, which is shown using one of the strands as a template for the synthesis of an mRNA precursor molecule. Note that new bases added to the growing RNA strand obey the rules of Watson–Crick base pairing (see text). Uracil (U) in RNA replaces T in DNA and, like T, forms base pairs with A. (C) Diagram of the antiparallel nature of the strands, based on the stereochemical $3' \rightarrow 5'$ polarity of the strands. The chemical differences between reading along the backbone in the $5' \rightarrow 3'$ and $3' \rightarrow 5'$ directions can be appreciated by reference to (A). A, Adenosine; C, cytosine; G, guanosine; T, thymine; U, uracil.

both). Most nucleic acid–synthesizing enzymes, for instance, add new bases to the strand in a $5' \rightarrow 3'$ direction.

The ability of DNA molecules to store information resides in the sequence of nucleotide bases arrayed along the polymer chain. Under the physiologic conditions in living cells, DNA is thermodynamically most stable when two strands coil around each other to form a double-stranded helix. The strands are aligned in an “antiparallel” direction, having opposite $3' \rightarrow 5'$ polarity (see Fig. 1.1). The DNA strands are held together by hydrogen bonds between the bases on one strand and the bases on the opposite (complementary) strand. The stereochemistry of these interactions allows bonds to form between the two strands only when adenine on one strand pairs with

thymine at the same position of the opposite strand, or guanine with cytosine—the Watson–Crick rules of base pairing. Two strands joined together in compliance with these rules are said to have “complementary” base sequences.

These thermodynamic rules imply that the sequence of bases along one DNA strand immediately dictates the sequence of bases that must be present along the complementary strand in the double helix. For example, whenever an A occurs along one strand, a T must be present at that exact position on the opposite strand; a G must always be paired with a C, a T with an A, and a C with a G. In RNA–RNA or RNA–DNA double-stranded molecules, U–A base pairs replace T–A pairs.

Fig. 1.2 SEMICONSERVATIVE REPLICATION OF DNA. (A) The process by which the DNA molecule on the left is replicated into two daughter molecules, as occurs during cell division. Replication occurs by separation of the parent molecule into the single-stranded form at one end, reading of each of the daughter strands in the 3' → 5' direction by DNA polymerase, and addition of new bases to growing daughter strands in the 5' → 3' direction. (B) The replicated portions of the daughter molecules are identical to each other (red). Each carries one of the two strands of the parent molecule, accounting for the term *semiconservative replication*. Note the presence of the replication fork, the point at which the parent DNA is being unwound. (C) The antiparallel nature of the DNA strands demands that replication proceed toward the fork in one direction and away from the fork in the other (red). This means that replication is actually accomplished by reading of short stretches of DNA followed by ligation of the short daughter strand regions to form an intact daughter strand.

STORAGE AND TRANSMISSION OF GENETIC INFORMATION

The rules of Watson–Crick base pairing apply to DNA–RNA, RNA–RNA, and DNA–DNA double-stranded molecules. Enzymes that replicate or polymerize DNA and RNA molecules obey the base-pairing rules. By using an existing strand of DNA or RNA as the template, a new (daughter) strand is copied (transcribed) by reading processively along the base sequence of the template strand, adding to the growing strand at each position only that base that is complementary to the corresponding base in the template according to the Watson–Crick rules. Thus, a DNA strand having the base sequence 5'-GCTATG-3' could be copied by DNA polymerase only into a daughter strand having the sequence 3'-CGATAC-5'. Note that the sequence of the template strand provides all the information needed to predict the nucleotide sequence of the complementary daughter strand. Genetic information is thus stored in the form of base-paired nucleotide sequences.

If a double-stranded DNA molecule is separated into its two component strands and each strand is then used as a template to synthesize a new daughter strand, the product will be two double-stranded daughter DNA molecules, each identical to the original parent molecule. This semiconservative replication process is exactly what occurs during mitosis and meiosis as cell division proceeds (Fig. 1.2). The rules of Watson–Crick base pairing thus provide for the

faithful transmission of exact copies of the cellular genome to subsequent generations.

EXPRESSION OF GENETIC INFORMATION THROUGH THE GENETIC CODE AND PROTEIN SYNTHESIS

The information stored in the DNA base sequence achieves its impact on the structure, function, and behavior of organisms by governing the structures, timing, and amounts of protein synthesized in the cells. The primary structure (i.e., the amino acid sequence) of each protein determines its three-dimensional conformation and therefore its properties (e.g., shape, enzymatic activity, ability to interact with other molecules, stability). In the aggregate, these proteins control cell structure and metabolism. The process by which DNA achieves its control of cells through protein synthesis is called *gene expression*.

An outline of the basic pathway of gene expression in eukaryotic cells is shown in Fig. 1.3. The DNA base sequence is first copied into an RNA molecule, called *premessenger RNA*, by messenger RNA (mRNA) polymerase. Premessenger RNA has a base sequence identical to the DNA coding strand. Genes in eukaryotic species consist of tandem arrays of sequences encoding mRNA (exons); these sequences alternate with sequences (introns) present in the initial mRNA transcript (premessenger RNA) but absent from the mature mRNA. The entire gene is transcribed into the large precursor, which is then

Fig. 1.3 SYNTHESIS OF mRNA AND PROTEIN—THE PATHWAY OF GENE EXPRESSION. The diagram of the DNA gene shows the alternating array of exons (red) and introns (shaded color) typical of most eukaryotic genes. Transcription of the mRNA precursor, addition of the 5'-CAP and 3'-poly (A) tail, splicing and excision of introns, transport to the cytoplasm through the nuclear pores, translation into the amino acid sequence of the apoprotein, and posttranslational processing of the protein are described in the text. Translation proceeds from the initiator methionine codon near the 5' end of the mRNA, with incorporation of the amino terminal end of the protein. As the mRNA is read in a 5' → 3' direction, the nascent polypeptide is assembled in an amino → carboxyl terminal direction.

further processed (spliced) in the nucleus. The introns are excised from the final mature mRNA molecule, which is then exported to the cytoplasm to be decoded (translated) into the amino acid sequence of the protein by association with a biochemically complex group of ribonucleoprotein structures called *ribosomes*. Ribosomes contain two subunits: the 60S subunit contains a single, large (28S) ribosomal RNA molecule complexed with multiple proteins, and the RNA

component of the 40S subunit is a smaller (18S) ribosomal RNA molecule.

Ribosomes read mRNA sequence in a ticker tape fashion three bases at a time, inserting the appropriate amino acid encoded by each three-base code word or codon into the appropriate position of the growing protein chain. This process is called *mRNA translation*. The glossary used by cells to know which amino acids are encoded by each

^aNote that most of the degeneracy in the code is in the third base position (e.g., lysine, AA [G or C]; asparagine, AA [C or U]; valine, GUN [where N is any base]).

^bAUG is also used as the chain-initiation codon when surrounded by the Kozak consensus sequence.

^cHydroxyproline, the 21st amino acid, is generated by posttranslational modification of proline. It is almost exclusively confined to collagen subunits.

^dThe codons that signal the end of translation, also called nonsense or termination codons, are described by their nicknames *amber* (UAG), *ochre* (UAA), and *opal* (UGA).

A, Adenosine; C, cytosine; G, guanosine; T, thymine; U, uracil.

DNA codon is called the *genetic code* (Table 1.1). Each amino acid is encoded by a sequence of three successive bases. Because there are four code letters (A, C, G, and U), and because sequences read in the 5' → 3' direction have a different biologic meaning than sequences read in the 3' → 5' direction, there are 4³, or 64, possible codons consisting of three bases.

There are 21 naturally occurring amino acids found in proteins. Thus more codons are available than amino acids to be encoded. As noted in Table 1.1, a consequence of this redundancy is that some amino acids are encoded by more than one codon. For example, six distinct codons can specify incorporation of arginine into a growing amino acid chain, four codons can specify valine, two can specify glutamic acid, and only one each methionine or tryptophan. In no case does a single codon encode more than one amino acid. Codons thus predict unambiguously the amino acid sequence they encode. However, one cannot easily read backward from the amino acid sequence to

decipher the *exact* encoding DNA sequence. These facts are summarized by saying that the code is degenerate but not ambiguous.

Some specialized codons serve as punctuation points during translation. The methionine codon (AUG), when surrounded by a consensus sequence (the Kozak box) near the beginning (5' end) of the mRNA, serves as the initiator codon signaling the first amino acid to be incorporated. All proteins thus begin with a methionine residue, but this is often removed later in the translational process. Three codons, UAG, UAA, and UGA, serve as translation terminators, signaling the end of translation.

The adaptor molecules mediating individual decoding events during mRNA translation are small (40 bases long) RNA molecules called *transfer RNAs* (tRNAs). When bound into a ribosome, each tRNA exposes a three-base segment within its sequence called the *anticodon*. These three bases attempt to pair with the three-base codon exposed on the mRNA. If the anticodon is complementary in sequence to the codon, a stable interaction among the mRNA, the ribosome, and the tRNA molecule results. Each tRNA also contains a separate region that is adapted for covalent binding to an amino acid. The enzymes that catalyze the binding of each amino acid are constrained in such a way that each tRNA species can bind only to a single amino acid. For example, tRNA molecules containing the anticodon 3'-AAA-5', which is complementary to a 5'-UUU-3' (phenylalanine) codon in mRNA, can only be bound to or charged with phenylalanine; tRNA containing the anticodon 3'-UAG-5' can only be charged with isoleucine, and so forth.

Transfer RNAs and their amino acyl tRNA synthetases provide for the coupling of nucleic acid information to protein information needed to convert the genetic code to an amino acid sequence. Ribosomes provide the structural matrix on which tRNA anticodons and mRNA codons become properly exposed and aligned in an orderly, linear, and sequential fashion. As each new codon is exposed, the appropriate charged tRNA species is bound. A peptide bond is then formed between the amino acid carried by this tRNA and the C-terminal residue on the existing nascent protein chain. The growing chain is transferred to the new tRNA in the process, so that it is held in place as the next tRNA is brought in. This cycle is repeated until completion of translation. The completed polypeptide chain is then transferred to other organelles for further processing (e.g., to the endoplasmic reticulum and the Golgi apparatus) or released into the cytosol for association of the newly completed chain with other subunits to form complex multimeric proteins (e.g., hemoglobin) and so forth, as discussed in Chapter 5.

mRNA METABOLISM

In eukaryotic cells, mRNA is initially synthesized in the nucleus (see Figs. 1.3 and 1.4). Before the initial transcript becomes suitable for translation in the cytoplasm, mRNA processing and transport occur by a complex series of events including excision of the portions of the mRNA corresponding to the introns of the gene (mRNA splicing), modification of the 5' and 3' ends of the mRNA to render them more stable and translatable, and transport to the cytoplasm. Moreover, the amount of any particular mRNA moiety in both prokaryotic and eukaryotic cells is governed not only by the composite rate of mRNA synthesis (transcription, processing, and transport) but also by its degradation by cytoplasmic ribonucleases (RNA degradation). Many mRNA species of special importance in hematology (e.g., mRNAs for growth factors and their receptors, proto-oncogene mRNAs, acute-phase reactants) are exquisitely regulated by control of their stability (half-life) in the cytoplasm.

Posttranscriptional mRNA metabolism is complex. Only a few relevant details are considered in this section.

mRNA Splicing

The initial transcript of eukaryotic genes contains several subregions (see Fig. 1.4). Most striking is the tandem alignment of exons and

Fig. 1.4 ANATOMY OF THE PRODUCTS OF THE STRUCTURAL GENE (mRNA PRECURSOR AND mRNA). This schematic shows the configuration of the critical anatomic elements of an mRNA precursor, which represents the primary copy of the structural portion of the gene. The sequences GU and AG indicate, respectively, the invariant dinucleotides present in the donor and acceptor sites at which introns are spliced out of the precursor. Not shown are the less stringently conserved consensus sequences that must precede and succeed each of these sites for a short distance.

Fig. 1.5 REGULATORY ELEMENTS FLANKING THE STRUCTURAL GENE. (*For more information refer to suggested readings from Jones B; Kumar A et al; Waddington S et al.)

introns. Precise excision of intron sequences and ligation of exons is critical for production of mature mRNA. This process is called mRNA splicing, and it occurs on complexes of small nuclear RNAs and proteins called snRNPs; the term *spliceosome* is also used to describe the intranuclear organelle that mediates mRNA splicing reactions. The biochemical mechanism for splicing is complex. A consensus sequence, which includes the dinucleotide GU, is recognized as the donor site at the 5' end of the intron (5' end refers to the polarity of the mRNA strand coding for protein); a second consensus sequence ending in the dinucleotide AG is recognized as the acceptor site, which marks the distal end of the intron (see Figs. 1.4 and 1.5). The spliceosome recognizes the donor and acceptor, and forms an intermediate lariat structure that provides for both excision of the intron and proper alignment of the cut ends of the two exons for ligation in precise register.

mRNA splicing has proved to be an important mechanism for greatly increasing the versatility and diversity of expression of a single gene. For example, some genes contain an array of more exons than are actually found in any mature mRNA species encoded by that gene. Several different mRNA and protein products can arise from a single gene by selective inclusion or exclusion of individual exons from the mature mRNA products. This phenomenon is called *alternative mRNA splicing*. It permits a single gene to code for multiple mRNA and protein products with related but distinct structures and

functions. The mechanisms by which individual exons are selected or rejected are complex and highly context-specific, varying among different cell types, differentiation stages, and physiologic states. For present purposes, it is sufficient to note that important physiologic changes in cells can be regulated by altering the patterns of mRNA splicing products arising from single genes.

Many inherited hematologic diseases arise from mutations that derange mRNA splicing. For example, some of the most common forms of the thalassemia syndromes and hemophilia (see Chapters 40 and 135) arise by mutations that alter normal splicing signals or create splicing signals where they normally do not exist (activation of cryptic splice sites). Conversely, mutations altering key protein factors that modulate alternative splicing pathways are known to contribute to the pathogenesis of bone marrow dyscrasias (see Chapters 58 and 60).

Modification of the Ends of the mRNA Molecule

Most eukaryotic mRNA species are polyadenylated at their 3' ends. mRNA precursors are initially synthesized as large molecules that extend farther downstream from the 3' end of the mature mRNA molecule. Polyadenylation results in the addition of stretches of 100 to 150 A residues at the 3' end. Such an addition is often called

the *poly-A tail* and is of variable length. Polyadenylation facilitates rapid early cleavage of the unwanted 3' sequences from the transcript and is also important for stability or transport of the mRNA out of the nucleus. Signals near the 3' extremity of the mature mRNA mark positions at which polyadenylation occurs. The consensus signal is AUAAA (see Fig. 1.4). Mutations in the poly-A signal sequence have been shown to cause thalassemia (see Chapter 40).

At the 5' end of the mRNA, a complex oligonucleotide having unusual phosphodiester bonds is added. This structure contains the nucleotide 7-methyl-guanosine and is called *CAP* (see Fig. 1.4). The 5'-CAP enhances both mRNA stability and the ability of the mRNA to interact with protein translation factors and ribosomes.

5' and 3' Untranslated Sequences

The 5' and 3' extremities of mRNA extend beyond the initiator and terminator codons that mark the beginning and the end of the sequences actually translated into proteins (see Figs. 1.4 and 1.5). These so-called 5' and 3' untranslated regions (5' UTRs and 3' UTRs) are involved in determining mRNA stability and the efficiency with which mRNA species can be translated. For example, if the 3' UTR of a very stable mRNA (e.g., globin mRNA) is swapped with the 3' UTR of a highly unstable mRNA (e.g., the *c-myc* gene), the *c-myc* mRNA becomes more stable. Conversely, attachment of the 3' UTR of *c-myc* to a globin molecule renders it unstable. Instability is often associated with repeated sequences rich in A and U in the 3' UTR (see Fig. 1.4). The UTRs in mRNAs coding for proteins involved in iron metabolism mediate altered mRNA stability or translatability by binding iron-laden proteins and thus govern iron storage and turnover (see Chapter 35).

Transport of mRNA From Nucleus to Cytoplasm: mRNP Particles

An additional potential step for regulation or disruption of mRNA metabolism occurs during the transport from nucleus to cytoplasm. mRNA transport is an active, energy-consuming process. Moreover, at least some mRNAs appear to enter the cytoplasm in the form of complexes bound to proteins (mRNPs). mRNPs may regulate stability of the mRNAs and their access to translational apparatus. Some evidence indicates that certain mRNPs are present in the cytoplasm but are not translated (masked message) until proper physiologic signals are received.

GENE REGULATION

Virtually all cells of an organism receive a complete copy of the DNA genome inherited at the time of conception. The panoply of distinct cell types and tissues found in any complex organism is possible only because different portions of the genome are selectively expressed or repressed in each cell type. Each cell must “know” which genes to express, how actively to express them, and when to express them. This biologic necessity has come to be known as *gene regulation* or *regulated gene expression*. Understanding gene regulation provides insight into how pluripotent stem cells determine that they will express the proper sets of genes in daughter progenitor cells that differentiate along each lineage. Major hematologic disorders (e.g., the leukemias and lymphomas), immunodeficiency states, and myeloproliferative syndromes result from derangements in the system of gene regulation. An understanding of the ways that genes are selected for expression thus remains one of the major frontiers of biology and medicine.

EPIGENETIC REGULATION OF GENE EXPRESSION

Most of the DNA in living cells is inactivated by formation of a nucleoprotein complex called *chromatin*. The histone and nonhistone

proteins in chromatin effectively sequester genes from enzymes needed for expression. The most tightly compacted chromatin regions are called *euchromatin*. Heterochromatin, less tightly packed, contains actively transcribed genes. Activation of a gene for expression (i.e., transcription) requires that it become less compacted and more accessible to the transcription apparatus. These processes involve both *cis*-acting and *trans*-acting factors. *Cis*-acting elements are regulatory DNA sequences within or flanking the genes. They are recognized by *trans*-acting factors, which are nuclear DNA-binding proteins needed for transcriptional regulation.

DNA sequence regions flanking genes are called *cis*-acting because they influence expression of nearby genes only on the same chromosome. These sequences do not usually encode mRNA or protein molecules. They alter the conformation of the gene within chromatin in such a way as to facilitate or inhibit access to the factors that modulate transcription. These interactions may twist or kink the DNA in such a way as to control exposure to other molecules. When exogenous nucleases are added in small amounts to nuclei, these exposed sequence regions become especially sensitive to the DNA-cutting action of the nucleases. Thus, nuclease-hypersensitive sites in DNA have come to be appreciated as markers for regions in or near genes that are interacting with regulatory nuclear proteins.

Methylation is another structural feature that can be used to recognize differences between actively transcribed and inactive genes. Most eukaryotic DNA is heavily methylated; that is, the DNA is modified by the addition of a methyl group to the 5 position of the cytosine pyrimidine ring (5-methyl-C). In general, whereas heavily methylated genes are inactive, active genes are relatively hypomethylated, especially in the 5' flanking regions containing the promoter and other regulatory elements (see “*Enhancers, Promoters, and Silencers*”). These flanking regions frequently include DNA sequences with a high content of Cs and Gs (CpG islands). Hypomethylated CpG islands (detectable by methylation-sensitive restriction endonucleases) serve as markers of actively transcribed genes. For example, a search for undermethylated CpG islands on chromosome 7 facilitated the search for the gene for cystic fibrosis.

DNA methylation is facilitated by DNA methyltransferases. DNA replication incorporates unmethylated nucleotides into each nascent strand, thus leading to demethylated DNA. For cytosines to become methylated, the methyltransferases must act after each round of replication. After an initial wave of demethylation early in embryonic development, regulatory areas are methylated during various stages of development and differentiation. Aberrant DNA methylation also occurs as an early step during tumorigenesis, leading to silencing of tumor suppressor genes and of genes related to differentiation. This finding has led to induction of DNA demethylation as a target in cancer therapy. Indeed, 5-azacytidine, a cytidine analog unable to be methylated, and the related compound decitabine, are approved by the United States Food and Drug Administration for use in myelodysplastic syndromes, and their use in cases of other malignancies is being investigated.

Although it is poorly understood how particular regions of DNA are targeted for methylation, it is becoming increasingly apparent that this modification targets further alterations in chromatin proteins that in turn influence gene expression. Histone acetylation, phosphorylation, and methylation of the N-terminal tail are currently the focus of intense study. Acetylation of lysine residues (catalyzed by histone acetyltransferases), for example, is associated with transcriptional activation. Conversely, histone deacetylation (catalyzed by histone deacetylase) leads to gene silencing. Histone deacetylases are recruited to areas of DNA methylation by DNA methyltransferases and by methyl-DNA-binding proteins, thus linking DNA methylation to histone deacetylation. Drugs inhibiting these enzymes have been demonstrated to be active anticancer agents and continue to be the focus of ongoing studies. The regulation of histone acetylation and deacetylation appears to be linked to gene expression, but the roles of histone phosphorylation and methylation are less well understood. Current research suggests that in addition to gene regulation, histone modifications contribute to the “epigenetic code” and are

thus a means by which information regarding chromatin structure is passed to daughter cells after DNA replication occurs.

ENHANCERS, PROMOTERS, AND SILENCERS

Several types of *cis*-active DNA sequence elements have been defined according to the presumed consequences of their interaction with nuclear proteins (see Fig. 1.5). Promoters are found just upstream (to the 5' side) of the start of mRNA transcription (the CAP). mRNA polymerases appear to bind first to the promoter region and thereby gain access to the structural gene sequences downstream. Promoters thus serve a dual function of being binding sites for mRNA polymerase and marking for the polymerase the downstream point at which transcription should start.

Enhancers are more complicated DNA sequence elements. Enhancers can lie on either side of a gene or even within the gene. Enhancers bind transcription factors and thereby stimulate expression of genes nearby. The domain of influence of enhancers (i.e., the number of genes to either side whose expression is stimulated) varies. Some enhancers influence only the adjacent gene; others seem to mark the boundaries of large multigene clusters (gene domains) whose coordinated expression is appropriate to a particular tissue type or a particular time. For example, the very high levels of globin gene expression in erythroid cells depend on the function of an enhancer that seems to activate the entire gene cluster and is thus called a *locus-activating region* (see Fig. 1.5). The nuclear factors interacting with enhancers are probably induced into synthesis or activation as part of the process of differentiation. Chromosomal rearrangements that place a gene that is usually tightly regulated under the control of a highly active enhancer can lead to overexpression of that gene. This commonly occurs in Burkitt lymphoma, for example, in which the MYC proto-oncogene is juxtaposed and dysregulated by an immunoglobulin enhancer.

Silencer sequences serve a function that is the obverse of enhancers. When bound by the appropriate nuclear proteins, silencer sequences cause repression of gene expression. Some evidence indicates that the same sequence elements can act as enhancers or silencers under different conditions, presumably by being bound by different sets of proteins having opposite effects on transcription. *Insulators* are sequence domains that mark the "boundaries" of multigene clusters, thereby preventing activation of one set of genes from "leaking" into nearby genes.

TRANSCRIPTION FACTORS

Transcription factors are nuclear proteins that exhibit gene-specific DNA binding. Considerable information is now available about these nuclear proteins and their biochemical properties, but their physiologic behavior remains incompletely understood. Common structural features have become apparent. Most transcription factors have DNA-binding domains sharing homologous structural motifs (cytosine-rich regions called zinc fingers, leucine-rich regions called leucine zippers, and so on), but other regions appear to be unique. Many factors implicated in the regulation of growth, differentiation, and development (e.g., homeobox genes, proto-oncogenes, antioncogenes) appear to be DNA-binding proteins and may be involved in the steps needed for activation of a gene within chromatin. Others bind to or modify DNA-binding proteins. These factors are discussed in more detail in several other chapters.

REGULATION OF mRNA SPLICING, STABILITY, AND TRANSLATION (POSTTRANSCRIPTIONAL REGULATION)

It has become increasingly apparent that posttranscriptional and translational mechanisms are important strategies used by cells to govern the amounts of mRNA and protein accumulating when a particular gene is expressed. The major modes of posttranscriptional

regulation at the mRNA level are regulated alternative mRNA splicing, control of mRNA stability, and control of translational efficiency. As discussed elsewhere (see Chapter 5), additional regulation at the protein level occurs by mechanisms modulating localization, stability, activation, or export of the protein.

A cell can regulate the relative amounts of different protein isoforms arising from a given gene by altering the relative amounts of an mRNA precursor that are spliced along one pathway or another (alternative mRNA splicing). Many striking examples of this type of regulation are known—for example, the ability of B lymphocytes to make both IgM and IgD at the same developmental stage, changes in the particular isoforms of cytoskeletal proteins produced during red blood cell differentiation, and a switch from one isoform of the *c-myc* proto-oncogene product to another during red blood cell differentiation. Abnormalities in mRNA splicing due to mutations at the splice sites can lead to defective protein synthesis, as can occur in β -globin, leading to a form of β -thalassemia. The effect of controlling the pathway of mRNA processing used in a cell is to include or exclude portions of the mRNA sequence. These portions encode peptide sequences that influence the ultimate physiologic behavior of the protein, or the RNA sequences that alter stability or translatability.

The importance of the control of mRNA stability for gene regulation is being increasingly appreciated. The steady-state level of any given mRNA species ultimately depends on the balance between the rate of its production (transcription and mRNA processing) and its destruction. One means by which stability is regulated is the inherent structure of the mRNA sequence, especially the 3' and 5' UTRs. As already noted, these sequences appear to affect mRNA secondary structure, recognition by nucleases, or both. Different mRNAs thus have inherently longer or shorter half-lives, almost regardless of the cell type in which they are expressed. Some mRNAs tend to be highly unstable. In response to appropriate physiologic needs, they can thus be produced quickly and removed from the cell quickly when a need for them no longer exists. Globin mRNA, on the other hand, is inherently quite stable, with a half-life measured in the range of 15 to 50 hours. This is appropriate for the need of reticulocytes to continue to synthesize globin for 24 to 48 hours after the ability to synthesize new mRNA has been lost by the terminally mature erythroblasts.

The stability of mRNA can also be altered in response to changes in the intracellular milieu. This phenomenon usually involves nucleases capable of destroying one or more broad classes of mRNA defined on the basis of their 3' or 5' UTR sequences. Thus, for example, histone mRNAs are destabilized after the S-phase of the cell cycle is complete. Presumably this occurs because histone synthesis is no longer needed. Induction of cell activation, mitogenesis, or terminal differentiation events often results in the induction of nucleases that destabilize specific subsets of mRNAs. Selective stabilization of mRNAs probably also occurs; α -globin mRNA, for example, is stabilized by the protective binding of a specific stabilizing protein to a nuclease target sequence in its 3' UTR.

The amount of a given protein accumulating in a cell depends on the amount of the mRNA present, the rate at which it is translated into the protein, and the stability of the protein. Translational efficiency depends on a number of variables, including polyadenylation and presence of the 5' cap. The amounts and state of activation of protein factors needed for translation are also crucial. The secondary structure of the mRNA, particularly in the 5' UTR, greatly influences the intrinsic translatability of an mRNA molecule by constraining the access of translation factors and ribosomes to the translation initiation signal in the mRNA. Secondary structures along the coding sequence of the mRNA may also have some impact on the rate of elongation of the peptide.

Changes in capping, polyadenylation, and translation factor efficiency affect the overall rate of protein synthesis within each cell. These effects tend to be global rather than specific to a particular gene product. However, these effects influence the relative amounts of different proteins made. mRNAs whose structures inherently lend themselves to more efficient translation tend to compete better for

rate-limiting components of the translational apparatus, but mRNAs that are inherently less translatable tend to be translated less efficiently in the face of limited access to other translational components. For example, the translation factor eIF-4 tends to be produced in higher amounts when cells encounter transforming or mitogenic events. This causes an increase in overall rates of protein synthesis but also leads to a selective increase in the synthesis of some proteins that were underproduced before mitogenesis.

Translational regulation of individual mRNA species is critical for some events important to blood cell homeostasis. For example, as discussed in Chapter 35, the amount of iron entering a cell is an exquisite regulator of the rate of ferritin mRNA translation. An mRNA sequence called the *iron response element* is recognized by a specific mRNA-binding protein but only when the protein lacks iron. mRNA bound to the protein is translationally inactive. As iron accumulates in the cell, the protein becomes iron bound and loses its affinity for the mRNA, resulting in translation into apoferritin molecules that bind the iron.

Tubulin synthesis involves coordinated regulation of translation and mRNA stability. Tubulin regulates the stability of its own mRNA by a feedback loop. As tubulin concentrations rise in the cell, it interacts with its own mRNA through the intermediary of an mRNA-binding protein. This results in the formation of an mRNA-protein complex and nucleolytic cleavage of the mRNA. The mRNA is destroyed, and further tubulin production is halted.

These few examples of posttranscriptional regulation emphasize that cells tend to use every step in the complex pathway of gene expression as points at which exquisite control over the amounts of a particular protein can be regulated. In other chapters, additional levels of regulation are described (e.g., regulation of the stability, activity, localization, and access to other cellular components of the proteins that are present in a cell).

SMALL INTERFERING RNA AND MICRO RNA

Another posttranscriptional mechanism of gene silencing utilizes so-called “small RNAs”. One such process is carried out by small interfering RNAs (siRNAs): short, double-stranded fragments of RNA containing 21 to 23 bp (Fig. 1.6). The process is triggered by perfectly complementary double-stranded RNA, which is cleaved by Dicer, a member of the RNase III family, into siRNA fragments. These small fragments of double-stranded RNA are unwound by a helicase in the RNA-induced silencing complex (RISC). The anti-sense strand anneals to mRNA transcripts in a sequence-specific manner and in doing so brings the endonuclease activity within the RISC to the targeted transcript. An RNA-dependent RNA polymerase in the RISC may then create new siRNAs to processively degrade the mRNA, ultimately leading to complete degradation of the mRNA transcript and abrogation of protein expression.

Although this endogenous process likely evolved to destroy invading viral RNA, the use of siRNA has become a commonly used tool for evaluation of gene function. Sequence-specific synthetic siRNA may be directly introduced into cells or introduced via gene transfection methods and targeted to an mRNA of a gene of interest. The siRNA will lead to degradation of the mRNA transcript, and accordingly prevent new protein translation. This technique is a relatively simple, efficient, and inexpensive means to investigate cellular phenotypes after directed elimination of expression of a single gene. The 2006 Nobel Prize in Physiology or Medicine was awarded to two discoverers of RNA interference, Andrew Fire and Craig Mello.

Micro RNAs (miRNAs, or MIRs) are 22-nucleotide small RNAs encoded by the cellular genome that alter mRNA stability and protein translation. These genes are transcribed by RNA polymerase II and capped and polyadenylated similar to other RNA polymerase II transcripts. The precursor transcript of approximately 70 nucleotides is cleaved into mature miRNA by the enzymes Drosha and Dicer. One strand of the resulting duplex forms a complex with the RISC that together binds the target mRNA with imperfect complementarity. Through mechanisms that are still incompletely understood,

Fig. 1.6 mRNA DEGRADATION BY siRNA. dsRNA is digested into 21- to 23-bp siRNAs by the Dicer RNase. These RNA fragments are unwound by RISC and bring the endonucleolytic activity of RISC to mRNA transcripts in a sequence-specific manner, leading to degradation of the mRNA. *dsRNA*, Double-stranded RNA; *mRNA*, messenger RNA; *RISC*, RNA-induced silencing complex; *siRNA*, small interfering RNA.

miRNA suppresses gene expression, likely either through inhibition of protein translation or through destabilization of mRNA. miRNAs appear to have essential roles in development and differentiation, and are aberrantly regulated in many types of cancer cells. The identification of miRNA sequences, their regulation, and their target genes are areas of intense study.

ADDITIONAL STRUCTURAL FEATURES OF GENOMIC DNA

Most DNA does not code for RNA or protein molecules. The vast majority of nucleotides present in the human genome reside outside structural genes. Structural genes are separated from one another by as few as 1 to 5 kilobases or as many as several thousand kilobases of DNA. Almost nothing is known about the reason for the erratic clustering and spacing of genes along chromosomes. It is clear that intergenic DNA contains a variegated landscape of structural features that provide useful tools to localize genes, identify individual human beings as unique from every other human being (DNA fingerprinting), and diagnose human diseases by linkage. Only a brief introduction is provided here.

The rate of mutation in DNA under normal circumstances is approximately $1/10^6$. In other words, one of 1 million bases of DNA will be mutated during each round of DNA replication. A set of enzymes called *DNA proofreading enzymes* corrects many but not all of these mutations. When these enzymes are themselves altered by mutation, the rate of mutation (and therefore the odds of neoplastic transformation) increases considerably. If these mutations occur in bases critical to the structure or function of a protein or gene, altered function, disease, or a lethal condition can result. Most pathologic mutations tend not to be preserved throughout many generations because of their unfavorable phenotypes. Exceptions, such as the hemoglobinopathies, occur when the heterozygous state for these

mutations confers selective advantage in the face of unusual environmental conditions, such as malaria epidemics. These “adaptive” mutations drive the dynamic change in the genome with time (evolution).

Most of the mutations that accumulate in the DNA of *Homo sapiens* occur in either intergenic DNA or the “silent” bases of DNA, such as the degenerate third bases of codons. They do not pathologically alter the function of the gene or its products. These clinically harmless mutations are called *DNA polymorphisms*. DNA polymorphisms can be regarded in exactly the same way as other types of polymorphisms that have been widely recognized for years (e.g., eye and hair color, blood groups). They are variations in the population that occur without apparent clinical impact. Each of us differs from other humans in the precise number and type of DNA polymorphisms that we possess. Most polymorphisms represent single-nucleotide changes and are called single-nucleotide polymorphisms (SNPs).

Similar to other types of polymorphisms, DNA polymorphisms breed true. In other words, if an individual's DNA contains a G 1200 bases upstream from the α -globin gene, instead of the C most commonly found in the population, that G will be transmitted to that individual's offspring. Note that if one had a means for distinguishing the G at that position from a C, one would have a linked marker for that individual's α -globin gene.

Occasionally, a DNA polymorphism falls within a restriction endonuclease site. (Restriction enzymes cut DNA molecules into smaller pieces but only at limited sites, defined by short base sequences recognized by each enzyme.) The change could abolish the site or create a site where one did not exist before. These polymorphisms change the array of fragments generated when the genome is digested by that restriction endonuclease. This permits detection of the polymorphism by use of the appropriate restriction enzyme. This specific class of polymorphisms is thus called *restriction fragment length polymorphisms* (RFLPs).

RFLPs are useful because the length of a restriction endonuclease fragment on which a gene of interest resides provides a linked marker for that gene. The exploitation of this fact for diagnosis of genetic diseases and detection of specific genes is discussed in [Chapters 2 and 3](#); [Fig. 1.7](#) shows a simple example.

RFLPs have proved to be extraordinarily useful for the diagnosis of genetic diseases, especially when the precise mutation is not known. Recall that DNA polymorphisms breed true in the population. For example, as discussed in [Chapter 135](#), a mutation that causes hemophilia will, when it occurs on the X chromosome, be transmitted to subsequent generations attached to the pattern (often called a framework or haplotype) of RFLPs that was present on that same X chromosome. If the pattern of RFLPs in the parents is known, the presence of the abnormal chromosome can be detected in the offspring.

Genomic technologies (see [Chapters 2 and 3](#)) have made it possible to characterize SNPs scattered across the entire genome, whether or not they alter restriction endonuclease sites. SNP analysis is gaining momentum as a means for characterizing genomes. The advent of highly efficient, speedy, and increasingly cheap genome sequencing technologies now permits one to identify SNPs almost at will, and is rapidly replacing the use of RFLPs. The principles of choosing the right comparison populations and of the “breeding true” through generations, however, remain important principles in interpreting the results.

An important feature of the DNA landscape is the high degree of repeated DNA sequence. A DNA sequence is said to be repeated if it or a sequence very similar (homologous) to it occurs more than once in a genome. Some multicopy genes, such as the histone genes and the ribosomal RNA genes, are repeated DNA sequences. Most repeated DNA occurs outside genes, or within introns. Indeed, 30% to 45% of the human genome appears to consist of repeated DNA sequences.

The function of repeated sequences remains unknown, but their presence has inspired useful strategies for detecting and characterizing individual genomes. For example, a pattern of short repeated DNA

Fig. 1.7 TWO USEFUL FORMS OF SEQUENCE VARIATION AMONG THE GENOMES OF NORMAL INDIVIDUALS. (A) Presence of a DNA sequence polymorphism that falls within a restriction endonuclease site, thus altering the pattern of restriction endonuclease digests obtained from this region of DNA on Southern blot analysis. (Readers not familiar with Southern blot analysis should return to examine this figure after reading later sections of this chapter.) (B) A variable-number tandem repeat (VNTR) region (defined and discussed in the text). Note that individuals can vary from one to another in many ways according to how many repeated units of the VNTR are located on their genomes, but restriction fragment length polymorphism differences are in effect all-or-none differences, allowing for only two variables (restriction site presence or absence).

sequences, characterized by the presence of flanking sites recognized by the restriction endonuclease Alu-1 (called “Alu repeats”), occurs approximately 300,000 times in a human genome. These sequences are not present in the mouse genome. If one wishes to infect mouse cells with human DNA and then identify the human DNA sequences in the infected mouse cells, one simply probes for the presence of Alu repeats. The Alu repeat thus serves as a signature of human DNA.

Classes of highly repeated DNA sequences (tandem repeats) have proved to be useful for distinguishing genomes of each human individual. These short DNA sequences, usually less than a few hundred bases long, tend to occur in clusters, with the number of repeats varying among individuals (see [Fig. 1.6](#)). Alleles of a given gene can therefore be associated with a variable number of tandem repeats (VNTR) in different individuals or populations. For example, there is a VNTR near the insulin gene. In some individuals or populations, it is present in only a few tandem copies, but in others, it is present in many more. When the population as a whole is examined, there is a wide degree of variability from individual to individual as to the number of these repeats residing near the insulin gene. It can readily be imagined that if probes were available to detect a dozen or so distinct VNTR regions, each human individual would differ from virtually all others with respect to the aggregate pattern of these VNTRs. Indeed, it can be shown mathematically that the probability of any two human beings sharing exactly the same pattern of VNTRs is exceedingly small if approximately 10 to 12 different VNTR elements are mapped for each person. A technique called *DNA fingerprinting* that is based on VNTR analysis has become widely publicized because of its forensic applications.

There are many other classes of repeated sequences in human DNA. For example, human DNA has been invaded many times in its history by retroviruses. Retroviruses tend to integrate into human DNA and then “jump out” of the genome when they are reactivated,

to complete their life cycle. The proviral genomes often carry with them nearby bits of the genomic DNA in which they sat. If the retrovirus infects the DNA of another individual at another site, it will insert this genomic bit. Through many cycles of infection, the virus will act as a transposon, scattering its attached sequence throughout the genome. These types of sequences are called *long interspersed elements*. They represent footprints of ancient viral infections.

KEY METHODS FOR GENE ANALYSIS

The foundation for the molecular understanding of gene structure and expression is based on fundamental molecular biologic techniques that were developed in the 1970s and 1980s. These techniques allow for the reduction of the multibillion nucleotide genome into smaller fragments that are more easily analyzed. Several key methods are outlined here.

Restriction Endonucleases

Naturally occurring bacterial enzymes called *restriction endonucleases* catalyze sequence-specific hydrolysis of phosphodiester bonds in the DNA backbone. For example, EcoRI, a restriction endonuclease isolated from *Escherichia coli*, cleaves DNA only at the sequence 5'-GAATTC-3'. Thus, each DNA sample will be reproducibly reduced to an array of fragments whose size ranges depend on the distribution with which that sequence exists within the DNA. A specific six-nucleotide sequence would be statistically expected to appear once every 46 (or 4096) nucleotides, but in reality, the distance between specific sequences varies greatly. Using combinations of restriction endonucleases, DNA several hundred million base pairs in length can be reproducibly reduced to fragments ranging from a few dozen to tens of thousands of base pairs long. These smaller products of enzymatic digestion are much more manageable experimentally. Genetic "fingerprinting," or restriction enzyme maps of genomes, can be constructed by analyzing the DNA fragments resulting from digestion. Many enzymes cleave DNA so as to leave short, single-stranded overhanging regions that can be enzymatically linked to

other similar fragments, generating artificially recombined, or recombinant, DNA molecules. These ligated gene fragments can then be inserted into bacteria to produce more copies of the recombinant molecules or to express the cloned genes. While still useful in a number of contexts, restriction enzyme analysis is increasingly being supplanted by direct DNA sequence analysis.

DNA, RNA, and Protein Blotting

There are many ways that a cloned DNA sequence can be exploited to characterize the behavior of normal or pathologic genes. Blotting methods deserve special mention because of their widespread use in clinical and experimental hematology. A cloned DNA fragment can be easily purified and tagged with a radioactive or nonradioactive label. The fragment provides a pure and highly specific molecular hybridization probe for the detection of complementary DNA (cDNA) or RNA molecules in any specimen of DNA or RNA. One set of assays that has proved particularly useful involves Southern blotting, named after Dr. E. Southern, who invented the method (Fig. 1.8). Southern blotting allows detection of a specific gene, or region in or near a gene, in a DNA preparation. The DNA is isolated and digested with one or more restriction endonucleases, and the resulting fragments are denatured and separated according to their molecular size by electrophoresis through agarose gels. By means of capillary action in a high-salt buffer, the DNA fragments are passively transferred to a nitrocellulose or nylon membrane. Single-stranded DNA and RNA molecules attach noncovalently but tightly to the membrane. In this fashion, the membrane becomes a replica, or blot, of the gel. After the blotting procedure is complete, the membrane is incubated in a hybridization buffer containing the radioactively labeled probe. The probe hybridizes only to the gene of interest and renders radioactive only one or a few bands containing complementary sequences. After appropriate washing and drying, the bands can be visualized by autoradiography.

Digestion of a DNA preparation with several different restriction enzymes allows a restriction endonuclease map of a gene in the human genome to be constructed. Southern blotting has thus become a standard way of characterizing the configuration of genes in the genome.

Fig. 1.8 SOUTHERN GENE BLOTTING. Detection of a genomic gene (red) that resides on a 14-kilobase Bam HI fragment. To identify the presence of a gene in the genome and the size of the restriction fragment on which it resides, genomic DNA is digested with a restriction enzyme, and the fragments are separated by agarose gel electrophoresis. Human genomes contain from several hundred thousand to 1 million sites for any particular restriction enzyme, which results in a vast array of fragments and creates a blur or streak on the gel; one fragment cannot be distinguished from another readily. If the DNA in the gel is transferred to nitrocellulose by capillary blotting, however, it can be further analyzed by molecular hybridization to a radioactive cDNA probe for the gene. Only the band containing the gene yields a positive autoradiography signal, as shown. If a disease state were to result in loss of the gene, alteration of its structure, or mutation (altering recognition sites for one or more restriction enzymes), the banding pattern would be changed. *cDNA*, Complementary DNA.

Northern blotting represents an analogous blotting procedure used to detect RNA. RNA cannot be digested with restriction enzymes (which cut only DNA); rather, the intact RNA molecules can be separated according to molecular size by electrophoresis through the gel (mRNAs are 0.5 to 12 kilobases in length), transferred onto membranes, and probed with a DNA probe. In this fashion, the presence, absence, molecular size, and number of individual species of a particular mRNA species can be detected.

Western blotting is a similar method that can be used to examine protein expression. Cellular lysates (or another source of proteins) can be electrophoresed through a polyacrylamide gel so as to separate proteins on the basis of their apparent molecular sizes. The resolved proteins can then be electrically transferred to nitrocellulose membranes and probed with specific antibodies directed against the protein of interest. As with RNA analysis, the relative expression levels and molecular sizes of proteins can be assessed with this method.

Polymerase Chain Reaction

The development of the polymerase chain reaction (PCR) was a major breakthrough that has revolutionized the utility of a DNA-based strategy for diagnosis and treatment. It permits the detection, synthesis, and isolation of specific genes and allows differentiation of alleles of a gene differing by as little as one base. It does not require sophisticated equipment or unusual technical skills. A clinical specimen consisting of only minute amounts of tissue will suffice; in most circumstances, no special preparation of the tissue is necessary. PCR thus makes recombinant DNA techniques accessible to clinical laboratories. This single advance has produced a quantum increase in the use of direct gene analysis for diagnosis of human diseases. Indeed, PCR analysis combined with direct DNA sequencing technologies have largely supplanted restriction enzyme mapping and blotting strategies for many research and diagnostic applications.

The PCR is based on the prerequisites for copying an existing DNA strand by DNA polymerase: an existing denatured strand of DNA to be used as the template and a primer. Primers are short oligonucleotides, 12 to 100 bases in length, having a base sequence complementary to the desired region of the existing DNA strand. The enzyme requires the primer to “know” where to begin copying. If the base sequence of the DNA of the gene under study is known, two synthetic oligonucleotides complementary to sequences flanking the region of interest can be prepared. If these are the only oligonucleotides present in the reaction mixture, then the DNA polymerase can only copy daughter strands of DNA downstream from those oligonucleotides. Recall that DNA is double stranded, that the strands are held together by the rules of Watson–Crick base pairing, and that they are aligned in antiparallel fashion. This implies that the effect of incorporation of both oligonucleotides into the reaction mix will be to synthesize two daughter strands of DNA, one originating upstream of the gene and the other originating downstream. The net effect is synthesis of only the DNA between the two primers, thus doubling only the DNA containing the region of interest. If the DNA is now heat denatured, allowing hybridization of the daughter strands to the primers, and the polymerization is repeated, then the region of DNA through the gene of interest is doubled again. Thus, two cycles of denaturation, annealing, and elongation result in a selective quadrupling of the gene of interest. The cycle can be repeated 30–50 times, resulting in a selective and geometric amplification of the sequence of interest to the order of 2^{30} to 2^{50} times. The result is a millionfold or higher selective amplification of the gene of interest, yielding microgram quantities of that DNA sequence.

PCR achieved practical utility when DNA polymerases from thermophilic bacteria were discovered; when synthetic oligonucleotides of any desired sequence could be produced efficiently, reproducibly, and cheaply by automated instrumentation; and when DNA thermocycling machines were developed. Thermophilic bacteria live in hot springs and other exceedingly warm environments, and their DNA polymerases can tolerate 100°C (212°F) incubations without substantial loss of activity. The advantage of these thermostable

polymerases is that they retain activity in a reaction mix that is repeatedly heated to the high temperature needed to denature the DNA strands into the single-stranded form. Microprocessor-driven DNA thermocycler machines can be programmed to increase temperatures to 95°C to 100°C (203°F to 212°F) (denaturation), to cool the mix to 50°C (101°F) rapidly (a temperature that favors oligonucleotide annealing), and then to raise the temperature to 70°C to 75°C (141.4°F to 151.5°F) (the temperature for optimal activity of the thermophilic DNA polymerases). In a reaction containing the test specimen, the thermophilic polymerase, the primers, and the chemical components (e.g., nucleotide subunits), the thermocycler can conduct many cycles of denaturation, annealing, and polymerization in a completely automated fashion. The gene of interest can thus be amplified more than a millionfold in a matter of a few hours. The DNA product is readily identified and isolated by routine agarose gel electrophoresis. The DNA can then be analyzed by restriction endonuclease, digestion, hybridization to specific probes, sequencing, further amplification by cloning, and so forth.

USE OF TRANSGENIC AND KNOCKOUT MICE TO DEFINE GENE FUNCTION

Recombinant DNA technology has resulted in the identification of many disease-related genes. To advance the understanding of the disease related to a previously unknown gene, the function of the protein encoded by that gene must be verified or identified, and the way changes in the gene's expression influence the disease phenotype must be characterized. Analysis of the role of these genes and their encoded proteins has been made possible by the development of recombinant DNA technology that allows the production of mice that are genetically altered at the cloned locus. Mice can be produced that express an exogenous gene and thereby provide an *in vivo* model of its function. Linearized DNA is injected into a fertilized mouse oocyte pronucleus and reimplanted in a pseudopregnant mouse. The resultant transgenic mice can then be analyzed for the phenotype induced by the injected transgene. Placing the gene under the control of a strong promoter that stimulates expression of the exogenous gene in all tissues allows the assessment of the effect of widespread overexpression of the gene. Alternatively, placing the gene under the control of a promoter that can function only in certain tissues (a tissue-specific promoter) elucidates the function of that gene in a particular tissue or cell type. A third approach is to study control elements of the gene by testing their capacity to drive expression of a “marker” gene that can be detected by chemical, immunologic, or functional means. For example, the promoter region of a gene of interest can be joined to the cDNA encoding green jellyfish protein and activity of the gene assessed in various tissues of the resultant transgenic mouse by fluorescence microscopy. Use of such a reporter gene demonstrates the normal distribution and timing of expression of the gene from which the promoter elements are derived. Transgenic mice contain exogenous genes that insert randomly into the genome of the recipient. Expression can thus depend as much on the location of the insertion as it does on the properties of the injected DNA.

In contrast, any defined genetic locus can be specifically altered by targeted recombination between the locus and a plasmid carrying an altered version of that gene (Fig. 1.9). If a plasmid contains that altered gene with enough flanking DNA identical to that of the normal gene locus, homologous recombination can occur, and the altered gene in the plasmid will replace the gene in the recipient cell. Using a mutation that inactivates the gene allows the production of a null mutation, in which the function of that gene is completely lost. To induce such a mutation, the plasmid is introduced into an embryonic stem cell, and the rare cells that undergo homologous recombination are selected. The “knockout” embryonic stem cell is then introduced into the blastocyst of a developing embryo. The resultant animals are chimeric; only a fraction of the cells in the animal contain the targeted gene. If the new gene is introduced into some of the germline cells of the chimeric mouse, then some of the offspring of that mouse will carry the mutation as a gene in all of

Fig. 1.9 GENE “KNOCKOUT” BY HOMOLOGOUS RECOMBINATION. A plasmid containing genomic DNA homologous to the gene of interest is engineered to contain a selectable marker positioned so as to disrupt expression of the native gene. The DNA is introduced into embryonic stem cells, and cells resistant to the selectable marker are isolated and injected into a mouse blastocyst, which is then implanted into a mouse. Offspring mice that contain the knockout construct in their germ cells are then propagated, yielding mice with heterozygous or homozygous inactivation of the gene of interest.

their cells. These heterozygous mice can be further bred to produce mice homozygous for the null allele. Such knockout mice reveal the function of the targeted gene by the phenotype induced by its absence. Genetically altered mice have been essential for discerning the biologic and pathologic roles of large numbers of genes implicated in the pathogenesis of human disease.

DNA-BASED THERAPIES

Gene Therapy

The application of gene therapy to genetic hematologic disorders is an appealing idea. In most cases, this would involve isolating hematopoietic stem cells from patients with diseases with defined genetic lesions, inserting normal genes into those cells, and reintroducing the genetically engineered stem cells back into the patient. A few candidate diseases for such therapy include sickle cell disease, thalassemia, hemophilia, and adenosine deaminase-deficient severe combined immunodeficiency. The technology for separating hematopoietic

stem cells and for performing gene transfer into those cells has advanced rapidly, and clinical trials have begun to test the applicability of these techniques. Despite the fact that gene therapy has progressed to the enrollment of patients in clinical protocols, major technical problems still need to be solved. Presently, there are only few (but increasing, such as severe combined immunodeficiency syndromes, Wiskott–Aldrich disease, and others) proven therapeutic successes from gene therapy.

Progress in this field continues rapidly and is likely to accelerate as a consequence of the development of “gene editing” technologies. Among these, “CRISPR” is the most prominent current example. It is based on the discovery of enzyme systems used by microorganisms to excise foreign DNA sequences (e.g., integrated viral genomes) from the host genome. These systems can be adapted to insert, replace, or delete, in principle, any desired DNA sequence in its naturally occurring position in the host genome. For example, one could excise the mutation causing sickle cell anemia and replace it with the normal DNA sequence in the β -globin gene of a patient’s hematopoietic stem cells, and then re-introduce them into the patient’s bone marrow without introducing any foreign DNA. This exciting technology is rapidly moving toward clinical trials. The scientific basis for gene therapy and the clinical issues surrounding this approach are discussed in [Chapter 98](#).

Antisense Therapy

The recognition that abnormal expression of oncogenes plays a role in malignancy has stimulated attempts to suppress oncogene expression to reverse the neoplastic phenotype. One way of blocking mRNA expression is with antisense oligonucleotides. These are single-stranded DNA sequences 17 to 20 bases long, having a sequence complementary to the transcription or translation start of the mRNA. These relatively small molecules freely enter the cell and complex to the mRNA by their complementary DNA sequence. This often results in a decrease in gene expression. The binding of the oligonucleotide may directly block translation and clearly enhances the rate of mRNA degradation. This technique has been shown to be promising in suppressing expression of *bcr-abl* and to suppress cell growth in chronic myelogenous leukemia. The technique is being tried as a therapeutic modality for the purging of tumor cells before autologous transplantation in patients with chronic myelogenous leukemia.

FUTURE DIRECTIONS

The elegance of recombinant DNA technology and its successor technologies of genomics, epigenomics, and proteomics resides in the capacity they confer on investigators to examine each gene as a discrete physical entity that can be purified, reduced to its basic building blocks for decoding of its primary structure, analyzed for its patterns of expression, and perturbed by alterations in sequence or molecular environment so that the effects of changes in each region of the gene can be assessed. Purified genes can be deliberately modified or mutated to create novel genes not available in nature. These provide the potential to generate useful new biologic entities, such as modified live virus or purified peptide vaccines, modified proteins customized for specific therapeutic purposes, and altered combinations of regulatory and structural genes that allow for the assumption of new functions by specific gene systems.

Purified genes facilitate the study of gene regulation in many ways. First, a cloned gene provides characterized DNA probes for molecular hybridization assays. Second, cloned genes provide the homogeneous DNA moieties needed to determine the exact nucleotide sequence. Sequencing techniques have become so reliable and efficient that it is often easier to clone the gene encoding a protein of interest and determine its DNA sequence than it is to purify the protein and determine its amino acid sequence. The DNA sequence predicts exactly the amino acid sequence of its protein product. By comparing normal sequences with the sequences of alleles cloned from patients

known to be abnormal, such as the globin genes in the thalassemia or sickle cell syndromes, the normal and pathologic anatomy of genes critical to major hematologic diseases can be established. In this manner, it has been possible to identify many mutations responsible for various forms of thalassemia, hemophilia, thrombasthenia, red blood cell enzymopathies, porphyrias, and so forth. Similarly, single base changes have been shown to be the difference between many normally functioning proto-oncogenes and their cancer-promoting oncogene derivatives.

Third, cloned genes can be manipulated for studies of gene expression. Many vectors allowing efficient transfer of genes into eukaryotic cells have been perfected. Gene transfer technologies allow the gene to be placed into the desired cellular environment and the expression of that gene or the behavior of its products to be analyzed. These surrogate or reverse genetics systems allow analysis of the normal physiology of expression of a particular gene, as well as the pathophysiology of abnormal gene expression resulting from mutations.

Fourth, cloned genes enhance study of their protein products. By expressing fragments of the gene in microorganisms or eukaryotic cells, customized regions of a protein can be produced for use as an immunogen, thereby allowing preparation of a variety of useful and powerful antibody probes. Alternatively, synthetic peptides deduced from the DNA sequence can be prepared as the immunogen. Controlled production of large amounts of the protein also allows direct analysis of specific functions attributable to regions in that protein.

Finally, all of the aforementioned techniques can be extended by mutating the gene and examining the effects of those mutations on the expression of or the properties of the encoded mRNAs and proteins. By combining portions of one gene with another (chimeric genes) or abutting structural regions of one gene with regulatory sequences of another, the researcher can investigate in previously inconceivable ways the complexities of gene regulation. These activist approaches to modifying gene structure or expression create the opportunity to generate new RNA and protein products whose applications are limited only by the collective imagination of the investigators.

The most important impact of the genetic approach to the analysis of biologic phenomena is the most indirect. Diligent and repeated application of the methods outlined in this chapter to the study of many genes from diverse groups of organisms is beginning to reveal the basic strategies used by nature for the regulation of cell and tissue behavior. As our knowledge of these rules of regulation grows, our ability to understand, detect, and correct pathologic phenomena will increase substantially.

EPIGENETICS AND EPIGENOMICS

Jennifer Wu and Myles Brown

Epigenetics can be defined as inheritance of variation above and beyond changes in the DNA sequence. In other words, epigenetics comprises the study of how cells sharing the same exhaustive DNA blueprint can appear and function so distinctly as white blood cells, hepatocytes, neurons, and so forth. Whereas the genome contains all of an organism's vital information, a cell's epigenome dynamically filters and organizes that information into highly coordinated programs of gene expression.

Within the nucleus, DNA interacts with a variety of proteins to form chromatin, which can be broadly classified as highly compacted and transcriptionally silent (heterochromatin) versus loosely compacted and transcriptionally active (euchromatin). Heterochromatin comprises two distinct classes of DNA: (1) noncoding, often repetitive, "structural" DNA of centromeres and telomeres (constitutive heterochromatin), and (2) gene-encoding and gene-regulatory "functional" DNA that is selectively rendered inactive in different cell types (facultative heterochromatin). When euchromatin is described as loosely compacted, the information content of its DNA is readily accessible to binding the protein and RNA machinery that regulate gene expression. The aim of the study of epigenetics and chromatin therefore is to describe and understand the chromatin dynamics that orchestrate the four-dimensional symphony of molecular and cellular biology from the (seemingly) one-dimensional score that is the genome.

The information contained within chromatin can be grossly divided into two main categories: (1) the structural genes themselves, which are transcribed and translated into proteins or act as functional RNAs, and (2) gene-regulatory regions, which control the timing and amount of transcription (Fig. 2.1A). The information contained in transcribed and translated regions can be interpreted using the "genetic code," wherein the DNA sequence of the gene specifies, through a messenger RNA (mRNA) intermediate, the amino acid sequences of resulting proteins. Although there is no genetic code for functional RNAs that are not translated into proteins, some, such as ribosomal RNA and transfer RNA genes, have well understood functions. There are in addition a number of other types of functional RNA genes whose functions are only partially elucidated. Transcribed regions comprise approximately 3% of the genome. In contrast, the information contained in gene-regulatory regions is the "epigenetic code," which has yet to be fully deciphered and is based on the accessibility of those regions to dynamic protein–DNA interactions, the identity of those interacting proteins, and the identity of the gene(s) whose expression is being modulated.

The most dramatic example of chromatin compaction is the condensation that occurs during mitosis, making individual chromosomes visible by light microscopy and allowing segregation of replicates equally among daughter cells. A condensed or compacted chromosome is folded many times upon itself and is highly protein bound, affording little or no access to genomic information and remaining transcriptionally silent (Fig. 2.1B). Contrast this with the "decondensed" chromatin state that is necessary for DNA replication during the synthesis phase of the cell cycle. DNA replication requires unfolding of chromatin, disruption of its protein–DNA interactions, and "unzipping" the double helix to allow every base in the genome to be copied. When not dividing, cells maintain their chromatin in intermediate states of compaction. Actively transcribed genes and their associated regulatory chromatin regions are "open" and "accessible" insofar as the underlying protein–DNA interactions are readily modified and disrupted to accommodate binding of transcription

factors, cofactors, RNA polymerases, and the totality of functional components underlying gene expression.

It is important to remember some key differences between genomic and epigenomic research. Whereas the genome is an essentially unvarying feature of every cell in an organism (with the important exception of T and B cells that rearrange and mutate their antigen receptor genes), the epigenome of each cell within that organism is unique. Moreover, epigenomes are fluid throughout a cell's life span, integrating intrinsic cellular "identity" with contextual signals to specify a program of gene expression. Finally, the mechanics of DNA replication and cell division necessarily disrupt the protein–DNA interactions that comprise the epigenome. How cells reestablish their epigenetic identity after cell division is not well understood.

FUNCTIONAL CHROMATIN DOMAINS

Regulatory, noncoding DNA regions can have a variety of different functions (illustrated in Fig. 2.1A), variously classified as promoters, enhancers/silencers, superenhancers, and insulators. Promoters are typically located within 1 to 2 kb of the transcriptional start site (TSS) of a gene. At a minimum, RNA polymerase II–dependent promoters contain binding sites for the general transcription factors TATA box-binding protein (TBP) and transcription factor IIB (TFIIB), which form the core of the transcriptional complex. Transcription factor binding sites within the promoter modulate gene expression by recruiting histone-modifying enzymes and transcriptional coactivators or corepressors.

An enhancer/silencer is a short (50- to 1500-bp) region of DNA that can be bound by transcription factors to increase/decrease the likelihood that transcription of a particular gene will occur. Enhancers/silencers can act both in *cis* (within a chromosome) and rarely in *trans* (between chromosomes), can be located up to 1 Mb away from the gene, and can be upstream or downstream from the TSS. Promoters physically interact with their associated enhancers or silencers via three-dimensional chromatin "looping" facilitated by Mediator and cohesin protein complexes (Fig. 2.1D). Genes may be regulated by several enhancers/silencers, and each enhancer/silencer may modulate expression of one or more genes. A superenhancer is a cluster of physically and functionally associated enhancers that regulates genes critical for cell identity. Superenhancers are marked by high levels of enhancer-associated histone modification and bind high levels of cell type–specific and lineage-defining transcription factors (known as "master" transcription factors).

Insulators help to restrict the set of genes that can be modulated by an enhancer by blocking the physical interactions between enhancers and promoters. Insulators are bound by cohesin and CTCF proteins and form boundaries between silenced and active genes. Clusters of insulators separate heterochromatin from euchromatin, and the segments of active chromatin bounded by these clusters are known as topologic domains—genomic regions within which regulation occurs.

DNA METHYLATION

Methylation of cytosine by DNA methyltransferases (DNMTs) occurs at 60% to 90% of CpG dinucleotides in the mammalian genome. Methylated DNA is bound by methyl-CpG-binding domain

Fig. 2.1 CHROMATIN STRUCTURE. (A) Functional chromatin domains and their characteristic histone modifications and protein-binding features. (B) Higher-order chromatin structure, from least condensed (*top*) to most condensed (*bottom*). (C) Schematic of nucleosome with DNA (*light blue*) wrapped around histone octamer (H2A, H2B, H3, H4) having protruding histone tails. (D) Three-dimensional chromatin looping brings enhancers into close proximity with promoters via interactions with cohesin and Mediator protein complexes. *eRNA*, Enhancer RNA; *mRNA*, messenger RNA; TF, transcription factor.

proteins (MBDs) that recruit histone-modifying enzymes and chromatin remodeling proteins, resulting in highly condensed heterochromatin. Methylation of promoter regions thereby represses transcription. Patterns of DNA methylation are replicated during DNA synthesis and cell division and can be used to distinguish cell types and stages of differentiation.

The genome-wide pattern of DNA methylation, known as the methylome, has been characterized for a wide variety of tissues. Approximately 75% of the methylome is consistent across all cell types. The remaining 25% is differentially hypo- or hypermethylated in a cell type-specific manner. Cell type-specific hypomethylated regions are enriched for nucleosomes with modifications associated with active regions and transcription factor-binding sites, whereas

cell type-specific hypermethylation is associated with transcription factor silencing during differentiation. Aberrant DNA methylation is an extremely common feature of cancers, where hypermethylation of tumor suppressor genes and hypomethylation of oncogenes may play important roles in oncogenesis and tumor progression.

HISTONES AND HISTONE VARIANTS

Histones H2A, H2B, H3, and H4 are known as the core histones, and histones H1 and H5 are known as the linker histones. The core histones all exist as dimers, and the four dimers come together to form one octameric nucleosome core. The smallest unit of chromatin

structure is the nucleosome, consisting of 147 bp of DNA double helix wrapped around the core histone octamer (Fig. 2.1C). Linker histones, primarily H1, bind the nucleosome at the entry and exit sites of the DNA and allow the formation of higher-order structure. Histone N-terminal domains are rich in lysine and arginine residues that are subject to a variety of posttranslational modifications (see later).

In addition to these major histones, dozens of minor histone variants have been identified and are highly evolutionarily conserved. Some minor variants have very specific roles in chromatin regulation. For example, histone H3-like centromere protein A (CENPA) is associated with centromeres. H2A.Z is associated with the promoters and enhancers of actively transcribed genes. Histone H3.3 is associated with the body of actively transcribed genes. Phosphorylated H2A.X is found in regions around double-stranded DNA breaks and recruits DNA repair machinery.

COVALENT HISTONE MODIFICATIONS

Histones undergo a variety of posttranslational modifications (including methylation, acetylation, phosphorylation, SUMOylation,

citrullination, ubiquitination, and ADP-ribosylation) that alter their interactions with DNA and nuclear proteins (Fig. 2.2). Histone-modifying enzymes are broadly classified as “writers,” such as histone methyltransferases (HMTs) and histone acetyltransferases (HATs) that add functional groups, or “erasers,” such as histone demethylases (HDMs) and histone deacetylases (HDACs). DNA-binding proteins contain a variety of “reader” protein domains (including bromodomains, chromodomains, tudor domains, SANT domains) that have increased affinity for modified histones. In this way, covalently modified histones constitute a “histone code” that is a defining feature of the dynamic epigenome. Each of the eight histones in a nucleosome can harbor multiple covalent modifications, giving the histone code tremendous combinatorial complexity.

Trimethylation of H3 lysine 4 (H3K4me3) and trimethylation of H3 lysine 36 (H3K36me3) are both associated with transcriptional activation. H3K4me3 occurs at the promoter of active genes, and the degree of trimethylation is broadly correlated with transcriptional activity of the gene. H3K36me3 is deposited by the lysine methyltransferase KMT2A (also known as MLL1) component of the Mediator complex and occurs in the body of active genes. H3K36me3 associates with elongating RNA polymerase II, thus marking actively transcribed genes. Mono- and dimethylation of H3 lysine

Fig. 2.2 HISTONE MODIFICATIONS AND HISTONE-MODIFYING ENZYMES. (A) The N-terminal tails of core histones contain lysine (K), arginine (R), serine (S), and threonine (T) residues that are common targets for a variety of posttranslational modifications, including methylation (Me), acetylation (Ac), phosphorylation (P), and ubiquitination (Ub). (B) Histone-modifying enzymes can be broadly classified as either “writers” or “erasers” based upon addition or removal of functional groups, respectively. Moreover, many DNA-binding proteins contain “reader” protein domains (bromodomains, SANT domains, tudor domains, or chromodomains) having increased affinity for acetylated, phosphorylated, methylarginine, and methyllysine modified nucleosomes, respectively. *HAT*, Histone acetyltransferase; *HDAC*, histone deacetylase; *KDM*, lysine demethylase; *KMT*, lysine methyltransferase; *PAD*, peptidylarginine deiminase; *PPTase*, protein phosphatase; *PRMT*, protein arginine methyltransferase.

4 (H3K4me1/2) and acetylation of H3 lysine 27 (H3K27ac) are marks of active enhancers, and the degree of H3K27ac is broadly correlated with enhancer activation. H3K27ac is the enhancer mark most commonly used to define superenhancers.

Several histone modifications are particularly associated with repressed genes: trimethylation of H3 lysine 27 (H3K27me3), di- and trimethylation of H3 lysine 9 (H3K9me2/3), and trimethylation of H4 lysine 20 (H4K20me3). H3K27me3 is deposited at both promoters and enhancers by the polycomb repressive complex 2 (PRC2) and mediates recruitment of PRC1, resulting in chromatin condensation and transcriptional repression. H3K9me2/3 and H4K20me3 are both highly associated with heterochromatin. H3K9me2/3 serves as a binding site for heterochromatin protein 1 (HP1). HP1 recruits additional histone-modifying enzymes, including the lysine methyltransferases KMT5B and KMT5C that produce H4K20me3.

Stem cells harbor promoters marked by both activating H3K4me3 and repressive H3K27me3. Upon cellular differentiation, these “bivalent” or “poised” promoters are rapidly converted to either an activated or a repressed state.

The Aurora B kinase phosphorylates histone H3 at serine 10 (phospho-H3S10), triggering chromosome condensation during mitosis. Phosphorylation of H2B at serine 14 (phospho-H2BS14) mediates chromatin condensation during apoptosis.

TRANSCRIPTION FACTORS

A transcription factor is a protein that binds to specific DNA sequences and contributes to modulation of gene expression. Transcription factors are the key determinants of the epigenetic state of the cell. They are modular in structure and contain the following domains:

- A DNA-binding domain (DBD), having high affinity for specific sequences of DNA
- A *trans*-activating domain (TAD) or *trans*-repressive domain (TRD), mediating protein–protein interactions with transcriptional coregulators
- An optional signal-sensing domain (SSD) (e.g., a ligand binding domain), which can modulate DNA-binding and/or protein-binding activity in response to cellular cues

DNA sequences having high affinity for transcription factor binding are often referred to as *response elements*. Transcription factor binding to accessible promoters and enhancers recruits additional proteins, such as coactivators/corepressors, chromatin remodelers, histone-modifying enzymes, and RNA polymerases, to modulate gene expression.

Although sequence-specific DNA binding is a defining feature of transcription factors, chromatin accessibility is a key determinant of transcription factor binding. Most transcription factors preferentially bind nucleosome-free DNA. In many cases, a transcription factor needs to compete for DNA binding with other transcription factors, histones, and nonhistone chromatin proteins. The competitive balance between nucleosome and transcription factor binding is critically affected by chromatin remodeling complexes (see later). In practice, only a small fraction of potential response elements is actually bound, and many experimentally detected transcription factor binding sites (TFBS) lack canonical response elements. The genome-wide pattern of transcription factor binding can be determined experimentally using chromatin immunoprecipitation (ChIP) and next-generation sequencing (ChIP-Seq; see later) and is known as the transcription factor cistrome.

Different cell types typically express both common and distinct transcription factors. Moreover, the cistrome of a transcription factor differs among cell types, reflecting differences in chromatin accessibility and helping to define active promoters and enhancers. Master transcription factors are a special subset of lineage-defining transcription factors having expression restricted to specific cell types and demonstrating very high binding at superenhancers.

CHROMATIN REMODELERS

Chromatin remodeling alters the position, occupancy, or histone composition of a nucleosome within chromatin. Adenosine triphosphate (ATP)-dependent changes in nucleosome position and occupancy are mediated by the multisubunit chromatin remodeling complexes, which fall into four families: switch/sucrose nonfermentable (SWI/SNF), imitation SWI (ISWI), chromodomain helicase DNA binding (CHD), and INO80. ATP-independent changes in nucleosome position and occupancy can occur in response to transcription factor binding or through the action of histone chaperones that can deposit, remove, or exchange histones. Each of these activities alters the accessibility of DNA to transcription factors and other DNA-binding proteins.

Complexes in the SWI/SNF family include the Brg1/Brm-associated factor (BAF) complex, polybromo-associated BAF (PBAF) complex, and Williams syndrome transcription factor *including* nucleosome assembly complex (WINAC). They contribute to transcriptional regulation and DNA repair. In addition to nucleosome sliding, SWI/SNF complexes have been implicated in chromatin looping as well as in eviction of H2A/H2B dimers from the nucleosome. Members of the INO80 family of complexes participate in transcription and DNA repair, but they can also catalyze the exchange of histones from the nucleosome structure. For example, SRCAP can exchange the H2A/H2B histone dimer for a variant H2A.Z/H2B dimer, which is associated with actively transcribed promoters. The CHD nucleosome remodeling family is the largest, and its best-characterized member is the nucleosome remodeling deacetylase (NURD) complex. A subset of NURD complexes incorporates the MBD2 subunit, which preferentially binds methylated DNA, and promotes the repression of genes through its remodeling and HDAC activities. Many alternative NURD complexes incorporate different DNA-binding proteins and can contribute to transcriptional activation. ISWI family chromatin remodeling complexes catalyze the sliding of nucleosomes in short increments and participate in nucleosome spacing after DNA replication, RNA polymerase elongation, transcriptional regulation, and DNA damage repair.

Remarkably, cancer genome sequencing studies have identified frequent inactivating mutations in chromatin remodelers in a variety of human cancers. The SWI/SNF complex has particularly emerged as a powerful tumor suppressor whose disruption occurs in nearly 20% of primary human tumors.

EXPERIMENTAL APPROACHES IN EPIGENETICS

As dramatically as high-throughput sequencing has impacted the ability to understand the genome, its facilitation of epigenomic research has been equally profound. A wide variety of experimental approaches are in use and in development for epigenomic research, but most are predicated on detecting (1) DNA methylation, (2) protein–DNA interactions, (3) chromatin accessibility, and (4) three-dimensional chromatin structure/looping (Fig. 2.3).

A key feature of all of these techniques is the ability to isolate a subset of DNA sequences from the larger genome on the basis of a specific chromatin feature. This has several practical implications for experiments. First, many techniques rely on cross-linking agents such as formaldehyde to covalently link proteins to each other and to the DNA they bind. Cross-linking rapidly kills cells and “freezes” chromatin. Second, all of these experimental techniques involve fragmenting chromosomes into much smaller pieces, either by physical disruption (sonication) or by endonuclease treatment. Third, the chromatin subset of interest is extracted and enriched by immunoprecipitation, isolation of chromatin fragments of specific sizes, and/or sequence-specific amplification via polymerase chain reaction (PCR). Finally, DNA is isolated from this chromatin subset and subjected to next-generation sequencing.

A common technique for determining the genome-wide methylome is bisulfite-sequencing. Treatment of DNA with bisulfite converts cytosine residues to uracil but leaves 5-methylcytosine (5mC)

Fig. 2.3 EXPERIMENTAL TECHNIQUES IN EPIGENOMICS. Schematic representations of bisulfite sequencing (Bisulfite-Seq), chromatin immunoprecipitation sequencing (ChIP-Seq), DNase I sequencing (DNase-Seq), assay for transposase-accessible chromatin with high-throughput sequencing (ATAC-Seq), and chromatin conformation capture-based (3C-based) experimental techniques. *PCR*, Polymerase chain reaction.

residues unaffected. Comparing results of bisulfite-treated and bisulfite-untreated DNA sequencing permits genome-wide differentiation of methylated and unmethylated cytosines. Alternatively, methylated DNA immunoprecipitation sequencing uses an antibody recognizing 5mC to enrich for methylated segments of the genome before next-generation sequencing.

DNA binding by transcription factors, transcriptional machinery, structural proteins, and covalently modified histones can all be mapped in genome-wide fashion using ChIP-Seq. ChIP-Seq typically requires cross-linking of proteins to DNA using formaldehyde or other chemical fixation techniques. Chromatin is then fragmented, antibodies are used to enrich for a protein of interest, and the associated DNA fragments are then identified by next-generation sequencing. ChIP-Seq is the most versatile technique in epigenomic research. For example, genome-wide maps of histone modifications (such as H3K27ac or H3K36me3), active RNA polymerase II, insulator protein CTCF, superenhancer-associated Mediator complex, and transcription factors can all be accomplished via ChIP-Seq using different antibodies.

DNase-Seq and assay for transposase-accessible chromatin sequencing (ATAC-Seq) are two common techniques used to assess genome-wide chromatin accessibility. DNase-Seq exposes native chromatin to cleavage by the DNase I endonuclease, the activity of which is inversely related to protein binding by DNA. Chromatin

regions most sensitive to DNase I cleavage are termed *DNase hypersensitive sites* (DHSs) and are highly enriched for transcriptionally active and gene-regulatory segments of the genome. ATAC-Seq is an alternative measure of chromatin accessibility based upon susceptibility of chromatin regions to the activity of a hyperactive transposase. Transposase activity is highest in nucleosome-free regions, and ATAC-Seq typically identifies transcriptionally active and gene-regulatory regions largely similar to those identified by DNase-Seq. Importantly, DNase-Seq and ATAC-Seq provide genome-wide snapshots of active chromatin regions without regard to the involved transcription factors or chromatin regulators.

Chromosome conformation capture (3C) techniques aim to identify three-dimensional chromatin loops, such as those bringing promoters in close proximity to enhancers. All 3C-based methods begin with chromatin cross-linking. Following DNA fragmentation, a random DNA ligation step is performed to generate circular DNA molecules. Sequencing these DNA loops yields fragment pairs that, although separated by many kilobases in linearly organized DNA, are physically approximated in functional chromatin. 3C-based methods have tremendous potential to map enhancers to the genes whose activity they modulate.

The fundamental challenge in epigenomic research is integrating the results of many different experiments to understand how myriad chromatin features interact in regulating transcription and cellular

behavior (Fig. 2.4). Thus, interpreting the epigenetic code requires measuring transcriptional activity in addition to chromatin features. Measurement of global transcript levels by mRNA sequencing (RNA-Seq) is now the most common technique used to study gene expression, but interest is growing in the related genomic run-on sequencing (GRO-Seq) technique. GRO-Seq measures active transcription rather than total cellular transcript level and therefore holds promise for improved correlation with epigenomic data.

Several collaborative research consortia are dedicated to generating and curating genome-wide epigenetic data for public use, including the National Human Genome Research Institute (NHGRI) ENCODE and Roadmap Epigenomics projects. These resources include results of histone modifications and transcription factor ChIP-Seq, DNase-Seq, DNA methylation sequencing, and RNA-Seq experiments for hundreds of human cancer cell lines and primary

human tissues, respectively. The most versatile and widely available tool for visualizing epigenomic data is the UCSC Genome Browser, which incorporates easy access to ENCODE, Roadmap, and other data sources for integrative analysis of epigenomic and gene expression data (Fig. 2.5).

MECHANISMS OF DISEASE

The mechanisms of disease described in this chapter are not strictly epigenetic, insofar as they are all predicated on changes in genome sequence or structure (genetic mutations). Nonetheless, insights into disease pathogenesis and development of novel therapeutic targets have been vastly informed by understanding the ways in which these genetic changes drive aberrant chromatin regulation and gene expression.

Sickle cell anemia has long been known to result from a point mutation in the hemoglobin beta gene. The severity of this often life-threatening hemoglobinopathy is attenuated in patients having increased expression of the fetal gamma hemoglobin variant, a trait known as hereditary persistence of fetal hemoglobin (HPFH). Genome-wide association studies in patients with HPFH identified frequent single-nucleotide polymorphisms (SNPs) in a small number of noncoding regions near the *BCL11A* gene on chromosome 2. Subsequent studies have elegantly demonstrated that these SNPs are located in erythroid-specific enhancers modulating *BCL11A* expression. The HPFH-associated SNPs diminish binding of transcription factors GATA-binding protein 1 (GATA1) and T-cell acute lymphocytic leukemia protein 1 (TAL1), which results in decreased expression of *BCL11A*. Because *BCL11A* is required for efficient silencing of fetal hemoglobin expression, patients with sickle cell anemia having these common variant SNPs demonstrate elevated fetal hemoglobin throughout adulthood and are often protected from the most severe manifestations of the disease. Just as sickle cell anemia is among the most striking examples of disease caused by a point mutation in the coding region of a gene, these *BCL11A* enhancer SNPs demonstrate the power of gene-regulatory elements to modulate the sickle cell disease phenotype.

Chromosomal translocations that result in aberrant expression of oncogenes or leukemogenic transcription factors are another common mechanism of disease. The classical example of this is Burkitt lymphoma, in which t(8;13) translocations juxtapose the highly active immunoglobulin heavy chain enhancers and the *c-myc* oncogene, driving myc overexpression and oncogenic transformation of mature B cells. Similarly, many different translocations have been identified in T-cell acute lymphoblastic leukemia (T-ALL) whereby

Fig. 2.4 DNA-PROTEIN INTERACTIONS IN EUCHROMATIN AND HETEROCHROMATIN.

Fig. 2.5 VISUALIZING THE EPIGENOMIC LANDSCAPE. Sample of a UCSC Genome Browser representation of a 700-kb segment of chromosome 2 in the lymphoblastoid human cell line GM12878. Integration of publicly available, genome-wide data for a variety of epigenomic experiments is the cornerstone of efforts to decode the epigenome.

overexpression of master transcription factors such as *TAL1*, *LIM* domain only 1 (*LMO1*), *LMO2*, and *HOX11* is driven by chromosomal rearrangements involving the T-cell receptor loci.

An alternate mechanism driving *TAL1* overexpression in T-ALL has recently been described in which small genomic insertions (2–18 bp) upstream of the *TAL1* coding region introduce novel binding sites for the myeloblastosis (MYB) transcription factor. This aberrant MYB binding recruits additional transcription factors Runt-related transcription factor 1 (RUNX1), GATA3, and TAL1, as well as the HAT CREB-binding protein (CBP), and forms a superenhancer driving leukemogenic *TAL1* overexpression.

Many different translocations resulting in fusion of the mixed-lineage leukemia (*MLL1/KMT2A*) gene, located on chromosome 11q23, with over 70 different partner proteins have been identified in infant ALL and therapy-associated acute myeloid leukemia (AML). The mechanisms underlying the leukemogenic nature of these translocations have been elucidated only recently. Leukemogenic MLL1 fusion proteins fuse the N-terminal targeting domain with a transcription elongation factor such as ENL or AF9. The resulting fusion protein drives overexpression of common MLL1 targets by recruiting the DOT1L complex (having H3K79 methyltransferase activity) and the positive transcription elongation factor b (P-TEFb) complex (containing CDK9 and phosphorylating RNA polymerase II). Moreover, a subset of leukemogenic MLL1 fusions can inhibit the transcriptional repressive activity of PRC1. In summary, MLL translocations in ALL and AML define a paradigm of leukemia development based upon transcriptional dysregulation through aberrant targeting and control of transcription elongation activity.

As noted earlier, inactivating mutations in components of chromatin remodeling complexes such as SWI/SNF have been identified in a wide variety of human cancers. For example, researchers in a recent study found mutations in the ARID1A subunit of SWI/SNF in 17% of patients with Waldenström macroglobulinemia, and patients with ARID1A mutations had more aggressive disease features. In addition to their nucleosome remodeling activities, chromatin remodeling complexes contribute to three-dimensional chromatin structure, participate in DNA damage repair, modulate transcription factor binding, and recruit histone-modifying enzymes. Precisely how disruption of these many chromatin regulatory activities contributes to disease is an extremely active area of research.

In addition to these epigenetic contributions to disease development, much interest has evolved in potential epigenetic mechanisms of resistance to existing cancer therapies. One example of this is resistance of T-ALL to γ -secretase inhibitors (GSIs), used to target abnormal *NOTCH1* activation. Treatment of T-ALL cell lines with GSIs in vitro kills a large proportion of cells, but it leaves behind a “persister” population of GSI-resistant cells. If GSI treatment is removed, these persister cells revert to their prior GSI-sensitive state, suggesting an epigenetic mechanism of drug resistance. A screen of chromatin regulators required for persister cell viability identified the bromodomain-containing 4 protein (BRD4), a key factor in activating transcriptional elongation. This study and many others have ignited broad interest in other potential epigenetic mechanisms of therapy resistance as well as BRD4 as a specific therapeutic target.

EPIGENETIC THERAPIES

Epigenetic therapies are among the most active areas of preclinical and clinical cancer research because of their potential to specifically target chromatin-mediated disease mechanisms and the expectation that these therapies will have fewer side effects than conventional cytotoxic chemotherapies. As seen in Table 2.1, several classes of drugs have emerged, and the rationales for their ongoing development are briefly discussed next.

The first class of epigenetic drugs to show significant clinical benefit is the DNMT inhibitors, particularly 5-azacytidine and its analogue decitabine. As discussed earlier, abnormal DNA methylation is a common feature of many cancers. However, azacytidine is

TABLE 2.1 Emerging Epigenetic Therapies

Class	Target	Disease
DNA Methylation Inhibitors	DNMTs	MDS, AML
Histone-modifying enzymes		
HMT inhibitors	DOT1L, EZH2, nonspecific	MLL-rearranged leukemias, NHL, MDS, AML
HDAC inhibitors	HDAC6, nonspecific	MM, CLL, lymphoma
HMT activators	SIRT1, SIRT5	MM
HDM inhibitors	KDM1A	AML
BET Bromodomain Inhibitors	BRD4, nonspecific	Hematologic malignancies

AML, Acute myeloid leukemia; BET, bromodomain and extra-terminal motif; CLL, chronic lymphocytic leukemia; DNMTs, DNA methyltransferases; HDAC, histone deacetylase; HDM, histone demethylase; HMT, histone methyltransferase; MDS, myelodysplastic syndrome; MLL, mixed-lineage leukemia; MM, multiple myeloma; NHL, non-Hodgkin lymphoma.

beneficial primarily in treating myelodysplastic syndromes and AML. The theoretical basis for this therapeutic effect is reactivation of key tumor suppressor genes by disruption of DNA methylation at their promoters. However, this mechanism has not yet been confirmed in azacytidine-treated patients, and alternate mechanisms of action are under investigation.

By far the largest class of epigenetic therapies is inhibitors of histone-modifying enzymes. Drugs inhibiting HMTs and HDACs are most prevalent, though several compounds that activate HDACs or inhibit HDMs are also being developed. For example, inhibitors of the H3K79 methyltransferase DOT1L are in clinical trials for MLL-rearranged leukemias. Alternatively, inhibitors of the H3K27 methyltransferase EZH2 (the catalytic component of the PRC2 complex) are being tested in non-Hodgkin lymphoma. Specific inhibitors of HDAC6 are being used in trials for multiple myeloma, and drugs having broad HDAC inhibitory activity are in ongoing trials for a wide variety of hematologic malignancies.

The newest class of epigenetic therapies includes the bromodomain and extra-terminal motif (BET) bromodomain inhibitors. As discussed briefly earlier, bromodomains are an extremely common feature of DNA-binding proteins and preferentially recognize acetylated chromatin. The abundance of bromodomain-containing DNA-binding proteins makes development of substrate-specific drugs extremely challenging. However, initial clinical trials using BET bromodomain inhibitors having broad binding specificity have been very promising in a wide variety of advanced hematologic and non-hematologic malignancies. The likely therapeutic targets of these drugs are the transcriptional machinery itself, though many additional mechanisms plausibly contribute.

FUTURE DIRECTIONS

Interpreting the epigenetic code holds great potential for bridging the gaps between the molecular biology of the genome, cellular biology, and physiology of health and disease. The application of next-generation sequencing technology and development of novel techniques to interrogate chromatin have produced a profusion of new epigenetic data. Collaborative epigenomic projects such as ENCODE and the Epigenome Roadmap, as well as genomics efforts such as the 1000 Genomes Project and The Cancer Genome Atlas, make these vast data widely available to researchers. The substantial challenge remains integrating and interpreting these data to generate novel insights into human health and disease. Substantial collaboration between biomedical scientists, computational biologists, and

physicians will be necessary to design, execute, and analyze projects with high relevance to medical progress.

GENOMIC APPROACHES TO HEMATOLOGY

Jens G. Lohr, Birgit Knoechel, and Todd R. Golub

The publication of the initial draft sequence of the human genome in 2001 heralded a new era of biomedical research. Just as molecular biology changed the face of research in the 1970s and 1980s, genomics has promised a novel perspective into the biologic basis of human disease. Genomics involves the systematic study of biologic systems, typically focusing on aspects of the genome (e.g., DNA and its derivatives RNA and protein). However, a major tenet of genomic research involves *hypothesis-generating* data collection as opposed to *hypothesis-testing* experimentation. The latter has formed the basis of biomedical research, whereby existing knowledge and insight guide the testing of a particular hypothesis. In contrast, genome-based research tends to make few prior assumptions, favoring unbiased data generation and analysis as a path to discovery. Clearly, both approaches are powerful and essential, and both should continue at full force in the future. Although still associated with substantial cost, sequencing approaches such as whole genome and whole exome DNA sequencing or whole-transcriptome RNA sequencing have become available at most academic institutions, either through in-house services or through a number of commercial providers. Large-scale national and multinational genomic profiling efforts such as The Cancer Genome Atlas have led to the establishment of repositories of genomic variants for the most common malignancies. Next-generation sequencing approaches are being integrated into clinical routine and are used as both prognostic and predictive biomarkers. The latter are proving particularly useful as more drugs become available that target specific genomic variants (e.g., BRAF inhibitors targeting *BRAF* V600E mutations). The assignment of a particular therapeutic agent to a specific genomic finding has gained momentum over the past several years and was recently termed *precision medicine*.

However, with the ability to generate data of unprecedented scale, including sequencing of the whole genome, comes the challenge of data analysis. This has driven an entirely new generation of computer scientists to focus on new approaches to genomic data analysis, leading to new methods of pattern recognition and large-scale data processing. Translating these data into useful knowledge that provides biologic insight and clinical utility is an ongoing challenge.

This chapter describes the principles underlying common genomic approaches in the study of hematologic and other diseases, focusing more on concepts than on technical detail. Undoubtedly, there will be continuous acceleration of the pace of use of genomic approaches in clinical research and clinical care in the years ahead.

PRINCIPLES OF GENOMIC APPROACHES

Measurements and Perturbations

A common feature of many genomic approaches is the systematic nature of the approach (e.g., interrogating *all* kinases for their potential role in a particular biologic system). A more traditional approach would be to first determine (on the basis of prior knowledge) the kinase (or kinases) most likely to be important and then develop highly validated assays for that particular kinase. On one hand, a strength of the traditional approach is that the quality of the final assay is often high, given the attention paid to the one (or a couple of) kinase(s) of interest. On the other hand, such an approach is limited by the quality of the initial hypothesis. In contrast, a genomic approach would be more systematic and comprehensive, attempting

to screen all kinases for the phenotype of interest. Although this is compelling, it also comes with an important limitation—the quality of the assay for each kinase's activity may not be uniformly high. For example, a screen for kinase phosphorylation as a surrogate for kinase activity has been reported. Such an approach is limited by the sensitivity and specificity of kinase-directed antibodies, which can be enormously variable across kinase family members.

Although genomics is most commonly associated with systematic *observational* studies, the same principles can also be applied to *perturbational* studies (i.e., systematic modulation of proteins followed by a phenotypic read-out). In this manner, all genes within a particular class (e.g., kinases) can be mutated, knocked down (e.g. by RNA interference), or completely knocked out (e.g., by genome editing), and the phenotypic consequence of each can be assessed. A number of genomic perturbational technologies have been developed recently, most notably the discovery of clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated protein 9 (Cas9)-mediated genome editing, as described later. Use of these perturbational technologies in combination with high-throughput sequencing will yield great insight into the biology of hematologic diseases in the years ahead.

Importance of Sample Acquisition

Acquisition of the appropriate samples for a genomic experiment is arguably the most crucial step for the generation of a dataset expected to be rich with biologic information. This is particularly true for gene expression analysis, in which a number of processes may affect data quality. Because gene expression is a dynamic process that can be affected by any type of cellular manipulation, RNA abundance measurements are potentially complicated by changes that occur between the time that the biopsy is taken and the time that the RNA is isolated from the specimen. In general, the highest-quality RNA is obtained if, as soon as possible after harvesting a sample, cells are dissolved in a solution such as TRIzol reagent that inactivates RNase enzymes and the sample is stored at -80°C until RNA can be extracted. Procedures for measuring gene expression in formalin-fixed, paraffin-embedded (FFPE) tissues (in which messenger RNA [mRNA] is degraded to less than 100 nucleotides) have been used, but the lack of robustness of these methods may preclude routine clinical implementation.

Another extremely important but complicated issue is the complexity of cell types (e.g., tumor cells, normal cells of the same lineage, stromal cells, immune cells) present in the sample. This may be less of an issue for bone marrow samples taken from patients with newly diagnosed leukemia, in whom the number of blasts often approaches 90% or greater. In the relapsed leukemia setting (where the percentage of blast cells may be low) or in other tumor types, however, the admixture of multiple cell types may be vexing for gene expression studies. Multiple methods are available for enrichment and selection of cells of interest from a biopsy sample; these methods include flow cytometry, immunomagnetic bead sorting, and laser-capture microdissection. All have the benefit of enrichment of the cell of interest but also increase the amount of processing time and sample manipulation. Although in principle “contaminating,” nonmalignant cells may reflect informative aspects of the tumor environment, the high degree of sample-to-sample variability makes such interpretations challenging. A promising new approach to the problem of cell-type

heterogeneity involves analyzing cells at the single-cell level, as described later.

At the level of DNA analysis (as opposed to RNA analysis), the admixture of nonmalignant cells within a tumor may not obscure the presence of mutations in the tumor cells, even if those cells represent a minority population. However, the detection of mutations in a subset of cells within a sample requires extra depth of sequencing beyond what would be required to sequence, for example, a normal diploid genome. Thus it becomes critical to have a rough estimate of the purity of a given sample so that the appropriate genomic approach can be used subsequently.

Analytical Considerations

Unsupervised learning approaches (often referred to as *clustering*) have become an important part of the discovery process in genomic analysis. This type of analysis involves grouping samples solely on the basis of data obtained without regard to any prior knowledge of the samples or the disease. Thus one can obtain the predominant “structure” of the dataset without imposing any prior bias. For example, unsupervised learning approaches have been used to cluster leukemia or lymphoma samples on the basis of their gene expression profiles with the goal of uncovering the most robust classification schemes. Clustering algorithms can also cluster genes that have a similar expression profile in a gene expression dataset. There are a number of methods for clustering genes and samples, all of which have computational strengths and weaknesses. Comparison of the clustering methods is beyond the scope of this chapter, but suffice it to say that

all of these methods identify major associations within a given dataset if the signature is strong and robust. Great care must be taken in the interpretation of clustering results because clusters with distinct gene expression profiles may be caused not only by biologically important distinctions but also by artefacts of sample processing. Unsupervised learning methods that have been used include hierarchical clustering, principal component analysis, nonnegative matrix factorization, *k*-means clustering, and *t*-distributed stochastic neighbor embedding.

Supervised learning approaches are best suited for comparing data between two or more classes of samples that can be distinguished by some known property (or class distinction), such as biologic subtype or clinical outcome. For example, to determine the gene expression differences between different leukemia subtypes with distinct genetic abnormalities, one would use a supervised approach (Fig. 3.1). The same genes might be clustered together on the basis of unsupervised approaches already described, but they might also be obscured by a more dominant gene expression signature that is unrelated to the distinction of interest. For example, if there were another major signature within the data (i.e., a stage of differentiation signature), the differences that the investigator was searching for might be lost. A number of metrics can be used to identify genes that are differentially expressed between two groups of samples, all of which are best suited to identification of genes that are uniformly highly expressed in one group. Although the different metrics may generate slightly different lists of gene expression differences, if the gene expression difference is robust, all should give comparable results.

With the ability to generate large-scale genomic datasets come a number of analytical issues that are unique to what has come to be known as “big data.” In particular, when the number of features

Fig. 3.1 COMPARISON OF GENE EXPRESSION IN ACUTE LYMPHOBLASTIC LEUKEMIA (ALL), MIXED-LINEAGE LEUKEMIA (MLL)-REARRANGED ALL (DESIGNATED MLL), AND ACUTE MYELOGENOUS LEUKEMIA (AML) SAMPLES USING A SUPERVISED LEARNING APPROACH. Gene expression in leukemia samples was analyzed using Affymetrix microarrays containing 12,600 unique probe sets. Genes that are highly expressed in one type of leukemia relative to the other two are shown. Each column represents a patient sample, and each row represents a gene. Red represents relative high-level expression and blue relative low-level expression. (From Armstrong SA, Staunton JE, Silverman LB, et al: MLL translocations specify a distinct gene expression profile that distinguishes a unique leukemia. Nat Genet 30:41, 2002.)

analyzed in an experiment (e.g., the expression of each of 22,000 mRNA transcripts) exceeds the number of samples (e.g., 50 patients with a particular type of lymphoma), there is potential for finding patterns in the data simply by chance. The more features analyzed and the fewer the number of samples, the more likely such a phenomenon is to be encountered. For this reason, the use of nominal *p*-values to estimate statistical significance of an observed observation is generally discouraged. Rather, some approach to correcting for multiple hypothesis testing is in order. (In the present example, 22,000 hypotheses are effectively being tested.) In the absence of such penalization, the significance of observations is likely to be grossly overestimated. Indeed, such misinterpretations of data were at the root of many of the early uses of gene expression profiling data in biomedical research.

Related to the challenges with high-dimensional data described, special considerations of pattern-matching algorithms must be made. With the availability of high-dimensional gene expression profiling data in the late 1990s came a flood of computational innovation from computer scientists looking to find biologically meaningful patterns amid biologic data. With that early wave of computational analysis came the realization that with often limited numbers of samples (compared with the number of features analyzed) comes the possibility of “overfitting” a computational model to a particular dataset—that is, defining a pattern (e.g., a spectrum of genes that are differentially expressed) that is correlated with a phenotype of interest (e.g., survival) in an initial dataset but then does not predict accurately when applied to an independent dataset. This failure to reproduce initial findings was variously attributed to technical defects in the genomic data itself, insufficiently complex algorithms, and the possibility that perhaps the most important features were not being analyzed in the first place (e.g., noncoding RNAs). In fact, however, nearly all of the early failures of pattern recognition algorithms to validate when applied to new datasets were attributable to overfitting of the models to an initial, small dataset. The solution to this problem is to ensure that discovery datasets are sufficiently large to avoid overfitting and to insist that, before any clinical or biologic claims are made, the model be tested on completely independent samples.

NEXT-GENERATION SEQUENCING TECHNOLOGY

Beginning around 2006, a number of new approaches to DNA sequencing burst onto the scene. These technical advances have transformed the field of genomics and will likely equally transform the diagnostics field in the years to come. A number of novel sequencing approaches have been commercialized, and their details are beyond the scope of this chapter. However, they differ fundamentally from traditional Sanger sequencing, which has been the mainstay for the past several decades. First, and most well recognized, is the dramatically lower cost of current sequencing methods compared with Sanger sequencing. Costs have dropped by nearly 1 million-fold compared with the sequencing of the first human genome. This drop in cost has transformed genome sequencing from the work of an entire community over the course of more than a decade (the initial sequencing of the human genome took 15 years and approximately \$3 billion) to a routine experiment that can be done for hundreds of samples by major sequencing centers in the course of a week in 2016. These exponential cost reductions have come about not through dramatic drops in reagent costs but rather through dramatic increases in data output. A single lane on a modern sequencer generates vastly more data than a lane of conventional sequencing. This is relevant because to realize the lower costs of contemporary sequencing, large-scale projects must be undertaken. That is, devoting a single lane of sequencing to the sequencing of a plasmid, for example, is *more* expensive with current technologies than with traditional Sanger sequencing; the cost savings are realized only when large data outputs are required (e.g., the sequencing of entire genomes or of isolated genes across large numbers of patients).

When executed and analyzed properly, next-generation sequencing technologies can yield nearly perfect fidelity of sequence. At the

same time, the error rates for any given sequencing read can be as high as 1%, depending on the sequencing platform. How can these two statements both be correct? Although a 1% error rate (99% accurate) may seem low, when taken in the context of sequencing all 3 billion bases of the human genome, that would in principle result in 30 million errors! Thankfully, this is not the case, because most sequencing errors are idiosyncratic—that is, they are not a function of a particular DNA sequence. The consequence of this is that by simply resequencing the same region multiple times and taking the consensus read, such idiosyncratic errors are lost; it is highly unlikely for them to occur over and over again at the same spot.

For normal, diploid genomes, sequencing is typically done at least 30-fold over (referred to as *30× coverage*). The consensus obtained by observing a given nucleotide 30 times is generally sufficient for rendering the correct read of that nucleotide. However, things get more complicated when dealing with (1) tumors containing gene copy number alterations (e.g., aneuploidy or regions of gene deletion or amplification) or (2) admixture of normal cells within the tumor sample. To compensate for copy number variation and normal cell contamination seen in most samples, typical cancer genome sequencing projects aim for a depth of coverage of at least 100×. Sequencing for diagnostic purposes may require even greater depth of coverage. In addition, the analysis of samples containing only rare tumor cells (e.g., 10%) would require ultradeep sequencing; otherwise, any tumor-specific mutations would likely become false negatives. Importantly, the frequency of cancer-associated mutations in studies performed using traditional Sanger sequencing methods may have been underestimated because of the lack of power to detect mutations in tumors with significant normal cell contamination. Whereas Sanger sequencing delivers the *average* allele observed in a sample, next-generation sequencing methods deliver a *distribution* of observed alleles, allowing for mutant alleles to be identified even if they represent a minority population.

Future of Sequencing Technologies

No one could have predicted the dramatic advances that have come to DNA sequencing technologies over the past decade. Costs have dropped dramatically, and it is predicted that costs will continue to drop, although less precipitously. The cost of whole-genome sequencing was estimated to be \$1000 in 2016; however, this cost can be achieved only when sequencing many samples from large cohorts of patients, not on an individual sample-by-sample basis. Also, in addition to sequence *generation*, there is a high cost associated with sequence *analysis*. The cost of storage of genome sequence and analysis may exceed the cost of generating the data in the first place, and a detailed analysis is far from straightforward. Nevertheless, it is likely that, over the decade ahead, genome sequencing will become a routine component of both clinical research and routine clinical care.

DNA-LEVEL CHARACTERIZATION

Somatic Versus Germline Events

It is important to recognize the fundamental difference between *germline* variants and *somatic* variants in genome sequences. Germline variants are present in all cells of the body (with the exception of rare mosaicism), and these variants can contribute to the risk of future disease. Germline variants can be common (i.e., seen in ≥5% of the human population), or they can be rare (in principle, unique to a single individual). Each individual also carries *de novo* variants that are present in neither of the individual's parents' genomes. It has been demonstrated recently by genetic analyses of large populations that aging individuals without evidence of hematologic disease acquire mutations over time in genes that are associated with leukemia. This observation has been named *clonal hematopoiesis of indeterminate potential*. This indicates that expansion of particular clones occurs that is associated with an increased risk of myeloid and lymphoid

neoplasia. Similarly, monoclonal gammopathy of undetermined significance and monoclonal B-cell lymphocytosis are characterized by clonal expansion of lymphoid clones that are usually associated with multiple myeloma and chronic lymphocytic leukemia, respectively. Because only a minority of individuals go on to develop a clinically symptomatic neoplasm, an important goal is to identify additional variants that promote the development of overt malignancy. Also of great interest is the question of the extent to which hematologic diseases (whether malignant or otherwise) are caused by germline genetic variation. Although it is clear that certain disorders (e.g., hemophilia) have a highly penetrant, Mendelian basis, it is less certain whether genetic variation substantially contributes to diseases that have been historically considered “sporadic” in the large majority of cases, such as multiple myeloma.

In contrast, mutations present in tumors but absent in the normal cells from that individual are referred to as *somatic*. Somatic mutations are thought to be a major driver of cancer behavior. However, all somatic mutations are not causal *drivers* of cancer. Indeed, the majority of somatic mutations observed in any individual tumor are likely passenger mutations—that is, they play no functional role in the pathogenesis of the tumor but rather were present in a cell that subsequently acquired a driver mutation that resulted in the cell’s clonal outgrowth. The proportion of passengers to drivers differs dramatically from tumor type to tumor type. For example, tumors associated with tobacco (e.g., lung cancer) or sunlight exposure (e.g., melanoma) have very high mutation frequencies, with the majority of the observed mutations being “passengers.” In contrast, many hematologic malignancies (e.g., acute myeloid leukemia) have relatively low mutation rates, and some cancers such as infant leukemias have extraordinarily low rates, with only a handful of protein-coding somatic mutations seen per patient.

Distinguishing passenger mutations from driver mutations is a major focus of cancer genome research. The complete delineation of the biologically important mutations in cancer requires both large-scale sequencing studies (enabling the identification of recurrent mutations) and the functional characterization of observed mutations.

Point Mutations

The most common type of genetic variants (both germline and somatic) are single-nucleotide variants (SNVs), also known as point mutations. As more individuals are sequenced and deposited into databases, it is becoming possible to catalog all common SNVs in the human population. Still, it is estimated that every individual will harbor 50 to 100 coding mutations not present in any database. For these reasons, it is particularly important to compare the somatic genome of a tumor with its matched normal germline sequence; otherwise, “private” germline variants may be mistaken for somatic mutations.

Certain patterns of point mutation are characteristic of particular environmental exposures. For example, G>T/C>A transversions are characteristic of tobacco-associated lung cancer, and C>T/G>A transitions are characteristic of ultraviolet radiation-associated skin cancers. Most hematologic malignancies lack a particular pattern of mutation, although B-cell lymphomas demonstrate a characteristic pattern of hot spots of mutations caused by activation-induced, adenosine deaminase-mediated.

Although not as common as point mutations, small somatic insertions or deletions (referred to collectively as *indels*) are also observed in tumors. These generally consist of the loss or gain of one or a few nucleotides that, when they occur within protein-coding regions, result in translational frameshifts that generally yield loss-of-function alleles.

Copy Number

Gains (amplifications) or losses (deletions) of genetic material at specific loci are recognized as playing an important role in the

pathophysiology of disease. Trisomy 21, for example, predisposes individuals to transient myeloproliferative disorders and acute megakaryoblastic leukemia. Deletions at the *RB1* locus encoding the retinoblastoma gene or deletions of the *TP53* gene encoding the p53 tumor suppressor predispose individuals to the development of solid cancers, although only rarely to hematologic malignancies. In a landmark set of studies, it was shown that tumors from patients who inherit a mutant copy of the retinoblastoma tumor suppressor gene often have deletions of the remaining allele. This process has been termed *loss of heterozygosity*, and the search for genetic loci showing loss of heterozygosity in tumor samples has identified a number of genes that are involved in critical cellular processes and are important for cancer progression. Similarly, amplification of genomic loci can play an important role in oncogenesis and cancer biology. For example, amplification of the *ERBB2* (*HER2*) oncogene in human breast cancer predicts a poor prognosis, and *ERBB2* has been shown to be an important therapeutic target in this disease.

The search for gains and losses of genetic material can be carried out using a number of techniques that require various levels of expertise and allow assessment of genomic integrity at various resolutions. The first method developed to assess genomic integrity, *cytogenetic analysis*, is still used today, but it allows identification only of abnormalities that encompass large regions of the genome. Nevertheless, cytogenetic analysis has provided tremendous insight into the pathophysiology of disease, particularly for leukemogenesis. Cytogenetic analysis remains a key part of the diagnostic workup for new cases of leukemia. It is likely, however, that over time it will be replaced by next-generation sequencing methods that have the ability to detect point mutations, deletions/insertions, copy number changes, and chromosomal translocations, all at high resolution.

More recently developed methods for assessing copy number variation include comparative genomic hybridization (CGH) and high-density single-nucleotide polymorphism (SNP) arrays. Although CGH and SNP arrays are falling out of favor, massively parallel genome sequencing can be used for copy number variant detection. Special note should be made of the analysis of copy number data. At the level of the individual sample (e.g., a tumor), one can easily visualize regions of aberration using tools such as the Integrative Genomics Viewer (IGV) (Fig. 3.2). Although this type of analysis highlights those aberrations in a *particular* sample, it does not reflect copy number abnormalities that are commonly observed across a *collection* of samples. Such recurrent copy number gains or losses tend to indicate biologically important events as opposed to copy number aberrations that simply reflect genomic instability but do not contribute to cancer pathogenesis (and therefore are nonrecurrent). To identify statistically significant regions of copy number abnormalities, algorithms such as the genomic identification of significant targets in cancer (GISTIC) method can be applied, yielding a plot of regions of amplification and deletion that are commonly observed in a set of samples (as shown in Fig. 3.3 for 24 patients with multiple myeloma).

Rearrangements

Chromosomal rearrangements (including balanced and unbalanced translocations, inversions, and more complex aberrations) are particularly important in the hematologic malignancies. Translocations were among the very first genomic defects to be discovered in cancer because cytogenetic analysis of metaphase chromosome spreads was feasible for the acute leukemias long before more technically advanced methods became available. Two basic types of translocations are common: those that result in fusion proteins involving two distinct genes and those that result in overexpression of an otherwise structurally normal gene. Translocations resulting in fusion transcripts (e.g., *ETV6/RUNX1* in acute lymphoblastic leukemia [ALL]) generally involve chromosomal breakage within intronic regions of the two genes, with in-frame fusion being a result of the normal process of RNA splicing. In contrast, translocations resulting in overexpression typically involve the juxtaposition of a coding region next to a highly active promoter or enhancer region such as an immunoglobulin

Fig. 3.2 GENOME DELETION IN A PATIENT WITH DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL). Genome sequencing of a patient with DLBCL revealed a clear region of genome deletion within the *TNFRSF14* gene, as visualized in the Integrative Genomics Viewer. The gray bars indicate the extent of the sequence read, with this region being interrogated multiple times. The white block in the middle (bracketed by arrows) indicates the region of genome deletion captured by all of the reads in the tumor but in none of the reads from the matched normal DNA sample (bottom portion of figure).

region in B cells. For example, in follicular lymphoma, translocations frequently involve juxtaposition of the antiapoptotic gene *BCL2* to the immunoglobulin heavy chain enhancer region, leading to massive overexpression of *BCL2* RNA and protein.

Translocations are best detected by either whole-genome sequencing or RNA sequencing (RNA-Seq), although their detection requires advanced computational analysis to distinguish them from artefactual errors in aligning sequence reads to a reference genome. For reasons that remain unclear, some tumors contain few, if any, translocations, but others contain hundreds, often involving multiple complex rearrangements. A particularly interesting phenomenon, termed *chromothripsis*, involves extensive complex genome rearrangements thought to occur via a single “big bang” genomic catastrophe (Fig. 3.4). It has been speculated that chromothripsis may represent a mechanism by which a cell can acquire multiple oncogenic events required for cellular transformation in a single event rather than in a stepwise manner.

SEQUENCING APPROACHES TO EPIGENOMICS

Sequencing approaches to epigenomics include chromatin immunoprecipitation followed by sequencing (ChIP-Seq), micrococcal nuclease (MNase) sequencing, DNase sequencing (DNase-Seq), bisulfite sequencing and assay for transposase-accessible chromatin with high-throughput sequencing (ATAC-Seq). Although the majority of information encoded in the genome is thought to emanate from its primary DNA sequence, the importance of epigenetic gene regulatory mechanisms has become increasingly evident over the past few years. Epigenetic modifications play a critical role in the regulation of transcription, DNA repair, and replication. For example, DNA methylation can occur, particularly in CpG-rich regions of the genome, and such methylation can lead to the silencing of gene

expression at that locus. Widespread methylation appears frequently in cancer and may serve as an important mechanism of silencing tumor suppressor genes. Massively parallel sequencing, coupled with bisulfite sequencing approaches, allows for genome-wide assessment of DNA methylation in development and disease. DNA methylation is an effective mechanism of silencing genes, for example, as is required to specify cell type, but with relatively few dynamic changes over time. In contrast, open chromatin regions may be analyzed by technologies that are based on sequencing of DNA regions that are accessible for certain DNA-cutting enzymes such as DNase, micrococcal nuclease, or transposase that preferentially cut at open chromatin regions. Several large-scale profiling efforts (e.g., through the National Institutes of Health ENCODE project) have used these technologies to annotate cancer cell lines and normal human and murine tissues, including hematopoietic subsets.

Modifications to histones are orchestrated and tightly regulated by a group of enzymes called *chromatin regulators*. Perhaps one of the most striking results derived from genome-wide sequencing analyses in cancer is the frequency of somatic mutations in chromatin regulators, which account for up to 25% of all cancer drivers. Detailed mechanistic analysis of epigenetic modifications and the contribution of individual chromatin regulators to these modifications have long been hindered by a lack of effective technologies. With the use of next-generation sequencing techniques combined with chromatin immunoprecipitation, it is now possible to comprehensively investigate the molecular mechanisms of epigenetic alterations and define their disease relevance. ChIP-Seq can be used to map histone modifications that are associated with actively transcribed regions, repressed regions, or regions found at distal regulatory elements. Optimized technologies now allow for ChIP-Seq with small input of samples or with FFPE samples, which has significant implications for translating this technology to approaches for the analysis of clinical specimens.

Fig. 3.3 RECURRENT COPY NUMBER ABERRATIONS IN MULTIPLE MYELOMA. Output of the genomic identification of significant targets in cancer (GISTIC) algorithm indicates recurrent regions of gene copy number gain and loss. Recurrent gains are shown in *red* (including the *MYC* gene at 8q24), and recurrent losses are shown in *blue* (including the *RB* gene at 13q14). The height of each peak indicates the statistical significance of the event (a function of frequency and the rate expected by chance).

RNA-LEVEL CHARACTERIZATION

mRNA Profiling

The most well-developed and widely used genomic technology is genome-wide expression profiling of protein-coding RNAs (mRNAs). Since the late 1990s profiling has been done using an array format in which sequence-specific probes are immobilized onto a solid surface (or are synthesized *in situ*). mRNA is isolated from a sample of interest (e.g., a tumor biopsy or a cell line). The mRNA is then labeled in some fashion, often with a fluorescent tag, and the extent of hybridization of the mRNA to the array is captured by a laser-scanning device. This technology enables the interrogation of all 22,000 or so mRNAs in the human and mouse transcriptomes.

Expression profiling of FFPE tissues deserves special mention because formalin fixation causes the degradation of mRNAs into fragments of only about 80 nucleotides in length. Conventional array-based profiling approaches therefore do not work well, particularly those that involve labeling of the mRNAs by priming of the 3' polyadenylation tail; however, approaches have been developed that allow for the profiling of FFPE-derived tissues. These include modification of standard arrays involving the use of 3'-biased probes for each mRNA transcript, such that even degraded mRNAs can be profiled. Although it is likely that any method applied to FFPE samples will yield noisier data than frozen samples, the ability to analyze archived material, particularly those samples with long-term clinical outcome data, will prove invaluable. Array-based approaches do not give absolute quantitation, but often this is not required.

Rather, researchers wish to compare the expression level of a gene (or genes) in one sample with another (or one group of samples with another). Most gene expression profiling thus requires the *relative* assessment of expression across a set of samples, and absolute quantitation (e.g., number of mRNA copies per cell) is neither possible nor in most cases necessary.

More recent sequencing-based approaches to expression profiling (RNA-Seq), however, provide the opportunity to provide a count of the number of transcripts in a given sample. In addition, RNA sequencing allows for the profiling of previously unknown genes (i.e., those not previously recognized to encode a transcript) as well as of alternative splice forms of known mRNAs. Furthermore, gene fusions within coding regions and SNVs can be detected simultaneously with gene expression. One advantage of hybridization-based (microarray) methods is that they effectively measure both abundant and non-abundant transcripts. RNA sequencing, however, favors abundant transcripts. The consequence of this is that, in order to capture less abundant mRNAs, deep sequencing is required, resulting in increased costs.

Noncoding RNA Profiling

Although the focus within the family of RNAs is often on those that code for proteins, a wealth of noncoding RNAs exist in mammalian cells. Two major classes of noncoding RNAs are short RNAs, known as *microRNAs* (miRNAs), and *large intergenic noncoding RNAs* (lincRNAs), as described later.

Fig. 3.4 CHROMOTHRIPSIS. Circos plot showing the extensive genomic rearrangements in a glioblastoma tumor. Each of the human chromosomes is displayed around the circle of the plot. Purple lines indicate rearrangements between different chromosomes, and green lines indicate intrachromosomal rearrangements. In this tumor, chromosome 1p has nearly 100 chromosomal rearrangements, indicative of a single-step genomic catastrophe mechanism known as *chromothripsis*.

miRNAs are small (approximately 22-nucleotide) RNAs that do not encode for proteins but bind to mRNA transcripts to regulate translation and mRNA stability. Several hundred miRNAs are thought to exist in the human genome. In *Caenorhabditis elegans*, zebrafish, and other model organisms, miRNAs play a critical role in development through regulation of translation of key proteins. In mammalian cells, a role for miRNAs has been recognized in the regulation of cellular differentiation. Not only are many miRNAs differentially expressed across hematopoietic lineages, but several miRNAs have also been demonstrated to play key functional roles in hematopoietic lineage specification and differentiation. Moreover, the expression or function of several miRNAs is altered by chromosomal translocations, deletions, or mutations in leukemia. In addition, members of the protein complex (including the protein DICER) that process the maturation of miRNAs from longer RNA forms have been implicated in malignancy.

Noncoding lincRNAs are approximately 1000 nucleotides in length and number approximately 5000 in the human genome. The widespread existence of lincRNAs was only discovered in 2009, and their function remains largely unknown. However, recent evidence suggests that they may play important roles in establishing and maintaining cell fate and may play key roles in regulation of the epigenome. Their role in the pathogenesis of disease is heavily investigated. Interestingly, lincRNAs appear to have exquisite tissue-specific patterns of expression, suggesting that they may have diagnostic potential. Evidence is also mounting that some RNAs encode short peptide sequences (less than 100 amino acids), which may eventually require reclassification from lincRNA to protein-coding RNA.

SINGLE-CELL RNA AND DNA SEQUENCING

Next-generation sequencing applications in hematology and oncology have typically focused on interrogating *populations* of cells. Although computational methods have been developed to decipher

the relative contribution of individual genetic subclones to the entire tumor, these approaches usually have limited resolution and are not able to detect very small subclones that comprise few tumor cells. Several novel technologies have been developed that allow DNA and RNA sequencing of *single* tumor cells as well as of single cells from the tumor microenvironment. Advances in microfluidic approaches make it possible to generate RNA sequencing data from thousands of cells simultaneously, and several different technological concepts have emerged for highly parallel sample preparation. For example, the entire sample processing workflow, from isolating single cells to generating sequencing libraries, can be generated in multiwell plates in order to perform multiple reactions at the same time. This can be done with typical multiwell plates, or the entire experimental workflow can take place in a fully integrated microfluidic “lab on a chip.” Another approach uses microdroplet technology. To this end, a single cell is packaged into an emulsion droplet, and thousands of droplets are generated. Although the single cells are segregated into individual droplets, a molecular barcoding step takes place with which every RNA molecule in each cell is labeled with a unique molecular tag. After this step, the droplets are dissolved and RNA sequencing preparation is performed in a single tube. The barcodes can later be used to precisely assign each RNA molecule to the correct cell, making it possible to determine the gene expression profile of each single cell.

These technologies currently enable sequencing of thousands of single cells simultaneously, but that number will undoubtedly increase with rapid progress in technology development. Having a methodology in hand that allows RNA sequencing with single-cell resolution is particularly useful to precisely define the composition of the tumor microenvironment in addition to the tumor itself. These novel technologies and their ability to successfully sequence even minimal amounts of DNA and RNA are not only useful for sequencing tumor tissue with single-cell resolution but also empower “blood biopsy” approaches. This approach is based on the discovery that various types of tumor-derived material can be detected in the blood of patients with cancer, including circulating tumor cells (CTCs), circulating tumor DNA, or cell-free DNA (cfDNA), as well as various types of circulating microvesicles, such as exosomes and apoptotic bodies. There is increasing evidence that interrogation of these materials from the blood provides a representation of the tumor simply by drawing a vial of blood. In some cancers, the entire genome or the entire exome can be reproduced by genomic sequencing of cfDNA or CTCs. Because blood draws are safer, less complicated, and less expensive than tissue biopsy, and because they can easily be done at many time points, there is great interest in genomic approaches to blood-derived materials, including DNA and RNA sequencing.

PROTEIN-LEVEL CHARACTERIZATION

Unlike the characterization of DNA and RNA, which has become routine, the systematic, genome-wide characterization of proteins remains extremely technically challenging. Not long ago, comparative proteomic experiments consisted largely of the comparison of single proteins across various conditions or samples. However, a number of new advances in technology have made for a dramatic acceleration of the pace at which the abundance of proteins can be measured and their posttranslational modification (e.g., phosphorylation) can be assessed.

Mass Spectrometry

The workhorse of proteomics remains mass spectrometry. The fundamental principles of mass spectrometry have not changed over the years, but technical advances (the details of which are beyond the scope of this chapter) have led to increased ability to detect proteins in complex mixtures. Previously, extensive biochemical fractionation of the proteome was required to render mixtures of proteins sufficiently limited in number and with sufficient abundance to be reliably detected and identified. Such fractionation required extensive time,

expertise, and instrumentation as well as a large amount of starting material, all of which tended to make systematic proteomic experiments difficult to perform routinely. However, newer instruments and methods allow for the analysis of significantly more complex mixtures, with increased sensitivity and speed. Sequence assignment confidence, especially for modified peptides, has also been markedly improved owing to the increase in both resolution and mass accuracy. For example, in mammalian cells, it is possible to confidently detect more than 8000 unique proteins and more than 15,000 phosphopeptides in a few days using a single instrument. Efforts to perform proteome-wide analysis of complex samples such as cells and tissues without extensive fractionation represent one end of the spectrum; proteomic analysis with single-cell resolution represents the other end. Although these methods (single-cell Western blot analysis and flow cytometry for intracellular proteins) can currently interrogate only one or a few analytes at the same time, these methods will evolve with ongoing technological progress.

Reverse Phase Lysates

An attractive alternative to mass spectrometry involves the use of *reverse phase protein arrays* (RPPAs). RPPAs involve the robotic spotting of minute amounts of total cell protein lysates onto glass slides (thus creating an array of lysates derived from different samples) (Fig. 3.5). The slides can then be probed with antibodies against particular proteins of interest, including phosphorylation-specific antibodies. The advantage of RPPAs is that only a tiny amount of cellular material is required, and hundreds of samples can be tested on a single array. The downside is that the method requires the availability of high-quality antibodies that are both sensitive and specific for the protein of interest. Unfortunately, such high-quality antibodies are available for only a minority of human proteins. In addition, RPPAs

are not suitable for the analysis of large numbers of proteins, because each protein to be interrogated requires a separate slide. Nevertheless, RPPA remains a useful tool in the armamentarium of proteomic research and may prove particularly useful for the comparison of proteins of interest across a large panel of samples (e.g., across a collection of patient samples or cell lines).

Bead-Based Profiling

Another proteomic method involves the multiplexed analysis of protein abundance or phosphorylation. Phosphorylation involves the use of microspheres (beads). In this approach, a different protein-specific antibody is coupled to beads of distinct color. A mixture of antibody-coupled beads is then mixed with protein lysate, and then binding events are detected with a labeled secondary antibody (e.g., antiphosphotyrosine antibody). Multiple analytes are thereby simultaneously profiled in a single sample. This approach was successfully used to profile the tyrosine phosphorylation status of nearly all protein tyrosine kinases across a panel of cell lines. The advantage of this approach is that multiple proteins (as many as 100 or more) can be assessed simultaneously in a single sample. Similar to RPPA, however, the method depends on the availability of high-quality antibodies, and this limitation makes the approach difficult to generalize broadly. Nevertheless, the method may prove useful for interrogating particular classes of proteins, such as kinases, for which suitable antibodies exist.

METABOLITE-LEVEL CHARACTERIZATION

Beyond nucleic acid and protein characterization, systematic profiling of small-molecule metabolites has also recently become possible. Such unbiased approaches to the assessment of metabolite levels have yielded new insights into the pathogenesis of metabolic diseases such as diabetes. In addition, the discovery of mutations in metabolic enzymes in acute myeloid leukemia has spurred interest in the metabolic consequences of these mutations on the “metabolome.” Metabolite profiling is at present not routinely used in biomedical research, but it is likely that the years ahead will see a significant surge in its use.

FUNCTIONAL GENOMICS

Although the bulk of genomic research takes the form of observational studies (i.e., determining the spectrum of mutations in a tumor), functional approaches to genomic research are increasingly becoming feasible. Several discoveries have led to technologies that allow gene-specific perturbation. Zinc finger nucleases, transcription activator–like effector *nucleases* (TALENs), RNA interference (RNAi), and random chemical mutagenesis with agents such as *N*-ethyl-*N*-nitrosourea have been used to functionally perturb genes. For example, RNAi technology made it possible to knock down the expression of all genes in a given cell line and measure the consequences. This approach has been used most extensively in the area of cancer, where the complete set of genes that are essential for the survival of a cancer cell line was identified via genome-wide RNAi screens (Fig. 3.6). In addition to loss-of-function RNAi screens, it has become possible to perform systematic gain-of-function screens by overexpressing a library of complementary DNAs and then selecting for a phenotype of interest. Zinc finger nucleases and TALENs are much more precise genomic tools that enable genetic mutations, insertions, and deletions. Although very powerful, all of these approaches have substantial disadvantages. Although RNAi is technically relatively easy to perform, it enables “knockdown” of genes but not complete “knockout” in most cases. It can be associated with off-target effects (i.e., perturbation of random genes that are not intended to be targeted). Insertion of precise genetic defects, such as single-nucleotide variants, is not possible with RNAi but can be done

Fig. 3.5 REVERSE PHASE PROTEIN ARRAYS (RPPAs). Schematic illustrating the concept of RPPA. Cellular lysates derived from patient samples or cell lines are robotically spotted onto a glass slide. Next, a primary antibody specific for a protein of interest is added to the slide, with the antibody sticking to the array in proportion to the abundance of the protein in question. To visualize the antibody-binding event, a secondary antibody that recognizes the primary antibody (generally fluorescently labeled) is added, and the slide is examined by microscopy or using a laser-scanning instrument.

Fig. 3.6 SYSTEMATIC RNA INTERFERENCE SCREENS. Lineage-specific dependencies are illustrated in this heatmap of differentially antiproliferative short hairpin RNAs (shRNAs) in cell lines from individual cancer lineages in comparison with all others. The top 20 shRNAs that distinguish each lineage from the others are displayed. *GBM*, Glioblastoma multiforme; *NSCLC*, non-small cell lung cancer; *SCLC*, small cell lung cancer. (From Cheung HW, Cowley GS, Weir BA, et al: Systematic investigation of genetic vulnerabilities across cancer cell lines reveals lineage-specific dependencies in ovarian cancer. *Proc Natl Acad Sci U S A* 108:12372, 2011.)

with zinc finger nucleases and TALENs. However, these latter two technologies are difficult to perform and expensive. In hematology and cancer research in general, all of these technologies have largely been superseded by the recent development of the transformative CRISPR/Cas9 technology. CRISPR/Cas9 technology combines the strengths of all of these approaches: The technology is relatively easy to use and allows precise and efficient editing of the genome. The method can be used to introduce specific genetic alterations in eukaryotic cells, and the consequences of these alterations can be identified by genomic approaches. CRISPR tools have been developed using programmable transcription factors that may activate targeted genes, or alternatively genes can be silenced without causing

double-stranded DNA breaks. The method can be used in cells from different species, and it can be used to create mouse models of human diseases faster and more efficiently than are possible with well-established homologous recombination to generate genetically engineered mouse models, allowing genetic modification of multiple loci at the same time. In 2015, another nuclease, Cpf1, was discovered with properties different from those of Cas9, including a different DNA cutting pattern, and requiring fewer components. Progress in this field is being made at a rapid pace, and the technology will undoubtedly develop rapidly. Although immensely powerful, there are several drawbacks of the technology that have to be addressed in the coming years, such as a genomic copy number bias that causes a

gene-independent cell response to CRISPR/Cas9 targeting. Moreover, the ability to express Cas9 or related nucleases is not consistent across cell types. As with every genome-editing technology, off-target effects exist, which may lead to editing of the wrong gene. Because of the ease of use, libraries have been created targeting the entire protein-coding region of the genome (i.e., exome), as well as many noncoding regions of the genome, which will allow scientists to perform comprehensive functional genetics. The combination of genomics with CRISPR/Cas9-mediated perturbation provides an unprecedented opportunity to understand the consequences of the genetic defects encountered in patients. In addition to pointing to new potential therapeutic targets for cancer, screens using these technologies hold the promise of identifying genetic predictors of gene dependency. Such predictors will be key for the translation of these in vitro approaches to use in the clinic.

PHARMACOGENOMICS

The use of the genome to study drug response deserves special mention and is the subject of an entire chapter of this book (see Chapter 8). As the cost of genome sequencing continues to fall, it will become increasingly feasible to perform population-scale genetic studies to identify genetic determinants of drug toxicity and response. Although some examples of such pharmacogenomic markers have been discovered (e.g., genetic predictors of antimetabolite chemotherapy), the field awaits truly large-scale, systematic studies of large numbers of patients with known drug response data.

CLINICAL USE OF GENOMICS

Sequencing-Based Diagnostics and Precision Medicine

With the falling cost of genome sequencing and streamlined workflows, next-generation sequencing has entered into routine clinical diagnostic use. Sequencing panels that target the genes commonly mutated in cancer are available at many academic centers and are actively being used to triage patients to specific treatments. Genomic variants in such a “precision medicine” approach either suggest a therapeutic agent that directly targets the variant itself (e.g., a BRAF inhibitor in a patient with a *BRAF* V600E mutated neoplasm) or inform therapeutic decisions that are less directly related (e.g., not using epidermal growth factor receptor inhibitors in colon cancers harboring *KRAS*-activating mutations). Similarly, genomic variants may predict an individual’s response to immunotherapy. In particular, it has been observed that tumors with high mutation burden tend to have more favorable responses to programmed death 1/programmed death ligand 1 (PD1/PDL1) blockade than in patients whose tumors have fewer mutations, presumably reflecting a lower neoantigen load.

Compared with RNA-based analysis, DNA-based diagnostics have the advantage of being more definitive in that one is looking, for example, for the presence of a mutation (an A, G, C, or T) as opposed to a relative abundance of a particular transcript or transcripts, the latter being confounded by an admixture of cell types within tumors or tissues. Because modern sequencing approaches allow for allele separation, the admixture of tumors with normal cells can be addressed at the DNA level simply by increasing the depth of sequencing coverage, as described earlier. Whether single-cell RNA sequencing approaches (which combat the issue of cellular heterogeneity) have the potential to be introduced into the routine clinical setting remains to be determined. Currently, their technical complexity precludes routine use. Similarly, if the cost of sequencing continues to drop, this will likely give way to more systematic approaches that include whole exome sequencing and whole-genome sequencing rather than just sequencing a limited number of loci. However, the pace of technology advancement will likely outstrip understanding of clinical utility and financial reimbursement by health insurance

payers, so demonstrating utility and measurable patient benefit of these approaches is of utmost importance.

Sequencing-based diagnostics will also likely have an increasingly important role in nonmalignant conditions, such as blood-clotting disorders, in which it will become possible to systematically resequence all genes in the coagulation cascade, thereby identifying either common or highly rare sequence variants that might explain or predict disease. The widespread use of germline sequencing to predict disease also raises a large set of ethical questions that must be addressed, particularly those relating to children and family members of individuals undergoing sequence analysis. Whether whole-genome sequencing will become a routine part of health care in the future remains to be determined, but it is almost certain that much of the current diagnostic approach to medicine will eventually be supplanted by DNA-level analysis.

Minimal Residual Disease Diagnostics

Combination therapies using multiple therapeutic agents have been a great success in hematologic malignancies. For instance, childhood ALL has been associated with very high cure rates for a long time. The therapy of multiple myeloma has been transformed over the last 15 years with the advent of many new therapeutic agents. Both of these are examples of diseases for which deep remissions can be achieved, and therefore the ability to detect minimal residual disease (MRD) is of increasing importance. Traditional approaches to detect MRD include quantitative PCR, as is used for the detection of the Bcr-Abl fusion in patients with chronic myeloid leukemia undergoing treatment with tyrosine kinase inhibitors, or multiparametric flow cytometry, which is used for MRD detection in multiple myeloma. Deep next-generation sequencing of T-cell receptors and B-cell receptors is now being used to detect MRD in B-cell and T-cell malignancies. This sequencing approach targets a limited number of genomic regions that are involved in VDJ recombination of the T-cell and B-cell receptors, thus allowing identification of monoclonal B and T cells, which define the malignant tumor cells. Because these regions are sequenced many times over (i.e., with great “depth”), malignant clones can be detected even if they occur with a frequency of only 1 in 10^5 to 10^6 . The advances in sequencing of very small cell numbers down to the single-cell level, as described earlier, allow for comprehensive detection of genomic alterations as well as interrogation of transcriptional profiles. Combining these sequencing approaches with highly sensitive cell isolation and cell-sorting technology holds great promise to better characterize what types of tumor cells remain viable at the stage of MRD.

Expression-Based Diagnostics

It has been over a decade since the first proof-of-principle studies were published demonstrating the possibility of using gene expression profiling to classify diseases such as cancer. Those studies raised the possibility that such promising gene expression signatures might be further validated and then implemented in the routine clinical setting as powerful diagnostic tests. The reality is that few such transitions to clinical practice have been made. One of these is the Oncotype Dx Breast Cancer Assay test, which consists of a tumor gene expression signature of 21 genes capable of determining the requirement for chemotherapy in women with early-stage breast cancer. This test has now become part of the standard of care at many cancer centers in the United States.

One should ask, however, why, despite thousands of papers being published on potential diagnostic applications of gene expression profiling, so few have progressed to routine clinical implementation. There are likely several reasons to explain the slow pace of advancement. First, to develop truly valid diagnostic tests, the test must be applied to large numbers of patients with known clinical outcomes, and in many cases, such cohorts of patients simply do not exist, making validation challenging. Second, because gene expression

signatures are based on relative transcript abundance (as opposed to, for example, genome sequencing), it is subject to technical variation such as stromal admixture of tumors that can distort a diagnostic signature. Third, although the academic publishing system tends to reward *initial* discoveries (which are often published in high-profile journals), the essential follow-up *validation* studies tend to be valued less, and therefore investigators do not have an incentive to follow up on their initial observations. Fourth, the economics of molecular diagnostics have in general not been favorable, thus discouraging companies from making major investments in the validation and commercialization of promising diagnostic tests. It is likely that diagnostic tests will command more of a premium in the future as a mechanism to use expensive therapeutics only in patients likely to benefit, but the time required for this to evolve is uncertain.

However, the potential utility of clinically relevant gene expression signatures has regained interest with the progress and greater availability of sophisticated RNA sequencing technology. Whether RNA sequencing provides data sufficiently robust to be used in clinical routine remains to be established.

FUTURE DIRECTIONS

The field of genomics has matured greatly over the past decade. Major analytical advances have made it possible to analyze and interpret complex datasets beyond what was previously possible. In addition, dropping costs have made it possible to generate data at a scale that was never before imaginable. DNA sequencing is now routine at many academic centers and is increasingly being used to drive precision medicine by suggesting potential therapies based on individual patients' genetic profiles. Nevertheless, such approaches are still in their infancy; the majority of patients do not receive direct benefit from such precision medicine approaches. The future will also hold an explosion of functional genomic studies, particularly using genome editing methods such as CRISPR/Cas9. With deep genomic, transcriptomic, and epigenetic data already available for the most common hematologic and malignant diseases, and with new data being generated at an ever-increasing rate, there will be great opportunity for diagnostic and therapeutic development. The integration of genomic and other high-throughput sequencing approaches into clinical research and routine clinical care will continue to be one of the greatest challenges and opportunities in medicine in the decade ahead.

REGULATION OF GENE EXPRESSION, TRANSCRIPTION, SPLICING, AND RNA METABOLISM

Christopher R. Cogle

INTRODUCTION TO GENE REGULATION IN HEMATOLOGY

The function of a cell is governed by the sum of the specific proteins expressed. Protein expression is most commonly regulated at the level of gene transcription into RNA, which is then processed and translated. The life of a cell is the life of its RNA. Therefore, to understand how a cell behaves, one must understand the expression of a gene through RNA.

Transcription of DNA into RNA controls cellular differentiation, proliferation, and apoptosis in all differentiating cell systems, but especially in hematopoiesis. For example, through regulation of transcription, hematopoietic stem cells maintain a balance between quiescence and differentiation to mature blood cell types. Regulation of transcription is also necessary for erythroid progenitors to produce vast quantities of hemoglobin, for myeloid cells to generate granules of immune responses, for lymphocytes to control immunoglobulin levels, and for platelets to regulate levels of thrombotic receptors.

Aberrant gene expression can result in hematologic disorders such as lymphomas, leukemias, and myelodysplastic and myeloproliferative syndromes, as will be discussed later. Understanding the process behind RNA synthesis is also crucial for the diagnosis and treatment of hematologic disorders. Converting genetic information contained in the DNA sequence of a gene into a finished protein product is a complex process consisting of several steps, with each step involving distinct regulatory mechanisms. Beginning with the basics of gene structure, this chapter will present the foundation necessary to understand the process of gene expression through RNA synthesis and processing, including transcription, splicing, posttranscriptional modification, and nuclear export. Subsequent chapters will present regulation of protein translation and posttranslational modifications.

The first step of gene expression is transcription, where RNA polymerases decode the DNA using specific start and stop signals to synthesize RNA. In the subsequent step, splicing removes portions of the RNA that do not code for protein. Next, the spliced RNA is modified for export out of the nucleus and into the cytoplasm, where ribosomes translate the RNA into protein products.

HOW GENES ARE ORGANIZED IN DNA

The gene is the fundamental unit for storage and expression of genetic information. Genes are made up of nucleotide sequences of DNA, and are transferred to daughter cells during mitosis (and meiosis in gametes) via semi-conservative replication. Each cell in the human body contains about 25,000 genes, which are distributed unevenly across the 46 individual chromosomes found within the nucleus. Chromosomes are dense DNA-protein complexes that are made up of individual linear DNA helices packed tightly together by specific protein repeats. Unwound completely and stretched out, the largest chromosome is about 1 m in length, demonstrating that the cell, to even exist, must be an expert at packaging.

Only 1% to 2% of human DNA actually serves as genes, which are the templates for protein production. Most genes are broken down into separated coding sections known as *exons* (Fig. 4.1). These

exons are separated from each other by intervening, noncoding sequences known as *introns*. Genes also have other noncoding DNA, typically short sequences near or within genes that function as regulatory sequences critical for controlling gene expression. Together these regulatory sequences determine in which cell, at what time, and in what amount the gene is converted into the corresponding protein.

In order for transcription to begin, RNA polymerase must attach to a specific DNA region at the beginning of a gene. These regions, known as *promoters*, contain specific nucleotide sequences and response elements. These provide a secure initial binding site on the gene for RNA polymerase. RNA polymerase often requires other proteins called *transcription factors* for proper recruitment to a given gene. Not all transcription factors are activating; some may inhibit RNA polymerase, and repress gene expression by attaching to specific promoters and blocking binding of RNA polymerase. Promoters can additionally function together with other more distant regulatory DNA regions (termed *enhancers*, *silencers*, *boundary elements*, or *insulators*) to direct the level of transcription of a given gene. Unlike RNA polymerase, transcription factors are not limited to the promoter region, but can be directed by these other regulatory DNA sequences to either promote or repress transcription. The minimum essential transcription factors needed for transcription to occur are termed *basal transcription factors* and include transcription factor (TF) IIA, TFIIB, TFIID, TFIIE, TFIIIF, and TFIIH. These ubiquitous proteins bind to the recognition sequence in the promoter, forming a transcription initiation complex that recruits the RNA polymerase. Basal transcription factors cannot by themselves increase or decrease the rate of transcription but may be linked to activators by coactivator proteins that can.

The promoter is a regulatory sequence located near the start of the gene, to provide the exact start site recognized by the transcription machinery where conversion of the DNA template into intermediary molecules begins. The promoter contains the consensus sequence to bind the transcription factors and then the RNA polymerase needed to initiate transcription. The best known example of this sequence is the TATA box sequence, TATAAA, which binds RNA polymerase and associated transcription factors. However, more than 80% of mammalian protein-coding genes are driven by TATA-less promoters, which contain different recognition sequences—often GC boxes. The GC promoters are repeats of guanine and cytosine nucleotides, frequently have multiple transcriptional start sites, and require alternative transcription factors, like Specificity Protein 1 (Sp1).

Genes can have more than one promoter. This results in different-sized mRNAs, depending on how far the promoter is from the 5' end of the gene. The binding strength between a promoter and the transcription factors determines the avidity of RNA polymerase binding, and subsequently of transcription. Some genetic diseases are associated with mutations in promoters, such as β -thalassemia, which can involve single nucleotide substitutions, small deletions, or insertions in the β -globin promoter sequence. The promoter mutations in β -thalassemias result in decreased RNA polymerase binding to the transcriptional start site, and thereby reduce β -globin gene expression.

Globin gene expression in erythroid cells is also dependent on another regulatory unit: the enhancer. Unlike promoters, which are situated close to the start site of the gene, enhancers can be positioned

Fig. 4.1 OVERVIEW OF GENE TRANSCRIPTION FROM DNA TO RNA AND THEN TRANSLATION FROM RNA TO PROTEIN. Protein synthesis requires multiple processes and regulatory steps including transcript of DNA into RNA, splicing and posttranscription modification of RNA, translation of RNA into protein, and posttranslational protein modification.

far from either side of the gene, or even within it. This means that there may be several signals determining whether a certain gene can be transcribed. In fact, multiple enhancer sites may be linked to one gene, and each enhancer may be bound by more than one transcription factor. Whether or not such a gene is transcribed is the sum of the activity of these transcription factors bound to the different enhancers. Enhancers can compensate for a weak promoter by binding activator transcription factors. For instance, regulation of gene expression during T-lymphocyte differentiation requires multiple activating transcription factors, such as lymphocyte enhancer factor (LEF-1), GATA-3, and ETS-1, binding to the T-cell receptor alpha gene (TCRA) enhancer.

Transcription factors can also influence multiple genes in coordination, like the globin family. Enhancers are often the major determinant of transcription of developmental genes in the differing lineages and stages of hematopoiesis. They can also inhibit transcription of specific genes in one cell type while at the same time activating it in another cell type. When gene sequences routinely negatively regulate gene transcription, they are termed *silencers*, not enhancers. Another type of DNA regulatory sequence is called *insulators*. These define borders of multigene clusters to prevent activation of one set of genes from affecting a nearby set of genes in another cluster.

TRANSCRIPTION OF GENES

The first phase of gene expression occurs when the RNA polymerase synthesizes RNA from a DNA gene template, which, as described in the previous section, is called *transcription*. The encoded material on the transcribed gene determines the kind of RNA synthesized. For example, proteins are coded for by messenger RNA (mRNA), which will later undergo the process of translation. Alternatively, the transcribed gene may encode transfer RNA (tRNA), which carries specific amino acids to the ribosome for incorporation into the growing protein chain during translation. Another type of RNA synthesized from genes in DNA is ribosomal RNA (rRNA), which serves as the backbone of ribosomes and interacts with tRNA during translation. Ribosomes catalyze the formation of proteins using the mRNA as the code and the tRNA to obtain the amino acids to build the proteins. Each amino acid is attached to the previous one by hydrolysis and aminotransferase activity residing within the ribosome.

Transcription of the different classes of RNAs in eukaryotes is carried out by three different RNA polymerase enzymes. RNA polymerase I synthesizes the rRNAs, except for the 5S species. RNA polymerase II synthesizes the mRNAs and some small nuclear RNAs (snRNAs) involved in RNA splicing. RNA polymerase III synthesizes 5S rRNA and tRNAs.

The most intricate controls of eukaryotic genes are those that govern the expression of RNA polymerase II-transcribed genes, the genes that encode mRNA. Most eukaryotic mRNA genes contain a basic structure consisting of alternating coding exons and noncoding introns, and have one of two major types of basal promoters, as defined earlier. These protein-coding genes also can have a variety of transcriptional regulatory domains, such as the enhancers or silencers mentioned previously. In addition to management of gene expression by the binding strength of the RNA polymerase promoters at the beginning of a given gene, the interaction between activator and inhibitor transcription factor proteins binding to the given promoter also exerts regulatory action on transcription.

To initiate transcription, the RNA polymerase must bind to the promoter sequence. However, as mentioned earlier, this can only happen with help from gene-specific transcription factors that mediate RNA polymerase binding to the promoter. These transcription factors are sequence-specific DNA binding proteins that can be modified by cell signals. Many transcription factors, such as signal transducer and activator of transcription (STAT) proteins, require phosphorylation in order to bind DNA. Because transcription factors can be targeted by kinases and phosphatases, phosphorylation can effectively integrate information carried by multiple signal transduction pathways, thus providing versatility and flexibility in gene regulation. For example, the Janus kinase (JAK)–STAT pathway is widely used by members of the cytokine receptor superfamily, including those for granulocyte colony-stimulating factor (G-CSF), erythropoietin, thrombopoietin, interferons, and interleukins. Normally, ligand-bound growth factor receptors lead to JAK2 phosphorylation, which then activates STAT, also by phosphorylation. Activated STAT then dimerizes, translocates to the hematopoietic cell nucleus, binds DNA, and promotes transcription of genes for hematopoiesis. Alteration of JAK2, such as a V617F mutation, results in a constitutively active kinase capable of driving STAT activation. This leads to constitutive transcription of STAT target genes, and results in myeloproliferative disorders such as polycythemia vera.

Fig. 4.2 ROLE OF TRANSCRIPTION FACTOR BINDING SITES IN THE REGULATION OF EUKARYOTIC GENE EXPRESSION. (A) Schematic diagram of a eukaryotic promoter showing transcription factor binding sites in the promoter region before the factor IX gene, the TATA box, and the start site of transcription (red X). Not shown are histones, coregulators, mediators, or chromatin remodeling complexes. (B) Effect of a mutation in the HNF4α1 binding site on expression of the blood coagulation gene factor IX.

Fig. 4.3 CHROMATIN STRUCTURE. (A) The nucleosome is the fundamental unit of chromatin and is made up of DNA coiled around histone proteins. In a condensed state, the DNA is tightly wrapped around histone complexes and target genes are inaccessible to transcription machinery. (B) Histones and DNA can be epigenetically modified by acetylation and methylation, rendering the target genes more accessible to transcription machinery.

Mutations in promoter sequences that result in decreased transcription factor binding, and therefore less RNA polymerase binding, result in decreased gene expression. One of the best examples of a mutation in a transcription factor binding site associated with a human disease is in the factor IX gene. The transcription factor HNF4α is required to bind to the factor IX promoter before this gene can be transcribed. Patients with a mutation in the HNF4α binding site can develop hemophilia B, an X-linked recessive bleeding disorder primarily affecting males (Fig. 4.2).

The ability of transcription factors and RNA polymerases to access specific promoters and transcribe genes is also regulated by the packaging of DNA into discrete packets by proteins generically termed *chromatin*. Chromatin can package DNA tightly or loosely, and this regulates the availability of a gene for transcription. Several

factors affect the openness of chromatin, and therefore regulate availability of the DNA to transcription factors and RNA polymerases. There are two types of chromatin: euchromatin and heterochromatin. *Euchromatin* refers to loosely packaged DNA, where RNA polymerases can freely bind to DNA and genes are actively transcribed. *Heterochromatin* refers to tightly packaged DNA, protected from transcription machinery, sequestering genes away from transcription. The basic unit of chromatin is the nucleosome, which contains eight histone proteins packaging 146 base pairs of DNA wound 1.7 times around the histone complex (Fig. 4.3).

These histones can be extensively modified to regulate the accessibility of the DNA to the transcriptional apparatus. Histones can be chemically modified by acetylation, methylation, phosphorylation, or ubiquitination. In general, acetylation opens the nucleosome to

increase transcription, while phosphorylation marks damaged DNA. Histone methylation can either open chromatin to increase transcription, or close it to repress transcription, depending on where the histone is methylated. Ubiquitination is the enzymatic addition or removal of the ubiquitin moiety from histones. Transcription factors can themselves recruit histone-modifying enzymes that can regulate transcription. In hematopoiesis, transcription factors including GATA-1, ELK1, NF-E2 and PU.1 recruit histone acetyltransferases (HATs) and histone deacetylases (HDACs) to promoters of target genes, leading to addition or subtraction of acetyl groups from histones, thereby affecting chromatin structure and the openness of DNA to transcription. A gene essential to erythroid maturation and survival, GATA-1, for instance, directly recruits HAT complexes to the β -globin locus to stimulate transcription activation.

Chromatin usually tightly packages DNA, which is essential for the cell to have a functional size and shape. Therefore, for transcription to take place, the DNA must be unwound from the chromatin. This process of unpackaging is called *chromatin remodeling* and is mediated by a family of proteins with switch/sucrose nonfermentable SWI/SNF domains. These proteins use ATP hydrolysis to shift the nucleosome core along the length of the DNA, a process also known as *nucleosome sliding*. By sliding nucleosomes away from a gene sequence, SWI/SNF complexes can activate gene transcription.

SWI/SNF proteins also contain helicase enzyme activity, which unwinds the DNA by breaking hydrogen bonds between the complementary nucleotides on opposite strands. By unwinding the DNA into two single strands, the DNA can then be read by RNA polymerases in the direction 3' to 5'. A new antiparallel RNA strand, 5' to 3', is produced by RNA polymerases to mirror the coding strand of the DNA, with the exception of all thymine nucleotides replaced by uracil nucleotides. SWI/SNF proteins have the ability to utilize Brahma (BRM) or Brahma-related gene 1 (BRG1) as alternative catalytic subunits with ATPase activity to remodel chromatin. The SWI/SNF complex has been shown to be active in the DNA damage response and is also responsible for tumor suppression. More recently, BRM and BRG1 have been proposed as independent tumor suppressors; however, their role in hematologic malignancies is not known.

DNA itself can be chemically modified to amplify or suppress transcription. CpG sites with gene promoter regions can be chemically modified by methylation enzymes DNA methyltransferases (DNMTs), which subsequently decrease binding of RNA polymerase and associated transcription factors. Hypermethylation has been observed in bone marrow cells of patients with myelodysplastic syndromes (MDS) and the degree of DNA hypermethylation correlates with disease stage. In MDS the promoters of genes that are important for myeloid differentiation are hypermethylated, repressing their transcription, and inhibiting proper maturation of the myeloid lineages. Hypomethylating agents such as azacitidine and decitabine can induce remission and prolonged survival in MDS patients. The regulation of gene expression by modification of chromatin or DNA itself is termed *epigenetic*, as it alters cell function without altering the nucleotide sequence of the DNA.

Such epigenetic modifications are crucial to the behavior of hematologic diseases. Mutation of the DNMT3 genes may have indirect effects on gene expression without altered DNA methylation, as have been observed in 20% of acute myeloid leukemia (AML) cases and are correlated with poor clinical outcome. The Ten-Eleven-Translocation oncogene member, TET2, which plays a role in DNA methylation and therefore epigenetic stability, is mutated in AML, MDS, chronic myelomonocytic leukemia (CMML), and other myeloproliferative neoplasms (MPNs). Another recurring observation in blood malignancies is aberrant histone methylation, for example at H3K27, seen in myelodysplasia. This is associated with altered gene expression affecting cell cycle, cell death, and cell adhesion pathways.

Before a final mRNA product is made that can be translated, several proofreading regulatory steps must take place. The RNA polymerase may not even clear the promoter and slip off, producing truncated transcripts. Once the transcript reaches approximately 23 nucleotides, the RNA polymerase no longer slips off, and full

transcript elongation can occur. RNA polymerase then continues to traverse the template DNA strand, using ATP while complementarily pairing bases and forming the phosphodiester-ribose backbone. Many RNA transcripts may be rapidly produced from a single copy of a gene, as multiple RNA polymerases may be transcribing the gene simultaneously, spaced out from one another. An important proofreading mechanism during elongation allows the substitution of incorrectly incorporated bases, usually by permitting short pauses during which the appropriate RNA editing factors can bind. RNA editing mechanisms in mRNAs include nucleoside modifications of cytidine to uridine (C-U) and adenosine to inosine (A-I) by deamination, as well as nucleotide insertions and additions without a DNA template by proteins called *editosomes*.

Another repair mechanism is transcription-coupled nucleotide excision repair, where RNA polymerase stops transcribing when it comes to a bulky lesion in one of the nucleotides in the gene. A large protein complex excises the DNA segment containing the bulky lesion, and a new DNA segment is synthesized to replace it, using the opposite strand as a template. The RNA polymerase then resumes transcribing the gene. However, in general, RNA proofreading mechanisms are not as effective as in DNA replication, and transcription fidelity is lower.

After a gene is transcribed, mRNA is modified to protect it and target it for translation to protein. These modifications include capping and polyadenylation. Capping occurs shortly after the start of transcription, when a modified guanine nucleotide is added to the 5' end of the mRNA. This terminal 7-methylguanosine residue is necessary for proper attachment to the ribosome during translation. It also protects the RNA from endogenous ribonucleases that degrade uncapped RNA, which is often viral in origin.

RNA polymerases do not terminate transcription in an orderly manner. They tend to be processive, yet the cell cannot tolerate a population of mRNAs that are enormous in size. Therefore, mRNAs have a signal, the sequence AAUAA, that defines the end of the transcript. Ribonucleases cut mRNAs shortly after that signal, and a chain of several hundred adenosine residues is added to that free 3' transcript end. Synthesis of this poly(A) tail and termination of transcription requires binding of specific proteins, including cleavage/polyadenylation specificity factor (CPSF), cleavage stimulation factor (CstF), polyadenylate polymerase (PAP), polyadenylate binding protein 2 (PAB2), cleavage factor I (CFI), and cleavage factor II (CFII), that function to catalyze cleavage and protect the mRNA from exoribonucleases. The poly(A) tail also assists in export of the mRNA from the nucleus and translation. Mutations in the poly(A) signal can result in hematologic disease. For example, there are thrombophilic patients with a mutation in the polyadenylation signal in the prothrombin gene that increases the stabilization of this mRNA, resulting in higher prothrombin protein levels and increased thrombosis.

RNA SPLICING

Before the mRNA can be translated into protein, introns must be removed and the exons re-connected (Fig. 4.4). This process, termed splicing, requires a series of reactions mediated by the spliceosome, a complex of small nuclear ribonucleoproteins (snRNPs). The types of snRNPs in the spliceosome determine the mechanism of splicing. Canonical splicing, also called the *lariat pathway*, utilizes the major spliceosome and accounts for more than 99% of splicing. The major spliceosome is composed of the nuclear active snRNPs U1, U2, U4, U5, and U6 along with specific accessory proteins, U2AF and SF1. This complex recognizes the dinucleotide GU at the 5' end of an intron, and an AG at the 3' end. Intermediately a lariat structure forms, connecting these ends, providing for both excision of the intron and proper alignment of the ends of the two bordering exons to allow precise ligation. When the intronic flanking sequences do not follow the GU-AG rule, noncanonical splicing removes these rare introns with different splice site sequences using the minor spliceosome. The same U5 snRNP is found in the minor spliceosome, in

Fig. 4.4 RNA SPLICING. Introns from pre-mRNA are removed by snRNPs, which form a protein complex called a spliceosome. The spliceosome loops introns into a lariat, excises them, and then joins exons. The mature mRNA is then ready for further posttranscriptional processing. *snRNP*, Small nuclear ribonucleoprotein.

addition to the unique yet functionally similar U11, U12, U4atac, and U6atac. Furthermore, there are splicing mechanisms, including tRNA splicing and self-splicing, that function without any spliceosome.

Splicing is central to proper gene expression, and therefore is required for appropriate hematopoietic development. One of the best examples of inappropriate splicing leading to hematologic disease is β -thalassemia, where there are a number of different mutations that occur in the GU-AG splicing signals, resulting in aberrant β -globin mRNAs. Abnormal splicing can also lead to AML and other hematologic disorders. Translocated in liposarcoma (TLS) is a protein that recruits splicing complexes to mRNAs, and it is involved in the TLS-ERG fusion oncogene in t(16;21) in AML. This fusion of TLS with the transcription factor ERG alters the splicing profile of immature myeloid cells, blocking the expression of genes required for proper differentiation.

Trans-splicing is a form of splicing that joins two exons that are not within the same mRNA transcript. Some trans-splicing events occur when the intron splice donor sites are not filled by spliceosomes. They can lead to mRNAs displaying exon repetitions or chimeric fusion RNAs, which can mimic the presence of a chromosomal translocation in normal cells. For example, specific chimeric fusion mRNA seen in acute leukemias, such as MLL-AF4, BCR-ABL, TEL-AML1, AML1-ETO, PML-RAR, NPM-ALK, and ATIC-ALK, have been found in blood cells of healthy individuals with normal chromosome karyotype. Interestingly, these individuals do not develop leukemia, indicating that these fusion oncoproteins must be heritable (in DNA) and that they must occur in the appropriate hematopoietic precursor cell for leukemogenesis.

Alternative splicing can enhance the versatility and diversity of a single gene. By alternatively excising different introns along with the intervening exons, a wide range of unique proteins of differing sizes can be generated. These alternative proteins, termed *isoforms*, come from one gene that generates a variety of mRNA with varying exon composition. Alternative splicing is common, and essential for the proper function of almost all hematopoietic cells. For example, B cells are able to produce both IgM and IgD at the same developmental stage using alternative splicing. Additionally, erythrocytes use alternative splicing to produce differing isoforms of cytoskeletal proteins. However, alternative splicing does not always give beneficial results. The mutations in the splicing signals in the β -globin gene mentioned earlier for β -thalassemia result in abnormal alternative splicing. In addition, in patients with chronic myelogenous leukemia (CML) resistance to tyrosine kinase inhibitor therapy has been linked to alternative splicing of the BCR-ABL transcript.

Fig. 4.5 NUCLEAR EXPORT OF RNA THROUGH NUCLEAR PORE COMPLEXES. The central core of the nuclear pore complex consists of a ring structure embedded in the nuclear envelope. Radiating in toward the nucleus is a nuclear basket that extends filamentous proteins in surveillance for mRNA. The central ring structure also radiates cytosolic protein filaments, which act to facilitate release of cargo into the cytoplasm.

Because RNA splicing is central to proper gene expression, mutations in spliceosomes can result in MDS and other related hematologic disorders. Mutations in the RNA spliceosome splicing factor 3b, subunit 1 (SF3B1) has been observed in 68% to 75% and 81% of RARS and RARS-T patients, respectively. The molecular consequences of altered SF3B1 splicing activity are yet to be determined.

Additional spliceosomal mutations that are associated with MDS include U2 small nuclear RNA auxiliary factor 1 (U2AF1) and serine/arginine-rich splicing factor 2 (SRSF2). U2AF1 is a subunit of the U2AF heterodimer, which is also composed of a 65-kDa subunit (U2AF2). While U2AF2 contacts the pyrimidine site, U2AF1 interacts with the AG splice acceptor of the target intron. Mutations in the U2AF1 gene are associated with a number of myeloid malignancies and occur in 8.7% to 11.6% of de-novo cases of MDS.

SRSF2 is a member of the serine/arginine-rich pre-mRNA splicing factors. SRSF2 appears to play an important role in the acetylation/phosphorylation processes of RNA splicing and may be vital to alternative mRNA splicing. Mutations in the SRSF2 gene are associated with MDS and related diseases, particularly CMML. Frequencies of mutations in CMML have been reported to occur in up to 47% of patients. While the overall consequences of these spliceosomal mutations are not fully understood, they each contribute to the overall survival outcomes of MDS and other hematologic disorders.

NUCLEAR EXPORT OF RNA

The nuclear envelope serves as a major regulator of gene expression by controlling the flow of RNA to the cytoplasm for translation. Nuclear pore complexes (NPCs) inserted within the nuclear envelope regulate the transport of molecules in and out of the nucleus. Ions, small metabolites, and proteins under 40 kDa passively diffuse across NPC channels. However, larger proteins and mRNA are transported through NPCs via energy-dependent (GTP) and signal-mediated processes that require chaperoning transport proteins.

NPCs are composed of three major parts: (1) a central core containing a 10-nm channel, (2) a nuclear basket that can dilate in response to large cargoes, and (3) flexible fibrils that extend from the central core into the cytoplasm (Fig. 4.5). These large NPCs are composed of nucleoporins (Nups). Demonstrating how crucial

nuclear export of mRNA is for correct hematopoietic development, mutations or deletions in Nups can result in MDS and leukemia. For example, point mutations of Nup98 in hematopoietic precursors results in myelodysplasia and eventual AML. Furthermore, multiple translocations involving Nup98 (up to 29 recognized partners) have been found in patients with MDS and AML as the sole cytogenetic abnormality.

Naked RNA cannot be exported through NPC channels. Rather, RNA export from the nucleus requires that newly synthesized RNAs undergo the previously described processing steps: 5' capping, splicing, and 3' polyadenylation. In addition, RNA binding proteins are required to fold and shuttle the modified RNA through NPCs. Several of these RNA binding proteins have been identified as important in hematopoiesis. For example, the eukaryotic translation initiation factor 4E (eIF4E) enhances nuclear export of specific RNA transcripts and is critical for proper granulocyte differentiation. Overexpression of eIF4E impedes myeloid maturation and can result in AML. Inhibiting eIF4E with ribavirin has shown activity in early-phase clinical trials of AML and may represent a promising novel class of leukemia therapy.

RNA METABOLISM

RNA does not live forever, and that is a good thing. In mammalian cells, mRNA lifetimes range from several minutes to days. The limited lifetime of mRNA enables a cell to alter protein synthesis in response to its changing needs. The stability of mRNA is regulated by the untranslated regions (UTRs) of mRNA. UTRs are sections of the mRNA before the start codon (5') and after the stop codon (3') that are not translated. These regions govern mRNA half-life, localization, and translational efficiency. Translational efficiency—both enhancement and inhibition—can be controlled by UTRs. Both proteins and small RNA species can bind to either the 5' or 3' UTRs, and these can either regulate translation or influence survival of the transcript. There are several fascinating mechanisms by which this occurs, and these will be described later. UTR sequence regulation of mRNA survival is essential for proper hematopoietic differentiation. The best example of this is globin synthesis, where its mRNA is quite stable because of UTR sequences. This long half-life meets the needs of reticulocytes to synthesize globin for up to 2 days after terminally mature erythroblasts lose the ability to make new mRNA.

Some of the elements contained in UTRs form a characteristic secondary structure that alters the survival of the mRNA transcript. One class of these mRNA elements, the riboswitches, directly bind the small molecules that their mRNA encodes enzymes that regulate its synthesis. For example, the mRNA for several enzymes in the cobalamin pathway has riboswitches that bind adenosylcobalamin, and this regulates the survival of these mRNAs. Thus, in states of high cobalamin, there is decreased survival of the mRNA for enzymes used in this synthetic pathway.

Another class of UTR secondary structures that regulate stability is exemplified by the prothrombin 3' UTR. This mRNA is constitutively polyadenylated at seven or more positions, and the 3' UTR folds into at least two distinct stem-loop conformations. These alternate structures expose a consensus binding site for trans-acting factors, like heterogeneous nuclear ribonucleoprotein 1 (hnRNP-I), polypyrimidine tract-binding protein-1 (PTB-1), and nucleolin, with translational regulatory properties. Another type of 3' UTR regulatory sequence involves selenocysteine insertion sequence (SECIS) elements. These represent another stem-loop RNA structure found in mRNA transcripts that serve as protein binding sites on UTR segments that direct the ribosome to translate the codon UGA as selenocysteines rather than as a stop codon. An example of this regulation can be found in selenoprotein P in plasma.

Another class of UTR binding site that affects the stability of the mRNA is the AU-rich elements (AREs). AREs are lengths of mRNA consisting mostly of adenine and uracil nucleotides. These sequences destabilize those transcripts attached to them through the action of ribonucleases that stimulate poly(A) tail removal. Loss of the

poly(A) tail is thought to promote mRNA degradation by facilitating attack by both the exosome complex and the decapping complex. Rapid mRNA degradation via AU-rich elements is a critical mechanism for preventing the overproduction of potent cytokines such as tumor necrosis factor (TNF) and GM-CSF. AU-rich elements also regulate the synthesis of mRNA for proto-oncogenic transcription factors like c-Jun and c-Fos. The AU elements in the mRNA of these genes mediate destruction of their transcripts in quiescent cells, preventing inappropriate cell proliferation that would occur if Fos/Jun were still active.

Eukaryotic mRNA messages are also subject to surveillance for accuracy by a mechanism termed *nonsense-mediated decay* (NMD). The NMD complex surveys the transcript for the presence of premature stop codons (nonsense codons) in the message. These premature stop codons can arise via either incomplete splicing mutations in DNA, transcription errors, or leaky scanning by the ribosome, causing frame shifts. Detection of a premature stop codon by NMD triggers mRNA degradation by 5' decapping, 3' poly(A) tail removal, or endonucleolytic cleavage.

Translational efficiency can be regulated by cellular factors that bind mRNA in a sequence-specific manner. Iron metabolism is an excellent example of how cells coordinate uptake and sequestration of an essential metabolite in response to availability. Transferrin is a plasma protein that carries iron. Receptors for transferrin (TfR) are expressed on cells requiring iron for maturation, such as erythroid progenitor cells. They mediate internalization of transferrin loaded with iron into the cytoplasm through receptor-mediated endocytosis. When a cell becomes iron deficient, a Krebs cycle enzyme, aconitase, is structurally altered, becoming an iron-responsive protein (IRP) so that it can bind to iron-responsive elements (IREs) in the UTR of transferrin receptor (TfR) mRNA (Fig. 4.6). UTR binding leads to stabilization of the TfR mRNA transcript, thus allowing greater availability for translation, which results in increased protein expression. However, when a cell has sufficient iron, aconitase is not altered, and TfR mRNA becomes unstable and prone to degradation. Therefore, in that situation, TfR receptor expression is low and the fewer receptors import less iron.

MICRO-RNA

In the last two decades another powerful mechanism of regulation of gene expression at the RNA level has been discovered. In this mechanism small RNA molecules, termed *micro-RNA* (miRNA), bind to complementary sequences on target mRNA transcripts. This binding results in either degradation or inhibition of translation, and consequent silencing of gene expression. There are roughly 1000 miRNA molecules coded in the human genome, indicating how robust this regulatory mechanism is. These miRNAs usually contain 18 to 25 nucleotides, and each miRNA has the potential to target about 500 genes. Conversely, an estimated 60% of all mRNAs have one or more sequences that are predicted to interact with miRNAs. This principle, often termed *RNA interference* (RNAi), has also been very useful in the laboratory, allowing investigators to repress the expression of specific genes to study artificially induced phenotypes. In these studies, small interfering RNAs (siRNA) are synthetically created to bind to homologous sequences within specific mRNAs. These are then transfected into cells, where they mediate destruction of their target mRNA through endogenous ribonucleases. Repression of gene expression in this manner has become known as “gene knock-down,” and is widely used to define the function of genes by assessing what function the cell lacks in the absence of the expression of the target gene.

miRNAs are produced from transcripts that form stem-loop structures, whereas siRNAs are produced from long double-stranded RNA (dsRNA) precursors (Fig. 4.7). Similarly, both miRNAs and siRNAs are processed in the nucleus by a multiprotein complex called the RNA-induced silencing complex (RISC), which contains the RNase III enzyme Dicer, DGCR8, and Argonaute. The specificity of miRNA and siRNA interactions with their target mRNAs mediates

Fig. 4.6 CONTROL OF TRANSFERRIN RECEPTOR GENE EXPRESSION. The transferrin receptor mRNA has five IREs in the 3' end of its UTR. In an iron-deficient state (-Fe), IRPs bind to IREs and stabilize the mRNA transcript for translation into protein product. In an iron-replete state (+Fe), IRPs are downregulated and the transferrin receptor mRNA is susceptible to endonucleases. Endonuclease cleavage of mRNA leads to RNA degradation and reduced availability of the transcript for protein production. *IRE*, Iron-responsive element; *IRP*, iron-responsive protein; *UTR*, untranslated region.

Fig. 4.7 RNA INTERFERENCE AND CONTROL OF GENE EXPRESSION. The stem-loop of the pri-miRNA gene transcript is first cleaved through the action of the Class 2 ribonuclease III enzyme called Drosha, which takes place in the nucleus and generates the pre-miRNA. In the siRNA pathway the duplex RNAs are cleaved into 22 to 25 nucleotide pieces through the action of the enzyme Dicer in the cytosol. Processed miRNA stem-loop structures are transported from the nucleus to the cytosol via the activity of exportin 5. In the cytosol the processed miRNA stem-loop is targeted by Dicer, which removes the loop portion. The nomenclature of the mature miRNA duplex is miRNA:miRNA*, where the miRNA* strand is the nonfunctional half of the duplex. Ultimately, fully processed miRNAs and siRNAs are engaged by the RISC, which separates the two RNA strands. The active strand of RNA derived either from the miRNA or siRNA pathway is complementary or antisense to a region of the target mRNA. RNA interference results in blockade of translation by ribosomes and/or degradation of mRNA. *Pre-miRNA*, Precursor miRNA; *Pri-miRNA*, primary miRNA; *RISC*, RNA-induced silencing complex; siRNA, small interfering RNA.

how they regulate gene expression. For example, the specificity of miRNA targeting is ruled by Watson–Crick complementarities between positions 2 and 8 at the 5′ end of the miRNA and the 3′ UTR of their target mRNAs.

Two models have been proposed to explain how miRNAs and siRNAs interfere with the expression of target genes. These models are: directed degradation of the target mRNA, or interference with the translation of a target mRNA. In the case of directed mRNA degradation, the proposed model involves miRNA–mRNA binding and recruitment of RISC, which ultimately leads to degradation of the target mRNA. In the interference model it is believed that the interaction of miRNA, RISC, and mRNA blocks the ribosomal machinery along the mRNA transcript, preventing translation yet sparing the mRNA from degradation. This latter model was hypothesized based on work on the *Caenorhabditis elegans* gene *lin-14*. In this example the amount of *lin-14* mRNA does not decrease, but the protein product of the *lin-14* mRNA is reduced. In the degradation model, the paired miRNA–mRNA becomes a target for double-stranded ribonucleases, which are thought to be part of the innate immune system as a defense against dsRNA viruses, like rotavirus.

Various disease states have aberrant expression of miRNA. One example in chronic lymphocytic leukemia (CLL) is the *miR-15a/miR16-1* cluster (located on chromosome 13q). When this cluster is deleted in B lymphocytes, there are higher levels of antiapoptotic proteins such as BCL2 and MCL1, but also higher levels of the tumor suppressor protein TP53. High levels of antiapoptosis yet with an intact TP53 tumor suppressor pathway could explain why 13q deletions in CLL are associated with an indolent form of the disease. Patterns of miRNA expression are correlated with disease progression in CML, although it is not clear whether these changes are causative or epiphenomena. An example of the prognostic information that can be provided by changes in miRNA levels is miR328, whose expression levels fall significantly when CML begins to progress to blast crisis.

SUMMARY

In summary, control of gene expression is a highly regulated process with several steps including: (1) DNA transcription into RNA, (2) splicing of mRNA into translatable transcripts, (3) modifying the

mRNA transcripts for stability, (4) packaging the mRNA for export from the nucleus to the cytoplasm, and (5) regulation by miRNA. The ultimate goal of most posttranscriptional modifications is to make the mRNA available for translation into proteins. Perturbations in any of these steps can result in hematologic disease. However, while the regulation of RNA has risk of disease at every step, it also possesses the promise of therapeutic intervention. Indeed, RNA metabolism has been an under-explored pathway for drug development in hematology, but that deficit is rapidly being overcome as more attention is being paid to targeting aberrant RNA pathways in an effort to restore normal gene expression.

PROTEIN SYNTHESIS, PROCESSING, AND TRAFFICKING

Randal J. Kaufman and Laura Popolo

The final step in the transfer of the genetic information stored in DNA into proteins is the translation of the intermediary messenger molecules, mRNAs (see [Chapter 1](#)). Protein synthesis occurs in the cytoplasm and generates a great variety of products endowed with a wide spectrum of functions. The complete set of proteins produced by a cell is called the *proteome* and is responsible for the remarkable diversity in cell specialization that is typical of metazoan organisms. To be functional, proteins need to be properly folded, assembled, often modified and transported to the final destination. The cell has in its interior several membrane-bound compartments, termed *organelles*, such as the mitochondria, the peroxisomes, the nucleus and the endoplasmic reticulum to which the proteins may be targeted. Since each compartment serves a particular purpose, protein transport is crucial to maintain the identity and functions of each organelle. Intracellular physiology depends on the proper and coordinated functioning of the organelles. In many cases protein folding and processing are coupled with protein trafficking so that the targeting process is unidirectional and irreversible.

This chapter briefly describes how proteins are synthesized and then focuses on their processing and delivery to their appropriate destinations within the cell. An understanding of the machines that catalyze protein folding, assembly, processing, and targeting is relevant to the study of hematology providing a basis for an explanation of how malfunctions in these processes can cause hematologic disorders.

PROTEIN SYNTHESIS

Among the biosynthesis of macromolecules occurring in a cell, protein synthesis is the most important in quantitative terms. It is a highly energy-consuming process and proceeds through a mechanism that has been conserved during evolution. Proteins are synthesized by the joining of amino acids, each of which has characteristic physico-chemical properties (see [Table 5.1](#) for single letter designations). Peptide bonds are created by the condensation of the α -carboxyl group (COOH) of one amino acid with the α -amino group (NH₂) of another. The free NH₂ and COOH groups of the terminal amino acids define the amino- or N-terminal end and the carboxyl- or C-terminal end of the resulting polypeptide chain, respectively. In many cases multiple polypeptide chains assemble into a functional protein. For example, hemoglobin is formed by four polypeptide chains, two α -globin chains and two β -globin chains that assemble with heme, an iron-containing prosthetic group, to yield the functional protein designed to deliver molecular oxygen to all cells and tissues.

The whole process of protein synthesis is orchestrated by a large ribonucleoprotein complex, called the *ribosome*. The ribosome 80S (S stands for Svedberg unit, and refers to the rate of sedimentation) is typical of mammalian cells and is constituted by a large subunit of 60S and a small one of 40S. Additional components are messenger RNAs (mRNAs), transfer RNAs (tRNAs), amino acids, soluble factors, ATP and GTP. Activation of amino acids by coupling to their cognate tRNAs occurs before polypeptide chain initiation. This crucial function is carried out by 20 different aminoacyl-tRNA synthetases, one for each amino acid, which generate aminoacyl-tRNAs at the expense of ATP and operate a quality control on the coupling reaction. Eukaryotic mRNA molecules typically contain a 5'-untranslated region (5' UTR), a protein coding sequence that

begins with the initiation codon AUG and ends with one of three stop codons (UAA, UAG, UGA), and a 3'-untranslated region (3' UTR). The 5'-end carries a 7-methylguanosine structure called a "cap" (m⁷GpppN mRNA) whereas the 3'-end is polyadenylated. These modifications are required to protect the mRNA from degradation, for export out of the nucleus, and for efficient recruitment of ribosomes for translation. Once in the cytoplasm, the 40S ribosomal subunit binds to the cap and then scans the mRNA toward the 3'-end until a translation start codon is encountered, usually the first AUG (underlined) located in a nucleotide context optimal for translation initiation which is called the Kozak consensus sequence (A/GNNAUGG). The assembly of the 60S subunit with the 40S produces an 80S ribosome. A special tRNA specific for methionine, called the initiator (tRNA^{Met}) is required for the initiation of protein synthesis at the initiation codon. Aminoacyl-tRNAs ferry amino acids to the ribosome for joining together in sequence as the ribosome moves toward the 3'-end of the mRNA. The codons in the mRNA interact by base-pairing with the anticodon of the tRNAs so that amino acids are incorporated into the nascent polypeptide chain in the right order. Translation is terminated when the ribosome encounters a stop codon where the polypeptide is released. Typically, multiple ribosomes are engaged in the translation of a single mRNA molecule in a complex termed a polyribosome or polysome.

Protein synthesis is divided into three phases: initiation, elongation and termination. Each phase requires a set of soluble proteins (or factors) which transiently associate with the ribosomes and are called initiation, elongation and termination (or release) factors that are termed eIFs, eEFs, and eRFs, respectively, where the prefix "e" indicates their eukaryotic origin. Many soluble factors required for protein synthesis belong to the G-protein (guanine nucleotide-binding proteins) superfamily which are regulatory molecules that promote unidirectionality of important cellular processes such as hormone and growth factor signaling, membrane trafficking and neurotransmission. Dysfunctions of G-proteins are involved in human diseases, including cancer.

REGULATION OF mRNA TRANSLATION

There are two major general regulatory steps in mRNA translation that are mediated by the initiation factors eIF2 and eIF4. All cells regulate the rate of protein synthesis through reversible covalent modification of eIF2, a soluble factor required for the binding and recruitment of the Met-tRNA^{Met} to the 40S ribosomal subunit.

eIF2 is a heterotrimeric G-protein that can exist in an inactive form bound to GDP or an active form bound to GTP. The eIF2-GTP/Met-tRNA^{Met} ternary complex binds to the 40S subunit. Joining of the 60S subunit triggers hydrolysis of GTP to GDP and thus converts eIF2 to the inactive form whereas the opposite reaction is catalyzed by a guanine nucleotide exchange factor (GEF) called eIF2B. Phosphorylation regulates eIF2 function. In reticulocytes, which primarily synthesize hemoglobin, heme starvation inhibits the synthesis of α - and β -globin chains by activating a protein kinase, called hemin-regulated inhibitor (HRI) that specifically phosphorylates the α subunit of eIF2. The phosphorylated form of eIF2 binds more tightly than usual to eIF-2B, so that eIF-2B is sequestered and not available for the exchange reaction. Thus, eIF2 molecules remain in the GDP-bound form and translation of globin mRNA comes to a halt. In this manner, globin chains are not synthesized in the

TABLE 5.1 Examples of Sorting Signals

Organelle	Signal Location ^a	Example
Posttranslational Uptake		
Nucleus	Internal	SPKKKKRVE (import; NLS of SV40 large T antigen) KR-spacer (PAATKKAGQ)-KKKK (import; bipartite NLS of nucleoplasmin) LQLPPLERLTLD (export; NES of HIV-1 rev)

absence of heme, which is required for assembly of functional hemoglobin. This mechanism of translational inhibition is of more general significance because eIF2 is a target of phosphorylation by additional protein kinases that cause translational arrest in response to different conditions of cell stress, such as amino acid starvation, glucose starvation, and viral infection. Overall, eIF2 phosphorylation is a central event mediated by four protein kinases activated by different stress conditions to inhibit protein synthesis and has been termed the *integrated stress response*.

A second major control point of general protein synthesis is mediated by the eIF4F protein complex that binds the cap (eIF4E) and uses an ATP-dependent RNA helicase (eIF4A) activity and its stimulatory subunit (eIF4B) to unwind structural elements in the 5'-end of mRNA to make it accessible for 40S ribosome subunit binding. The eIF4E subunit binds the 5'-cap structure and is the least abundant factor regulating translation in mammalian cells. eIF4E forms a complex with the RNA helicase eIF4A and eIF4G, another crucial factor that binds mRNA and recruits the 40S ribosomal subunit. Increased levels of eIF4E stimulate protein synthesis. The cap-binding activity of eIF4E is inhibited by eIF4E-binding proteins (eIF4EBPs) which prevent assembly of the eIF4F complex. The activity of eIF4EBP is regulated by phosphorylation mediated by the protein kinases AKT (also named PKB) and TOR. Since phosphorylated eIF4BP cannot bind eIF4E, eIF4BP phosphorylation stimulates translation initiation since it permits eIF4G binding and recruitment of the 40S subunit. Extracellular factors, such as insulin, activate signaling pathways that stimulate protein synthesis through this mechanism. Insulin also activates eIF2B exchange activity and in the long term also increases the cellular ribosome content.

The efficiency of mRNA translation can also be modulated by cellular factors that bind mRNA in a sequence-specific manner. An example of this mode of regulation is the control of iron metabolism in animal cells. Key players of this system are (i) the **iron-responsive element (IRE)**, a hairpin structure that is formed in the untranslated regions of the mRNAs and (ii) **iron regulatory proteins** that bind IRE (IRPs). In the transferrin receptor (Tfr) mRNA and ferritin mRNA, IREs are located in the 3' UTR and

5' UTR respectively. In iron-starved cells, the binding of IRPs to IREs results in the stabilization of Tfr mRNA and inhibition of translation initiation of ferritin mRNA. Conversely, when iron is abundant, IRPs have a lower affinity to IREs and as a result Tfr mRNA is degraded whereas ferritin mRNA translation is stimulated. In this manner, cells can coordinately regulate iron uptake and iron sequestration in response to the changes in iron availability.

Among the cellular factors that modulate translation, noncoding small RNAs called micro-RNAs (miRNAs) are currently intensely studied.¹ miRNAs are single stranded RNAs of 20–22 nucleotide in length that result from the nuclear processing of double-stranded RNA precursors. miRNAs regulate translation by three molecular mechanisms: translation repression, mRNA degradation, and miRNA-mediated mRNA decay. miRNAs anneal to the 5'-end, but even more frequently to the 3'-end of the target mRNA, and block translation by inhibiting eIF4F or ribosome scanning of the 5' UTR, keeping in mind that mRNA circularizes because of interaction of proteins that bind the 5' and 3' UTRs. Base pairing at the 3'-end can also lead to deadenylation of the mRNA and degradation or to endonucleolytic cleavage of the mRNA. Degradation of mRNA takes place in specialized cytoplasmic organelles, called P-bodies, that are rich in enzymatic machinery for RNA degradation. Interestingly, miRNAs contribute to the fine regulation of processes such as apoptosis, cell proliferation, hematopoietic differentiation and in cancer progression.

Finally, another destiny of mature mRNAs is to remain silent in the cytoplasm. In oocytes or during the first stages of embryogenesis, latent mRNAs are present and they are quickly translated as the appropriate signal is triggered.

PROTEIN FOLDING

As the polypeptide emerges from the ribosome, it must fold to become a mature functional protein. The conformation of a protein is dictated primarily by the primary structure. Some proteins can spontaneously acquire their mature three-dimensional conformation as they are synthesized in the cell and can even fold in a test tube by a self-assembly process. However, most polypeptides require assistance from other protein for proper folding. These proteins are *molecular chaperones* that either directly assist folding reactions and/or prevent aberrant interactions, such as aggregation that can occur in a densely packed environment as the cytosol of eukaryotic cells (protein concentration of 200–300 mg/mL). Most molecular chaperones are heat-shock proteins (Hsps) and in particular are members of the Hsp70 family. Chaperones bind to short sequence protein motifs, in many cases containing hydrophobic amino acids. By undergoing cycles of binding and release (linked to ATP hydrolysis), chaperones help the nascent polypeptide to find its native conformation, one aspect of which is hiding hydrophobic sequence motifs in the protein interior so that they no longer contact the hydrophilic environment of the cytosol. Some properly folded protein monomers are assembled with other proteins to form multisubunit complexes. The population of chaperones that assist folding and assembly in the cytosol is distinct from those that operate within the endoplasmic reticulum (ER) or mitochondria.

PROTEIN MODIFICATIONS

Proteins often need to be modified to become functional or be localized to the correct site. More than a hundred protein modifications were identified in mammals. These modifications can take place during synthesis of the polypeptide (cotranslational) or after synthesis (posttranslational) and can also be reversible or irreversible. Most of the reversible modifications are carried out by enzymes that catalyze the transfer of a chemical group from a donor molecule to the target amino acid and counterpart enzymes catalyze the opposite reaction. In contrast, proteolytic cleavage of precursor proteins to generate

mature products is irreversible. Here are some features of the most common protein modifications:

- **Acetylation:** ribosome-associated Met-aminopeptidases and acetylases cotranslationally cleave off the N-terminal methionine and acetylate the second residue if it is small (Gly, Ala, Ser, Thr, Cys, Pro or Val). Approximately 90% of human proteins are N-acetylated (acetyl group: COCH_3). In general, the N-terminal residue affects the lifetime of a protein.

Another type of *acetylation* is posttranslational and occurs on the α -amino group of the side chain of lysine. This modification abolishes the positive charge of this amino acid. The N-terminal tails of histones, are targets of acetylation that is carried out by histone acetyltransferases (HATs) and is reversed by histone deacetylases (HDACs). The degree of histone acetylation increases transcriptional activity by relaxing chromatin structure.

- **Methylation:** is the reversible addition of a methyl group (CH_3) to lysine or arginine residues. This modification abolishes the positive charge and increases the hydrophobicity of the protein. Histone methylation by histone methyltransferases affects transcriptional activity by modifying the accessibility to DNA either positively or negatively.

Other processing reactions add anchors to the proteins for membrane association. Among the most important of these modifications are:

- **Myristoylation:** is the attachment of a 14-carbon myristoyl group to the N-terminal glycine residue of a protein. This modification is co- or posttranslational, irreversible and allows the association of the target protein with membranes or with other proteins or lipids.
- **Prenylation:** involves the attachment of the 15 carbon farnesyl group or 20 carbon geranyl group to acceptor proteins that harbor at the C-terminus the CAAX consensus sequence (C = cysteine, AA = any aliphatic amino acid except alanine, X = any amino acid). AAX is first removed by a CAAX protease and the prenyl group is attached to the side chain of cysteine that is finally also methylated by a prenylcysteine methyltransferase that uses S-adenosylmethionine. This complex modification occurs on RAS protein family members and variants involving CC or CXC elements at the C-terminus take place on the RAB protein family that is involved in signaling pathways that control intracellular membrane traffic (see later). Lack of prenylation on these otherwise soluble proteins leads to lack of membrane association and generates severe phenotypes.

Other modifications are crucial to regulate protein function:

- **Phosphorylation:** is the transfer of a phosphate group from ATP to target amino acids in a protein (serine, threonine or tyrosine with a ratio of occurrence of 1000:100:1). It can be reversed by the action of protein phosphatases that remove the phosphate group. It has been estimated that the human genome encodes about 500 protein kinases and 100 protein phosphatases. The catalytic or biologic activity of many enzymes is transiently regulated by reversible phosphorylation. Another role of phosphorylation emerged from studies on intracellular signaling pathways. Phosphorylation of a protein substrate can create an interaction site (or docking site) to bind another protein. Interestingly, many pairs of docking sites that bind specific small protein domains to promote protein–protein interaction have been identified. An example is the SH2 domain of the c-Src protein kinase and other signal-transducing proteins that recognizes specific phosphotyrosine in other proteins. About 111 SH2 domains are found in proteins encoded by the human genome.
- **Sulfation:** this modification occurs at tyrosine residues and is catalyzed by tyrosyl-protein sulfotransferases (TPST) which are membrane-associated enzymes of the *trans*-Golgi network. An

BOX 5.1

Protein γ -Carboxylation: A Rare Posttranslational Modification Crucial for Life

γ -Carboxylation of glutamic acid residues in the Gla domain serves to coordinate calcium ions and is essential for the proper biologic activity of factors involved in blood coagulation. These factors are prothrombin, factors VII, IX and X which are involved in the coagulant response, and protein C and S which play roles in an antithrombotic pathway that limits coagulation. Bone proteins osteocalcin and matrix Gla protein also require processing by γ -carboxylation for full activity.

This posttranslational modification is catalyzed by γ -glutamyl carboxylase, an endoplasmic reticulum (ER) membrane protein. Its obligate cofactor, reduced vitamin K, is produced by the action of vitamin K-epoxide reductase (VKOR) which converts oxidized vitamin K to the reduced form. The activity of VKOR is inhibited by warfarin, a potent anticoagulant compound. γ -Carboxylase homozygous null mutants manifested dramatic effects on development with partial midembryonic loss and postnatal hemorrhage. Similar effects were observed in prothrombin or factor V-deficient mice. Thus, the results of these studies have suggested that the functionally critical substrates for γ -carboxylation are primarily restricted to components of the blood coagulation cascade. These results highlight the importance of a rare protein modification for blood coagulation.

unusual nucleotide, a 3'-phosphoadenosine 5'-phosphosulfate (PAPS), is the universal sulfate donor for TPST-catalyzed reactions. Addition of sulfate occurs almost exclusively on secreted or membrane proteins and is believed to play a role in the modulation of protein-protein interactions. This protein modification is critical in the processes of blood coagulation, various immune functions, intracellular trafficking, and ligand recognition by several G protein-coupled receptors. Notably, coagulation factors V and VIII, the gut peptides gastrin and cholecystokinin are modified by sulfation.

- **γ -Carboxylation:** this modification converts glutamate into γ -carboxyglutamate that is found in several components of the coagulation pathway, as well as in a number of other proteins. This modification is carried out by the enzyme γ -glutamyl carboxylase (GGCX) that requires vitamin K as an essential cofactor. The formation of modified glutamate residues is crucial for the process of blood coagulation and is described in more detail in [Box 5.1](#).
- **Ubiquitination:** this posttranslational modification results from the sequential activity of three enzymes, the first activates a small protein of 76 amino acids named *ubiquitin*, the second transfers ubiquitin to ubiquitin ligase that links ubiquitin to lysine residues present in target proteins and then other ubiquitin molecules to ubiquitin lysine residues (polyubiquitination). Seven lysine residues in ubiquitin may serve as sites of linkage in formation of a polyubiquitin chain. Initially discovered as a mechanism to regulate protein degradation via the proteasome, in recent years, ubiquitination was described to regulate different cellular processes including DNA repair, vesicle trafficking, and inflammation. According to the pattern of modification of the target proteins (monoubiquitinated, polyubiquitinated) different processes can be triggered (see next section).
- **Sumoylation:** this modification belongs to a group of ubiquitin-like proteins (Ubl) that are added to proteins via posttranslational reactions. The small peptide SUMO (small ubiquitin-related modifier) is among the best characterized Ubl and over 50 proteins are modified by SUMO addition.
- **Proteolysis:** this modification consists in the cleavage of the polypeptide chain at a specific site during its maturation (proinsulin to insulin), or occurs upon secretion of its inactive form (zymogen) to prevent potential toxic effects of the processed protein in the cell (digestive proteases) or because proteolysis is regulated as occurs for coagulation factors that are secreted into the blood in an inactive form and are activated by proteolysis at sites of damaged blood vessels. Proteolysis can take place in more than one site to generate smaller products as for instance in the maturation of hormones starting from a larger precursor. Proteolytic

processing of propeptides into their mature forms occurs after the Arg-Xxx-Lys-Arg motif and is mediated by the general protein processing protease *FURIN*. *FURIN* is expressed in all cell types and removes propeptides from many proteins, including clotting factors, growth factors, and proteases, and is responsible to convert these proteins into their functional forms. Other members of the proprotein convertase (PC) family cleave after pairs of dibasic amino acids (for example Lys-Arg) and are expressed in specific cell types, such as neuroendocrine cells. The PCs are responsible for cleavages that occur to generate many hormones, such as insulin, glucagon, and adrenocorticotrophic hormone.

Other modifications such as *N*-glycosylation, *O*-glycosylation and attachment of a glycosylphosphatidylinositol (GPI) anchor will be discussed in a separate section.

Finally, proteins can also be susceptible to nonenzymatic modifications that take place under particular conditions, such as during oxidative stress or in the presence of excess glucose in the blood as in the case of hemoglobin glycation.

PROTEIN DEGRADATION

The level of a protein in the cell results from the balance between its synthesis and degradation and a protein's half-life can vary from minutes to hours. Moreover, the cell eliminates proteins that contain mutations that cause protein misfolding. Such misfolded proteins are marked for destruction and then degraded to avoid toxic effects of their accumulation. The breakdown of these molecules is achieved in two major phases. First, the molecules are tagged with *ubiquitin*, which is covalently linked to the substrate protein as described earlier. Second, the tagged molecules are ferried to an ATP-dependent protease complex called the 26S proteasome, a multi-subunit molecular machinery specialized in protein destruction. Peptides and amino acids derived from protein disposal are recycled.

Since its first discovery in carrying out the disposal of damaged and misfolded proteins, protein ubiquitylation was found associated to an increasing number of specific regulatory events involving a selective degradation of key regulatory proteins. Thus, ubiquitylation is responsible for regulating a wide array of cellular processes including differentiation, tissue development, induction of inflammatory responses, antigen presentation, cell cycle progression and programmed cell death also named apoptosis (Chapter 18 will review cell death). In addition, according to the pattern of modification of the target proteins (monoubiquitination, polyubiquitination) different proteins can trigger DNA repair (monoubiquitination of N-terminal tails in histones) or be subjected to endocytosis (monoubiquitination of surface receptors).

SORTING FROM THE CYTOSOL INTO OTHER COMPARTMENTS

Most proteins are synthesized on free polysomes and remain in the cytosol. These include enzymes involved in many metabolic and signal transduction pathways, proteins required for mRNA translation or assembly of the cytoskeleton. Other proteins are imported from the cytosol into organelles including the nucleus, the mitochondrion, and the peroxisome (Fig. 5.1).

In general, there are two types of protein trafficking. In one type, the protein crosses a lipid bilayer. The polypeptide crosses the membrane in an unfolded state through an aqueous channel composed of proteins. In the second type, the protein does not traffic across a lipid bilayer and is exemplified by trafficking into the nucleus or from the endoplasmic reticulum (ER) to the Golgi compartment. In these cases, proteins and protein complexes are transported in their folded/assembled state.

The trafficking events are governed by sorting signals (i.e., short linear sequences or three-dimensional patches of particular amino acids) and by their cognate receptors (see some examples in Table

5.1). The first sorting decision occurs after approximately 30 amino acids of the nascent polypeptide are extruded from the ribosome. If the nascent polypeptide lacks a "signal sequence," most often found near the amino-terminal end, the translation of the polypeptide is completed in the cytosol. Then the protein either remains in the cytosol or is posttranslationally incorporated into one of the indicated organelles (see Fig. 5.1). If the protein does contain an amino-terminal signal sequence it is imported co- or posttranslationally into the ER or mitochondrion. Trafficking of proteins from the ER to the Golgi compartment and lysosomes occurs via vesicle budding and fusion events (see Fig. 5.1).

Targeting of Nuclear Proteins

One of the distinctive features of all eukaryotic cells is that the genome is contained in an intracellular compartment called the *nucleus*. The nucleus is bounded by a double membrane that forms the nuclear envelope (NE) (see Fig. 5.1). The outer nuclear membrane is continuous with the ER and has a polypeptide composition distinct from that of the inner membrane. About 3000 nuclear pore complexes (NPCs) perforate the NE in animal cells. Although NPCs allow unrestricted, bidirectional movement of molecules smaller than 40,000 Daltons, traversal of larger molecules across NPCs is tightly regulated. NPCs are approximately 120 nm in external diameter and comprise approximately 50 different proteins (nucleoporins), arranged in a complex cylindrical structure with an octagonal symmetry. Nucleoporins constitute the scaffold of the NPC and are arranged in rings. In the inner ring, nucleoporins containing repeats of two hydrophobic amino acids, phenylalanine and glycine (FG-repeats), seem to be essential for the movement of the cargo-carrier complexes and for creating a selectivity barrier against the diffusion of nonnuclear proteins. The FG-nucleoporin filaments protrude toward the inner core of the NPC and the weak hydrophobic interactions between the FG-repeats and the cargo-carrier complexes mediate the passage of molecules.

NPCs are capable of importing and exporting molecules or complexes, provided that the molecules have an exposed nuclear localization signal (NLS) or nuclear export signal (NES). These signals are not always easy to predict. In Table 5.1 some of the best-known signals are listed. The function of these signals in importing or exporting a protein was analyzed by critically testing both the effects of amino acid substitutions on transport and the capability of the signal to target in or out of the nucleus an attached reporter protein. The nuclear localization signals are not cleaved off as occurs for other signals (see later) and thus can function repetitively. Candidates exposing signals for nuclear import (i.e., transcription factors, coactivators or corepressors, DNA repair enzymes, ribosomal proteins and mRNA processing factors, etc.) or export (ribosomal subunits, mRNA-containing particles, tRNAs, etc.) are transported through the NPC in association with soluble carrier proteins, called karyopherins (also called importins, exportins or transportins), which function as shuttling receptors for different protein cargos. According to the direction of transport, they are divided into two groups: (i) importins, if they bind their cargo on the cytoplasmic side of the NPC and release it on the other and (ii) exportins if they bind the cargo in the nucleus and release it in the cytoplasm.

Ran is a small Ras-like GTPase, belonging to the G-protein superfamily, that controls both the docking of carrier proteins with their cargo and the directionality of transport through cycles of GTP binding and hydrolysis. Fig. 5.2 exemplifies a cycle of import into the nucleus. An importin binds the cargo in the cytosol and then associates with Ran-GDP for trafficking into the nucleus where a Ran-GEF (guanine-nucleotide exchange factor) catalyzes GTP exchange for GDP on Ran that triggers cargo release. The importin-Ran-GTP complex is transported back to the cytoplasm where the conversion of GTP to GDP is stimulated by a Ran-GAP protein (GTPase-activating protein) that causes dissociation of Ran from the importin which can initiate a new cycle. The movement of cargo from the nucleus to the cytoplasm occurs by formation of a Ran-GTP-exportin-cargo

Fig. 5.1 SORTING OF PROTEINS FROM THE CYTOSOL TO DIFFERENT DESTINATIONS. *Left:* steps 1 to 4a and 4b depict the sorting of proteins destined to organelles of the secretory pathway, endoplasmic reticulum (ER), Golgi, plasma membrane, lysosome or extracellular space. *Right:* steps 5 and 6: synthesis of a cytosolic protein; steps 7, 8 and 9: sorting of proteins to mitochondrion, the nucleus and the peroxisome.

complex that is transported to the cytoplasm where Ran-GAP triggers the hydrolysis of GTP. The conformational change of the exportin releases the cargo in the cytoplasm. The different localization of Ran-GEF and Ran-GAP and the continuous transport of Ran-GDP in the nucleus create an asymmetry that is important for the directionality of the process. In conclusion, karyopherins possess a cargo-binding domain but also binding domains for nucleoporins and Ran-GTPase.

Interestingly, there are remarkable examples of regulation of protein transport into the nucleus. NF κ B, a nuclear factor for the transcriptional enhancer of the κ light chain in B lymphocytes, is a key element of the stress response. This factor is normally retained in the cytoplasm by interaction with I κ B. The TNF- α dependent phosphorylation of I κ B releases NF κ B that exposes an NLS and migrates into the nucleus where it activates transcription of several target genes. For the glucocorticoid receptor (GR), which is localized in the cytoplasm, the binding to the lipophilic ligand exposes an NLS which is recognized by an importin and allows translocation into the nucleus where GR activates genes by binding to GR-responsive-elements in their promoter regions.

Targeting of Mitochondrial Proteins

The mitochondrion is an essential cellular compartment in eukaryotes. Although it contains a genome organized in a circular DNA

molecule and independent transcriptional/translational machinery, 98% of the approximately 1500 proteins that constitute the mitochondrial proteome are encoded by nuclear DNA and are imported from the cytosol after their synthesis. A small number of highly hydrophobic proteins is encoded by mitochondrial DNA and synthesized inside the organelle by a translational machinery of bacterial origin using organelle-transcribed mRNAs.

Like nuclei, mitochondria have two membranes: the outer membrane (MOM) contacts the cytosol whereas the inner membrane (MIM) forms numerous invaginations named *cristae* where the enzymes that synthesize ATP through reactions of the electron transport chain and oxidative phosphorylation reside. Where the MOM is permeable to small molecules (less than 5 kDa) and ions, the inner membrane is highly impermeable, a property essential to create an electrochemical gradient necessary to drive the synthesis of ATP. The space enclosed by the two membranes is the intermembrane space (IMS) and the space enclosed by the inner membrane is the *matrix*. Protein transport into mitochondria appears to be unidirectional, as no proteins are known to be exported from mitochondria. A remarkable exception is represented by apoptosis. Upon this condition, there is a mitochondrial permeability transition that permits release of cytochrome c and other factors from the IMS to the cytosol that trigger an intracellular pathway leading to death. Posttranslational translocation and sorting of nuclear-encoded proteins into the various mitochondrial subcompartments are achieved by the concerted action of translocases.

Fig. 5.2 MECHANISM OF PROTEIN IMPORT INTO THE NUCLEUS. The figure shows the different localization of Ran-GAP and Ran-GEF that regulate the direction of nuclear transport. A Ran-GTP-exportin-cargo complex is transported from the nucleus to the cytoplasm where a Ran-GAP stimulates the GTPase activity of Ran. Ran-GDP dissociates from the complex and induces the release of the cargo from exportin. Ran-GDP is transported back to the nucleus by association with an importin-cargo complex and in the nucleus the activity of a Ran-GEF triggers GDP-GTP-exchange and this induces the dissociation of the cargo from importin. Ran-GTP binds an exportin-cargo complex and another cycle begins. *GAP*, GTPase-activating protein; *GDP*, guanosine diphosphate; *GEF*, guanine nucleotide exchange factor; *GTP*, guanosine triphosphate; *NLS*, nuclear localization signal, *NPC*, nuclear pore complex. (Adapted from Lodish H, Berk A, Matsudaira P, et al: Molecular cell biology, ed 5, New York, 2003, W.H. Freeman.)

Precursor proteins usually have one of two targeting signals: (1) an amino-terminal presequence that is generally between 10 and 80 amino acids long and forms an amphipathic α -helix, which is rich in positively charged, hydrophobic and hydroxylated amino acids (Table 5.1); or (2) a less well-defined, hydrophobic targeting sequence distributed throughout the protein. The translocase of the outer membrane (TOM) complex functions as a single entry point of incoming precursors into the mitochondria and is crucial for the biogenesis of the organelle and for the viability of eukaryotic cells. Preproteins translocate through the TOM complex in an N-to-C direction in an unfolded state. TOM translocase is a heteromolecular protein complex whose central component is Tom40, an essential protein that forms the protein-conducting channel. After crossing the outer membrane, proteins segregate according to their signals and recognize two distinct translocases of the inner membrane (TIM23 and TIM22). Presequence-containing proteins are directed to the TIM23 complex that mediates transport across the inner membrane, a process which requires the electrochemical membrane potential and the ATP-driven action of the matrix heat shock protein 70 (mtHsp70). Once in the matrix, the presequence is often cleaved by a mitochondrial processing peptidase (MPP). Proteins with internal targeting signals are guided to the TIM22 complex. Membrane insertion at the TIM22 complex is also dependent on the membrane potential. Other machineries of protein sorting are the intermembrane space import

and assembly machinery (MIA) that drives the import of proteins with cysteine-rich motifs, the sorting/assembly machinery (SAM) that inserts precursors of proteins with a transmembrane β -barrel domains in the MOM and the mitochondrial import machinery (MIM) that import outer membrane proteins with α -helical transmembrane segments after their recognition by the Tom70 subunit of the TOM complex.²

In the context of cell biology, mitochondria play relevant roles in apoptosis, in the communication with the ER and in oxidative stress. Among the proteins associated with the cytosolic side of MOM, those of the Bcl-2 family have both pro- or antiapoptotic functions. In addition, recent studies unveiled an ER-mitochondria linkage that is important in Ca^{2+} homeostasis and phospholipid biogenesis whereas oxidative stress generated in the mitochondria is connected to cell aging and senescence.

Targeting of Peroxisomal Proteins

Peroxisomes are membrane-bound compartments in which oxidative reactions that generate hydrogen peroxide, such as β -oxidation of fatty acids, occur. In this organelle hydrogen peroxide is rapidly degraded by catalase to prevent oxidative reactions that have potential damaging effects on cellular structures. A single membrane surrounds the peroxisome that encloses an interior matrix. This organelle lacks a genetic system and transcriptional/translational machinery. Therefore, all peroxisomal proteins are nuclear-encoded. Their mRNAs are translated on cytosolic-free ribosomes and then proteins are imported posttranslationally by proteins called peroxins (Pex).³

The targeting of matrix proteins is directed by two types of peroxisomal targeting signals (PTSs). Type 1 is a carboxyl-terminal tri- or tetra-peptide (PTS1) whereas type 2 is an amino-terminal peptide of nine amino acids (PTS2) (see Table 5.1). Two cytosolic Pex, Pex5 and Pex7, recognize PTS1 and PTS2. Pex5p is sufficient for targeting PTS1-containing proteins whereas both Pex5 and Pex7 are required for import of PTS2-containing proteins. These proteins function as cargo receptors; they bind cargo proteins in the cytosol, release them into the matrix and cycle back to the cytosol. In humans, Pex5 has two isoforms, Pex5S and Pex5L. The latter has an additional exon that is required for binding of Pex7 to Pex5. Matrix proteins cross the membrane in a folded state, or even as oligomers. Other peroxins are involved in the import of peroxisomal membrane proteins (PMPs). Pex3, Pex16 and Pex19 are thought to be involved in the formation of the peroxisomal membrane and/or insertion of PMPs in the peroxisomal membrane. Experimental evidence suggests the existence of two routes by which PMPs can reach peroxisomes, one direct route and one via the ER. Some PMPs are targeted to peroxisomes by Pex19 and others are not. The PMP binds Pex19, a soluble recycling receptor/chaperone, to form a cargo-receptor complex that docks on Pex3 in the peroxisomal membrane and then membrane insertion occurs. The indirect targeting via the ER involves only some PMPs, Pex3 for example, and so far, has been demonstrated only in yeast where the Sec61 translocon is required. Other Pex proteins are involved in ubiquitination. Ubiquitination of the receptors has been proposed to function in concert with ATPases associated to diverse activities (AAA^+ ATPases) that move proteins across membrane using an ATP-dependent mechanism that resembles the retrotranslocation of misfolded proteins from ER lumen to the cytosol and in recycling the receptors to the membrane surface.

One consequence of the existence of two different mechanisms for protein import is that when the import of matrix proteins is defective, membrane ghosts of peroxisomes persist in the cells. In contrast, when the import of membrane proteins is impaired, neither normal peroxisomes nor membrane ghosts are present. Defects in *PEX3* underlie Zellweger syndrome that is characterized by the presence of empty peroxisomes and abnormalities in the brain, liver, and kidney that cause death shortly after birth. Other syndromes in peroxisome biogenesis were identified and their occurrence underlines the essential role of these organelles for human metabolism and development.⁴

COTRANSLATIONAL PROTEIN TRANSLOCATION INTO THE ENDOPLASMIC RETICULUM

The ER is an extensive membranous network that is continuous with the outer nuclear membrane and is the site for the synthesis of the massive amounts of lipid and protein used to build the membranes of most cellular organelles. The ER comprises three interconnected domains: rough ER, smooth ER, and ER exit sites. The rough ER is so called because it is studded with bound ribosomes that are actively synthesizing proteins. Cells specialized in protein secretion, such as cells of the exocrine glands and plasma cells are rich in rough ER. The smooth ER lacks ribosomes, is not very abundant in most cells (except hepatocytes), and is thought to be the site of lipid biosynthesis and of cytochrome P450-mediated detoxification reactions. Finally, ER exit sites are specialized areas of the ER membrane where transport cargo is packaged into transport vesicles en route to the Golgi apparatus.

Nascent secretory proteins are marked for translocation into the ER by the presence of an amino-terminal signal sequence (see Table 5.1). This sequence has a length of about 15–30 amino acids and displays no conservation of amino acid sequence, although it contains a hydrophobic core flanked by polar residues that preferentially have a short side chain in proximity to the cleavage site. As the signal sequence emerges from the ribosome, it is recognized by the signal recognition particle (SRP), a ribonucleoprotein, and this binding induces a temporary arrest in translational elongation (Fig. 5.3). The docking of ribosomes to the ER occurs by interaction of the SRP with the SRP receptor. Upon binding of GTP to both the SRP and its receptor, the ribosome and the nascent chain are transferred to the Sec61 translocon complex allowing translation to resume. Preproteins translocate through the Sec61 complex in an N-to-C direction. As the nascent polypeptide emerges from the luminal side of the translocon, its signal sequence is cleaved by signal peptidase.

In the absence of specific targeting sequences, proteins that completely translocate into the ER lumen traffic through bulk flow

to the cell surface. In contrast, proteins that have specific targeting signals may be localized to the lumen of the ER, the Golgi compartment, or lysosomes. Other proteins that reside in membranes of the cell contain topologic sequences called transmembrane domains that consist of ~20 largely apolar amino acids. When a transmembrane domain enters the translocon, the polypeptide is released laterally from the Sec61 channel into the lipid bilayer. Membrane proteins can assume different topologies according to the number and type of TM domains.

PROTEIN TRAFFICKING WITHIN THE SECRETORY PATHWAY

Proteins that enter the ER are transported towards the plasma membrane through the secretory pathway (Fig. 5.4). Specific signals cause resident proteins to be retained in the ER, Golgi or plasma membrane. Proteins may also be targeted from the Golgi compartment to lysosomes or from the plasma membrane to endosomes (see Fig. 5.4, pathways 8 and 9). Initially the study of this complex protein trafficking took advantage of the use of yeast genetics to isolate temperature-sensitive mutants (*sec*) that were defective at different stages of the secretory pathway. The subsequent characterization of *SEC* genes, thanks to the advent of DNA recombinant techniques, made possible the isolation of the counterparts in mammalian cells and the beginning of molecular and biochemical investigation of protein secretion. Many genes encoding products involved in secretion are strikingly conserved from yeast to mammals, indicating the importance of this pathway for the life of a eukaryotic cell.

Transport through the secretory pathway is mediated by vesicles. Different sets of structural and regulatory proteins control the fusion of the appropriate vesicles with the target membrane. Sorting motifs dictate the selective incorporation of cargo proteins into these vesicles and their delivery to the intended destination. A major question in cell biology today is how the identity of the compartments of the secretory pathway is maintained while allowing unimpeded transit of other nonresident proteins.

Fig. 5.3 SYNTHESIS OF PROTEINS SORTED FOR IMPORT IN THE ENDOPLASMIC RETICULUM. The figure depicts the main steps of the cotranslational translocation of a secretory protein into the endoplasmic reticulum (ER). *Steps 1 and 2:* the signal sequence of the emerging polypeptide binds the signal recognition particle (SRP) to induce a translation arrest. *Steps 3 and 4:* the binding of the SRP-nascent polypeptide-ribosome complex to the SRP-receptor triggers GTP hydrolysis on both SRP and the SRP-receptor. The translocon channel (Sec61p) opens and translation resumes. SRP is recycled. *Step 5:* the polypeptide chain elongates and emerges on the luminal side of the ER where a signal peptidase removes the signal sequence. *Steps 6, 7 and 8:* the synthesis of the polypeptide proceeds until the end of translation and the protein assumes its native conformation (concurrent glycosylation is not shown). The ribosome dissociates and its subunits are released.

Fig. 5.4 PROTEIN TRAFFICKING THROUGH THE SECRETORY PATHWAY. The figure depicts the secretory pathway starting from the endoplasmic reticulum (ER) (1) to the plasma membrane. Anterograde ER-Golgi intermediate compartment (ERGIC) and retrograde ERGIC-ER transport are shown (2 and 3). The transit through the Golgi apparatus is represented according to the cisternae progression and maturation model described in the text (4 and 5). In the trans-Golgi the constitutive secretory pathway (6) and the regulated secretory pathway (7) separate. In specialized secretory cells, selected proteins are sorted from the trans-Golgi and diverted to secretory vesicles where proteins are stored until an extracellular signal triggers their fusion with the plasma membrane and release of the content in the extracellular space (regulated exocytosis). In addition, at the trans-Golgi proteins destined to the lysosome are sorted and delivered to the organelle through vesicles (8). The endocytotic pathway (9) mediates the internalization of membrane or soluble extracellular proteins and their targeting to the lysosome or the recycling of some proteins to the cell surface (not shown in the figure).

PROCESSING OF PROTEINS IN THE ENDOPLASMIC RETICULUM

Protein Folding in the Lumen of the ER

Protein chaperones facilitate protein folding in the ER, but amino acid posttranslational modifications such as asparagine(N)-linked-glycosylation and disulfide bond formation are also involved. Proteins

start to fold cotranslationally by interaction with a host of chaperones, among which is the Hsp70 family member BiP. In addition, there are folding catalysts that increase the rate of protein folding. For example, the proper pairing and formation of disulfide bonds is catalyzed by oxidoreductases, such as protein disulfide isomerase (PDI), that also shuffle nonnative disulfide bonds. In the current model, the oxidation of two thiols produces a disulfide bond (S-S) in the substrate protein and concomitantly reduces two thiols within PDI which return to the oxidized state by another thiol-disulfide exchange catalyzed by

Fig. 5.5 *N*-GLYCOSYLATION OF PROTEINS. In the lumen of the endoplasmic reticulum (ER), a core oligosaccharide, $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$, is transferred from a lipid-linked precursor (dolichol donor) to the asparagine residue in an N-X-S/T motif in the nascent polypeptide chain. The terminal glucose residues are removed by GI and GII and cycles of reglucosylation by UGT1 (UGGT1) can occur (curved arrows). When the protein is folded, one mannose is trimmed by ER-mannosidase I and the protein is transported to the Golgi. Core oligosaccharides are further trimmed by mannosidases to produce the $\text{Man}_5\text{GlcNAc}_2$ unit. Further elaboration is catalyzed by glycosyltransferases that add various sugars and create branches. Bi, tri and tetra antennary chains are generated. In the figure, only one pathway of terminal glycosylation is shown. (Modified from Helenius A, Aebi M: *Intracellular function of N-linked glycans*. Science 291:2364, 2001.)

ERO1, a membrane associated oxidoreductase. ERO1 returns to the oxidized state by transfer of electrons to molecular oxygen via its cofactor flavin adenine dinucleotide (FAD). In contrast to the highly reducing environment of the cytosol where disulfide bonds do not typically form, the lumen of the ER is very oxidizing so that disulfide bonds formation is favored.

Protein Modifications in the ER

Most proteins that enter the secretory pathway are modified by *N*-glycosylation (Fig. 5.5). This process starts with the transfer of a core oligosaccharide from a lipid-linked dolichol donor to an asparagine residue within the consensus sequence N-X-S/T of a nascent polypeptide (X can be any amino acid except for proline). The N-linked oligosaccharide is composed of a glucose₃-mannose₉-N-acetylglucosamine₂ unit ($\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$). The oligosaccharide is transferred to the asparagine residue by an ER oligosaccharyltransferase (OST) that is composed of a catalytic subunit (STT3A or STT3B) and a set of accessory subunits. Further processing of the terminal sugars occurs in the ER and after the polypeptide transits the Golgi compartment (see Fig. 5.5). Many blood proteins, for example immunoglobulins, antiproteases, coagulation factors, and many membrane proteins of the cell are glycosylated.

Although glycan chains are often not required for the enzymatic activity of glycoproteins, they are important for the physical properties they confer and for many physiologic functions. Glycans protect proteins from protease digestion and heat denaturation, confer hydrophilicity and adhesive properties to the proteins, and mediate interaction with other proteins or receptors. A remarkable example is the hormone erythropoietin that requires a particular

complex type of *N*-glycan chains for its biologic function to stimulate erythropoiesis.

In the recent years several studies have revealed the importance of protein *N*-glycosylation in promoting folding. The addition of glycan chains may prevent aggregation or provide steric influences that affect polypeptide folding and disulfide bond formation and also mediate interaction with specific chaperones. In mammalian cells, N-linked oligosaccharides are also used as signal for monitoring protein folding and trafficking. They are ligands for a complex chaperone system composed of the lectin chaperones calnexin (CNX) and calreticulin (CRT), Erp57 (an oxidoreductase), two α -glucosidases (GI and GII) and one folding sensor (UGT1) endowed with reglucosylation activity (UDP-glucose:glycoprotein glucosyltransferase). GI removes the most terminal glucose and diglucosylated polypeptides associated with malectin, an ER resident lectin. Then, GII removes the second terminal glucose residue to form a monoglucosylated N-linked chain (see Fig. 5.5) that is a ligand for CNX and CRT. CNX and CRT associate with the thiol-disulfide oxidoreductase ERP57 which promotes proper rearrangement of disulfide bonds. Then the remaining glucose residue is removed by GII. UGT1 recognizes and reglucosylates N-linked oligosaccharides on proteins that have not completed the folding process. The addition of glucose residues allows reassociation with the CNX/CRT chaperone system for another attempt for the polypeptide to attain its proper conformation.⁵

Besides N-core glycosylation and oxidative folding, the ER is also site of other protein modifications. A remarkable one is γ -carboxylation of glutamic acid residues. Although this is a rather rare modification, it is crucial for the functionality of specific proteins, such as the coagulation factors VII, X, IX and prothrombin, and is essential for life as described earlier (see Box 5.1). Another modification is the attachment of a GPI to the C-terminal end of protein with

concomitant release of the GPI signal peptide. The GPI attachment promotes membrane association.

Destruction of Misfolded or Misassembled Proteins: Endoplasmic-Reticulum Associated Degradation (ERAD)

In the ER, proteins undergo a so-called quality control, which ensures that only correctly folded proteins exit the ER. Consequently, misfolded proteins are extracted from the ER folding environment for disposal. This mode of degradation is referred to as *endoplasmic reticulum-associated degradation* (ERAD). The destruction of proteins that undergo ERAD occurs in three major steps: (1) detection by the ER quality control machinery and targeting for ERAD, (2) transport across the ER membrane into the cytosol, and (3) ubiquitylation and release in the cytosol for degradation by the proteasome. One model for misfolded protein recognition is that hydrophobic patches or sugar moieties, which remain exposed on the protein for an extended period of time, are recognized by chaperone proteins like PDI or by

the CNX/CRT chaperone system. In a number of cases retrotranslocation appears to require reduction of disulfide bridges by PDI. Similarly, BiP association with substrates (e.g., unassembled immunoglobulin light chains) can direct them to ERAD. If a protein remains in its unfolded state for an extended period of time, trimming of the $\text{Man}_8\text{GlcNac}_2$ also occurs. This processing is catalyzed by ER-degradation enhancer mannosidase α -like proteins EDEM1, EDEM2, EDEM3 (Htm1p in yeast). The current model postulates that *N*-glycan structure generated by extensive demannosylation is the signal for glycoprotein degradation. ER-resident lectins (OS-9 and XTP3-B) bind to the remaining mannose residues and assist the retrotranslocation.

Proteins retrotranslocate to the cytosol through a protein-conducting channel, possibly formed by derlin and/or the Sec61 complex. On their emergence at the cytosolic face of the ER membrane, substrates targeted for degradation start undergoing ubiquitylation. Tagged peptides are released into the cytosol in an ATP-dependent fashion, where they are degraded by the 26S proteasome.

Fig. 5.6 illustrates the main steps of ERAD.

Fig. 5.6 ENDOPLASMIC RETICULUM-ASSOCIATED PROTEIN DEGRADATION (ERAD). The figure depicts the steps in the degradation of misfolded proteins in the ER. *Step 1:* Recognition factors, some of which are lectins, and ubiquitin ligases of the ER membrane cooperate in recognizing substrate proteins. *Step 2:* proteins are exported into the cytosol. *Step 3:* on the cytosolic face of the ER, the protein is ubiquitinated by an ER ligase. *Step 4:* the substrate is removed from the membrane by the AAA⁺ ATPase Cdc48 and directed to the 26S proteasome. (From: Hirsch C, Gauss R, Horn SC, Neuber O, Sommer T: The ubiquitylation machinery of the endoplasmic reticulum. Nature 458:453, 2009.)

The Unfolded Protein Response

The ER monitors the amount of unfolded protein in its lumen. When that number exceeds a certain threshold, ER sensors activate a signal transduction pathway. The set of responses activated by this pathway is called the unfolded protein response (UPR). A number of cellular insults disrupt protein folding and cause unfolded protein accumulation in the ER lumen. The UPR is an adaptive response signaled through three ER-localized transmembrane proteins PERK, IRE1, and ATF6. These proteins function as sensors through the properties of their ER-luminal domains and trigger a concerted response through the function of their cytosolic domains. The activation of the sensors results in a complex response aimed to (i) limit accumulation of unfolded protein through reducing protein synthesis, (ii) increasing the degradation of unfolded protein, and (iii) increasing the ER protein folding capacity.

IRE1 is conserved in all eukaryotic cells and has protein kinase and endoribonuclease activities that, upon activation, mediate unconventional splicing of a 26-base intron from the XBP1 mRNA to produce a basic Leucine Zipper (bZip) potent transcription factor. ATF6, upon accumulation of unfolded protein in the ER lumen, is transported to the Golgi compartment where it is cleaved by two proteases, S1P and S2P. These enzymes release a cytosolic fragment of ATF6 containing a bZip-transcription factor that migrates to the nucleus to activate gene transcription. S1P and S2P are two important Golgi proteases as they are also involved in the regulation of cholesterol metabolism. Finally, PERK-mediated phosphorylation of eIF2 α attenuates general mRNA translation; however, paradoxically, it increases translation of the transcription factor ATF4 mRNA to also induce transcription of UPR genes. If the UPR adaptive response is not sufficient to correct the protein folding defect, the cells enter apoptotic death.

ER is now regarded as a sensor of perturbations of cell homeostasis.^{6,7} Activation of the UPR and defects in UPR are known to be important factors that contribute to many disease processes ranging from metabolic disease, neurologic disease, infectious disease, and cancer (reviews on cancer and on UPR and diseases under the section Suggested Readings).

Control of Exit From the Endoplasmic Reticulum

On achieving transport competence, proteins are granted access to higher-ordered membrane domains termed ER exit sites. At ER exit sites, membrane-bound and soluble proteins are concentrated into transport vesicles for trafficking to a network of smooth membranes called the *ER-Golgi Intermediate Compartment* (ERGIC, see Fig. 5.4). COPII complex, composed of coat proteins, concentrate and package the protein cargo into vesicles. COPII binds to cargo molecules either directly, if they span the membrane, or through intermediate cargo receptors and then provides some of the force that causes vesicle budding, thereby linking cargo acquisition to vesiculation.

ER resident proteins are selectively sequestered in the ER both for the absence of export signals and to the presence of ER retention signals. Soluble luminal ER resident are retained through a C-terminal ER tetrapeptide retention motif KDEL. Frequently, transmembrane proteins have either a C-terminal dilysine motif KKXX or an N-terminal diarginine motif XXRR, or variants thereof for transmembrane proteins. However, it is more accurate to indicate ER localization signals as “retrieval motifs” because proteins bearing these signals can transiently escape from the ER into the ERGIC, from which they are returned to the ER through the retrograde vesicular transport (see Fig. 5.4).

For the KDEL motif of luminal ER proteins, a specific retrieval receptor has been identified, first in yeast and then in mammals. The KKXX motif has been shown to interact directly with the COPI coat protein complex that is involved in retrograde transport from the ER to the Golgi. Retrograde transport also serves to replenish the vesicle components lost as a result of anterograde (forward) transport. In conclusion, selective protein exit from the ER is achieved by

monitoring/regulating (1) transport competence of nascent proteins, (2) capture of cargo in transport vesicles, and (3) protein retention/retrieval for ER-localized proteins.

INTRAGOLGI TRANSPORT AND PROTEIN PROCESSING

Organization of the Golgi Apparatus

The Golgi complex comprises a stack of flattened, membrane-bound cisternae that is highly dependent on microtubules for structural integrity. The stack of cisternae can be subdivided into three parts referred to as *cis*, *medial*, and *trans* with the *cis* and *trans* sides facing the ER and the plasma membrane, respectively (see Fig. 5.4). Both the *cis* and *trans* faces are associated with tubulovesicular bundles of membranes. The ERGIC comprises the bundle on the *cis* side of the Golgi stack and is the site where incoming proteins from the ER are sorted into those directed for anterograde or for retrograde transport. The tubulovesicular bundle at the *trans* side is the *trans-Golgi* network (TGN, see Fig. 5.4).

A major feature of the Golgi is polarity. The processing events are temporally and spatially ordered because the processing enzymes have a characteristic distribution across the Golgi stack. In the Golgi, different types of modifications take place as for example proteolytic processing, protein *O*-glycosylation and elaboration of N-linked chains, phosphorylation or sulfation of oligosaccharides, and sulfation of tyrosines.

The importance of protein glycosylation for human biology is underlined by the identification of many inherited human disorders that are caused by defects in these processes and cause clinical manifestations in members of families as described in Box 5.2.

Retention of Resident Golgi Proteins

Extensive analysis has failed to reveal a clear retention motif enabling subdomain-specific retention of resident Golgi proteins. Two possible models have been proposed. One model is *retention by preferential interaction with membranes of optimal thickness*. It is based on the finding that the transmembrane domains of Golgi proteins are shorter than transmembrane domains of plasma membrane proteins. These differences should allow a preferential interaction with the Golgi membrane lipid bilayer that is thinner than that of plasma membrane. The other model is *kin-recognition/oligomerization*. It postulates that proteins of a given subdomain of the Golgi membrane can aggregate

BOX 5.2 Human Glycosylation Disorders

In humans, the three main glycosylation pathways are the *N*- and *O*-glycosylation and the glycosylphosphatidylinositol (GPI) anchoring. About 2% of the human genome encodes glycosylation reactions. Moreover, glycosylation pathways intersect with glucose, lipid, and isoprenoid metabolism, expanding the number of players involved in these key protein modifications. Nearly 70 inherited glycosylation disorders have been identified so far and this number is steadily increasing because of the progress in the technology of DNA sequencing and in mapping mutations.⁸ The characterized mutations combined to the biochemical lesion and to the clinical manifestations are classified in the CDG (congenital disorders of glycosylation) database. Mutations affect almost every organ and some proved to block embryo development in animal models of disease. Abnormalities in *N*-glycosylation cause severe myasthenic syndromes caused by hypoglycosylation of the acetylcholine receptor that affects the signal transmission at the neuromuscular plaque. Other cause neurologic disorders. Complications also arise from secondary effects caused by ER stress consequent to poor glycosylation. *O*-Glycosylation defects are associated mainly to severe muscular dystrophy (Walker-Warburg syndrome) whereas lack of the first step of GPI synthesis provokes paroxysmal nocturnal hemoglobinuria, a well-known hematologic disorder that results in erythrocyte lysis.

into large detergent-insoluble oligomers as a way of minimizing lipid-protein contact. This would prevent the entry of proteins into the vesicles and thus their traffic to more distal cisternae. There is evidence in support of both models.

Protein Trafficking to and Through the Golgi Apparatus

Cargo proteins exit the ER in COPII-coated vesicles that enter the ERGIC and are ultimately delivered to the *cis*-Golgi either in vesicles or along extended tubules. However, the mechanism whereby cargo proteins move across the Golgi complex from *cis* to *trans* remains controversial. Two models have been proposed. The vesicular transport model contends that anterograde transport occurs in vesicles or tubules that traffic cargo in an anterograde direction. The second suggests that there is a cisternal progression and maturation. This alternative model proposes that Golgi cisternae are not fixed structures but move forward from the *cis* side to the *trans* side generating an anterograde movement. As cisternae mature, resident Golgi proteins that belong to more *cis*-like cisternae must be selectively pinched off in vesicles and trafficked back to the *cis* side of the Golgi stack. This would occur by COPI-mediated retrograde vesicular transport (see Fig. 5.4). Although which of these models is correct is currently unclear, a majority of the experimental data supports the cisternal maturation model. In particular, technical progress in live-cell imaging provided evidence supporting a very dynamic nature of this organelle as expected by the progression/maturation model.

SORTING EVENTS AT THE TRANS-GOLGI NETWORK

Overview

The TGN is an important site of intracellular sorting, where proteins bound for lysosomes or regulated secretory vesicles are separated from those entering the constitutive pathway leading to the plasma membrane (see Fig. 5.4, pathways 6, 7 and 8). The secretion process is called exocytosis. The molecular basis for diversion of proteins into lysosomes and regulated secretory granules are described later.

Sorting Into Lysosomes

Lysosomes are acidic (pH of approximately 5.0–5.5), membrane-bound organelles containing numerous hydrolytic enzymes designed to degrade proteins, carbohydrates, and lipids. Soluble hydrolases are selectively marked for sorting into lysosomes by phosphorylation of their *N*-linked oligosaccharides that creates the mannose-6-phosphate sorting signal (M6P). On arrival at the TGN, the M6P-modified hydrolase is bound by a cargo receptor, the M6P-receptor (M6P-R), which delivers it first to a “late endosomal compartment,” where the low pH releases the hydrolase from the M6P-R. Subsequently, the hydrolase is delivered to the lysosome, and the M6P-R is recycled from the endosomes through retromer-coated vesicles to the TGN to be reused (for simplicity the endosome to Golgi transport is not represented in Fig. 5.4).

The motif responsible for targeting M6P-R to lysosomes is YSKV and is recognized by all three distinct adaptor protein (AP) complexes (AP-1, -2, and -3) that contribute to delivery of cargo to lysosomes by linking cargo acquisition to vesiculation. Cargo recruitment occurs in a manner similar to that described for the COPI- and COPII-dependent vesicles, except that the cytosolic coat complex is clathrin. In addition to luminal hydrolases, lysosomes also contain a wide array of membrane proteins that are targeted to lysosomes via one of two consensus motifs: (1) YXXe, where X is any amino acid and e is any amino acid with a bulky hydrophobic side chain and (2) a leucine-based motif (LL or LI). Trafficking of these membrane-bound proteins to lysosomes is indirect, proceeding first to late endosomes or the plasma membrane before their retrieval to lysosomes. Failure to accurately target lysosomal hydrolases underlies two well-known human diseases, Hurler syndrome and I-cell

disease. *Hurler syndrome* is caused by a mutation in a hydrolase responsible for breakdown of glycosaminoglycans that prevents the hydrolase from acquiring the mannose-6-phosphate (M6P) modification, consequently preventing targeting to lysosomes. Similarly, in *I-cell diseases* undigested material accumulates in lysosomes because a mutation in the enzymes that create the M6P modification, causes missorting of lysosomal hydrolases.

Autophagy: A Lysosomal Degradation Pathway

Autophagy, the most common name for *macroautophagy*, consists in the capture and degradation of cellular components and organelles. Cellular material is sequestered inside double-membrane vesicles, called autophagosomes, and degraded upon fusion with lysosomal compartments. Raw precursors are then recycled for new biosyntheses. Constitutive autophagy serves to demolish damaged organelles or cytosolic components and contributes to the maintenance of cell homeostasis.

Autophagy is also stress responsive. It accelerates the catabolism of cellular components to sustain the demand of energy in adverse conditions and promotes cell survival. From yeast to human cells, starvation typically activates autophagy. Yeast has been a useful model microorganism to identify the first autophagy genes (ATG) that allowed the subsequent isolation of the mammalian counterparts. Atg proteins are involved in the basic mechanism of autophagy on which a complex regulation has been superimposed in mammals to respond to a wider variety of hormonal, environmental and intracellular signals. An increasing body of evidence suggests that autophagy plays an important role in development and cell differentiation by facilitating cell and tissue remodeling. Remarkably, the basis for erythrocyte maturation into reticulocytes, which involves mitochondria loss, remained mysterious for decades, but is now known to be partly dependent on autophagy (mitophagy).

Defects in constitutive autophagy compromise fitness of an organism. As a consequence, defective autophagy increases susceptibility to tumorigenesis, neurodegenerative disorders, liver disease, aging, inflammatory diseases and defective host defense against pathogens. However, recent evidence suggests autophagy provides a survival advantage for tumor cells in a hostile microenvironment. Thus, autophagy is regarded as a target for tumor prevention and cancer therapy.

Sorting Into Regulated Secretory Granules

In regulated secretion proteins are condensed into stored secretory granules that require an appropriate stimulus for release from the cell (see Fig. 5.4, pathway 7). After budding from TGN, the granule proteins are concentrated (up to 200-fold in some cases) by selective removal of extraneous contents from clathrin-coated vesicles. Mature secretory granules are thought to be stored in association with microtubules until the stimulation of a surface receptor triggers their exocytosis. One example of stimulus-induced exocytosis is the binding of a ligand to the T-cell antigen receptor (TCR) complex on a cytotoxic T lymphocyte. Conjugation of a cytotoxic T cell with its target causes its microtubules and associated secretory granules to reorient toward the target cell. Subsequently, the granules are delivered along microtubules until they fuse with the plasma membrane, releasing their contents for lysis of the target cell. Following release of the granule contents, the granule membrane components are internalized and transported back to the TGN, where the granule can be refilled with cargo proteins.

ENDOCYTIC TRAFFIC

Overview

Substances are imported from the cell exterior by a process termed *endocytosis* (see Fig. 5.4, pathway 9). Endocytosis also serves to recover

the plasma membrane lipids and proteins that are lost by ongoing secretory activity. There are three types of endocytosis: (1) phagocytosis (cell eating), (2) pinocytosis (cell drinking) and (3) receptor-mediated endocytosis. Defects in endocytosis can underlie human diseases. For example, patients with familial hypercholesterolemia (FH) have elevated serum cholesterol because of mutations in the low-density lipoprotein (LDL) receptor that prevents the endocytic uptake of LDL and its catabolism in lysosomes.

Phagocytosis

During *phagocytosis*, cells are able to ingest large particles (greater than 0.5 μm in diameter) which serves not only to engulf and destroy invading bacteria and fungi but also to clear cellular debris at wound sites and to dispose of aged erythrocytes. Primarily, specialized cells, including macrophages, neutrophils and dendritic cells, execute phagocytosis. Phagocytosis is triggered when specific receptors contact structural triggers on the particle, including bound antibodies, complement components as well as certain oligosaccharides. Then actin polymerization is stimulated, driving the extension of pseudopods, which surround the particle and engulf it in a vacuole called phagosome. The engulfed material is destroyed when the phagosome fuses with a lysosome, exposing the content to hydrolytic enzymes. In addition, phagocytosis is a means of “presenting” the pathogen’s components to lymphocytes, thus eliciting an immune response.

Pinocytosis

Pinocytosis refers to the constitutive ingestion of fluid in small pinocytotic (endocytic) vesicles (0.2 μm in diameter) and occurs in all cells. Following invagination and budding, the vesicle becomes part of the endosome system that is described later. The plasma membrane portion that is ingested returns later through exocytosis. In some cells, pinocytosis can result in turnover of the entire plasma membrane in less than 1 hour.

Receptor-Mediated Endocytosis

Receptor-mediated endocytosis is a means to import macromolecules from the extracellular fluid. More than 20 different receptors are internalized through this pathway. Some receptors are internalized continuously whereas others remain on the surface until a ligand is bound. In either case, the receptors slide laterally into coated pits that are invaginated regions of the plasma membrane surrounded by clathrin and pinch off to form clathrin-coated vesicles. The immediate destination of these vesicles is the endosome.

The endosome is part of a complex network of interrelated membranous vesicles and tubules termed the *endolysosomal system*. The endolysosomal system comprises four types of membrane-bound structures: early endosomes (EEs), late endosomes (LEs), recycling vesicles, and lysosomes. It is still a matter of debate whether these structures represent independent stable compartments or one structure matures into the next. The interior of the endosomes is acidic (pH about 6). Endocytosed material is ultimately delivered to the lysosome, presumably by fusion with LE. Lysosomes also digest obsolete parts of the cell in a process called autophagy.

During the formation of clathrin-coated vesicles, clathrin molecules do not recognize cargo receptors directly but rather through the adaptor proteins, that form an inner coat. The AP-2 components bind both clathrin and sorting signals present in the cytoplasmic tails of cargo receptors close to the plasma membrane. These internalization motifs are: YXX ϕ (where ϕ is a hydrophobic amino acid), as a most common motif, and the NPXY signal that was first identified in the LDL receptor. For receptors that are internalized in response to ligand binding, the internalization signal may also be generated by a conformational change induced by the binding of the ligand. Through the specificity of the AP-2 complex, the capture of a unique

set of cargo receptors is linked to vesiculation resulting in concentration of the cargo. The coated pit pinches off from the plasma membrane by the action of a GTP-binding protein, dynamin, which forms a ring around the neck of each bud and contributes to the vesicle formation. After release and shedding of the clathrin coat, the vesicle fuses with the EE compartment.

SPECIFICITY OF VESICULAR TARGETING

As described earlier, COPI-, COPII-vesicles transport material early in the secretory pathway whereas clathrin-coated vesicles transport material between the plasma membrane and Golgi. Coating proteins assemble at specific areas of the membrane in a process controlled by the coat-recruitment GTPases: Arf1 is responsible for the assembly of COPI coats and clathrin coats at Golgi membranes whereas Sar1p is responsible for COPII coat assembly at the ER membrane. In yeast, the process of vesiculation in the transport from the ER to Golgi has been dissected at a molecular level. On the cytosolic face of the ER membrane, Sar1p is activated by the ER localized GEF Sec12p. Sar1-GTP assembles with the Sec23-Sec24 complex whose Sec24 subunit binds directly or through a membrane receptor to specific signals displayed by the cargo. This prebudding cargo complex recruits the outer layer Sec13-Sec31 complex leading to coat polymerization, membrane deformation and COPII-vesicle formation.

Clathrin-coat assembly at the plasma membrane is also thought to involve a GTPase but its identity is unknown. These regulatory proteins also ensure that membrane traffic to and from an organelle are balanced.

After budding, vesicles are transported to their final destination by diffusion or motor-mediated transport along the cytoskeletal network (microtubules or actin). The molecular motors kinesin, dynein and myosin have been implicated in this process. The vesicles undergo an uncoating process before fusion with the correct target membrane. Both transport vesicles and target membranes display surface markers that selectively recognize each other.

Three classes of proteins guide the selectivity of transport vesicle docking and fusion: (i) complementary sets of vesicles SNAREs, v-SNAREs, (soluble NSF association protein receptor) and target membrane SNAREs (t-SNAREs) that are crucial for the fusion, (ii) a class of GTPases, called Rabs, and (iii) protein complexes called tethers that, together with Rabs, facilitate the initial docking of the vesicles to the target membrane.

Rab GTPases function as the master regulators of membrane traffic but are themselves regulated by factors that control their activation by GEFs or their inactivation by GAP, proteins that stimulate the intrinsic GTPase activity.

CONCLUSIONS

The mechanisms regulating protein synthesis, processing, degradation and transport are under intense investigation. Protein motifs and their cognate receptors have been identified for many intracellular sorting and processing reactions. Studies are now directed to elucidate these processes at a molecular level by resolution of the three dimensional structures of the proteins involved in protein processing and trafficking. The future challenge will be to find ways of exploiting this knowledge to intervene in the numerous disease states that result from errors in these processes.

PROTEIN ARCHITECTURE: RELATIONSHIP OF FORM AND FUNCTION

Jia-huai Wang and Michael J. Eck

Previous chapters have outlined the central dogma of molecular biology: the storage of genetic information in DNA and its regulated transcription into messenger RNA and eventual translation into proteins. In this chapter, we briefly outline the chemical structure of proteins and their posttranslational modifications. We explain how the properties of the 20 amino acids of which proteins are composed allow these polymers to fold into compact, functional domains and how particular domains and motifs have been assembled, modified, and reused in the course of evolution. Finally we describe a sampling of proteins and domains of relevance to the hematologist and explore briefly how point mutations, chromosomal translocations, and other genetic alterations may modify protein structure and function to cause disease.

AMINO ACIDS AND THE PEPTIDE BOND

Proteins are linear polymers of the 20 naturally occurring amino acids, linked together by the peptide bond. All of the amino acids share a common core or backbone structure and differ only in the “side chain” emanating from the central “ α -carbon” of this core. The common backbone elements include an amino group, the central α -carbon, and a carboxylic acid group. Peptide bonds are formed by reaction of the carboxylic acid of one amino acid with the amino group of the next amino acid in the chain. This reaction is templated and catalyzed by the ribosome and leads to the release of water formed by the loss of an $-OH$ group from the carboxylic acid of one amino acid residue and a hydrogen atom from the amino group of the next residue in the chain. Coupling of multiple amino acids together via the peptide bond produces the repeating main-chain structure of the polypeptide chain, composed of the amide (NH) nitrogen, alpha carbon ($C\alpha$), and carbonyl carbon (CO), followed by the amide nitrogen of the next amino acid in the chain (Fig. 6.1A). The resonant, partial double-bond character of the peptide bond prevents rotation about this bond; thus the five main-chain carbon, nitrogen, and oxygen atoms of each peptide unit lie in a plane. The conformational flexibility in the polypeptide chain is conferred by rotation about the bonds on either side of the α -carbon atom; these bond angles are referred to as phi and psi angles. The angle of the N– $C\alpha$ bond is the phi angle (Φ), and that of the $C\alpha$ –CO bond is the psi angle (Ψ).

The *primary structure* or primary sequence of a protein refers to the order in which various residues of the 20 amino acids are assembled into the polypeptide chain, and this sequence is critically important for determining the three-dimensional fold and thus function of the protein. It is the diverse chemical structure and physicochemical properties of the 20 amino acid side chains that guide the three-dimensional fold of proteins and also provide for the enormous repertoire of protein function, from catalysis of myriad chemical reactions to immune recognition, to establishment of muscle and skeletal structure.

The amino acids can be divided into general classes based on the physicochemical properties of their side chains, and in particular their propensity to interact with water. *Hydrophobic* amino acids have aliphatic or aromatic side chains and include alanine, valine, leucine, isoleucine, proline, methionine, and phenylalanine. The

hydrophobic amino acids predominate in the interior of proteins, where they are sequestered from water. They tend to pack against each other via *van der Waals* interactions, which contribute to the overall stability of folded protein domains. By contrast, *hydrophilic*, or *polar*, amino acids (including serine, threonine, tyrosine, asparagine, glutamine, cysteine, and tryptophan) are often exposed on the surface of proteins, where they can form *hydrogen bonds* with each other, with the protein main chain, and with water or ligand molecules. Hydrogen bonding refers to the attractive interaction of a proton covalently bonded to one electronegative atom (usually a nitrogen or oxygen in proteins) with another electronegative atom. Hydrogen bonds are an important contributor to the stability of proteins and to the specificity of protein–protein and protein–ligand interactions. *Charged* amino acids are also polar and are important participants in hydrogen bonding. Hydrogen bonds between negatively charged (acidic) and positively charged (basic) amino acids, also termed *salt bridges*, are also important components of protein stability and protein–protein interactions. The acidic amino acids are aspartate and glutamate, and the basic amino acids are lysine, arginine, and histidine. Histidine merits special mention, as it is the only amino acid whose side chain can be protonated or unprotonated, and therefore charged or uncharged, around physiologic ranges of pH. For this reason, histidine is part of many enzyme-active sites. For example, in the serine proteases of the coagulation cascade, an active site histidine acts as a general base, accepting and then releasing a proton in sequential steps of the enzymatic reaction. It is also important to note that some of the polar amino acids are *amphipathic*; in other words, they have both polar and hydrophobic character. This dual nature of threonine, lysine, tyrosine, arginine, and tryptophan makes them well suited for participating in protein–protein interactions, where they may be alternately exposed to solvent or buried upon formation of a complex.

Protein Secondary Structure

The alternating pattern of hydrogen bond–donating amide groups and hydrogen bond–accepting carbonyl groups gives rise to repeating elements of protein structure that are stabilized by hydrogen bonds between these main-chain groups. These *secondary structure* elements include α -helices and β -sheets. In an α -helix, the main chain adopts a right-handed helical conformation in which the carbonyl oxygen of the i^{th} residue in the polypeptide chain accepts a hydrogen bond from the amide nitrogen of the $(i + 4)^{\text{th}}$ residue (see Fig. 6.1B). The pattern may repeat for only a few residues, forming a single turn of β -helix, or for more than 100 residues, forming dozens of turns of helix. There are 3.6 residues per turn of helix, and the pitch or rise of the helix is 1.5 Å per residue or 5.4 Å per turn. The side chains of residues in an α -helix project outward, away from the central axis of the helix. Often a polar side chain will “cap” the end of a helix by forming a hydrogen bond with the otherwise unpartnered amide or carbonyl group at the N- or C-terminal end of the helix.

In a β -sheet secondary structure, the protein backbone adopts an extended conformation and two or more strands are arranged side by side, with hydrogen bonds between the strands. The strands can run in the same direction (parallel β -sheet) or antiparallel to one another.

Fig. 6.1 (A) Diagram showing a polypeptide chain where the main-chain atoms are represented as peptide units, linked through the C_{α} atoms. Each peptide unit is a planar, rigid group (shaded in pink) and has two degrees of freedom; it can rotate around the C_{α} -CO bond and the N- C_{α} bond. The peptide bonds are depicted in the trans conformation: adjacent C_{α} carbons and their side chains (highlighted in blue) on opposite sides of the N-C bond. This is the preferred configuration for most amino acids, as it minimizes steric hindrance. (B) The α -helix. The hydrogen bonds between residue n and residue $n + 4$, which stabilizes the helix, are shown as dashed lines. (C) Schematic drawing of a mixed β -sheet. The first three β -strands are antiparallel to one another, whereas the last two β -strands are parallel. The hydrogen bonds that stabilize their structures are highlighted.

Mixed sheets with both parallel and antiparallel strands are also possible (see Fig. 6.1C). In β -sheets, the side chains of a given strand extend alternately above and below the plane defined by the hydrogen-bonded main chains. Other common types of secondary structure include a variant of the helix with an $I + 3$ hydrogen bonding pattern (the 3_{10} helix) and specific types of β -turns, short segments connecting other elements of secondary structure that are stabilized by intrachain hydrogen bonds. Although any of the amino acids can be found within α -helices or β -sheets, the special characteristics of proline and glycine merit mention. The cyclic structure of proline means that it lacks an amide proton; thus it introduces an irregularity in hydrogen bonding. For this reason it is infrequently found in α -helices, but if present it will introduce a “kink” stemming from its constrained structure. Glycine lacks a side chain—it has only a second hydrogen atom on its α -carbon—and therefore has less steric restriction and can adopt a wider range of backbone phi and psi angles. This added flexibility means that it tends to disfavor regular secondary structure.

Because proteins are large and complicated structures, they are typically illustrated with “ribbon” diagrams that trace the path of the polypeptide backbone. In such representations helices are drawn as helical coils or cylinders, and β -strands as elongated rectangles with an arrow as a guide to the direction of the protein chain from its amino- to carboxy-terminal end. Specific side chains of amino acids of functional interest can then be added to illustrate a particular feature.

Disulfide Bonds and Posttranslational Modifications

The covalent structure of proteins is commonly modified in structurally and functionally important ways beyond the linear coupling of amino acids via the peptide bond. Regulated proteolysis can be considered a posttranslational modification and can serve an important regulatory role, as in the cleavage of prothrombin in the blood-clotting cascade. The structure of cell-surface and extracellular proteins is often stabilized by *disulfide bonds*, covalent bonds formed between the thiol groups of spatially juxtaposed cysteine residues. In general, disulfide bonds are not found in intracellular proteins, where the reducing environment disfavors their formation. Disulfide bonds can form between cysteines within the same polypeptide chain, stabilizing the fold of the polypeptide backbone, or they may covalently join two different polypeptide chains, such as the heavy and light chains of immunoglobulins. In addition to their role in disulfide bond formation, cysteine residues often contribute to protein stability via their participation in metal ion coordination, in particular zinc, which is often bound by conserved sets of cysteine and histidine residues in small protein domains.

A number of functional groups are appended to proteins to regulate their function, localization, protein interactions, and degradation. Examples of these posttranslational modifications (PTMs) include phosphorylation, glycosylation, ubiquitination, methylation, acetylation, and lipidation.¹ PTMs occur at distinct amino acid side chains or peptide linkages; they are most often mediated by enzymatic activity and can occur at any step in the “life cycle” of a protein. As discussed below, a number of protein domains have evolved to recognize and bind specifically to proteins labeled by a particular PTM. Protein *phosphorylation*, most commonly on serine, threonine, or tyrosine residues, is one of the most important and well-studied posttranslational modifications. Phosphorylation is mediated by protein kinases and can activate or deactivate many enzymes through conformational changes and as such plays a critical role in the regulation of many cellular processes including cell cycle, growth, apoptosis, and signal transduction pathways. Protein *glycosylation* encompasses a diverse selection of sugar-moiety additions to proteins that ranges from simple monosaccharide modifications to highly complex branched polysaccharides. Glycosylation has significant effects on protein folding, conformation, distribution, stability, and activity. Carbohydrates in the form of asparagine-linked (N-linked) or serine/threonine-linked (O-linked) oligosaccharides

are major structural components of many cell surface and secreted proteins, and also of many viral proteins. Protein *methylation* on arginine or lysine residues is carried out by methyltransferases with *S*-adenosyl methionine (SAM) as the primary methyl group donor. Methylation is an important mechanism of epigenetic regulation, as histone methylation and demethylation influence the availability of DNA for transcription. *N*-*acetylation*, the transfer of an acetyl group to the amine nitrogen at the N-terminus of the polypeptide chain, occurs in a majority of eukaryotic proteins. Lysine acetylation and deacetylation is an important regulatory mechanism in a number of proteins. It is best characterized in histones, where histone acetyl transferases (HATs) and histone deacetylases (HDACs) regulate gene expression via modification of histone tails. Many cytoplasmic proteins are also acetylated, and therefore acetylation seems to play a greater role in cell biology than simply transcriptional regulation.² *Lipidation* is a modification that targets proteins to membranes in organelles, vesicles, and the plasma membrane. Examples of lipidation include *myristoylation*, *palmitoylation*, and *prenylation*. Each type of modification gives proteins distinct membrane affinities, although all types of lipidation increase the hydrophobicity of a protein and thus its affinity for membranes. In *N*-myristoylation, the myristoyl group (14-carbon saturated fatty acid) is transferred to an N-terminal glycine by N-myristoyltransferase. The myristoyl group does not always permanently anchor the protein in the membrane; in a number of proteins the N-terminal myristoyl group has been observed to pack into the protein core. *N*-myristoylation can therefore act as a conformational localization switch, in which protein conformational changes influence the availability of the handle for membrane attachment.

The Domain Structure of Proteins

In general, the minimal biologically functional unit of protein three-dimensional structure is the protein *domain*. Domains are locally compact and semi-independent units of usually contiguous polypeptide chain. The common size of a domain is between 100 and 200 amino acid residues, although much larger and smaller domains are also frequently observed. Protein domains are composed of closely packed secondary structure elements— α -helices, β -sheets, or a combination of both—and the loops that connect them. Domains are stabilized by hydrophobic interactions among these elements and typically have very hydrophobic central cores, with more hydrophilic amino acids extending from their surface. Alternating patterns of hydrophobic residues in secondary structure elements are a reflection of the role of hydrophobicity in driving protein folding and stability. Helices are often amphipathic and pack in a folded domain such that their hydrophobic face is buried in the domain interior and their hydrophilic face is exposed on the surface. Likewise, β -sheets often have a buried hydrophobic face and an exposed hydrophilic face. The importance of the hydrophobic core to the stability of protein domains is highlighted by the fact that point mutations that introduce polar or charged residues into the protein interior often cause misfolding and thus a loss of function. Although these general characteristics are shared by protein domains that are found in an aqueous environment, such as that on the cytosol or on the cell surface, membrane-embedded proteins have very different properties reflective of their residence in the lipid bilayer. Several common domain structures representing different categories with regard to their secondary structure composition are shown in Fig. 6.2.

Fig. 6.2 SEVERAL COMMON DOMAIN STRUCTURES. (A) The α -globin domain of hemoglobin is all α -helical (Protein Data Bank [PDB] entry 2MHB). (B) The β -propeller domain is an all β -strand structure found in many extracellular matrix and cell surface proteins (PDB entry 1NPE). (C) The integrin “I” domain is composed of alternate β -strands and α -helices (PDB entry 1ID0). (D) The SH2 (Src homology-2) domain is found in proteins involved in tyrosine kinase signaling and is also a mixed α/β fold (PDB entry 1FMK). (E) The EGF (epidermal growth factor) domain is found in many extracellular matrix proteins and cell adhesion molecules. Its structure is stabilized by 3 to 4 disulfide bonds (PDB entry 1UZJ).

Deciphering this basic protein building block is key for understanding the structure and evolution of proteins. Kinetically, the domain structure of a protein may simplify the folding process into a step-wise course.³ Thus a long amino acid sequence may fold into multiple domains rapidly and correctly. For many proteins, individual domains fold in a cotranslational manner; from the N-terminal region, a growing nascent polypeptide chain immediately begins to fold domain-by-domain during translation from the ribosome in a very efficient manner.⁴ Genetically, it was long suspected that the exon structure of genes was correlated with the domain structure of proteins.⁵ Subsequent multigenome analysis did find a strong correlation between domain organization and exon–intron arrangement in genomic DNA. The exon–domain correlation facilitates extensive exon shuffling events during evolution,⁶ although it is not necessarily always one-exon/one-domain. This mechanism ensures that a stable and functionally efficient domain can be repeatedly used as a module assembled into many proteins with shared functions. A well-known early example is the nucleotide-binding domain identified in various dehydrogenases; its robust alternate β -strand– α -helix– β -strand fold provides a common structural unit for these enzymes.⁷

Recent computational approaches demonstrate that almost all the growing number of known sequences come from new combinations of various domains, and more than 70% of all sequences can be partially modeled from known structures with homologous domains.⁸ This has been reflected in the human genome sequence.⁹ Impressive progress has already been made in computational protein prediction and design, principally based on the known structural elements.¹⁰

Importantly, not all protein sequences fold into a compact domain. Depending on computational methods used, 35% to 50% of the human proteome is estimated to lack a folded three-dimensional structure. Nevertheless, these *intrinsically disordered* proteins (or more often, intrinsically disordered regions within proteins) can perform critically important biologic functions that complement those of structured proteins.¹¹ Intrinsically disordered protein segments typically contain relatively few bulky hydrophobic amino acids such as tryptophan, phenylalanine, leucine, and isoleucine, which are required to form the hydrophobic core of a domain. Many disordered regions mediate protein–protein interactions and may undergo a disorder-to-order transition upon binding to an interacting partner, a process dubbed folding-upon-binding. They function in crucial areas such as transcriptional regulation, translation, and cellular signal

transduction.¹² Unstructured segments are well suited for protein interactions controlled by posttranslational modifications. For example, sites of tyrosine phosphorylation are typically unstructured and therefore accessible for modification, but after phosphorylation they become ordered upon phosphorylation-dependent binding to a partner protein.

Most proteins are composed of multiple domains, which may confer multiple functions, couple a targeting function to a catalytic function, or provide for allosteric regulation. In the following sections we highlight the structure of a few proteins and domains and that are of central and recurring importance in hematology in order to illustrate the relationship between domain architecture and function. We discuss representative examples from the extracellular space (the immunoglobulin domain), from intracellular signaling (protein kinase domain), and from the cell membrane (G protein–coupled receptors and the vitamin K receptor).

The Immunoglobulin Domain and Variations

As implied by its name, the immunoglobulin (Ig) domain was first recognized in antibodies.¹³ A detailed discussion on antibody biology can be found in [Chapter 24](#). The human genome project has identified the Ig superfamily (IgSF) as the largest superfamily in human genome, due to its extensive usage in a more recently developed immune system in vertebrates.⁹ In fact, the Ig domain is an evolutionarily ancient structural unit that can be found in *Caenorhabditis elegans*.¹⁴ Although Ig-like domains also exist in a few intracellular proteins, they are found predominantly in the extracellular space and are the most abundant structural unit found in cell surface receptors, serving key recognition functions in both the immune and nervous systems. Along with a handful of other modular domains such as fibronectin type III domains and epidermal growth factor (EGF) domains, they form modular structures of most receptor molecules on the cell surface.¹⁵

An Ig domain is composed of roughly 100 residues, folding into two β -sheets packing face-to-face, forming a β -barrel. This distinctively folded structure is commonly known as the immunoglobulin fold ([Fig. 6.3A](#)). An intact IgG antibody consists of two heavy chains and two light chains. Each heavy chain contains four Ig domains, one “variable” domain, and three “constant” domains; whereas each light chain contains two Ig domains, one constant and one variable.

Fig. 6.3 Ig DOMAIN ARCHITECTURE. (A) V-set Ig domain (Protein Data Bank [PDB] entry 3IDG). (B) C-set Ig domain (3IDG). (C) I-set Ig domain, which can be described as a truncated V-set domain (PDB entry 2V5M). Disulfide bonds are highlighted in orange.

Fig. 6.4 (A) Structure of an HIV-neutralizing antibody in complex with an antigenic peptide. Complementarity-determining region of the heavy and light chains are shown in *red* and *purple*, respectively. Note that only the two variable domains of the antibody are shown (drawn from Protein Data Bank [PDB] entry 3IDG). (B) Structure of an antigenic peptide bound to a major histocompatibility complex (MHC) molecule in complex with T-cell receptors (TCR) (PDB entry 2CKB).

The variable and constant Ig domains differ somewhat in structure and are correspondingly classified as V-set and C-set Ig folds. A V-set Ig domain has β -strands A, B, E, and D on one sheet and A', G, F, C, C', and C'' strands on the other (Fig. 6.3A), whereas a C-set Ig domain lacks A', C', and C'' strands on either edge (Fig. 6.3B). In both, the two sheets are linked together by a conserved disulfide bond between the B and F strands (as reviewed by Williams et al.¹⁶). Within variable domains, hypervariable sequences are found in three connecting loops at one end of the domain. These loops are termed complementarity-determining regions or CDRs (Fig. 6.3A). In the intact antibody, the CDRs of the heavy and light chains combine to make up the antigen-binding site. Fig. 6.4A depicts how the CDRs of an HIV-neutralizing antibody form an antigen-binding pocket that recognizes an antigenic peptide from an HIV surface protein.¹⁷ A similar structural platform is used in cellular immunity by T-cell receptors (TCR), which, distinct from antibodies, recognize an antigenic peptide along with the MHC (major histocompatibility complex) molecule that presents the peptide on the infected cell surface. In this case, CDR3 loops of the variable domains of TCR play a key role in antigen recognition, whereas germline-encoded CDR1 and CDR2 loops are responsible for contacting the polymorphic region of the MHC molecule, with CDR1 also taking part in peptide binding.^{18,19} Fig. 6.4B illustrates a typical structure of a TCR in a complex with an antigenic peptide bound to the MHC molecule. An extensive discussion on the role of these proteins in cellular immunity can be found in Chapter 21.

A number of variations on the Ig fold are found in other cell surface receptors. These Ig-like domains include the topologically similar fibronectin type III domains²⁰ and the domains of cadherins, which also assume the same strand topology.²¹ The fibronectin domains and cadherins lack the disulfide bridge found in the Ig domain, which demonstrates the thermodynamic robustness of the immunoglobulin fold.

Further variations are found in modular cell surface receptors, which often have a V-set Ig-like domain at their N-terminus, positioned to extend from the plasma membrane for ligand-binding, serving a role analogous to antigen-recognition. By contrast, "I-set" Ig-like domains (see Fig. 6.3C) usually function as one of the building

blocks lined up in tandem to present the ligand-binding V-set domain on the cell surface. This can be seen in many immune receptors such as CD2²² and CD4.²³ There are also many receptors that are exclusively composed of I-set domains, including immune receptor ICAM-1 (intercellular adhesion molecule-1),²⁴ neuroreceptors NCAM,²⁵ and Dscam.^{26,27} Thus the I-set variant is the most abundant Ig-like domain and plays a critical biologic role in cell surface receptors.

The Protein Kinase Domain

Protein kinases catalyze the transfer of a phosphate group from ATP to specific sites on target proteins. More than 500 protein kinases have been identified in the human genome; approximately 90 of these are tyrosine kinases, the remainder specifically phosphorylate serine or threonine residues. Both ser/thr and tyrosine kinases share a conserved bi-lobed protein fold, composed of a smaller N-terminal subdomain (N-lobe) and larger C-terminal subdomain (C-lobe).²⁸ The active site cleft, including the site for binding the substrate ATP, is found at the interface between the N- and C-lobes. The phosphate-coordinating "P-loop" is a portion of the β -sheet in the N-lobe that coordinates the triphosphate moiety of ATP. The activity of protein kinases is typically regulated by phosphorylation on a loop in the C-lobe termed the activation loop or A-loop. In the absence of phosphorylation the A-loop may play an inhibitory role, sometimes blocking binding of ATP in the active site; or it may be disordered altogether. Upon autophosphorylation, or phosphorylation in trans by an upstream activating kinase the activation loop rearranges to adopt a characteristic hairpin conformation that creates the site for docking of the polypeptide segment that will become phosphorylated. Activation loop phosphorylation may also induce other structural rearrangements required for catalytic activation, in particular a reorientation of a helix within the N-lobe (known as the C-helix) that brings a glutamic acid residue into proper position within the active site (see Fig. 6.5A).

Deregulated tyrosine kinases are the cause of a number of hematologic malignancies. Two general classes of tyrosine kinases can be

Fig. 6.5 (A) A kinase domain in complex with an ATP analog and peptide substrate (Protein Data Bank [PDB] entry 1IR3). The phosphate-binding loop is highlighted in *purple*, the activation loop is *red*, the substrate peptide is *yellow*, and the ATP analog is *gray*. (B) The autoinhibited structure of Abelson tyrosine kinase (c-Abl) in complex with the kinase inhibitor PD166326 (PDB entry 1OPK). The Src-homology-3 (SH3), SH2, and kinase domains are shown in *yellow*, *green*, and *blue*, respectively. The SH2–kinase-domain linker and the SH3–SH2 connector are shown in *red*. The myristate is shown in *orange spheres* in the C-lobe of the kinase.

defined: receptor and nonreceptor tyrosine kinases. Receptor tyrosine kinases are transmembrane proteins with an extracellular ligand-binding domain—often composed of Ig-like domains as described above, a single transmembrane domain, and the cytoplasmic tyrosine kinase domain. They are typically activated by dimerization upon binding of ligands to their extracellular region, which induces autophosphorylation and activation of their catalytic domains inside the cell.²⁹ Chromosomal translocations that underlie a number of human leukemias fuse a tyrosine kinase domain to an oligomerization domain from an otherwise unrelated protein, often the dimerization domain of a transcription factor, to generate a constitutively dimeric, and therefore constitutively active, kinase. Examples of such oncogenic translocations include the fusion of the dimerization domain of an ETS-family transcription factor to a Jak-family tyrosine kinase in the leukemogenic Tel-Jak2 fusion,³⁰ and the fusion of the oligomerization domain of nucleophosmin with the tyrosine kinase domain of ALK in the NPM-ALK fusion in anaplastic large cell lymphoma.³¹ These translocations are further described in [Chapters 56 and 73](#), respectively.

Perhaps the best characterized kinase translocation is the BCR–Abl fusion protein produced by the (9:22) chromosomal translocation in chronic myelogenous leukemia (see also [Chapter 67](#)). Treatment of this disease with imatinib, a specific inhibitor of Abl, has established a paradigm for targeted therapy in cancer.³² Abl is a nonreceptor tyrosine kinase that contains Src-homology 3 and 2 (SH3 and SH2) domains in addition to its tyrosine kinase domain. Additionally, the normal Abl protein is myristoylated at its N-terminus. In the normal protein, the N-terminal region including the myristoyl-group and adjacent sequences and the SH3 and SH2 domains assemble with the kinase domain to lock it in an inactive conformation ([Fig. 6.5B](#)).³³ These interactions are released to activate the kinase when the phosphotyrosine-binding SH2 domain and proline motif-binding SH3 domains bind their cognate ligands in a target protein.³⁴ Upon activation the myristoyl group may also be released from its docking site in the C-lobe of the kinase to promote membrane localization of the protein.³⁵ Thus in its normal state the various domains of Abl comprise an exquisite signaling switch that is regulated by appropriate binding interactions; in the absence of the proper targeting interactions the kinase is maintained in an inactive state by the intramolecular associations of its domains. In the oncogenic BCR–Abl fusion protein, this regulatory control is lost because the N-terminal regulatory region including the myristoylation site is truncated and replaced

with unrelated sequences from the BCR protein. Interestingly, the vacant myristate pocket in BCR–Abl is the target of recently developed allosteric inhibitors of BCR–Abl, which may synergize with ATP-site inhibitors.³⁶

Membrane Proteins

Membrane proteins account for 20% to 30% of all gene products in most genomes, and they are the targets of 50% of modern drugs.³⁷ Proteins embedded in or transverse the lipid bilayer mediate exchange of information and materials across membrane barriers. They are architecturally and functionally diverse. Single-pass transmembrane proteins have functional extracellular and/or intracellular domains connected by a single membrane-spanning helix; for example, the receptor tyrosine kinases described previously and cell adhesion molecules such as ICAM-1 and VCAM-1, which are anchored to the endothelial surface of blood vessels for leukocyte recruitment via a single transmembrane helix.

By contrast, integral membrane proteins typically have much of their mass embedded within the lipid bilayer, with multiple membrane-spanning segments connected by cytoplasmic and extracellular loops. Historically, integral membrane proteins have been difficult to study at a structural level. However, innovations in membrane protein crystallization and protein engineering have made such studies more tractable, allowing elucidation of many important structures at near-atomic resolution. Most membrane-embedded proteins are predominately helical, although β -strand membrane proteins also occur. Diverse ion channels and G-protein–coupled receptors (GPCRs) are integral membrane proteins. One of the largest and most complicated membrane protein complexes characterized to date is that of mitochondrial complex I. This huge proton-pumping machine features 82 transmembrane helices, accounting for approximately half of its molecular mass.³⁸

GPCRs are the largest family of membrane proteins—more than 800 have been identified in the human genome. GPCRs mediate fundamental signal transduction processes touching virtually every aspect of human physiology, from vision, taste, and smell to cardiovascular, endocrine, immunologic, and reproductive functions. Not surprisingly, they represent an important class of drug target. The conserved domain structure of GPCRs includes seven transmembrane helices that pack together across the lipid bilayer.^{39,40} They form a

Fig. 6.6 (A) Structures of the β_2 adrenergic receptor (β_2 AR) in the inactive (*left*) and active (*right*) conformations. Like all GPCRs, β_2 AR contains seven transmembrane helices. The inactive structure was determined with the antagonist carazolol bound in the ligand binding site, whereas the active structure was determined in complex with the tight-binding agonist BI-167107 (ligands are shown as *yellow spheres*). Agonist binding induces conformational changes on the cytoplasmic face of the receptor, including reorientation of the sixth transmembrane helix (TM6) and lengthening of TM5, which in turn promote binding of the heterotrimeric $G\alpha\beta\gamma$ complex. Interactions with the receptor are mediated by the $G\alpha_s$ subunit (*green*). This interaction induces exchange of GDP for GTP in the $G\alpha_s$ subunit, and promotes dissociation of $\beta\gamma$ complex (shown in *cyan* and *magenta* for β and γ , respectively). Illustration is drawn from Protein Data Bank (PDB) entries 2RH1 and 3SN6 for the inactive and active structures, respectively. T4 lysozyme fusion partners and a nanobody that was engineered to facilitate crystallization are not illustrated. (B) Structure of a bacterial homolog of the human vitamin K epoxide reductase (VKOR). VKOR is expected to bind vitamin K in a pocket homologous to that formed by four conserved transmembrane helices (*green*) that is occupied by a ubiquinone (*magenta*) in this structure. Warfarin inhibits VKOR by displacing vitamin K from this pocket. See text for further details. (Illustration drawn from PDB entry 3KP9, www.rcsb.org, accessed June 1, 2016.)

ligand-binding cleft that opens to the extracellular space. The cleft can vary dramatically in size and shape in different GPCRs, as some receptors recognize small molecules (for example, the β_2 -adrenergic receptor), whereas others have protein ligands (for example, chemokine receptors).

Structural studies of the β_2 -adrenergic receptor have recently revealed its mechanism of transmembrane signal transduction via the heterotrimeric G-protein $G\alpha\beta\gamma$ (Fig. 6.6A). Binding of the agonist in the extracellular-facing cleft induces key conformational changes in the cytoplasmic region, in particular a large movement of the sixth

transmembrane helix and an extension of the cytoplasmic end of the fifth transmembrane helix. These alterations promote binding to the $G\alpha$ -subunit of $G\alpha\beta\gamma$. In binding $G\alpha$, the agonist-bound receptor functions as a guanine-nucleotide exchange factor (GEF), inducing exchange of GDP for GTP. GTP-bound $G\alpha$ dissociates from the $\beta\gamma$ heterodimer to activate adenylyl cyclase, whereas the free $\beta\gamma$ component signals to Ca^{2+} channels. The inactive and active β_2 -adrenergic receptor structures are illustrated in Fig. 6.6A.

Membrane proteins can also fulfill catalytic roles; they operate not only in the plasma membrane but in every lipid membrane in

the cell. One example of interest is vitamin K epoxide reductase (VKOR), the target of the anticoagulant drug warfarin (see [Chapter 125](#)). VKOR resides in the endoplasmic reticulum membrane, and catalyzes a key step in the vitamin K cycle: regeneration of vitamin K hydroquinone. This compound is a cofactor for the enzyme that converts glutamic acid residues in the N-termini of vitamin K-dependent clotting factors to γ -carboxy glutamate (Gla) residues. This posttranslational modification is required for interaction of these proteins with Ca^{2+} , and thus for their function in coagulation. Although the structure of the human enzyme has not been elucidated, the structure of a homologous bacterial protein was recently described.⁴¹ In this crystal structure ([Fig. 6.6B](#)), the bacterial homologue of VKOR is naturally fused to a thioredoxin (Trx)-like domain, which supplies reducing equivalents. The core of VKOR structure is a four-helix bundle embedded in the membrane (transmembrane helices TM1–TM4, shown in green), with a fifth transmembrane helix (TM5) linked to the Trx-like domain on the extracellular surface (topologically equivalent to the luminal side of ER-resident mammalian VKOR). The ubiquinone compound has its quinone ring located near the membrane surface with its isoprenyl tail intercalated into the V-shaped cleft between TM2 and TM3. All the enzymatically important residues are on or close to the extracellular side of the membrane, adjacent to the Trx-like domain, providing a plausible path for electron transfer.⁴¹ Interestingly, mapping of mutations that confer resistance to warfarin onto the bacterial structure reveals striking clustering around the ligand-binding pocket, confirming that it is also the site of warfarin binding. This pocket is not large enough to accommodate both vitamin K and warfarin, an indication that warfarin exerts its inhibitory effect by displacing vitamin K.⁴¹

FUTURE DIRECTIONS

In this chapter, we have reviewed basic principles of protein structure and introduced a few representative protein folds that recur in proteins of key importance in hematology. Further examples found throughout the text reflect the value of understanding the structural foundations of biologic processes. Structure is key for understanding macromolecular function at a mechanistic level, and by extension for understanding pathogenic mutations and mechanisms of drug action. Increasingly powerful structural methods, in particular in cryo-electron microscopy,^{42,43} promise to bring ever larger and more complicated proteins and macromolecular complexes into focus.

SIGNALING TRANSDUCTION AND METABOLOMICS

Pere Puigserver

Hematopoiesis is a cellular process in which self-renewing stem progenitor cells differentiate into mature blood cells, which carry out specific biologic functions. These functions include oxygen delivery, clot formation, and defense of the host from infection. Homeostasis of the whole hematopoietic system *in vivo* requires a tight control of systems and networks governing proliferation, cell fate, cell death, differentiation, cell–cell interaction, and migration. Imbalance in or dysregulation of these processes results in pathologic alterations. For example, uncontrolled cell proliferation is a signature of leukemias, and defective lymphocyte differentiation can lead to immunodeficiency. A better understanding at the molecular level of these biologic events will help to identify new therapeutic targets for the design of better drugs to treat hematologic diseases.

Because of the diversity in cellular types and their respective, specific biologic functions, hematopoietic cells respond to a broad array of extrinsic and intrinsic signals transduced through signaling and metabolic pathways. It is therefore important to recognize that these pathways serve to ultimately define a specific functional response in a given cell type. These regulatory signals (Table 7.1) can be general, such as growth factors (e.g., insulin growth factor [IGF], fibroblast growth factor [FGF]), or amino acids that control proliferation, or highly specific, such as the antigen signaling response in immune cells or 2,3-diphosphoglycerate in erythrocytes. Importantly, the action of these signals, as well as their integration inside the cell, is needed to accomplish a specific cellular task (either a physiologic or cellular fate decision). Moreover, as will be discussed later in this chapter, these signals also serve to tightly control metabolites in hematopoietic cells, defining a metabolomic profile involved in processes such as anaerobic glycolysis for energy generation in red blood cells.

Extrinsic cellular signals, often polypeptides, are recognized by plasma membrane receptors that trigger a phosphorylation cascade (using tyrosine and/or serine/threonine residues) that propagates through the cytoplasm and cellular organelles, including the nucleus. Thus, the sequential activation of this cascade occurs in a temporal and spatial manner to define the specific biologic response. In general, there are two types of signals (Fig. 7.1): (1) signals that transduce immediate- or short-term biologic outputs without changes in gene expression, and (2) signals that transduce medium- and long-term biologic outputs with changes in gene expression. In the first case, for example, chemoattractants induce the phosphatidylinositol 3-kinase (PI3K) and Cdc42 pathways to rapidly establish neutrophil polarity. One example in the second case is the signaling transduced through Frizzled (Fz) receptors and the transcription factor T-cell-specific transcription factor (TCF)-1 necessary for T-cell development. In both cases, the signals transduced are amplified through a series of physical interactions and chemical modifications on proteins, the most common being phosphorylation, but others such as ubiquitination, acetylation, and sumoylation also play important roles.

In this chapter, a general survey of the different key signaling and changes in metabolite profiles that operate in hematopoietic cells will be reviewed. The goal is to provide the molecular basis by which signals are transduced and control fundamental cellular processes in different lineages of the hematopoietic system.

SIGNALING TRANSDUCTION

Hematopoietic cells use general signaling transduction pathways that are common to most cell types. The specificity in these signaling transduction pathways is often established at the beginning of the pathway's activation; for example, by specific antigen-binding or ligand–membrane receptor complexes (Table 7.2), and at downstream targets including transcription of the specific genes that will serve to define a particular biologic response (see Fig. 7.1). Here we will review these general signaling transduction pathways, illustrating some of the specific components of hematopoietic cells.

Receptor Tyrosine Kinases, Phosphoinosite-3-Kinase, and Mitogen-Activated Protein Kinase Pathways

Receptor Tyrosine Kinases

Receptor tyrosine kinases (RTKs) are enzyme-linked receptors localized at the plasma membrane containing an extracellular ligand-binding domain, a transmembrane domain, and an intracellular protein–tyrosine kinase domain. In general, the ligands for RTKs are proteins such as IGF, epidermal growth factor (EGF), platelet-derived growth factor (PDGF), and FGF. Ephrins that bind to Eph receptors also form a large subset of RTK ligands. Colony-stimulating-factor 1 (CSF-1), which is important for macrophage function, is another example of an RTK ligand. RTKs can function as monomers or multimeric subunits assembled at the plasma membrane that, upon ligand binding, cause oligomerization or conformational changes followed by tyrosine (trans)-phosphorylation in the kinase activation loop. Activation of RTKs results in phosphorylation of additional sites in the cytoplasmic part of the receptor, leading to docking of protein substrates, which initiates the intracellular signaling cascade. These substrates bind to RTK-phosphorylated tyrosines through Src Homology domain-2 (SH2) or phosphotyrosine-binding (PTB) domains. Examples of these types of proteins are insulin receptor substrates or the p85 regulatory subunit of PI3K. RTKs recruit, assemble, and phosphorylate different proteins including adaptors and enzymes.

There are mechanisms to terminate ligand-induced RTK activity through cellular processes including receptor-mediated endocytosis and/or through a family of regulated protein tyrosine phosphatases (PTPs), some of which are transmembrane and have extracellular domains, suggesting the possibility of ligand-mediated regulation. Interestingly, there is also intracellular regulation of PTPs through negative-feedback loops to attenuate the signal or direct control through reactive oxygen species (ROS) (see later discussion).

Phosphatidylinositol-3-Kinase Pathway

One of the key signaling components associated with RTKs is the phosphatidylinositol-3-kinase (PI3K) signaling transduction pathway. This pathway is also activated by cytokine receptors and G-protein–coupled receptors (GPCRs). Among the many functions of this pathway in hematopoietic cells, the IL-3–dependent survival

Fig. 7.1 EXAMPLES OF LIGANDS AND RECEPTORS THAT TRANSDUCE BIOLOGIC RESPONSES. Signals can originate from fixed ligands (e.g., the extracellular matrix, ECM) or soluble ligands that are not membrane permeable and bind to extracellular regions of transmembrane receptors. Membrane-permeable ligands bind to intracellular receptors, such as the nuclear receptor family. Signals can also originate from within the cell, such as increases in ROS levels. These signals cause short-term biologic outputs without changes in gene expression, or transduce medium- and long-term biologic outputs with changes in gene expression. *ECM*, Extracellular matrix; *ROS*, Reactive oxygen species.

TABLE 7.1 Signals in the Hematopoietic System

Types of Ligands	Examples
Peptide or Protein	
Soluble	Growth factors or cytokine
ECM	Fibronectin, collagen
Cell surface bound	ICAM, Kit ligand
Small organics	Thyroid hormone
Nucleotides	
Soluble	ADP
DNA	Double-strand breaks
Lipids	Eicosanoids, LPA
Gases	H ₂ O ₂ , nitric oxide ^a

^aFunction in hematopoietic system not well defined.

ADP, Adenosine diphosphate; ECM, extracellular matrix; ICAM, intercellular adhesion molecule; LPA, lipopolysaccharide.

of these cells largely depends on activation of the PI3K pathway. PI3K is a heterodimeric complex formed of a regulatory and a catalytic subunit. The regulatory protein subunits are encoded by isoforms (which include p85 α and p85 β) that contain SH3-binding domains that mediate binding to activated RTKs. This binding allows additional recruitment and activation of the PI3K catalytic subunits (p110 α , p110 β and p110 γ). At the plasma membrane, activated PI3K phosphorylates phosphoinositide-2 (PIP₂) at position 3 of the inositol to produce PIP₃. In addition, Ras, a small GTP-binding protein and potent oncogene, also activates PI3K. PTEN, an important lipid phosphatase and tumor suppressor, dephosphorylates PIP₃, counteracting PI3K and decreasing the intensity of the pathway. Accumulation of PIP₃ at the plasma membrane recruits several pleckstrin homology domain (PHD) containing proteins, among them PDK and AKT serine/threonine kinases, which are key components

TABLE 7.2 Receptors in the Hematopoietic System

Types of Receptors	Examples	Types of Ligands
RTK	Insulin, Kit, Fms	Kit ligand, M-CSF
RSK	TGF β receptors	Activin, BMPs, TGF- β
GPCR	Thrombin receptor, CXC, CC receptors	Thrombin chemokines
PTK-associated MIRR	Cytokine receptors BCR/TCR/FcR	Epo, interleukins, IFN peptide/MHC, Fc domains
TNF family	Fas, TNFR, CD40	Fas, TNF, CD40L
Notch	Notch	Delta-serrate-LAG-2
Frizzled family	Wnt receptors	Wnts
Toll receptors	TLR1-10	Bacterial DNA, LPS
RPTP	CD45	Unknown
Nuclear receptors	AR, RAR	Testosterone, retinoids
Adhesion receptors	Integrins	Fibronectin, collagen

AR, Androgen receptor; BCR, B-cell antigen receptor; BMP, bone morphogenetic protein; CC, CXC, types of chemokine receptors; CD40L, ligand for CD40; Epo, erythropoietin; FcR, receptors for Fc portion of antibodies; GPCR, G protein-coupled receptor; LPS, lipopolysaccharide; M-CSF, macrophage colony-stimulating factor; MIRR, multichain immune recognition receptor; RAR, retinoic acid receptor; RPTP, receptor protein-tyrosine phosphatase; RSK, receptor serine kinase; RTK, receptor tyrosine kinase; TCR, T-cell antigen receptor; TGF β , transforming growth factor β ; TNF, tumor necrosis factor.

in transducing PI3K signaling. Activated AKTs target different protein substrates for initiation of a biologic response. For example, the Bad protein, phospho-Bad, does not bind Bcl-2 and functions as an antiapoptotic mechanism, promoting cell survival. Another key target of AKTs are the Forkhead transcription factors (FoxOs)

Fig. 7.2 EXAMPLES OF SIGNALING/TRANSCRIPTIONAL PATHWAYS PROGRAMMING GENE EXPRESSION. Proteins involved in gene expression are a common target of many signaling pathways, and receptors often stimulate multiple pathways that can regulate common and distinct transcription factors. In the examples shown here, production of PtdIns-3,4,5-P3 by PI3K leads to the activation of the serine/threonine kinase Akt. Akt phosphorylates and inactivates FoxO transcription factors. Ras is activated by the guanine nucleotide exchange factor Sos. Ras activation initiates a cascade of serine/threonine kinase activity: Ras activates Raf, Raf phosphorylates and activates Mek1, and Mek1 phosphorylates and activates Erk. Phosphorylation of the transcription factor Elk1 by Erk activates gene expression. Increased intracellular calcium is also a common signaling event. Activation of phospholipase C leads to hydrolysis of PtdIns-4,5-P2 and production of IP3. IP3 binds to its receptor, leading to intracellular calcium release and then extracellular calcium influx. Calcium activates the serine phosphatase calcineurin, which dephosphorylates NFAT proteins, allowing them to enter the nucleus and stimulate transcription. *FoxO*, Forkhead transcription factors; *IP3*, inositol triphosphate; *NFAT*, nuclear factor of activated T cells; *PI3K*, phosphatidylinositol 3-kinase; *Sos*, Son of Sevenless.

(Fig. 7.2). When phosphorylated by AKT, phospho-FoxOs are sequestered and inactive in the cytoplasm through direct binding to 14-3-3 proteins. Dephosphorylated FoxOs, on the other hand, activate gene expression associated with stress resistance and cell growth arrest. Another major component downstream of Akt is mammalian target of rapamycin (mTOR, a kinase that belongs to the PI3K-related protein kinase family), which is involved in metabolism, growth, and proliferation. Akt phosphorylates TSC2, which forms a complex with TSC1, decreasing its GTPase-activating protein (GAP) activity for the small GTPase Rheb; as a consequence, the increases in GTP-Rheb activate mTORC1 (one of the mTOR complexes). Among the key downstream targets of mTOR are S6K and 4EBP1, which control protein translation. mTOR can also be activated independently of RTKs through nutrients including branched chain amino acids. Interestingly, mTORC1 inhibitors such as rapamycin are used as immunosuppressors in organ transplantation.

MAPK/ERK Pathway

Activated RTKs recruit docking proteins, such as Grb2 and SOS, that allow binding of GTP to Ras to become active and trigger a kinase signaling cascade. Ras activates RAF kinase that, in turn, triggers a series of MEKs, which finally activate MAPK or Erk kinases. Erk phosphorylates many proteins involved in cell growth including ribosomal S6K, which is involved in protein translation, and AP-1 and c-myc transcription factors, which increase many

different cell cycle and antiapoptotic-related genes (see Fig. 7.2). Other MAPKs include the stress-activated kinases JNK and p38. Constitutive MAPK in hematopoietic stem cells is known to induce myeloproliferative disorders.

The Transforming Growth Factor- β Pathway

The TGF β family of cytokines contains two subfamilies: the TGF β /Activin/Nodal and the bone morphogenetic protein (BMP)/growth and differentiation factor (GDF)/Müllerian-inhibiting substance (MIS) subfamilies. At the plasma membrane TGF β ligands bind with high affinity to the ectodomain of type II receptors, which then recruit type I receptors. This forms a large ligand–receptor complex involving a ligand dimer and four receptor subunits. Upon ligand binding, the type II receptor phosphorylates multiple serine and threonine residues in the cytoplasmic GS-rich region of the type I receptor, leading to its activation. The phosphorylated TGF β type I receptor binds to and phosphorylates Smad2 and Smad3 transcription factors, which are critical mediators of TGF β signaling and function. Upon phosphorylation, Smad proteins translocate to the nucleus to activate gene expression through binding to specific DNA-binding sites. There are several mechanisms to terminate Smad activation, which include proteasomal degradation and dephosphorylation. TGF β -1 has been shown to be associated with active centers of hematopoiesis and lymphopoiesis in the developing fetus.

Signaling Through Receptors Associated With Protein-Tyrosine Kinases

Here, three different types of receptors and their signaling are included: (1) cytokine receptors; (2) multichain immune recognition receptors; and (3) integrin receptors.

Cytokine Receptors and Janus-Activated Kinase Signaling

The cytokine receptor superfamily mediates many of the central specific responses in hematopoietic cells. Ligands for these receptors include interleukins, thrombopoietin, erythropoietin, and so on. Cytokine receptors possess a conserved extracellular region (cytokine receptor homology domain [CDH]) and several structural modules, including extracellular immunoglobulin or fibronectin type III–like domains, transmembrane domains, and intracellular homology regions. Based on the divergence of the CHD, cytokine receptors are classified into two classes: class I and class II receptors. Class I receptors contain two pairs of cysteines linked through a disulfide bond and a C-terminal WSXWS motif within the CHD. This class is further subdivided into three families: IL-2R, IL-3R, and IL-6R. All three receptor families share similar receptor chains. The class I cytokine receptors are formed by one chain containing two motifs (Box 1 and Box 2), which transduce signaling through binding to Janus-activated kinase (JAK; see later discussion). Also included in this class are the homomeric receptors that form homodimers upon ligand binding. Examples of these receptors include the erythropoietin, thrombopoietin, prolactin, and growth hormone receptors. Class II receptors also have two pairs of cysteines but lack the WSXWS motif found in class I receptors. There are pools of 12 class II receptor chains that are capable of forming a total of 10 receptor complexes. This class is functionally divided into antiviral receptors (three receptor complexes that bind interferons) and non-antiviral receptors, which bind to several interleukins such as IL-10 and IL-20.

The oligomeric structures of cytokine receptors are complex and cannot be generalized. Cytokine binding often induces oligomerization, which activates protein tyrosine kinases in the JAK family that are constitutively associated with the Box 1 and 2 motifs of the cytokine receptor. Oligomerization brings JAKs in close enough proximity to transphosphorylate on Tyr residues. This activates JAK,

which results in the phosphorylation of other cytokine receptors as well as other substrate proteins. Among these substrates, the signal transducer and activator of transcription (STAT) family of transcription factors are pivotal to JAK-mediated cytokine signaling. STATs are phosphorylated on Tyr residues by JAKs upon cytokine binding to the receptor. Phospho-STATs homo- or hetero-dimerize, and translocate to the nucleus to activate gene expression. STATs are also phosphorylated on a serine residue via MAPK, which serves to strengthen the intensity of the signal. As part of the cytokine signaling attenuation, STATs induce genes encoding for suppressors of cytokine signaling proteins (SOCS), which bind to phospho-tyrosine residues of the cytokine receptor and JAK through SH2-binding domains.

JAK inhibitors, based on their ability to block cytokine signaling, are used in allergic and rheumatoid arthritis disease therapy.

Multichain Immune Recognition Receptors

This family of receptors include antigen receptors in B and T lymphocytes, activating receptors in natural killer (NK) cells, and immunoglobulin E (IgE) and Fc receptors. This class of receptors contains different integral membrane subunits that bind the ligand at the cell surface and transduce the signal. Ligand binding induces oligomerization of receptor subunits that contain immunoreceptor tyrosine-based activation motifs (ITAMs) within their cytoplasmic domains. These domains become phosphorylated on tyrosine residues upon receptor activation. These phosphotyrosines are involved in activation of a series of protein tyrosine kinases containing SH2 domains that include Src (Src family kinase [SFK]), Syk (Syk or ZAP-70), and Tec (Btk, Itk, Rlk), which mediate immune signaling through downstream pathways that include MAPK, calcium signaling, and NF- κ B, among others. In Tec kinases, additional downstream targets include enzymes such as phospholipase C γ (PLC γ). The precise mechanism of this activation is not completely understood, and in some cases, such as T-cell receptors, a protein tyrosine phosphatase (-CD45, which counteracts the action of SFKs) is regulated upon ligand binding.

The activities of some of these receptors are the basis of immunotherapy in cancer. For example, programmed death-1 (PD-1) mediates tumor-induced immunosuppression. Cancer cells express the PD-1 ligand, which activates the PD-1 receptor present in tumor-infiltrated lymphocytes, suppressing the immune response. Blockade of PD-1 activation with monoclonal antibodies has been successful in treating several human tumors such as melanoma. Mechanistically, T cells are activated through the T-cell receptor upon binding of major histocompatibility complex (MHC) plus peptides on an antigen-presenting cell (APC; in this case in the tumor cell), and binding of APC CD80/86 to T cell CD28. Activation of the T-cell receptor increases expression of PD-1 to suppress the immune/inflammatory response. Cancer cells activate this pathway, upregulating the PD-1 ligand to promote survival and suppress the immune-mediated death of tumor cells.

Integrin Signaling

Integrin receptors are involved in cell adhesion, migration, survival, and growth. This signaling is central in hematopoietic cell function, for example, at places of inflammation or infection, where integrins trigger a cascade by which leukocytes exit the vasculature. Interestingly, these receptors signal bidirectionally through the plasma membrane in pathways referred to as *inside-out* and *outside-in signaling*. Integrins are a class of receptors that comprise heterodimeric type I transmembrane proteins consisting of α and β subunits. These subunits contain a large extracellular domain, a single transmembrane domain, and a short cytoplasmic tail. There are 18 α and 8 β subunits that are associated and form 24 different integrins with different affinities for ligands. Most of the ligands are ECM proteins containing one of the two motifs: arginine-glycine-aspartate (RGD) or leucine-aspartate-valine (LDV). Examples of integrin ligands are ICAM-1, which is

present at the plasma membrane of antigen-presenting cells and binds to the integrin receptor LFA-1 to promote cell-cell adhesion.

Ligand binding to the extracellular domain induces clustering of integrins, allowing separation of the different subunits cytoplasmic portions forming interactions with cytoskeleton proteins involved in actin polymerization (outside-in signaling). Signals arising from the cellular interior, including phosphorylation, can also separate these cytoplasmic domains and can affect ligand binding (inside-out). Ligand binding to integrin receptors also signals to protein tyrosine kinases such as the SFKs and focal adhesion kinase (Fak). This part of the signaling is not completely understood, but appears to involve a domain in the β -integrin tail (NPXY motif) that binds talin, which in turn recruits paxillin that binds Fak, which, once activated, phosphorylates SFKs to mediate integrin response.

Tumor Necrosis Factor Receptors and Signaling

Tumor necrosis factor receptors (TNFRs) influence inflammation, innate immunity, lymphoid organization and T-cell responses. There are approximately 19 different ligands for TNFR that mediate cellular responses through 29 TNFRs. TNFRs are a family of single-membrane-spanning proteins that contain an extracellular TNF-binding region and a cytoplasmic tail. As in the case of other cytokine receptors, ligand binding causes oligomerization and the formation of a mature receptor complex that is required to transduce the signal. TNFRs fall into three classes: (1) death domain (DD) containing receptors (fatty acid synthase, TNFR1, and DR3), which activate the caspase cascade via the DD-initiating extrinsic apoptotic pathway; (2) decoy receptors, which lack a cytoplasmic tail and therefore cannot transmit the signal, making these receptors ligand sequesters; and (3) TNFR-associated factor (TRAF) receptors such as TNFR2, which lack the DD-recruiting TRAF proteins. In general, TRAFs are associated with either proapoptotic or survival pathways through activation of the NF- κ B family of transcription factors and MAPK signaling (Erk, JNK, and p38). TRAFs activate NF- κ B through ubiquitin-mediated degradation of their inhibitor I κ B α , which retains NF- κ B inactive in the cytoplasm. This process is initiated by phosphorylation of I κ B α by the I κ B α kinase (IKK) complex, mainly by the IKK- β catalytic subunit, and requires a regulatory subunit (also known as NEMO). Upstream of IKKs are other kinases including NF- κ B-inducing kinase (NIK), which binds to TRAFs. Nuclear-activated NF- κ B modulates gene expression, which mediates TNF biologic responses.

Toll-Like Receptors and Signaling

Toll-like receptors (TLR) play essential roles in the innate immune response. Ten TLRs have been identified and can be grouped into two classes based on their extracellular domain: (1) TLRs with leucine-rich repeats; and (2) TLRs with immunoglobulin domains. The ligands for TLRs are diverse and include the different constituent components of the microorganism, such as lipopolysaccharides and heat shock proteins (which bind to TLR2 and TLR4). Host defense against microorganisms mainly relies on signals originating from the TIR (Toll/IL-1) intracellular domain (a domain present in TLRs and IL-1Rs). The TLR signaling pathway is similar to the one triggered by the IL-1R. Ligand binding induces TLR multimeric receptor complexes, recruiting adaptor proteins such as MyD88, which contains a TIR domain and a death domain, that in turn binds to the IL-1R-associated kinase (IRAK). IRAK is activated by phosphorylation and then associates with TRAF6, leading to activation of mainly two different pathways, JNK and NF- κ B to activate the innate immune response, including release of inflammatory cytokines.

Wnt Signaling

Wnt proteins are lipid-modified, secreted proteins of approximately 400 amino acids that bind to Wnt cell surface transmembrane

receptors, called Frizzled (Fz), to initiate the canonical Wnt signaling transduction pathway. At the plasma membrane, binding of Wnt ligands to Fz receptors connect through direct binding to several intracellular proteins including Disheveled (Dsh), glycogen synthase kinase-3 β (GSK3 β), Axin, and adenomatous polyposis coli (APC), inhibiting proteasome-mediated degradation of the transcriptional protein β -catenin. This degradation is regulated through GSK3 β -mediated phosphorylation of β -catenin. As a consequence, β -catenin accumulates in the cytoplasm and translocates to the nucleus, where it interacts with transcription factors such as lymphoid enhancer-binding factor 1 (LEF)/TCF to modulate gene expression.

Notch Signaling

Notch ligands are plasma single-pass transmembrane proteins named Delta-like and Jagged. Thus, cells expressing the ligands are adjacent to cells expressing the Notch receptors, which are also transmembrane proteins. The Notch receptor interacts with a Notch ligand on a contacting cell; this interaction produces Notch receptor cleavage, which releases the Notch intracellular domain (NICD). The NICD translocates to the nucleus where it binds to several DNA-binding proteins including CBF1/Suppressor of Hairless/LAG-1 (CSL). As a result of this interaction between NICD and CSL, changes in Notch target genes occur. In contrast to the other signaling pathways discussed in this chapter that mainly function through phosphorylation, there is no amplification from the initial Notch ligand binding to the receptor. Moreover, this core pathway is modulated through auxiliary proteins that influence the response to the Notch ligand. Among these proteins are acute myeloid leukemia 1 (AML1), discoidin domain receptor family (DDR1), NECD, Notch extracellular domain, and CBF1-interacting protein.

Hedgehog Signaling

Hedgehog (Hh) signaling is a ligand-dependent signaling pathway. There are three different protein ligands—Sonic, Desert, and Indian—that are secreted and produce an N-terminal active fragment. Indian appears to be highly expressed in hematopoietic tissue. These ligands bind to Patch transmembrane receptors and are internalized, and Smoothened (a GPCR member) translocates to the plasma membrane of the primary cilium and promotes activation of the Gli family of zinc finger transcription factors. Hg targets include genes involved in differentiation, apoptosis, and the cell cycle. Abnormal activation of Hh signaling occurs in hematologic malignancies and maintains stem cell expansion. Because these cells are resistant to conventional chemotherapy, Hh antagonism is considered a plausible target in these malignancies.

Nuclear Hormone Receptor Superfamily

Nuclear hormones include steroid hormones (sex hormones, glucocorticoids, and mineralocorticoids), sterol hormones (vitamin D and its derivatives), thyroid hormones, and retinoids. These hormones are lipophilic and need carrier proteins to be transported in the blood. Due to this hydrophobicity, they can diffuse across the plasma membrane to reach the receptor proteins inside the cells, either in the cytoplasm or in the nucleus. These receptors are called the nuclear hormone receptor (NHR) superfamily. What distinguishes this receptor family from those discussed previously is their ability to directly bind to DNA and coordinate gene expression, which effectively makes them a form of transcription factor. NHRs contain a central DNA-binding domain, which targets the receptor to DNA sequences known as hormone response elements. In addition, the C-terminal part of the receptor contains a ligand-binding domain where the ligand or hormone binds. Upon ligand binding, NHRs control the expression of diverse sets of genes related to the hormonal response. Based on the types of ligands that they can bind, NHRs can be

grouped into four classes: (1) steroid receptors, which include receptors for glucocorticoids, mineralocorticoids, progesterone, androgen, and estrogen; (2) retinoid X receptor heterodimers, such as thyroid receptor, retinoic acid receptor, vitamin D receptor, and peroxisome proliferator-activated receptors; (3) dimeric orphan receptors, such as COUPTF or HNF4; and (4) monomeric orphan receptors, such as NGFI. The cognate ligands for orphan receptors have yet to be identified.

G Protein–Coupled Receptor and Chemokine Signaling

GPCR Signaling

The GPCR superfamily comprises a large collection of proteins, with approximately 2000 annotated genes in the human genome (~10% of the entire genome). GPCRs are involved in a large array of physiologic functions, including platelet aggregation and leukocyte chemotaxis. GPCRs are single polypeptides with seven-pass transmembrane domains containing both cytoplasmic and extracellular regions. Ligands for GPCRs are very diverse and include proteins or peptides, amino acids, lipids, and nucleotides that bind at the cell surface where GPCRs are localized. In spite of its vast size and variety of activational ligands, the GPCR superfamily relies upon three main intracellular signaling cascades for communicating receptor activation: the cyclic adenosine monophosphate (cAMP)/protein kinase A (PKA), the phosphatidylinositol/phospholipase C, and the Rho GTPase-based cascades.

GPCRs are coupled to a heterotrimeric G protein formed from three unique subunits (α , β , and γ) that are membrane bound. The G- α subunit contains a GTPase domain, which is capable of hydrolyzing GTP to GDP. When bound to GDP, the complex is functionally inactive, with the G- α subunit remaining tightly associated with the other subunits of the GPCR complex. Upon ligand binding to the GPCR, structural conformational changes produce the release of GDP from the heterotrimeric complex, allowing GTP to bind to the G- α subunit. In this GTP-bound form, the G- α subunit dissociates from the G- β and G- γ subunits with which it interacts. The G- α subunit then proceeds to interact with its downstream cognate targets to affect a particular signal response, depending upon the GPCR and the specific G- α subunit isoform. Among these second-messenger effectors are the cAMP/PKA pathway, ion channels, Rho GTPase, MAPK, PI3K, and inositol-3-phosphate/diacylglycerol (InsP3/DAG) pathways. In the case of the cAMP pathway, adenylate cyclase is downstream of different GPCRs (e.g., adrenergic receptors) and is activated by GTP-bound G- α . Adenylate cyclase converts ATP to cAMP, a freely diffusible second-messenger molecule. A key effector of intracellular cAMP is PKA, an inactive tetrameric protein complex consisting of two regulatory and two catalytic subunits. Binding of cAMP to the regulatory subunits causes release and activation of the catalytic subunits, which phosphorylate different cellular targets. Among them are the transcription factor cAMP-responsive element (CREB) and several ion channels. In addition to adenylate cyclase, there are other common effectors downstream of GPCRs, such as phospholipase C, a plasma membrane-bound enzyme that cleaves phosphatidyl inositol (PIP2) into two products and messengers: inositol triphosphate (IP3) and diacyl glycerol (DAG). IP3 can diffuse through the cytoplasm and bind receptors in the endoplasmic reticulum, resulting in calcium release to the cytoplasm. Importantly, calcium propagates the signaling cascade through different proteins such as calcineurin and nuclear factor of activated T cell (NFAT) transcription factors (see Fig. 7.2), which are involved in, for example, IL-2 gene expression. DAG at the plasma membrane binds and activates, in conjunction with calcium, protein kinase C (PKC), which will phosphorylate other downstream targets. Rho guanine nucleotide exchange factor (RhoGEF) is also a target for some G- α subunits. Binding of the G- α subunit to Rho allosterically activates it, causing GTP to be preferentially bound. This, in turn, allows RhoGEFs to activate Rho kinase, which is involved in the cytoskeletal reorganization necessary for changes in cell shape and motility.

Fig. 7.3 INTEGRATION OF CENTRAL METABOLIC PATHWAYS. The metabolic fluxes within anabolic and catabolic routes are controlled by different signals including metabolite concentrations. These metabolic pathways are localized in different cellular compartments to adequately provide cellular energetic and nutrient homeostasis necessary for growth and survival. See text for further details. *ACC*, Acetyl-CoA carboxylase; *CoA*, coenzyme A; *FAS*, fatty acid synthase; *LDHA*, lactate dehydrogenase A; *PDH*, pyruvate dehydrogenase; *PDK*, pyruvate dehydrogenase kinase; *ROS*, reactive oxygen species; *TCA*, tricarboxylic acid.

Chemokine Signaling

Chemokines mediate cell migration in immune surveillance, inflammation, and development. There are nearly 50 human chemokines divided into four families (CXC, CC, C, and CX3C) on the basis of the pattern of internal cysteine residues; thus C stands for cysteine and X/X3, one or three noncysteine amino acids. Expression of some of these chemokines is induced by inflammatory signals such as TNF α , interferon- γ , trauma, or microbial infection. There are approximately 20 signaling chemokine receptors and they are all GPCR receptors, thus the chemokine acts as a ligand, and activation of the chemokine receptor follows the principles described previously. The major downstream effectors are cAMP and calcium messengers. Interestingly, some of the chemokine receptors also bind HIV viral proteins.

cGAS–cGAMP–STING Signaling Pathway

The presence of cytoplasmic DNA, through infection or DNA damage, activates innate immune responses. A mechanism of sensing this misplaced DNA is through the cGAS–cGAMP–STING signaling pathway. Cytosolic DNA binds and activates the cGAS enzyme (cGAMP synthase), which produces a second messenger, the cyclic dinucleotide 2',3'-cGAMP, using ATP and GDP as substrates. 2',3'-cGAMP is a high-affinity ligand for STING, an endoplasmic reticulum membrane protein that undergoes several structural conformations. 2',3'-cGAMP bound to STING binds to the protein kinase TBK1, which phosphorylates IRF3; in addition, activated

STING signals to IKK to phosphorylate and degrade I κ B α , which sequesters NF κ B in the cytoplasm. Both phosphorylated and dimerized IRF3 and NF κ B translocate to the nucleus to activate expression of type I interferons and other cytokines.

METABOLOMICS AND CONTROL OF HEMATOPOIETIC CELL METABOLISM

There are three important general pathways by which metabolism impacts cellular function and the metabolomic state (Fig. 7.3): (1) activity of catabolic routes that supply energy in the form of ATP, such as glycolysis or oxidative phosphorylation; (2) activity of anabolic routes that synthesize molecules that are used for cellular growth or a specific function; and (3) changes in metabolites that control intrinsic and extrinsic cellular activities. This regulation is intimately connected to signaling transduction, as most of the pathways described in the previous section directly control cellular metabolism and metabolite levels. Here, this part of the review will cover the main metabolic pathways and new metabolomic research, taking into consideration their implications in hematopoietic cells.

Glucose Metabolism

Hematopoietic cells have different types of glucose transporters; for example, activation of T cells causes dramatic increases in Glut1 expression in order to maintain immune homeostasis. Once transported into the cell, glucose is metabolized through different

biochemical pathways to provide energy and building blocks for macromolecules that constitute the cell or regulatory metabolites. Glucose can be stored in cells in the form of glycogen, which constitutes a rapid source of energy through its breakdown to free glucose (glycogenolysis), although this pathway is limited to a certain number of hematopoietic cells. Chemotaxins (FMLP, C5ades arg, arachidonic acid) activate granulocytes to catabolize significant amounts of endogenous glycogen.

Glycolysis

Glycolysis is a series of reactions by which six-carbon glucose is converted into two three-carbon keto-acids (pyruvate). Importantly, these oxidative reactions generate energetic molecules such as ATP and NADH, and can occur in the absence of oxygen and mitochondria. In some cells, such as erythrocytes, anaerobic glycolysis produces lactate, but in most cell types pyruvate is completely oxidized to acetyl coenzyme-A and carbon dioxide by the mitochondrial pyruvate dehydrogenase complex and the tricarboxylic acid (TCA) cycle coupled to oxidative phosphorylation. In general, hematopoietic stem cells are thought to largely depend on glycolysis, while more differentiated cells, except for erythrocytes, use mitochondrial oxidative metabolism. Glycolytic fluxes are under intrinsically tight control through intermediate metabolites in the pathway. The most powerful control is exerted by fructose 2,6-bisphosphate (F-2,6-BP), which is generated by phosphofructokinase 2. F-2,6-BP allosterically activates phosphofructokinase, providing a “feed-forward” mechanism of stimulation. Activation of growth factor signaling pathways potentially stimulate glycolysis at different points, including phosphorylation of phosphofructokinase 2 and pyruvate kinase. The PI3K pathway is a major signaling pathway that controls glycolysis.

Interestingly, in erythrocytes, 1,3-diphosphoglycerate can be diverted from glycolysis to synthesize 2,3-diphosphoglycerate (2,3-DPG) via the enzyme diphosphoglycerate (Rapoport–Laubering shunt). 2,3-DPG is an important metabolite that regulates oxygen binding to hemoglobin; thus increased levels of 2,3-DPG (e.g., under hypoxic conditions) allow hemoglobin to release oxygen under low partial oxygen tensions.

Pentose Phosphate Pathway

The pentose phosphate pathway (PPP) derives from glycolysis in the cytoplasm. The first enzyme in this pathway is glucose-6-phosphate dehydrogenase (G6PDH) and produces NADPH, a substrate utilized for lipogenesis and glutathione regeneration by glutathione reductase. The regulation of NADPH production through G6PDH is through NADPH-mediated product inhibition. The PPP is also important in generating ribose-5 phosphate, which is a precursor for nucleotide synthesis in proliferating cells. Interestingly, G6PDH deficiency leads to low levels of NADPH, which is essential for controlling reactive oxygen species (ROS) through glutathione reductase. It is one of the most common erythrocyte enzymopathies and these cells cannot prevent oxidative damage in critical molecules such as heme, causing overall irreparable damage to the cell at a much higher rate than normal, particularly in response to certain environmental triggers such as drugs and stress. The damaged erythrocytes are removed from circulation in the spleen and destroyed by macrophages at an elevated rate, leading to anemia. This enzymopathy occurs in areas with high malarial burden, in part because the mutated recessive allele confers malarial resistance. This resistance is because red blood cells with low G6PDH activity, when infected with the parasite, are continuously removed from the circulation.

Tricarboxylic Acid or Krebs Cycle

A major route for pyruvate oxidation is conversion to acetyl-CoA, a reaction catalyzed by the mitochondrial pyruvate dehydrogenase

enzymatic complex. Acetyl-CoA is a high-energy intermediate that can be further oxidized by the TCA cycle or utilized for fatty acid synthesis. The TCA cycle is initiated by the condensation of oxaloacetic acid with acetyl-CoA, forming citrate. In reactions involving decarboxylation and oxidation, CO₂ is produced and NADH and flavin adenine dinucleotide (FADH) are produced for use in the mitochondrial respiratory chain. The flux of the TCA cycle is regulated by the levels of acetyl-CoA and oxaloacetic acid, which are entry points in the cycle, and by the availability of NAD⁺ and FAD⁺ substrates. The rate of oxidation through the TCA cycle depends on mitochondrial electron transport activity, which is governed in part by NADH levels. The TCA cycle also produces metabolites for biosynthetic processes (anaplerotic reactions). For example, citrate is converted to fatty acids and sterols, and succinyl CoA is an intermediate in heme and porphyrin synthesis. Aside from the bioenergetic and anaplerotic aspect of this cycle, several reactions have important clinical implications.

Oxidative Phosphorylation

In most cell types, oxidative phosphorylation is dominant on ATP generation. Exceptions include red blood cells, which lack mitochondria. Oxidative phosphorylation complexes are located at the inner mitochondrial membrane and receive high-energy electrons from NADH (produced from the oxidation of acetyl-CoA). These electrons are passed through the different oxidative phosphorylation complexes (which contain heme, copper iron–sulfur groups, and flavins as electron carriers) until they reach the final electron acceptor, molecular oxygen. As a consequence of electron transfer, protons are pumped into the mitochondrial intermembrane space, generating an electrochemical gradient used to synthesize ATP. There are five oxidative phosphorylation complexes: complex I (NADH–CoQ reductase complex), complex II (succinate–CoQ reductase complex), complex III (CoQH₂–cytochrome c reductase complex), complex IV (cytochrome c oxidase complex), and complex V (ATP synthase complex). In general, hematopoietic stem cells are located in low-oxygen niches and largely depend on glycolysis instead of oxidative phosphorylation to maintain ATP levels. The differentiation process is associated with increases in mitochondria, which allow for the generation of ATP through the respiratory chain. For example, this occurs in quiescent T cells that are in a catabolic phase, producing ATP mainly through oxidative phosphorylation. Upon stimulation, activated T cells shift towards an anabolic phase, relying upon a high rate of glycolysis for ATP generation. Mitochondrial DNA encodes for several oxidative phosphorylation subunits and mutations in this DNA produce mitochondrial diseases. Interestingly, anemia, a symptom associated with patients having Pearson syndrome, is caused by accumulation of mutated mitochondrial DNA in sideroblasts. This suggests that hematopoietic cell-specific respiration defects can be responsible for anemia by inducing abnormalities in erythropoiesis during development.

Reactive Oxygen Species Metabolism

Reactive oxygen species (ROS) are chemically reactive small molecules with oxygen in different oxidation states, such as partially reduced oxygen ions and peroxides. The three major species are superoxide, hydrogen peroxide, and hydroxyl radicals. The major cellular sites for ROS production are the mitochondria and NADPH oxidase, a plasma membrane or phagosome-bound enzyme. Approximately 85% of cellular ROS is a subproduct of normal oxidative phosphorylation. Superoxide is the initial ROS produced in the electron transport chain, and it is transformed to hydrogen peroxide by the enzyme superoxide dismutase. Hydrogen peroxide is the substrate of catalase or glutathione peroxidase, which reduces it to water. Hydrogen peroxide, however, is also converted to hydroxyl radicals, the most reactive oxygen species, in a Fenton reaction with ferrous

iron. NADPH oxidase catalyzes the NADPH-dependent reduction of oxygen into the superoxide anion.

ROS cause cellular damage through oxidation and chemical modifications of proteins, lipids, and DNA. Nuclear and mitochondrial DNA can be oxidized, producing strand breaks. Intracellular levels of ROS are regulated through different signaling transduction pathways. Growth factor-mediated signaling increases ROS levels, for instance. Conversely, ROS also affect this signaling through modulation of protein tyrosine phosphatases that contain cysteine-sensitive residues that modulate their enzymatic activity and regulate the biologic responses associated with this signaling.

ROS are particularly deleterious to hematopoietic stem cells because of their effect on genomic stability and survival. In phagocytic cells (neutrophils, macrophages, or eosinophils), NADPH oxidase is responsible for the oxidative burst that is triggered upon phagocytosis of pathogens. Superoxide generated by NADPH oxidase is rapidly converted to other ROS, which, in cooperation with pH-sensitive proteases, are responsible for killing the microorganisms in the phagosome vacuole.

Recently, gain-of-function mutations of isocitrate dehydrogenase 1 and 2 (IDH1 is cytoplasmic and is unrelated to the TCA cycle; IDH2 is the TCA mitochondrial form) have been found in 20% of acute leukemia patients. IDH1 and IDH2 are highly homologous but distinct (in structure and function) from the NAD⁺-dependent heterotrimeric IDH3 enzyme that is part of the TCA cycle producing NADH to the respiratory chain. The cellular function of the NADP-dependent IDH1/2 enzymes is not clear but they are part of glucose, fatty acids, and glutamine metabolism, and contribute to the maintenance of cellular reduction-oxidation balance. In three identified mutations, the enzyme undergoes a change in its normal physiologic catalytic reaction (i.e., oxidative decarboxylation of isocitrate to produce α -ketoglutarate and CO₂ while converting NAD[P] to NAD[P]H) and instead produces 2-hydroxyglutarate, which is now considered to be a protoncometabolite. The mechanism appears to be linked to competition with α -ketoglutarate for the active site of ketoglutarate-dependent dioxygenases, such as TET2, which functions as a cytosine demethylase.

Lipid Metabolism

Fatty acids and triglycerides (the storage form of fatty acids) constitute an energetic reserve in the body. Most of the cells are able to synthesize fatty acids, but there are essential fatty acids such as linoleic acid, α -linoleic, and arachidonic acid that cannot be synthesized. Arachidonic acid is made from linoleic acid, and is the precursor for prostaglandins, thromboxanes, and leukotrienes that participate in different pathways such as the inflammatory response. Drugs that block the enzyme cyclo-oxygenase and prostaglandin synthesis such as acetaminophen, ibuprofen, and acetylsalicylate provide pain relief. Fatty acids can directly mediate transcriptional responses, acting as ligands for peroxisome proliferator-activated receptors, a family of nuclear hormone receptors. In addition, there are specific GPCR receptors such as GPR40 and GPR120 activated by medium- or long-chain fatty acids. GPR43 is activated by short-chain fatty acids and is highly abundant in leukocytes.

Fatty Acid Synthesis

In the mitochondrial matrix acetyl-CoA is generated from pyruvate and is the precursor for fatty acid synthesis. Acetyl-CoA cannot cross the mitochondrial membrane; thus acetyl-CoA condenses with oxaloacetate (first reaction in the TCA cycle) to form citrate, and is exchanged into the cytoplasm through TCA translocases. Once in the cytoplasm, citrate is converted to acetyl-CoA by ATP citrate lyase. The rate-limiting reaction of fatty acid synthesis is the carboxylation of acetyl-CoA to form malonyl CoA, which is catalyzed by acetyl-CoA carboxylase (ACC). Malonyl CoA is a potent inhibitor of fatty acid oxidation. ACC is allosterically regulated by citrate to

form active enzyme polymers, which are depolymerized by the end product of fatty acid synthesis: long-chain fatty acids. Growth factors positively control ACC dephosphorylation. Catecholamines, on the other hand, result in the phosphorylation and inhibition of ACC via PKA. Fatty acids are synthesized in the cytoplasm by a multifunctional enzyme, fatty acid synthase (FAS). Two of these functional domains are the acyl carrier protein and the condensing enzyme (CE). After completion of the different rounds of synthesis, the palmitoyl group is transferred to CoASH. In macrophages, lipopolysaccharide (LPS) activates lipogenesis through activation of sterol regulatory element-binding protein (SREBP), a key transcriptional mediator of cholesterol and fatty acid synthesis.

Fatty Acid Oxidation

Fatty acids are “charged” before oxidation to form acyl-SCoA, a cytoplasmic reaction catalyzed by the enzyme fatty acyl-CoA synthetase. Fatty acid β -oxidation, however, occurs in the mitochondrial matrix and charged fatty acids must first be conjugated to carnitine in order to cross the mitochondrial membrane. This transport is carried out by the carnitine acyltransferases I and II. These enzymes constitute a rate-limiting step for β -oxidation of fatty acids and are allosterically regulated by malonyl CoA, allowing the cell to avoid a futile cycle of fatty acid synthesis and breakdown. Inside the mitochondria, acyl-CoA undergoes a cycle of reactions removing acetyl-CoA from the main chain. This acetyl-CoA is then processed through the TCA cycle.

Cholesterol

Cholesterol is an important component of cellular membranes and a substrate for the production of steroid hormones. Free cholesterol is tightly controlled in cells through synthesis, storage, and transport. Excess cholesterol in cells is secreted through reverse cholesterol transport or stored in the cytoplasm as cholesterol ester, produced by Acy-CoA:cholesterol acyltransferase located in the endoplasmic reticulum. Cholesterol is transported in the plasma by lipoproteins including chylomicrons and very low-density lipoprotein (VLDL). The main sources of cellular cholesterol for hematopoietic cells are the cholesterol-rich lipoprotein, low-density lipoprotein (LDL), and de novo synthesis from acetyl-CoA. The rate-limiting step for cholesterol synthesis is catalyzed by HMG-CoA reductase, the direct target of cholesterol-lowering statin drugs, and converts hydroxymethylglutaryl CoA to mevalonic acid. Cellular cholesterol levels are sensed in the endoplasmic reticulum through the SREBP transcription factor, which directly controls most of the enzymes in cholesterol synthesis as well as LDL transport. Excess of LDL becomes oxidized and taken by macrophages, a main cause of atherosclerosis. The SREBP pathway is also important for T-cell activation under antigenic challenge, as its activation favors cholesterol synthesis and transport, which is used for membrane biogenesis and cell proliferation in the activated T cell.

Amino Acid Metabolism

The major sources of amino acids derive from the diet or protein breakdown. Nonessential amino acids are synthesized from carbon skeletons using different metabolic pathways. Amino acids conjugated to tRNA are used in protein synthesis; however, in excess they can be used for energy production. In addition, amino acids are necessary for the synthesis of other compounds. For example, tryptophan catabolism constitutes a route for de novo NAD⁺ synthesis in a pathway that is important in leukocytes for the replenishment of NAD⁺ levels after oxidative stress. Interestingly, different metabolites derived from tryptophan catabolism via the kynurenine pathway play a role in immune tolerance. Plasma amino acids are transported in cells against a concentration gradient. Amino acid transporters are specific for neutral (small and larger), basic, and acidic amino acids.

Depending on the cell type and specific state (growth, hypoxia, fasting, and so on) intracellular amino acids are used in anabolic or catabolic pathways.

Most of the regulation of amino acid metabolism is achieved through substrate fluxes affecting specific enzyme kinetics. However, there are two major regulatory pathways that involve amino acid sensing mechanisms and metabolic control. (1) General control nonrepressed 2 (GCN2) is a protein kinase that senses amino acid deficiency through direct binding to uncharged tRNA. GCN2 controls the transcription factor ATF4, affecting different enzymes of amino acid metabolism. (2) mTOR is a protein kinase activated in response to increased amino acid concentrations (particularly branch chain amino acids). mTOR controls many aspects involved in protein synthesis, inhibition of protein degradation, and amino acid biosynthetic enzymes. The high asparagine requirement of certain acute lymphoblastic leukemias has resulted in the use of asparaginase to deplete circulating levels of asparagine. Limited amounts of asparagine result in activation of GCN2 in leukemic cells, and reduce their proliferation and viability rates.

Biosynthesis of Nonessential Amino Acids

Nonessential amino acids are synthesized by most of the cells, including hematopoietic lineages. Nonessential amino acids are mainly synthesized from glucose (alanine, arginine [from the urea cycle in hepatic cells], asparagine, aspartate, cysteine, glutamate, glutamine, glycine, proline, and serine), except for tyrosine, which is synthesized from phenylalanine. The rest of the nine amino acids are essential and the body needs to obtain these from the diet. Serine, glycine, and cysteine are synthesized from glycolytic intermediates. Serine synthesis has recently been found to be increased and necessary in stem cells. For some hematopoietic cells, the synthesis of cysteine and glycine is of elevated importance owing to their use in the synthesis of the tripeptide glutathione. Aspartate and asparagines are synthesized by transamination of oxaloacetate by glutamate and amide transfer from glutamine, respectively. Glutamate, glutamine, proline, and arginine are formed from the TCA cycle intermediate α -ketoglutarate.

Amino Acid Catabolism

Two central reactions in amino acid catabolism are the generation of ammonia through transamination (catalyzed by amino transferases) and oxidative deamination (catalyzed by glutamate dehydrogenase) in which the α -amino group of the different amino acids is transferred to α -ketoglutarate to form glutamate, which undergoes the release of free NH_3 . Free ammonium is added to glutamate to generate glutamine, which is then exported into the circulation to the liver, where it then enters the urea cycle. The urea cycle only occurs in the liver and has two purposes: (1) to get rid of free ammonium; and (2) to supply arginine. Interestingly, one of the enzymes of the urea cycle, arginase (which converts arginine to ornithine) is expressed in immune cells. Myeloid cell arginase depletes arginine and suppresses T-cell immune response, and is an important mechanism of inflammation associated with immunosuppression. Arginase is viewed as a promising strategy in the treatment of cancer and autoimmunity. Arginine is also essential for the differentiation and proliferation of erythrocytes.

Nucleotide Metabolism

Nucleotides are involved in a diverse array of cellular functions including (1) energy metabolism (ATP, NAD^+ , NADP^+ , and FAD^+ and their corresponding reduced forms); (2) units of nucleic acids (NTPs are substrates for RNA and DNA polymerases); and (3) physiologic mediators such as adenosine, ADP (which is critical in platelet aggregation), cAMP and cGMP (second messenger molecules), and GTP (which participates in signal transduction via GTP-binding proteins).

Most of the regulatory pathways that are associated with nucleotide synthesis and degradation are strictly controlled by regulatory components of the cell cycle machinery. The amount of intracellular nucleotides has to reach certain levels in order for the cell to proceed through the S-phase checkpoint. In addition, several of the key cell cycle regulators, including the c-myc oncogene (which is translocated in certain myelomas), directly increase the expression of most of the key enzymes associated with nucleotide synthesis.

Nucleotide Synthesis

There are two pathways for the synthesis of nucleotides, salvage and de novo. The salvage pathway uses free bases via a reaction with phosphoribosyl pyrophosphate (PRPP) and generation of nucleotides. De novo pathways synthesize pyrimidines and purine nucleotides from amino acids, carbon dioxide, folate derivatives, and PRPP. Importantly, both salvage and de novo pathways depend on PRPP, which is produced from ATP and ribose-5-phosphate (generated in the pentose phosphate pathway) by PRPP synthetase, an enzyme that is inhibited by metabolic markers of low-energy AMP, ADP, and GDP to avoid nucleotide synthesis in these conditions. In general, PRPP levels are low in postmitotic cells but high in proliferating cells. Folate is essential in nucleotide biosynthesis, and lack of folate in the diet can lead to anemia due to inhibition of proliferation of red blood cell precursors.

Nucleotide Degradation

Nucleotidases and nucleosidases initially participate in purine nucleotide degradation. For example, adenosine is deaminated to produce inosine, which, after ribose is removed, generates hypoxanthine, which is used by xanthine oxidase to form uric acid. Immune cells have potent nucleotide salvage pathways, and a lack of adenosine deaminase causes severe combined immune deficiency (SCID) syndrome. SCID is associated with a large accumulation of dATP in immune cells, which, through a negative-feedback mechanism on ribonucleotide reductase, blocks production of dNTPs and results in a failure to replicate DNA.

Introduction to Metabolomics

Analytical measurements of blood metabolites such as glucose, urea, and cholesterol is part of clinical biochemistry to track diseases. Along these lines and facing the new era of personalized medicine emerges metabolomics, which evaluates metabolism with a comprehensive and quantitative analysis of all metabolites, as well as its impact on cell biology, and aims to discover novel biomarkers or targets for therapy. Recent technical innovations in mass spectrometry and nuclear magnetic resonance (NMR) have allowed the measurement of many metabolites simultaneously. These advances, in combination with metabolite flux analysis with isotopic tracers, have provided new information on many metabolic processes. The use of metabolomics also offers a tool to identify metabolic enzymes as drug targets, as they are poised for inhibition with small-molecule drugs and possess allosteric sites that can be utilized to alter catalytic activity.

A major effort in metabolomics has been the identification of biomarkers for diseases and therapeutic targets. As an example, metabolomics was used to analyze plasma from diabetic patients showing increases in branch chain amino acids before hyperglycemia. Another example comes from the combination of genome-wide sequencing analysis and metabolomics: sequence analysis of acute myeloid leukemias was able to identify IDH1 or IDH2 mutations in 20% of patients. Metabolomics analysis revealed accumulation of a noncanonical metabolite, 2-hydroxyglutarate, which promotes the tumorigenic process (see following discussion). In general, there are two different metabolomic approaches: targeted, which measures

Fig. 7.4 METABOLITE PROFILING UPON T-CELL ACTIVATION. Metabolomic analysis has revealed that glycolytic fluxes and glutaminolysis are increased during activation of T cells. Polyamines that are required for T-cell proliferation are synthesized from glutamine. See text for further details. *TCA*, Tricarboxylic acid.

known and specific metabolites; and nontargeted, which includes analytical measurements of unknown metabolites.

Metabolomics of Glucose Metabolism

Systematic and simultaneous quantitative targeted polar metabolite analysis of glucose metabolic pathways using metabolomic and flux measurement techniques has introduced new basic and clinically relevant information in hematology (Fig. 7.4). For example, increases in glucose metabolism signatures measuring serum metabolite linked to glycolysis and the TCA cycle have been correlated with a prognostic risk score in AML patients.

Metabolic reprogramming or switches are crucial for T-cell activation. Quiescent naive T cells obtain most of their ATP from mitochondrial oxidative phosphorylation for energy, whereas activated T cells switch to glycolytic, glutaminolysis, and anabolic metabolism to promote clonal expansion that appears to be dependent on the transcription factor Myc. Moreover, metabolomic signatures have revealed that Th1, Th2, and Th17 cell lineages and T effectors exhibit an increased glycolytic metabolism. However, regulatory T cells and CD8⁺ memory T cells depend more on mitochondrial oxidative phosphorylation. In addition, T cells are exposed to different nutrient environments, from high nutrient levels in the lymphoid organs to a more restricted nutrient availability in the effector sites such as tumors or infection. Under these conditions metabolic reprogramming through mTOR and AMP kinases control and maintain survival and immune function of T cells.

Metabolomics of Lipid Metabolism

Nonpolar metabolomics has provided metabolite profiles linked to lipid metabolism. In the case of fatty acids, de novo fatty acid

synthesis is necessary for differentiation of T helper 17. Bioactive lipids have also been profiled in different types of blood cells. For example, sphingosine-1-phosphate is stored in erythrocytes, and is found highly elevated in the blood of sickle cell disease patients owing to increased erythrocyte sphingosine kinase 1.

Metabolomics of Nucleotide Metabolism

Measurements of the different polar metabolites in nucleotide metabolism are linked to particular stages of cell growth. For example, unbiased metabolomics has identified that pyrimidine starvation is a mechanism for specific types of cell death in multiple myeloma cells.

Metabolomics of Amino Acid Metabolism

Metabolomic studies have revealed that activated T cells reprogram their metabolism from fatty acid and pyruvate oxidation, and the TCA cycle, to aerobic glycolysis, the PPP, and glutaminolysis, and metabolic fingerprint similar to tumor cells. In particular, glutamine is used to increase polyamine biosynthesis, which is essential for T-cell proliferation, a process controlled by the transcription factor Myc.

SUMMARY AND PERSPECTIVES

This short review summarizes the central signaling and metabolic pathways that play a pivotal role in all the processes executed by hematopoietic cellular systems. In normal physiologic conditions these pathways are regulated and operating to achieve homeostatic cellular functions in healthy individuals. In pathologic conditions, however, dysregulation or failure of these pathways leads to diseases of lymphohematopoietic tissues. To a large extent, the main components and regulatory circuitries of these pathways have been elucidated, but the challenge for the future is to fully integrate them and identify therapeutic targets that will enable the development of effective treatments for these diseases. New technologies in metabolomics are promising for the identification of biomarkers that can be used in personalized medicine, as well as new therapeutic targets including metabolic enzymes.

PHARMACOGENOMICS AND HEMATOLOGIC DISEASES

Leo Kager and William E. Evans

A fundamental hypothesis pursued in genetics is that heritable genetic variation (i.e., genotypes or haplotypes) translates into inherited phenotypes (e.g., disease risk, drug response). On the basis of this hypothesis, one aim of medical genetics and pharmacogenomics is to understand the myriad associations between inherited genotypes and specific phenotypes of disease or drug response, with the ultimate goal of better defining the risk for, or outcome of, diseases and the response to specific medications. In cancer, disease prognosis and treatment response can be affected by both inherited (germline) and acquired (somatic) genome variation, and both types of genome variation have been shown to alter the effects of certain medications. Many seminal discoveries in medical genetics were made in the course of investigating hematologic disorders, as exemplified by the fact that the most prevalent monogenic disorders, the hemoglobinopathies, affect approximately 7% of the world's population. Pharmacogenomics also has a long tradition in hematology; one of the first documented clinical observations of inherited differences in drug effects was the relationship between hemolysis after antimalarial therapy and the inherited glucose-6-phosphate dehydrogenase (G6PD) activity in erythrocytes.¹

In the pregenomic era, efforts concentrated on mapping highly penetrant monogenic (Mendelian) loci for both specific diseases and drug-metabolizing pathways that influence the effects of medications. Completion of the Human Genome Project and the development of arrays for genome-wide single-nucleotide polymorphism (SNP) and DNA methylation analyses, “next-generation” DNA sequencing technologies (whole-exome sequencing [coding regions only] and whole-genome sequencing [coding and noncoding regions]) have enabled relatively inexpensive and essentially agnostic genome-wide approaches to identify genomic variants that predispose to diseases and/or modify drug responses and/or contribute to heterogeneity of monogenic disorders and complex diseases that are polygenic in nature.² In addition to genome sequence variation, epigenetic differences are increasingly recognized as important for the development of diseases and contribute to differences in the pharmacologic effects of many medications, referred to as *pharmacoepigonomics*.³ This chapter provides a brief overview of pharmacogenomics and pharmacoepigonomics, using selected examples to illustrate its current and potential impact on the treatment of hematologic diseases.

VARIATION IN THE HUMAN GENOME

The genome-wide systematic identification of heritable (i.e., germline) and acquired (i.e., somatic) variants, and the functional analysis of genes, their variants, their expression, and their related products (i.e., proteins) have revolutionized the study of many diseases, the development of new medications, and the optimization of drug therapy. Genomics increasingly enable clinicians to make intelligent and reliable assessments of a person's risk for acquiring a particular disease, to identify drug targets, and to explain interindividual differences in the effectiveness and toxicity of medications.²

The Human Genome Project and subsequent projects such as the International HapMap Project, the 1000 Genomes Project, and the ENCODE Project have unveiled many types of variations within the 3 billion base pairs (bp) of the human haploid genome (Table 8.1); the spectrum ranges from single-base-pair differences to large chromosome events. Variations encompass SNPs, insertions or deletions of chromosomal DNA, and structural variants (SVs; genomic

rearrangements that affect >50 bp of sequence). Comparisons among human genomes showed that they differ more as a consequence of structural variation than as a result of single-nucleotide variation. For practical purposes, the term *sequence variation* is mainly used herein. *Polymorphisms* are defined as common inherited variations in DNA sequence that are typically, although somewhat arbitrarily, defined as the least common allele having a frequency of 1% or more in the population.

SINGLE-NUCLEOTIDE POLYMORPHISMS

The most common and important inherited sequence variations are SNPs, positions in the genome where individuals have inherited a nucleotide that differs from the most common sequence (“wild-type”) at the position in the genome. Many efforts are underway to catalogue these variants, because a comprehensive SNP catalog offers the possibility to pinpoint important variants in which nucleotide changes alter the function or expression of a gene that influences diseases or response to medications. The main public database is the “Database of Short Genetic Variations” (dbSNP; a repository of genetic variations less than 50 bp in length) and a growing number of SNPs (currently about 88 million validated) has recently been driven largely by the International HapMap Project and the 1000 Genomes Project (see Table 8.1).

SINGLE-NUCLEOTIDE POLYMORPHISMS AND PHENOTYPES

SNPs are present in exons, introns, promoters, enhancers, and intergenic regions. To elucidate the relationship between SNPs and phenotypes of interest, initial efforts have concentrated mainly on SNPs that are likely to alter the function or expression of a gene. However, only a small portion of the identified SNPs lie within coding regions; only about half of those SNPs cause amino acid changes in expressed proteins, and only a subset of those alter the function of the encoded protein (“damaging SNPs”). SNPs that cause amino acid changes are referred to as *nonsynonymous SNPs* (nsSNPs), and are the main sequence variants underlying most of the highly penetrant inherited monogenic diseases currently known, such as hemoglobinopathies. The likelihood that nsSNPs will result in disease or functional changes in drug metabolism or transport depends on the localization and nature of the amino acid change within the encoded protein; software algorithms have been developed to “predict” whether a certain amino acid change is likely to have a major or minor effect on protein function (i.e., “damaging” versus “non-damaging”).

Although it is intuitively obvious that amino acid substitutions have the potential to change the function of a protein, gene expression also can be affected by SNPs positioned in regulatory sequences or intronic regions. For example, a “silent” or synonymous SNP has been identified that affects protein folding and function of an important drug transporter, namely ATP-binding cassette transporter ABCB1, and this variant has the potential to influence the intracellular accumulation of drugs that are substrates for ABCB1 (a transporter out of cells).⁴ Moreover, SNPs in the promoter region can alter the regulatory promoter function and the gene's expression, thereby influencing drug effects. Using a genome-wide association study (GWAS), the rs924607 TT polymorphism in the promoter

region of the gene encoding a centrosomal protein 72 kD (*CEP72*) was recently found to be significantly associated with vincristine-induced peripheral neuropathy in children with acute lymphoblastic leukemia (ALL), and in vitro experiments have shown that the *CEP72* promoter rs924607 TT polymorphism creates a binding site for a transcriptional repressor leading to lower expression of *CEP72* mRNA and increased sensitivity of neurons and ALL cells to vincristine.⁵

In addition, diverse classes of small to long noncoding RNAs (ncRNAs) have emerged as important regulators of gene expression and genome stability. For example, micro-RNAs (miRNAs) are small (19- to 22-nucleotide-long), single-stranded RNA molecules that can influence cellular mRNA levels or impair translation after binding to miRNA binding sites at the target gene's 3'-untranslated region. SNPs in miRNA binding sites or in the sequence encoding miRNAs have the potential to alter binding and function of miRNAs, respectively. Indeed, a so-called miRSNP, which is defined as a functional SNP that can interfere with miRNA function, had been reported to affect the expression of the antifolate target dihydrofolate reductase, thereby influencing antifolate pharmacodynamics.⁶

Collectively, these examples demonstrate that SNPs in functionally different genomic regions can influence drug disposition and response.

HAPLOTYPES, LINKAGE DISEQUILIBRIUM, AND HAPMAP

Combinations of SNPs are commonly inherited together in the same region of DNA, forming haplotypes. Genome-wide haplotypes can be constructed by linkage disequilibrium (LD) analysis. LD analysis is a statistical measure of the extent to which particular alleles or SNPs at two loci are associated with each other in the population, and LD occurs when haplotype combinations of alleles or SNPs at different loci occur more frequently than would be expected from random association. SNPs and alleles of interest are presumably inherited together if they are physically close to each other (usually <50 kilobases [kb]), producing strong LD. Therefore SNPs that are in LD with a disease phenotype or response-to-drug phenotype can *mark* the position on the chromosome where a susceptibility gene is located, even though the SNP itself may not be the cause of the phenotype.

By studying millions of SNPs in hundreds of individuals from geographically diverse populations, the international HapMap consortium created genome-wide maps of haplotypes (see Table 8.1). The HapMap project has revealed a block-like structure of LD, as well as the existence of areas of low or high recombination rate, and

this has helped to identify so-called tagging (tag) SNPs. Such tagging SNPs can be used to predict with high probability the alleles at other co-segregating “tagged” SNPs, and the number of identified tag SNPs varies considerably among populations of different ancestry. Of note, common SNPs are also in LD with other common variants in the human genome (e.g., structural variants [SVs]).

STRUCTURAL GENOMIC VARIANTS

SVs are balanced or unbalanced changes in DNA content, and encompass alterations ranging from submicroscopic sequence variants greater than 50 bp to larger, sometimes cytogenetically visible, variants. Unbalanced DNA alterations that change the number of base pairs in comparison with a reference genome are as frequent as or even more common than SNPs, and include copy number variants (CNVs) or smaller insertions/deletions (indels). Balanced variations such as inversions and translocations are less common. Many efforts focus on the identification, validation, and mapping of these variants, and the major catalogs are the Database of Genomic Variants (DGV) and the Database of Genomic Structural Variation (dbVAR; see Table 8.1). CNVs are found in a wide spectrum of genomic regions; therefore, many pharmacologically relevant genes can be affected by these variants. Indeed, CNVs have been described to influence activity of some of the most important drug-metabolizing enzymes, such as cytochrome P450 enzymes and glutathione S-transferases.⁷

SOMATIC GENOMIC VARIANTS

Genomic instability is a hallmark of cancer cells. Nonrandom genetic abnormalities, including aneuploidy (gains and losses of whole chromosomes) and structural rearrangements that often result in the expression of chimeric fusion genes (e.g., *BCR-ABL1*), can be found in the majority of hematologic malignancies. These acquired (somatic) genomic variations can differ significantly from inherited (germline) genomic variations and can, for example, create allele-specific copy number differences between normal host cells and cancer cells. Such differences can have pharmacologically relevant consequences. Indeed, it was shown that the cellular acquisition of additional chromosomes in leukemia cells—for example, the gain of additional chromosomes 21 in hyperdiploid ALL (>50 chromosomes)—can cause discordance between germline genotypes and leukemia cell phenotypes, which are important when these discordant genotypes/phenotypes influence the disposition of antileukemic agents. Moreover, somatic deletions of genes encoding proteins that regulate the stability of the DNA mismatch repair enzyme mutS Homolog 2 (MSH2) have been identified in approximately 11% of children with newly diagnosed ALL. These deletions in ALL cells have been shown to cause DNA mismatch repair deficiency and increased resistance to thiopurines, representing another genomic mechanism by which leukemia cells can acquire MSH2 deficiency and mercaptopurine (MP) resistance.⁸

CATALOGUES OF GENOMIC VARIANTS, GENOTYPING PLATFORMS, AND GENOME-WIDE ASSOCIATION STUDIES

Cataloguing the pattern of genome variation in diverse populations is fundamental in understanding areas of human phenotypic diversity such as interindividual and interethnic differences in drug responses; increasingly detailed maps of human genomic variation are provided in public databases (see Table 8.1). Information from these maps has been used to design high-throughput genotyping platforms (e.g., SNP chips), thereby providing tools to interrogate the relationship between genetic variation across the human genome and important phenotypes such as disease or response to medications in a relatively unbiased (agnostic) fashion.²

SNP catalogues have been used in GWASs to pinpoint genes important to diseases and drug responses, and in the past few years more than 2000 robust associations with more than 300 complex diseases and traits have been identified.⁹

Variation in the Human Epigenome

Epigenetics encompasses inherited and acquired changes in gene function that cannot be explained by alterations in sequence of nucleic acids. The epigenome is a complex layer of regulatory information that is superimposed on the genome (*epigenetics* literally means “above genetics”), with major mechanisms that contribute to epigenetic variation including DNA methylation, DNA hydroxymethylation, and various histone modifications such as histone acetylation and methylation. As in medical genetics, many seminal discoveries in medical epigenetics were made during investigations of hematologic diseases, and the myelodysplastic syndrome is considered a prototypical example of an epigenetic disease. In contrast to stable sequence variants, the epigenetic cellular state is principally malleable and can be influenced by environmental factors such as diet and toxin exposure. Of note, the expression of genes that encode important drug-metabolizing enzymes (e.g., cytochrome P450) and drug transporters (e.g., solute carrier family) have been shown to be altered via intrinsic and extrinsic factors that modify the epigenetic signature, thereby influencing the disposition and effects of drugs.³ Moreover, the dynamic nature of epigenetics provides a mechanism to modulate the expression of genes that influence drug sensitivity, and so-called “epidrugs” (i.e., drugs that influence gene expression via epigenetic mechanisms) have already been successfully incorporated into the treatment of hematologic diseases (e.g., hypomethylating agents such as decitabine and vidaza for myelodysplastic syndrome, and histone deacetylase inhibitors such as vorinostat and romidepsin for cutaneous T-cell lymphomas).³

Major efforts are ongoing to generate detailed epigenomic maps to provide a basis for understanding cellular processes, the pathogenesis of diseases, and alterations in drug responses, such as the Encyclopedia of DNA Elements (ENCODE) and the Epigenomics Roadmap (see Table 8.1).

GENETIC VARIATIONS INFLUENCING DRUG RESPONSE: PHARMACOGENETICS–PHARMACOGENOMICS–PHARMACOEPIGENOMICS

Pharmacogenomics is a major element of the recently announced U.S. President’s Precision Medicine initiative. Mostly empiric approaches are used to select drug therapy for most patients and most diseases, despite the fact that there is great heterogeneity in the way people respond to medications, in terms of both host toxicity and treatment efficacy. Unfortunately, for almost all medications, interindividual differences are the rule, not the exception, and these differences result from the interplay of many variables, including genetics and environment. Variables influencing drug response include pathogenesis and severity of the underlying disease being treated; drug interactions; the patient’s age, sex, nutritional status, and renal and liver function; the presence of concomitant illnesses; and other components of treatment. In addition to these clinical variables, both inherited and acquired (e.g., somatic mutations in cancers) genome variation can influence the disposition and effects of medications, including many used to treat hematologic diseases. Clinical observations of inherited differences in drug effects (based on family studies and twin studies) were first documented in the 1950s, and the concept of pharmacogenetics was defined initially in 1959 by Friedrich Vogel as “the study of the role of genetics in drug response.” The number of recognized clinically important pharmacogenetic traits grew steadily in the 1970s; the elucidation of the molecular genetics underlying these traits began in the late 1980s and 1990s, with their translation to molecular diagnostics to guide drug therapy being well underway in the 2000s. The study of pharmacogenetics began with the

analysis of genetic variations in drug-metabolizing enzymes and how those variations translate into inherited differences in drug effects. Subsequently, the field has incorporated genome-wide approaches to identify networks of genes that govern the clinical response to drug therapy (i.e., pharmacogenomics). The terms *pharmacogenetics* and *pharmacogenomics*, however, are generally considered to be synonymous for all practical purposes. With the recognition that epigenetic modification affects gene expression and can contribute to variability in drug effects, the field of pharmacoeigenomics has gained additional attention and importance.

Overall, pharmacogenomics can be viewed as a broad strategy to establish models of drug disposition and effects by integrating information from genome sequencing, functional genomics, high-throughput molecular analyses, pharmacokinetics (e.g., drug metabolism and disposition), and pharmacodynamics (treatment response). Approaches to establish pharmacogenomic models include candidate gene analyses (which focus on the analysis of single genes or sets of functionally related genes in pathways thought to be important for the medicine under study) and more agnostic genome-wide analyses. Pharmacogenomic models can be used to maximize efficacy and reduce toxicity of existing medications, as well as to identify novel therapeutic targets.

Comprehensive reviews on pharmacogenomics and epigenomics are available elsewhere.^{1–3,6,7} Herein, clinically relevant examples are provided to illustrate the potential of pharmacogenomics and epigenomics to improve current drug therapy for hematologic disorders, to prevent hematologic toxicity, and perhaps to identify novel targets for developing new therapeutic approaches in hematology.

OPTIMIZATION OF DRUG THERAPY

Drug effects are typically determined by the interplay of several gene products that influence the pharmacokinetics and pharmacodynamics of medications. Pharmacokinetics entails characterization of the absorption, distribution, metabolism, and excretion (ADME) of medications. Pharmacodynamics is the relationship between the pharmacokinetic properties of drugs and their pharmacologic effects, either desired or adverse. The ultimate goals of pharmacogenomics and pharmacoeigenomics in this context are to elucidate the inherited determinants for drug disposition and response to select medications and dosages on the basis of each patient's inherited ability to metabolize, eliminate, and respond to specific drugs. A model of how polygenic variables can determine drug response is illustrated in Fig. 8.1.

GENETIC VARIATIONS THAT INFLUENCE DRUG DISPOSITION

Drug Metabolism

There are many enzymes involved in drug metabolism, which are often categorized into phase I reactions that involve oxidation, reduction, or hydrolysis of medications, and phase II enzymes that conjugate drugs via acetylation, glucuronidation, sulfation, or methylation. Although phase I metabolism often inactivates medications, this is not always the case, as exemplified by codeine's activation by cytochrome P450 CYP2D6 and clopidogrel's activation via CYP2C19. Phase II conjugation generally makes medications more water soluble and therefore more readily excreted in the urine, but some phase II conjugates have pharmacologic effects. Although the liver is generally considered the major organ for drug metabolism, phase I and phase II metabolic enzymes are found in many other tissues, including the kidney, intestinal tract, lung, brain, spleen, erythrocytes, and lymphocytes.

Essentially all genes encoding drug-metabolizing enzymes with more than 30 families of enzymes in humans exhibit genetic variation, many of which translate into functional changes in the proteins encoded. Inheritance of genes containing sequence variations that

alter the function of enzymes they encode, as well as CNVs or epigenetic signatures that alter the expression of functionally relevant genes, can influence either drug activation or inactivation, and ultimately determine the extent of drug effects. This is most evident when polymorphic genes encode enzymes that are involved in crucial pathways of elimination or activation of the administered medication. It should also be recognized that genetic polymorphism in genes that encode the protein targets of medications (e.g., VKORC1, the target of warfarin) can also have a significant influence on drug effects.

The focus of this chapter is to provide examples that are relevant to hematologists to illustrate the potential impact of genome variation on the effects of medications. We discuss enzymes involved in inactivation of the antileukemic agent MP, as well as genes encoding the enzyme (CYP2C9) that metabolizes active warfarin and the gene that encodes its target (VKORC1). These examples therefore involve both phase I (CYP2C9) and phase II (thiopurine S-methyltransferase [TPMT]) drug-metabolizing enzymes and the target of the most widely prescribed anticoagulant. Our examples include both inherited genome variations (*CYP2C9*, *TPMT*, *NUDT15*, and *VKORC1*) and somatically acquired genome variants (*NT5C2*) that have been shown to alter drug effects in humans. This is a rapidly evolving component of "precision medicine," thus providing an understanding of their relevance and potential is of greater value than attempting a current and comprehensive literature review.

Thiopurines and Inherited Variants in *TPMT* and *NUDT15*, and Acquired Somatic Variants in *NT5C2*

MP is metabolized by numerous enzymes, either to activate it to thioguanine nucleotides (TGNs) or to inactivate it via methylation or dephosphorylation of TGNs. Although there is genetic polymorphism in enzymes involved in MP activation (e.g., hypoxanthine phosphoribosyltransferase 1 [HPRT1]), there is little evidence that genetic polymorphisms in these enzymes play an important role in controlling the pharmacologic effects of MP, with the exception of patients who inherit HPRT1 deficiency, an X-linked disease that occurs in approximately 1 in 350,000 Caucasian males (Lesch–Nyhan syndrome). In contrast, genetic polymorphisms in two enzymes involved in the inactivation of thiopurines (MP and the MP prodrug azathioprine and thioguanine) increase the accumulation of their active TGNs, thereby increasing the risk of hematopoietic toxicity; *TPMT* and *NUDT15* (nucleoside diphosphate linked moiety X-type motif 15). Inherited variants in *TPMT* were first discovered in the 1990s, with two major inactive variant alleles accounting for the majority of inherited *TPMT* deficiency in major world populations studied to date (*TPMT*3C* [rs1800460] for persons of Asian and African ancestry, and *TPMT*3A* [rs1142345 and rs1800469] for persons of European ancestry). *TPMT*3A*, *TPMT*3C*, and *TPMT*2* (rs1800462) account for more than 95% of the clinically relevant *TPMT* variants; variant *TPMT* alleles encode unstable proteins. Patients who are heterozygous (5% to 10% of persons) are about five times more likely to develop hematologic toxicity, whereas patients who inherit two variant alleles (1 in 300 persons) will all develop hematologic toxicity if treated with conventional doses of thiopurines.¹⁰

It has been recognized for many years that patients of Asian ancestry develop more hematologic toxicity than patients of European or African ancestry, yet the frequency of nonfunctional *TPMT* alleles is lower in Asians. Important new insights were recently provided by the identification of variant alleles of *NUDT15* in South Korean patients with inflammatory bowel disease who developed hematologic toxicity while receiving azathioprine therapy.¹¹ The *NUDT15* variant was very strongly related to thiopurine hematopoietic toxicity. In a GWAS of children with ALL receiving MP therapy, both *TPMT* and *NUDT15* were significantly related to thiopurine intolerance in U.S. children.¹² Together, these studies show that genetic polymorphisms in both of these genes influence thiopurine tolerance, and that *TPMT* variants are more common in patients of European and African

Fig. 8.1 POLYGENIC DETERMINANTS OF DRUG RESPONSE. The potential effects of two genetic variants are illustrated. One genetic variant involves a drug-metabolizing enzyme (*top*), and the second involves a drug receptor (*middle*). Differences in drug clearance (or the AUC) and receptor sensitivity are depicted in patients who are either homozygous for the wild-type allele (WT/WT) or heterozygous for one wild-type and one variant allele (WT/V), or have two variant alleles (V/V) for the two genetic variants. At the *bottom* are shown the nine potential combinations of drug metabolism, drug-receptor genotypes, and the corresponding drug-response phenotypes, which were calculated with data from the *top*. The therapeutic indexes (efficacy-to-toxicity ratios) ranged from 13 (65%:5%) to 0.125 (10%:80%). AUC, Area under the plasma concentration-time curve; V, variant; WT, wild-type. ancestry, whereas *NUDT15* variants are much more common in Asians.¹²

In addition, it was recently discovered that somatic mutations in the *NT5C2* gene (encoding 5'-nucleotidase, cytosolic II) are relatively common in ALL cells at the time of disease relapse, conferring resistance to MP.^{13,14} The mechanisms by which each of these genetic polymorphisms or somatic mutations influence the pharmacologic effects of thiopurine medications and the appropriate dosage adjustments for such patients are discussed in greater detail in the following section.

Inherited Variants in TPMT and NUDT15, and Their Influence on Thiopurine Hematopoietic Toxicity

The prodrugs MP and thioguanine (TG) are among the agents that constitute the backbone of treatment for childhood ALL. Childhood ALL studies have shown that all “homozygous” TPMT-deficient patients experience dose-limiting hematotoxicity, and some

experience life-threatening hematotoxicity if given conventional doses of thiopurines.¹⁰ In TPMT-deficient patients, the thiopurine dose must be reduced to 10% to 15% of the conventional dose to avoid severe hematopoietic toxicity. Although many patients with one nonfunctional TPMT allele can tolerate essentially full doses of thiopurines (dependent on starting dose and other therapy), thiopurine-intolerant heterozygous patients typically require a 30% to 50% dose reduction. Multivariate analyses have demonstrated that children who have ALL and at least one *TPMT*-variant allele tend to respond well to MP therapy (i.e., 75 mg/m² per day), and may experience better leukemia control than is obtained in those who have two wild-type *TPMT* alleles. Most importantly, in the St. Jude Total protocols prospective MP dose adjustments (i.e., reduced doses in heterozygotes) were associated with less toxicity without compromise in treatment efficacy.¹⁰

In children in whom MP dose was adjusted according to *TPMT* genotypes, a sequence variant in inosine triphosphatase (*ITPA*) was

Fig. 8.2 GENETIC POLYMORPHISM OF THIOPURINE METHYLTRANSFERASE AND ITS ROLE IN DETERMINING TOXICITY TO THIOPURINE MEDICATIONS. Under “Genotype/phenotype” (*far left*) are depicted the predominant TPMT mutant alleles that cause autosomal-codominant inheritance of TPMT activity in humans. As shown in the graphs under “Drug dose”, “Systemic exposure”, and “Toxicity”, when uniform (conventional) dosages of thiopurine medications (e.g., azathioprine, MP, thioguanine) are administered to all patients, TPMT-deficient patients accumulate markedly higher (10-fold) cellular concentrations of the active TGNs, and TPMT-heterozygous patients accumulate approximately twofold higher TGN concentrations, which translates into a significantly higher frequency of toxicity (*far right*). As depicted in the bottom row of graphs, when genotype-specific dosages of thiopurines are administered, comparable cellular TGN concentrations are achieved, and all three TPMT phenotypes can be treated without acute toxicity. In the two graphs under “Drug dose”, the *solid* or *striped* portion of each bar depicts the mean MP doses that were tolerated in patients who presented with hematopoietic toxicity; the *stippled* portion depicts the mean dosage tolerated by all patients in each genotype group, not just those patients presenting with toxicity. MP, Mercaptopurine; TGN, thioguanine nucleotide; TPMT, thiopurine S-methyltransferase; *v*, variant; *wt*, wild-type. (Courtesy Evans WE: Thiopurine S-methyltransferase: a genetic polymorphism that affects a small number of drugs in a big way. *Pharmacogenetics* 12:421, 2002.)

identified as a risk factor for febrile neutropenia, illustrating that when treatment is adjusted for the most penetrant genetic polymorphism, less penetrant polymorphisms can emerge as clinically important.¹⁰ TPMT genotypes do not fully explain all variability in MP sensitivity, and “trans” effects of SNPs that affect TPMT activity in patients with wild-type TPMT genotypes have recently been discovered in the protein kinase C and casein kinase substrate in neurons 2 (*PACSIN2*) gene. More importantly, GWAS investigations have identified germline variants in the nucleoside diphosphate-linked moiety X-type motif 15 (*NUDT15*) gene, which predisposed patients to azathioprine-related hematopoietic toxicities during treatment of Crohn disease or MP therapy for ALL: *NUDT15* variants were especially common in East Asians and in Hispanics with high Native American ancestry.^{11,12}

The TPMT genotype is the strongest genetic factor for MP effects in patients of European and African ancestry, and in 2004 the U.S. Food and Drug Administration (FDA) added information about TPMT testing for determining the appropriate dosage of MP. Evidence suggests that TPMT genotyping before initiation of MP treatment can be cost effective in children with ALL. By using the TPMT genotype to individualize thiopurine therapy, clinicians can now diagnose inherited differences in drug response, thereby preventing serious toxicities. Guidelines for TPMT genotype and thiopurine dosing are available from the Clinical Pharmacogenetics Implementation Consortium (CPIC); these guidelines are periodically updated at the Pharmacogenomics Knowledge Base (PharmGKB)¹⁰ (also see Table 8.1, box on Relevance to Clinical Hematology, and Fig. 8.2). There are no consensus guidelines for using *NUDT15* variants to

adjust thiopurine dosages, but they are likely to be forthcoming as these early findings are replicated.

Relevance to Clinical Hematology

MP Dosage Adjustment Based on TPMT Genotypes in Acute Lymphoblastic Leukemia

MP is a mainstay of treatment of childhood ALL. However, conventional doses of this prodrug can induce severe hematotoxicity in patients who have impaired thiopurine metabolism in hematopoietic tissues owing to less stable TPMT enzyme variants. The three major variant alleles (*TPMT*2*, *TPMT*3C*, and *TPMT*3A*) encoding the variant proteins can quickly be determined by commercially available Clinical Laboratories Improvement Act–certified molecular diagnostics or in special laboratories (e.g., Prometheus Labs, CA, USA) using samples obtained from peripheral blood before MP therapy. In patients with two nonfunctional alleles (1 out of 300), MP dosage must be reduced to 10% to 15% of conventional 75 mg/m² per day dosages. Patients with one variant allele (5% to 10% of the population) can tolerate MP at full dosage; however, in intolerant patients, a dose reduction of 50% often is required.¹⁰

Although inherited variants in *NUDT15* are strongly associated with thiopurine intolerance,^{11,12} precise dosage adjustments to avoid toxicity without compromising treatment efficacy based on *NUDT15* genotype have not yet been defined owing to its relatively recent discovery.

Thiopurines and Somatic Variants in *NT5C2*

To explore molecular mechanisms for drug resistance in childhood ALL, two study groups recently sequenced the transcriptomes and whole exomes of diagnostic, remission, and relapse samples from ALL patients.^{13,14} In B-cell precursor (BCP)-ALL up to 10% and in T-ALL up to 19% of the relapse samples had mutations in the *NT5C2* nucleotidase. The *NT5C2* nucleotidase can inactivate the thiopurines MP and TG. Remarkably, six of the identified variants in *NT5C2* increased the enzyme activity of the variant proteins (up to 48-fold), thereby protecting ALL blast cells against thiopurine-induced apoptosis. Of note, no resistance to other antileukemic agents was observed when the variant proteins were expressed in cell lines. Maintenance therapy with the antimetabolites MP and methotrexate is an essential element for successful ALL therapy, and one can speculate that resistance to MP can give rise to early relapse of ALL. Indeed, a significant association of activating *NT5C2* variants and early ALL relapse was found.^{13,14} Novel strategies are necessary to overcome this drug resistance phenotype in the subset of patients with *NT5C2* mutations, and such strategies may help to further improve outcome in ALL by avoiding inappropriate drug levels at the target site (e.g., by using drugs that are not inactivated via *NT5C2* or by design of small molecules that inhibit *NT5C2* function).

Inherited Genome Variants in Cytochrome P450 Enzymes

The cytochrome P450 (CYP) superfamily is a system of phase I enzymes involved in the metabolism of endogenous substances and exogenous compounds (e.g., drugs, environmental chemicals). In humans the CYP enzymes are encoded by more than 57 genes, and the majority of these genes are polymorphic. Updated information regarding the nomenclature and properties of the variant alleles with links to the dbSNP database is available at the human CYP allele website (see Table 8.1).

On the basis of patient genotype (diplotype) CYP variant alleles, individuals are often categorized into one of four major predicted drug metabolism phenotypes: poor metabolizers (having two loss-of-function alleles), intermediate metabolizers (being deficient in one allele), extensive metabolizers (having two copies of functional alleles), and ultrarapid metabolizers (having three or more functional gene copies due to gene duplications, or two increased-activity alleles, or one functional allele plus one increased activity allele).

Different populations of metabolizers have been linked to different types of variants in the coding region of CYP genes (i.e., SNPs that alter the amino acid encoded, thereby altering protein function or stability); SNPs in intronic regions, which can alter CYP gene mRNA expression; CNVs (e.g., gene deletions, gene duplications) of CYP genes; or differences in the methylation at CpG islands in promoter and 5' regions, which alter expression of CYP genes.

Many pharmacologically relevant variants in CYP genes have been identified. The focus here is on the variants in *CYP2C9*, which have been shown to influence the metabolism of an extensively prescribed medication: warfarin.

CYP2C9, *VKORC1*, and Warfarin

In the United States, the oral vitamin K antagonist warfarin is still widely used to prevent thromboembolic events in patients with chronic conditions such as atrial fibrillation, and the drug is prescribed to more than 1 million persons annually. A narrow therapeutic index with a risk for serious hemorrhage and interindividual variability in response to warfarin necessitate individualization of treatment, which has been based primarily on monitoring prothrombin time via international normalized ratio (INR) testing. Compared with the therapeutic INR range (i.e., 2–3), INR greater than 4 is associated with a 25-fold higher risk of bleeding in elderly patients treated with warfarin, and the percentage time in therapeutic range (PTTR) is a widely accepted read-out for treatment effect. Complications

from inappropriate warfarin dosing remain among the most common reasons for hospitalization due to adverse drug reactions.

Pharmacologically, warfarin is a racemic mixture of *R*- and *S*-enantiomers that differ in their patterns of metabolism and in their potency of pharmacologic effects, with *S*-warfarin being more potent. Warfarin dose requirements can be influenced by both modifiable (e.g., compliance, dietary vitamin K intake, therapeutic level surveillance) and nonmodifiable factors (e.g., age, gender, genetics). Candidate gene studies initially demonstrated that the *CYP2C9* genotype influences warfarin clearance, and alters oral anticoagulant dose requirements and bleeding risks. *CYP2C9* is the principal *CYP2C* isoenzyme in the human liver, and it is involved in the oxidative metabolism and inactivation of *S*-warfarin.¹⁵

The two most common *CYP2C9* variants with diminished enzyme activities are *CYP2C9**2 (rs1799853) and *CYP2C9**3 (rs1057910). Approximately 35% of Caucasians have one or two of these variant alleles; the *2 and *3 variants are virtually nonexistent in Africans and Asians (95% express the wild-type genotype [i.e., extensive metabolizers]).

Compared with the wild-type genotype (*CYP2C9**1/*1), patients with two nonfunctional variants have a reduction of enzyme activity to approximately 12% for *CYP2C9**2/*2 and approximately 5% for *CYP2C9**3/*3. Therefore, the required dose of warfarin is lowest in homozygous carriers of the *CYP2C9**3 variant (e.g., dose reduction of about 1.6 mg/day) and intermediate in homozygote carriers of the *CYP2C9**2 variant (e.g., dose reduction of about 1 mg/day).¹⁵

An important finding was the identification of a novel mechanism underlying warfarin resistance—the discovery of sequence variants in the warfarin target gene *VKORC1*, which encodes the vitamin K epoxide reductase complex 1. This complex regenerates reduced vitamin K for another cycle of catalysis, which is essential for the posttranslational γ -carboxylation of vitamin K–dependent clotting factors. A common noncoding variant (–1639G>A, rs9923231) was shown to be significantly associated with warfarin dose requirements. Patients with the –1639 AA genotype require lower initial warfarin doses (e.g., dose reduction of up to 3 mg/day) when compared with individuals with the –1639 GG variant. As the –1639G>A polymorphism affects a *VKORC1* transcription factor binding site, the functional effect of the variant is thought to be related to decreased *VKORC1* transcription, leading to lower protein expression. There are major differences in the distribution of *VKORC1* haplotypes among ethnic groups, and this may explain interethnic differences in coumarin requirement.¹⁵ GWAS in patients treated with warfarin showed two major signals in and around *VKORC1* and *CYP2C9*, and identified a much weaker association with *CYP4F2*. The *CYP2F4* enzyme catalyzes vitamin K oxidation, and the V433M variant (rs2108622) was identified to require increased warfarin dosing. Overall, *VKORC1* explains approximately 25% of the variance in coumarin dose requirement, *CYP2C9* explains about 15%, and *CYP4F2* explains about 3%.¹⁵

In 2010 the FDA updated the label on warfarin, providing *VKORC1* and *CYP2C9* genotype-specific ranges of doses, and suggested that *VKORC1* and *CYP2C9* genotypes be taken into consideration when the drug is prescribed. Additionally, dosing algorithms are available online (e.g., from the International Warfarin Pharmacogenetics Consortium [IWPC]), including genetic and non-genetic information that can help to optimize the warfarin starting dose (see CPIC Guidelines: Table 8.2).

The results of two large randomized trials, which have prospectively evaluated the benefit of genotype-guided warfarin dosing, have recently been reported. Whereas the European Pharmacogenetics of Anticoagulant Therapy (EU-PACT) trial demonstrated that pharmacogenetic-guided dosing is superior to a fixed-dosing regimen for achieving therapeutic INRs, the U.S. Clarification of Optimal Anticoagulation Through Genetics (COAG) study failed to demonstrate an improvement in PTTR with genotype-guided dosing compared with the algorithm-guided dosing control arm. Potential reasons for the differences include differences in the algorithmic strategies and control arms, as well as ethnic heterogeneity. In summary, the results of these trials and recent metaanalyses indicate

TABLE 8.2 CPIC Recommendations on Medications Whose Adverse Effects Have Been Associated With Variability in Candidate Genes and Manifest Predominantly as Hematologic Abnormalities (see Table 8.1, CPIC website)

Adverse Drug Reaction	Drug(s) That Cause ADR	Important Genetic Variant(s)	CPIC Recommendation
Myelosuppression	6-Mercaptopurine 6-Thioguanine azathioprine	<i>TPMT</i> *2 (rs1800426), *3A (rs1800460 + rs1142345), *3C (rs1142345)	Start with reduced doses for patients with one nonfunctional <i>TPMT</i> allele, or drastically reduced doses for patients with malignancy and two nonfunctional alleles; adjust dose based on degree of myelosuppression and disease-specific guidelines. Consider alternative nonthiopurine immunosuppressant therapy for patients with nonmalignant conditions and two nonfunctional alleles
Bleeding risk	Clopidogrel	<i>CYP2C19</i> *17 (rs12248560)	Recommends an alternative antiplatelet therapy (e.g., prasugrel, ticagrelor) for poor or intermediate <i>CYP2C19</i> metabolizers if there is no contraindication
Myelosuppression (mucositis, neurotoxicity)	5-Fluorouracil (5-FU)	Dihydropyrimidine dehydrogenase: <i>DPYD</i> *2A (rs3918290), *13 (rs55886062), <i>DPYD</i> rs67376798 A (on the positive chromosomal strand)	For fluoropyrimidines (i.e., 5-FU, capecitabine, or tegafur) recommends an alternative drug for patients who are homozygous for <i>DPYD</i> nonfunctional variants, as these patients are typically DPD deficient. Consider a 50% reduction in starting dose for heterozygous patients (intermediate activity)
Bleeding risk	Warfarin and other coumarin derivatives	<i>CYP2C9</i> *2 (rs1799853), <i>CYP2C9</i> *3 (rs1057910), <i>VCORC1</i> (rs9923231)	The best way to estimate the anticipated stable dose of warfarin is to use the algorithms available on http://www.warfarindosing.org
Acute hemolytic anemia	Rasburicase and other drugs (see Ref. 20 and 21 for a full list of drugs)	Deficient or deficient with chronic nonspherocytic hemolytic anemia (CNSHA). A male carrying a class I, II, or III allele, a female carrying two deficient class I–III alleles (see text for more details)	Rasburicase is contraindicated in G6PD-deficient patients with or without CNSHA. In patients with a negative or inconclusive genetic test results an enzyme activity test is recommended prior to rasburicase treatment to determine whether a patient is G6PD deficient

that pharmacogenetic-guided warfarin dosing is more accurate than standard fixed, but not algorithm-guided, dosing. Neither the EU-PACT nor the COAG trial were powered for clinically relevant endpoints, such as bleeding and thromboembolic events, and the currently ongoing randomized Genetics Informatics Trial (GIFT) of Warfarin to Prevent Deep Venous Thrombosis will assess the clinical outcome benefit of pharmacogenetic-guided warfarin dosing.¹⁵

Alternative anticoagulants (e.g., dabigatran, apixaban, rivaroxaban, and edoxaban) have been developed; for example, the dosing of dabigatran, which acts as a direct thrombin inhibitor, is not influenced by these genetic polymorphisms, which makes this drug a potential alternative for patients in whom heredity is associated with extreme variations in warfarin effects.

DRUG TRANSPORTERS

Although passive diffusion is thought to account for tissue distribution of some drugs and their metabolites, there is a growing body of evidence that membrane transporters play an important role in drug disposition and effects. Membrane transporters are highly expressed in epithelial cells, and move drugs and other xenobiotics across the gastrointestinal (GI) tract into systemic circulation and across hepatic and renal tissue into the bile and urine, respectively, for excretion. They also distribute drugs into and out of “therapeutic sanctuaries” such as the brain and testes, and transport them into and out of sites of action, such as leukemia cells.

The two multi-specific drug transporter superfamilies encompass the adenosine triphosphate (ATP)-binding cassette (ABC) and the solute carrier (SLC) transporters.¹⁶ Whereas SLC transporters largely, but not exclusively, mediate cellular uptake, the ABC drug transporters mainly efflux substrates from cells. The function, substrate specificity, and organ distribution among different transporters vary

and comprehensive drug transporter databases are available elsewhere (see Table 8.1). There is also a growing body of data on the endogenous functions (e.g., transport of metabolites, antioxidants, signaling molecules, and hormones) of ATP and SLC transporters, and a number of hematologic diseases were identified to be caused by variants in these transporters (e.g., variants in *SLC19A2* in thiamine-responsive megaloblastic anemia, variants in *SLC11A2* in sideroblastic anemia, variants in *SLC4A1* in hereditary spherocytosis type 4 and southeast Asian ovalocytosis, and variants in *ABCG5* and *ABCG8* in mitochondrialopathies with large platelets and ovalocytes). Herein we provide one selected example on how variants in a drug transporter (i.e., *SLCO1B1*) have been identified to influence the disposition and toxicity of the antileukemic drug methotrexate (MTX).

SLCO1B1 and Methotrexate

The solute carrier organic anion-transporter family member 1B1 (*SLCO1B1*) gene, for example, encodes an organic anion transporter 1B1 (OATP1B1) that is located primarily on the sinusoidal face of human hepatocytes. OATP1B1 mediates the hepatic uptake of many endogenous compounds (e.g., bilirubin) and xenobiotics such as HMG-CoA reductase inhibitors (e.g., simvastatin) from sinusoidal blood, resulting in their net excretion from blood, likely via biliary excretion. A common sequence variant in the coding region of *SLCO1B1* (rs4149056) decreases the transport activity of the encoded protein and results in markedly increased plasma concentrations of drugs that are eliminated from the blood via hepatic uptake. Using GWAS, correlations have been established between variants in *SLCO1B1* and myopathy after treatment with the HMG-CoA reductase inhibitor simvastatin.⁹

In the field of hematology, a GWAS identified the rs4149056 variant to be significantly associated with MTX clearance and GI

toxicity; this association was robustly confirmed with five different MTX treatment regimens in more than 1000 pediatric ALL patients.¹⁷ Deep sequencing of *SLCO1B1* identified additional rare (minor allele frequency of <1%) “damaging” nsSNPs that had larger effect sizes than the common “damaging” nsSNPs.¹⁸ *SLCO1B1*, however, is associated with hepatobiliary excretion, which is a relatively minor path for MTX elimination (<30%). Therefore, the overall contribution of *SLCO1B1* variants to explaining interindividual variability in MTX pharmacokinetics is approximately 12% to 15%, and the major genetic contributors remain largely unknown.

GENETIC VARIATIONS INFLUENCING DRUG TARGETS

To exert their pharmacologic effects most drugs interact with specific target proteins, such as receptors, enzymes, or proteins involved in signal transduction, cell cycle control, or other cellular events. Molecular studies have revealed that many of the genes encoding these drug targets exhibit genetic variations, which can alter the sensitivity of these targets to specific medications (e.g., *VKORC1* and warfarin effects).

The following section illustrates this, focusing on somatic genetic variants in chronic myeloid leukemia (CML) cells that alter the targets of tyrosine kinase inhibitors (TKIs).

BCR–ABL1 and Tyrosine Kinase Inhibitors

Somatic genome variants caused by major structural variants, such as the t(9;22) chromosomal translocation producing the *BCR–ABL1* fusion gene, are major mechanisms underlying many forms of hematopoietic malignancies. The increased tyrosine kinase activity of the *BCR–ABL1* protein (encoded by the chimeric *BCR–ABL1* or “Philadelphia [Ph] chromosome”) is the driving oncogenic event in the majority of patients with CML and in a subset of patients with ALL (Ph-ALL). This realization resulted in the development of specific TKIs. The treatment of CML was revolutionized with the introduction of the first TKI imatinib, a small-molecular-weight drug that binds to ABL1, thereby leading to inhibition of tyrosine phosphorylation of proteins involved in signal transduction. Imatinib was shown to induce durable remissions in CML patients, which led to a paradigm shift in cancer treatment—that is, a more targeted therapy instead of the nonspecific inhibition of rapidly dividing cells.

Although most patients with CML have a favorable outcome when treated with imatinib, some patients eventually fail on therapy, mainly as a result of acquired point mutations in the target kinase ABL1 that induce drug resistance. Of note, the second-generation TKIs nilotinib and dasatinib can successfully inhibit the majority of these mutation proteins that confer resistance to imatinib. However, one relatively common variant, the T315I or “gatekeeper” variant, confers resistance to all three drugs.¹⁹ To overcome the resistance mechanisms of the T315I variant, ponatinib, which has activity against all known single amino acid *ABL1* mutations including T315I, was designed and successfully tested in clinical trials, and its use was first approved by the FDA in 2012 for patients with CML resistant to other TKIs. However, ponatinib was temporarily suspended in 2013 due to serious vascular adverse events (VAEs; i.e., arterial and venous thromboembolic events, arterial hypertension), and VAEs are now recognized as also limiting the use of second-generation TKIs. Moreover, the strong selective pressure of ponatinib has led to the emergence of TKI resistance due to so-called “compound mutations” in ABL1.¹⁹ Compound mutations are multiple-point variants occurring in the same *BCR–ABL1* allele, and this drug-resistance mechanism is different to the emergence of multiple clones with different mutations. In a recent investigation, computed modeling and in vitro proliferation studies were used to analyze the impact of compound mutations in *BCR–ABL1* on TKI resistance. Molecular dynamic simulations showed, for instance, that the compound mutation Y253H/E255V induced a shift in the

P-loop of the ABL1 kinase, obstructing the ponatinib binding site, resulting in resistance to ponatinib. Moreover, it was found that additional acquisition of an E255V variant in T315I-positive CML confers resistance to ponatinib.¹⁹

As second- and third-generation TKIs have a risk for VAEs, especially in older patients with preexisting vascular disease, TKI selection based on cardiovascular risk factors and mutational *BCR–ABL1* status is of utmost importance to guide CML therapy. Upfront and repeated monitoring of the mutational status of patients with *BCR–ABL1*-positive leukemias can help select appropriate TKIs and tailor TKI treatment, and also has the potential to provide new insights into mechanisms underlying selection of resistant clones during TKI therapy.

ADVERSE DRUG EFFECTS PRESENTING AS HEMATOLOGIC DISORDERS

Adverse drug reactions (ADRs) constitute a major clinical problem, and strong evidence indicates that ADRs account for approximately 5% of all hospital admissions and increase the length of hospitalization by approximately 2 days. Although the factors that determine susceptibility to ADRs are unclear in most cases, there is increasing interest in the role of genetic predisposition to these ADRs; the possibility of a genetic test to identify patients at risk for rare but serious adverse effects would be of great clinical value. Based on the clinical relevance of ADRs, the FDA has provided advice on the use of certain biomarkers (e.g., variants in *TPMT*, *UGT1A1*, *CYP2C9*, *CYP2C19*) to avoid serious adverse drug effects; a full list of these biomarkers is available on the FDA website (see Table 8.1).

CPIC recommendations on medications whose adverse effects have been associated with variability in candidate genes and manifest predominantly as hematologic abnormalities are listed in Table 8.2. In the following section, we provide information on genetic variants in *G6PD* that can cause acute hemolytic anemia (AHA) after administration of certain drugs.

Glucose-6-Phosphate Dehydrogenase Deficiency and Rasburicase

Occurrence of AHA after mass administration of the antimalaria drug primaquine (PQ) was first documented in some U.S. soldiers in Korea. The so-called “PQ sensitivity syndrome” was more common among African Americans, and clinically identical to “favism” (i.e., AHA after ingestion of fava beans). The underlying biochemical (Fig. 8.3) and genetic (variants in *G6PD*) causes of the clinical phenotype (i.e., AHA after PQ and fava beans) were identified, and the disease was named G6PD deficiency.²⁰ The severity of AHA in individuals with G6PD deficiency after treatment with drugs that induce oxidative stress is influenced by host and environmental factors (Fig. 8.3).

The *G6PD* gene is localized on Xq28, and currently more than 180 genetic variants have been identified, most of which are missense mutations resulting in single-amino acid substitutions, thereby affecting G6PD stability.²⁰ Complete loss of G6PD is lethal; the very rare, more complex variants, for instance, in-frame deletions in exon 10, which affect important regions within the enzyme-like the substrate binding site, can cause severe transfusion-dependent chronic nonspherocytic hemolytic anemia (CNSHA). Variants have been divided into five classes based on enzyme activity in red blood cells (RBCs) and clinical presentation: class I (CNSHA, activity <10%), class II (no CNSHA, activity <10%), class III (no CNSHA, >10% to 60%), class IV (normal activity; variants G6PD B and G6PD A); class V (higher activity). It is estimated that about 5% of the world’s population have G6PD deficiency, and almost all of these individuals have class II or III variants.²¹

Drugs that have the potential to cause oxidative stress in erythrocytes, which results in AHA in G6PD-deficient patients, have been recently classified into two groups: (1) predictable hemolysis (i.e., AHA can be expected in a G6PD-deficient patient after

Fig. 8.3 Damaging variants in the G6PD gene lead to G6PD deficiency in red blood cells, which, under oxidative stress (1), leads to depletion of glutathione (with low cellular NADPH and GSH pools causing low activity of GPX [the enzyme that detoxifies H_2O_2]) and subsequent loss of protection against oxidation of proteins, with precipitation of denatured hemoglobin leading to AHA, and (2) oxidation of hemoglobin iron with formation of methemoglobin (MetHb is converted back to Hb via an NADPH-dependent reaction; as the cellular NADPH pool is low, MetHb accumulates), resulting in methemoglobinemia. The severity of AHA and tissue hypoxia in individuals with G6PD deficiency after treatment with drugs that induce oxidative stress is influenced by host factors such as genetic variants in G6PD and (3) comorbidities such as malaria, methemoglobinemia, and ALL, as well as environmental factors (i.e., drugs, their dose, and schedule of administration). *6PG*, 6-Phosphogluconolactone; *AHA*, acute hemolytic anemia; *ALL*, acute lymphoblastic leukemia; *G6P*, glucose 6-phosphate; *G6PD*, glucose-6-phosphate dehydrogenase; *GPX*, glutathione peroxidase; *GSH*, glutathione; *GSR*, glutathione reductase; *GSSG*, glutathione disulfide; H_2O_2 , hydrogen peroxide; *NADP(H)*, nicotinamide adenine dinucleotide phosphate; *ROS*, reactive oxygen species.

administration of the drug) and (2) possible hemolysis (i.e., AHA may or may not occur, related to dosage and administration of the drug, comorbidities).²⁰ Drugs with predictable hemolysis include, for instance, the antimalaria drug PQ and the recombinant urate oxidase rasburicase. A comprehensive list of drugs is provided in two exhaustive recent reviews,^{20,21} and we focus on rasburicase herein.

Rasburicase is used in the prophylaxis and treatment of hyperuricemia, and the most important indications are tumorlysis (e.g., in patients with hyperleukocytosis leukemia or lymphoma) or after acute renal failure in infants. Rasburicase catalyzes the cleavage of uric acid, thereby producing hydrogen peroxide. Normally, hydrogen peroxide is promptly inactivated via glutathione peroxidase (GPX). In individuals with G6PD deficiency, however, the activity of GPX is markedly reduced due to impaired glutathione metabolism, and rasburicase induces AHA and often significant methemoglobinemia. This can cause severe tissue hypoxia, especially in patients with leukemia who have already reduced RBC counts, and fatalities have been reported after rasburicase administration in ALL patients with G6PD deficiency (Fig. 8.3).²¹

The FDA and the European Medicines Agency (EMA) have contraindicated the use of rasburicase in individuals with G6PD deficiency. However, tumorlysis syndrome (TLS) is also a life-threatening

condition, and one must carefully balance the risk of reversible severe AHA and methemoglobinemia, which can be treated via RBC transfusions, and the risk of renal failure and hyperkalemia in TLS. Online enzyme activity testing before the use of rasburicase (i.e., providing results within 1 h) is an ideal but not commonly achievable scenario. More information on available genetic and activity test options is provided in the recently published CPIC guidelines (Table 8.2).²¹

Of interest are the results of a recent pharmacoepigenetic investigation, in which it was shown that histone deacetylase inhibitors (HDACis) can selectively reinstate enzyme activity in G6PD-deficient erythroid precursors in vitro by boosting *G6PD* gene transcription.²² Whether administration of the epidrug HDACi sodium butyrate can also increase G6PD activity in patients with G6PD deficiency to levels that protect their erythrocytes from oxidative damage by rasburicase or other oxidative stressors, and if such an approach is not associated with severe side effects, remains to be proven. However, the ability of HDACi to increase the transcription of a subset of active genes, like *G6PD*, would offer a novel and appealing therapeutic approach, especially for the subset of patients with severe forms of enzymopathies, such as CNSAH class I G6PD deficiency.

DRUG DEVELOPMENT

Optimizing the selection and dosage of medications is a principal goal of pharmacogenomics. Another important application is in drug development, which is evolving in parallel with improved insights into the mechanisms by which medications exert their pharmacologic effects. Such improved insights into the mechanism(s) of drug action in target cells can help elucidate mechanisms that confer drug resistance (e.g., inactivation of thiopurines via NT5C2), and they will facilitate the development of strategies to further enhance efficacy. This knowledge can be used as a basis to engineer drugs that amplify treatment effects or bypass resistance mechanisms, or both.

Here we focus on examples to show how insights from pharmacogenomic investigations have helped to develop novel strategies to further improve outcome in subgroups of children with ALL who still have a poor outcome despite intensive treatment with current multiagent risk-adapted therapies (so-called high-risk ALL [HR-ALL]). Although excellent outcomes with 5-year event-free survival of higher than 85% can be achieved in childhood ALL in more developed countries, ALL is still a leading cause of death from disease in children older than 1 year, and treatment of children with HR-ALL remains one of the greatest challenges in pediatric oncology. HR-ALL features include the resistance of leukemia cells to steroids and multidrug therapy (clearance of leukemia blasts in the peripheral blood, bone marrow, and sanctuary sites), and the presence of certain genetic alterations in leukemia cells—for instance, mixed-lineage leukemia rearrangements (MLL-R), the BCR-ABL1 fusion gene (Ph-ALL), and the recently identified so-called “Ph-like ALL.”^{23,24}

The introduction of TKIs in the treatment of Ph-ALL has led to a significant improvement in outcome, as demonstrated by results from the Children’s Oncology Group (COG) AALL0031 trial. The following sections focus on further examples of the development of novel approaches to treat infants, children, and adolescents with HR-ALL.

Identification of Novel Therapies for MLL-Rearranged Infant ALL

Infants (age <1 year) with BCP-ALL have long been recognized to have very poor outcomes when treated with ALL standard therapy. The identification that transcriptome profiles separate infant ALL from ALL and acute myeloid leukemia (AML), and that infant ALL blast cells are highly sensitive to cytarabine in vitro, provided the rationale to establish an ALL/AML hybrid treatment concept. Indeed, Infant-99 hybrid therapy resulted in better, but still poor, outcomes, and further improvements of infant ALL therapy are needed. Of note, the pharmacokinetics of many conventional antileukemia drugs differ between infants and older children, and recently an intensive induction therapy concept (with intensive dosing of standard ALL medications) in the COG AALL0631 trial had to be modified because of a high rate of fatal toxicities during this treatment phase. Therefore, the unique drug metabolism profile in infants (i.e., developmental pharmacology) needs to be considered when planning future infant ALL trials and novel, less toxic therapies are needed.

About 80% of infants with ALL have rearrangements of the *MLL* gene (MLL-R) at 11q23 and MLL translocations. Recently, next-generation sequencing approaches were used in a Pediatric Cancer Genome Project investigation and identified that infant MLL-R ALL has one of the lowest frequencies of somatic mutations of any as yet sequenced cancer, with a mean of 1.3 nonsilent mutations.²⁵ Wild-type *MLL* is a histone methyltransferase that targets lysine 4 on histone 3 (H3K4), and leukemias carrying MLL-R (i.e., BCP-ALL in infants and older age groups, and AML in adults) can be considered as prototypical cancers driven by dysregulated epigenetic mechanisms. *MLL* rearrangements lead to the loss of the catalytic methyltransferase domain, with subsequent in-frame fusion to one

of 70 known translocation partners. The resulting chimeric oncoproteins interact with another methyltransferase—DOT1-like histone H3K79 methyltransferase (DOT1L)—which then methylates lysin 79 in the globular region of histone H3 (H3K79) at MLL target genes, causing aberrant gene expression and leukemogenesis. Inhibition of DOT1L has emerged as an attractive concept for therapeutic intervention in MLL-R leukemias, and in vitro and animal studies have shown that the recently designed small molecular inhibitors of DOT1L selectively target MLL-R leukemia cells.²⁶ A phase I trial (NCT01684150) for the clinical evaluation of the epidrug EPZ-5676 was initiated for patients older than 18 years with MLL-R leukemias, and if this approach proves to be successful, it remains primed for testing in infants with MLL-R ALL.

A different approach focuses on targeting the class III receptor tyrosine kinase (RTK) FMS-like tyrosine kinase-3 (FLT3). Using genome-wide gene expression analyses, the *FLT3* wild-type gene was identified as being overexpressed in MLL-R ALL. FLT3 inhibitors have been shown to inhibit growth in cells that overexpress FLT3.²⁷ The COG AALL0631 trial investigates the combination of the FLT3 inhibitor lestaurtinib given after induction therapy in combination with an intensive chemotherapy backbone in children with MLL-R infant ALL, and this approach may also help to improve outcomes in this poor prognostic ALL subtype.

Identification of Novel Therapies for “BCR-ABL1-like” ALL

In contrast to the prognostically favorable BCP-ALL subtypes ETV6-RUNX1, TCF3-PBX1, and hyperdiploid ALL (which account for almost 50% of childhood ALL cases), BCP-ALL with the *BCR-ABL1* (or Philadelphia [Ph]) fusion gene responds poorly to conventional ALL therapy, and patients with Ph-ALL belong to the HR-ALL group. Ph-ALL is rare in children (1–15 years, 4.2%), but is more common in adolescents (16–20 years, 5.9%) and young adults (21–39 years, 22%); and this is a contributor to the overall poor prognosis of adolescents and young adults (AYAs) with ALL.

In 2009, genome-wide transcriptome analyses identified a subtype of HR-BCP-ALL that has a gene expression profile similar to that of Ph-ALL.^{23,24} In contrast to Ph-ALL, leukemia cells in the identified subtype did not harbor the *BCR-ABL1* fusion gene; therefore this HR-ALL subtype has been named Ph-like ALL. Ph-like ALL is more common, but has the same age distribution pattern as Ph-ALL (i.e., 1–15 years, 11.9%; 16–20 years, 20.6%; 21–39 years, 27.4%). It was speculated that genetic alterations that can influence tyrosine kinase signaling pathways similar to those downstream of BCR-ABL1 might be involved in the pathogenesis of Ph-like ALL. Indeed, kinase-activating alterations (fusions, deletions, or point mutations) were recently identified in a comprehensive analysis, which included transcriptome, whole-genome, and whole-exome sequencing in 91% of 154 patients with Ph-like ALL.²⁸

This large-scale investigation corroborated and extended previous findings in Ph-like ALL and identified two major subgroups, distinguished by the type of cytokine receptor or kinase alterations. For example, 60% of adolescents with Ph-like ALL had rearrangements in the lymphoid signaling receptor gene *CRLF2* (encoding cytokine receptor-like factor 2) and concomitant mutations in *JAK1* or *JAK2* (which encode the Janus kinases [JAKs]). These rearrangements (e.g., the frequently observed *PAX5-JAK2* fusion), when ectopically expressed in cell lines, activated JAK-STAT signaling and conferred cytokine-independent proliferation that can be suppressed by the JAK2 inhibitor ruxolitinib in vitro. The second major subgroup within the Ph-like ALL cohort was identified to have fusions that involve the nonreceptor Abelson-related (ABL)-class kinase genes (e.g., *ABL1* and *ABL2*), as well as activated oncogenic signaling pathways and cellular proliferation that is potentially inhibited by TKIs such as dasatinib. Other less frequently observed targetable alterations affect the *NTRK3* gene, which encodes the neurotrophic tyrosine kinase receptor type 3, and *ETV6* (ets variant 6)–*NTRK3* fusions have been shown to respond to the ALK inhibitor crizotinib

in vitro. The in vitro results with the TK, JAK2, and ALK inhibitors were confirmed in mouse xenograft models, when patient-derived Ph-like ALL cells were exposed to respective inhibitors based on the genetic profile of the leukemia cells.²⁸

In summary, this provides evidence that kinase-activating genetic alterations are biologically relevant drivers in Ph-like ALL, and that the genetic signature can help to select drugs such as TKIs, JAK2 or ALK inhibitors. However, rapid molecular profiling is needed to identify potentially actionable mutations in patients with Ph-like ALL, and additional prospective trials are needed to establish their benefit in the clinical setting. In contrast to children, outcomes in ALL have not improved significantly during recent decades in the AYA cohort; and as Ph-like ALL is the most common subtype in AYAs, the introduction of signaling pathway inhibitors may be an attractive strategy to improve outcome in these patients who have been therapeutically neglected for too long.

FUTURE DIRECTIONS

Pharmacogenomics has already proven to be an important approach to improve drug therapy, and as of March 2015 the FDA has included information on pharmacogenomic biomarkers in the labels of more than 130 medications. A full list of these medications and further details are available on the FDA's website (see Table 8.1). There is, however, a relatively slow pace of translating pharmacogenomics into clinical practice. Laboratory tests (e.g., liver and kidney function tests) are widely used to adjust drug dosages, but even though technology for testing relevant pharmacogenomic biomarkers is widely available, simple, robust, and inexpensive genotyping tests are rarely used to optimize drug therapy. As of 2015 only five institutions in the United States are routinely performing "preemptive genotyping" for pharmacogenomic traits to guide the optimal selection of medications and their dosage. Because genotyping at the time of prescribing is compromised by the relatively long delay until genotype results are available, prospective genotyping early in a person's life or at the time of initial illness is a more efficient and cost-effective approach. In addition, because a person's germline genotype does not change over a lifetime, it only needs to be done once. As genotyping becomes faster and cheaper, it is anticipated that this issue may no longer be an obstacle. In addition, educative and legislative initiatives, and the implementation of user-friendly decision-support systems (e.g., as realized in the "Clinical implementation of pharmacogenomics—PG4KDS protocol" at St. Jude Children's Research Hospital)²⁹ will help to make pharmacogenomic biomarkers a routine part of clinical care.

The recent unprecedented gain of insights into the human genome and genomic variations among individuals has already changed the practice of medicine. High-throughput technologies, such as hybridization-based microarray approaches and next-generation sequencing technologies, are available for genome-wide analyses of genomic variants, gene expression patterns, epigenetic patterns, and proteomic and metabolomic profiles. Moreover, sophisticated methods have been developed to integrate these data in order to uncover genotype–phenotype interactions, and some of the most important methods are metadimensional and multistaged analyses.³⁰ The recent application of these genome-wide tools has already yielded novel insights into drug actions and led to important drug discoveries.

Moreover, these tools are being used to elucidate differences between genomes of normal cells and cancer cells (e.g., the Pediatric Cancer Genome Project; see Table 8.1), and this knowledge has the potential to illuminate paths toward novel prognostic markers (those that can be used for risk stratification in clinical trials) and/or novel therapeutic targets (those that can be used to discover new medications).

Once novel candidate genes have been identified via GWA studies, functional investigations such as systematic mutagenesis, RNA interference, and genome-wide CRISPR/Cas9 knockouts or enhancement of gene expression, use of overexpression systems (cDNA, open-reading frame and miRNA expression libraries), and

chemistry-based approaches to biologic pathway perturbations are likely to accelerate the discovery of pharmacogenomics mechanisms. The outputs of such studies will advance understanding of the pharmacology of existing medications and will help to identify genes and pathways involved in drug resistance and novel therapeutic targets.

One important consideration in modern medicine is that clinically useful approaches must also be cost effective. About a decade ago, the cost for the first full human genome sequence was approximately US\$3 billion; this cost is now (2015) about US\$1000. The markedly lower cost for robust genotyping points to an exciting future for genomics and pharmacogenomics research and translation, suggesting that the current approach to selecting medications (often "trial and error") will continue to evolve into more scientific-based methods for selecting the optimal medications and doses for individual patients—with genomics playing an increasing role in such therapeutic decisions. As pharmacogenomics research expands the number of robust associations between genome variation and drug response, the challenges of successful clinical translation and implementation will be hurdle that will need to be overcome for precision medicine is to become a reality.³¹

CELLULAR BASIS OF HEMATOLOGY

This page intentionally left blank

HEMATOPOIETIC STEM CELL BIOLOGY

Marlies P. Rossmann, Stuart H. Orkin, and John P. Chute

Hematopoietic stem cells (HSCs) are characterized by their unique ability to self-renew and give rise to the entirety of the blood and immune system throughout the lifetime of an individual.^{1–3} HSCs are very rare cells, representing approximately one in 100,000 bone marrow (BM) cells in the adult.⁴ The concept of the existence of an HSC that is capable of reconstituting hematopoiesis *in vivo* was first introduced more than 60 years ago, when Jacobson et al⁵ demonstrated that lead shielding of the spleen protected mice from otherwise lethal γ -irradiation.⁵ Subsequently, Jacobson and colleagues⁶ demonstrated that similar radioprotection of mice could be achieved via shielding of one femur. Shortly thereafter, it was demonstrated that intravenous injection of BM cells also provided radioprotection of lethally irradiated mice.⁷ Interestingly, investigators initially hypothesized that the radioprotected spleen or BM provided soluble factors that mediated radiation protection.^{8,9} However, subsequent experiments by Nowell et al¹⁰ and Ford et al¹¹ critically demonstrated that transplanted BM cells provided radioprotection directly via cellular reconstitution of the blood system. The historical significance of these studies cannot be overestimated because they provided the basis for not only the ultimate isolation and characterization of HSCs but also for the field of hematopoietic cell transplantation.

Subsequent landmark studies by Till and McCulloch¹² demonstrated that transplantation of limiting doses of BM cells gave rise to myeloid and erythroid colonies in the spleens of irradiated recipient mice. Importantly, Till and McCulloch showed that the numbers of colonies detected in recipient mice was proportional to the numbers of BM cells injected into the irradiated mice, suggesting that a particular population of hematopoietic cells was capable of reconstituting hematopoiesis *in vivo*.^{12–14} The clonogenic nature of a subset of BM cells was definitively shown when these investigators irradiated BM cells and then transplanted the cells into lethally irradiated mice. Persistent chromosomal aberrations were demonstrated in spleen colonies in recipient mice.¹⁵ It was subsequently shown that cells within the spleen colonies were radioprotective of lethally irradiated mice and contained myeloid, erythroid, and lymphoid cells.^{12,16} Taken together, these data strongly suggested the presence of hematopoietic stem or progenitor cells that were capable of *in vivo* engraftment and generation of multilineage progeny from a small number of parent cells.¹⁷

EMBRYONIC ORIGIN OF HEMATOPOIETIC STEM CELLS

Mammalian hematopoiesis occurs in several waves, which are separated temporally and spatially and produce different cell types: a transient first “primitive” is followed by a “prodefinitive” and then a “definitive” wave, which is lasting through life.^{18–20} While most of the evidence is derived from the mouse, data from humans, albeit limited, point to a very comparable hematopoietic program.^{21,22}

During embryogenesis, the hematopoietic cells of the first, primitive wave are formed when cells from the epiblast that constitute the prospective mesoderm ingress and migrate through the primitive streak between the endoderm and ectoderm, both in the embryo proper and in the extraembryonic yolk sac (YS). In the latter, mesodermal cells aggregate to form blood islands surrounded by visceral endodermal cells on mouse embryonic day (E) 7–7.5. The close proximity of erythroid cells and vascular endothelium in YS blood islands, their origin from mesoderm and their simultaneous differentiation led to the proposal of a common precursor, the hemangioblast,

over a century ago.^{23,24} In support of this hypothesis, a spontaneous zebrafish mutant, *cloche* (named for its bell-shaped heart because of the loss of endothelium), lacks both vasculature and hematopoietic cells but no other mesodermal lineages such as cardiac progenitors.^{25,26} The gene mutated in *cloche* was recently cloned and encodes a PAS (PER-ARNT-SIM)-domain-containing basic helix-loop-helix (bHLH) transcription factor (*npas4l*), which belongs to the same class that also includes the aryl hydrocarbon receptor and HIF-1 α .^{26a} Also, mice lacking FLK1 (VEGFR2, a receptor for vascular endothelial growth factor), expressed on endothelial (progenitor) cells, fail to develop both vascular endothelium and blood islands during embryogenesis.^{27,28} Indeed, gene tracing studies in mouse and human embryonic stem cell cultures identified a progenitor with both hematopoietic and endothelial potential.^{29–31}

Primitive hematopoiesis encompasses the generation of primarily large erythroid cells and primitive macrophages.^{32–34} Following this initial wave, beginning at mouse E8.25, erythromyeloid progenitors are generated as prodefinitive progenitors.^{35,36} Both waves arise transiently in the YS during a time comparable to the first trimester in humans,³⁷ but the cells lack the capacity for self-renewal and multilineage differentiation present in definitive HSCs. The first definitive HSCs capable of long-term, multilineage reconstitution of irradiated adult recipient mice appear at E10.5 in the intraembryonic region encompassing the aorta, gonads, and mesonephros (AGM), in particular in hematopoietic intraaortic clusters in the ventral wall of the dorsal aorta.^{20,38–40} Then, within a remarkably short period of 1.5 days during embryonic development virtually all HSCs are born that will replenish the hematopoietic system throughout fetal and adult life.^{41,42} Several complementary studies using lineage tracing experiments in both mice and zebrafish have demonstrated that within the dorsal aorta, hemogenic endothelial cells (ECs) are the direct precursors of definitive HSCs.^{42–47} In a process known as endothelial-to-hematopoietic transition, HSCs bud off the hemogenic endothelium to form intraaortic hematopoietic clusters from which they are released into circulation. Interestingly, while the AGM gives rise to HSCs, it is not the site of hematopoietic differentiation.⁴⁸ Rather, HSCs colonize the fetal liver where they expand and then differentiate⁴⁹ (and references therein).

Evidence from studies in mice suggests that some adult hematopoiesis also occurs at sites other than the AGM. By E12 the fetal liver contains more HSCs than can be accounted for by HSCs generated in the AGM alone.⁵⁰ Quantitative analysis of HSC distribution showed that both YS⁵⁰ and placenta^{51,52} generate definitive HSC that migrate to the liver and other hematopoietic sites.⁵³ Lastly, a *c-Myb*- and thus HSC-independent cell lineage that emerges between E8.5 and E9.5 in the YS has recently been shown to give rise to YS macrophages and later on to tissue macrophages in brain (microglia), liver (Kupffer cells), and skin (Langerhans cells).⁵⁴

DEFINITION AND CHARACTERIZATION OF HEMATOPOIETIC STEM CELLS

Phenotype

Murine HSCs

The HSC is the most well-defined somatic, multipotent stem cell in the body. With the emergence of antibody technology and flow

Fig. 9.1 PHENOTYPE OF MURINE AND HUMAN HEMATOPOIETIC STEM CELLS (HSCs). Long-term HSCs (LT-HSCs), short-term HSCs (ST-HSCs), and multipotent progenitor cells (MPPs) have precise cell surface markers that discriminate them from more committed progenitor cells. (Adapted from *Probaska SS, Weissman I: Biology of hematopoietic stem and progenitor cells. In Appelbaum F, Forman SJ, Negrin RS, Blume K, editors: Thomas' hematopoietic cell transplantation, UK, 2008, Wiley-Blackwell, p 36-63.*)

cytometry^{17,55,56} and coupled with in vitro and in vivo functional assays,⁵⁷⁻⁶² biologists have developed reproducible methods to analyze and isolate murine and human HSCs with a high level of enrichment. In mice, Weissman and colleagues were able to show that antibody-based depletion of BM cells expressing myeloid, B cell, T cell, and erythroid cells along with positive selection for cells expressing c-Kit, Sca-1, and Thy-1.1^{lo} ("KTLS" cells), allowed for enrichment for HSCs to approximately one of 10–30 cells as measured by the capacity to provide long-term, multilineage hematopoietic reconstitution in a competitively transplanted, lethally irradiated congenic mouse.^{58,63-66} Because Thy-1.1 is not expressed in many strains of mice,⁶⁴ additional markers were developed, including FLK2 (FLT3), the absence of which was shown to substantially enrich for murine long-term (LT)-HSCs.^{67,68} Similarly, it has been demonstrated that the isolation of murine BM $c\text{-Kit}^+ \text{Sca-1}^+ \text{Lin}^-$ (KSL) cells based upon the lack of expression of CD34 (34⁺ KSL) enriches for HSCs with long-term reconstituting capability at the level of one of 5–10 cells (Fig. 9.1).⁶⁹

An alternative and effective method for isolating BM HSCs involves the use of intravital dyes, Hoechst 33342 (Ho33342) and Rhodamine 123 (Rh123).⁷⁰⁻⁷⁴ HSCs, unlike more committed progenitor cells, efficiently efflux these dyes such that HSCs display low-intensity staining for these dyes.^{74,75} Li and Johnson⁷³ demonstrated that HSCs capable of long-term, multilineage repopulation in lethally irradiated mice were significantly enriched in the $\text{Rh123}^{\text{lo}} \text{Sca-1}^+ \text{Lin}^-$ cells, but $\text{Rh123}^{\text{hi}} \text{Sca-1}^+ \text{Lin}^-$ cells possessed little repopulating activity. Similarly, McAlister et al⁷² showed that isolation of $\text{Ho33342}^{\text{lo}}$ BM mononuclear cells significantly enriched for both the potential to produce colony-forming units in the spleen (CFU-S) on day 14 and cells capable of radioprotection and multilineage reconstitution in lethally irradiated mice. A subsequent and important refinement in the use of Ho33342 to isolate HSCs was made by Goodell et al,⁷⁴ who showed that a Ho33342 side population (SP) can be identified via the emission of Ho33342 at two wavelengths, which yields a tail profile on flow cytometric analysis. Importantly, isolation of $\text{Ho33342}^{\text{lo}}$ SP cells has been shown to yield variable enrichment for HSCs compared with 34⁺ FLT3⁺ KSL cells, and this may be caused by the sensitivity of the assay to variations in staining techniques and batch-to-batch differences in Ho33342 dye.⁷⁶⁻⁷⁸ However, Matsuzaki et al⁷⁹ demonstrated that transplantation of

single $\text{Ho33342}^{\text{lo}}$ SP 34⁺ KSL cells into lethally irradiated C57BL/6 mice yielded donor cell multilineage engraftment greater than 1% in more than 95% of transplanted mice. Therefore, the combination of $\text{Ho33342}^{\text{lo}}$ SP cells with 34⁺ KSL markers provides a basis for isolation of highly enriched LT-HSCs from mice.^{55,76-78}

A major advance in this field involved the discovery by Kiel et al⁸⁰ that the surface expression of CD150, a member of the signaling lymphocyte activation molecules (SLAM) family, significantly enriched for murine BM HSCs. It was also shown that the absence of CD41 and CD48 on CD150^+ cells enriches further for the HSC population and that approximately half of $\text{CD150}^+ \text{CD41}^- \text{CD48}^-$ or $\text{CD150}^+ \text{CD48}^-$ KSL cells reconstitute lethally irradiated mice competitively transplanted with limiting numbers of cells.⁸⁰ Taken together, isolation of SLAM- and KSL-enriched BM cells has become a reproducible and efficient strategy to isolate murine LT-HSCs with maximal enrichment (see Fig. 9.1).⁸¹

Although this chapter focuses on the phenotypic and functional characterization of HSCs, increasing evidence suggests that a subset of adult T-cell progenitors may possess myeloid potential.⁸²⁻⁸⁴ Using various methodologies, Bell et al⁸³ and Wada et al⁸² first reported that adult T-cell thymic progenitors possessed myeloid differentiation potential. However, a subsequent study using in vivo transplantation models did not confirm the myeloid potential of adult T cells.⁸⁴ More recently, De Obaldia et al reported that the majority of resident granulocytes in the mouse thymus were derived from early thymic progenitors.⁸⁵ Mechanistically, it has also been shown that the transcription factor, HES1, constrains myeloid gene expression in T-cell progenitors via repression of *C/EPB- α* .⁸⁶ Taken together, these data suggest that a population of common lymphoid progenitors (CLPs) may indeed possess myeloid differentiation potential.^{85,86} Recent studies have also clarified the nature of CLPs and have dissected this population further into an all-lymphoid progenitor cell (ALP), which retains full lymphoid potential and thymic seeding capability, and B lymphoid progenitor cells (BLPs), which is restricted to the B-cell lineage.⁸⁷ Whereas ALPs are characterized by the lack of surface expression of LY6D, BLPs demonstrate expression of LY6D and upregulate the B-cell-specific factors, EBF1 and PAX5.⁸⁷ The phenotypic markers of the hematopoietic hierarchy through myeloid and lymphoid differentiation are shown in Fig. 9.2.

Fig. 9.2 HEMATOPOIETIC CELLULAR HIERARCHY. The phenotypes of murine hematopoietic stem cells (HSCs) and oligopotent progenitor cells, as well as transcription and epigenetic factors critical for specification and differentiation of HSCs are shown. *CLP*, common lymphoid progenitor; *CMP*, common myeloid progenitor; *GMP*, granulocyte-macrophage progenitor; *LT-HSC*, long-term HSC; *MEP*, megakaryocytic-erythroid progenitor; *NK*, natural killer; *RBC*, red blood cell; *ST-HSC*, short-term HSC. Human HSCs

Significant progress has also been made in the phenotypic characterization of human HSCs via flow cytometric analysis combined with in vivo transplantation assays in immune-deficient mice.^{88,89} Of particular note, although murine HSCs can be characterized by the absence of CD34 expression on the cell surface, human HSCs are primarily enriched using CD34 surface expression, and this provides the basis for confirming sufficient HSC content to allow for successful hematopoietic cell transplantation in patients.^{17,90,91} There is also some controversy in this area because some investigations have suggested that LT-HSCs can be isolated from CD34⁺ human hematopoietic cells.⁹²⁻⁹⁵ Of note, only a small percentage (<0.1%) of CD34⁺ human hematopoietic cells possess the capacity to engraft following intravenous injection into nonobese diabetic/severe combined immune deficient (NOD/SCID) mice.^{4,89} Further enrichment of human HSCs has been demonstrated via negative

selection for surface expression of CD38 and depletion of lineage surface markers.^{89,96,97} Thy-1 (CD90) surface expression also enriches for multilineage colony-forming ability and in vivo reconstituting capacity of human hematopoietic cells.^{17,98} Majeti et al showed that the Lin⁺CD34⁺CD38⁺CD45RA⁺Thy-1⁺ population in human cord blood (CB) was enriched at the level of one in 10 cells for LT-HSCs.⁹⁸ The authors also showed that candidate multipotent progenitor cells (MPPs) were demarcated by the Lin⁺CD34⁺CD38⁺CD45RA⁺Thy-1⁺ population, suggesting that the loss of Thy-1 reflects the transition of LT-HSCs to short-term (ST)-HSCs/MPPs.^{17,98}

CD49f⁺ Human HSCs

Although it is possible to enrich murine BM HSCs to the level of nearly single-cell purity using various combinations of cell surface markers, isolation of human BM HSCs to the same level of purity has not been readily achieved.^{74,80,99} However, Notta et al demonstrated that intrafemoral injection of a fluorescence-activated

cell sorting (FACS)-purified population of human CB CD34⁺CD38[−]CD45RA[−]Thy-1⁺ cells that were additionally purified based on surface expression of the integrin $\alpha 6$ (CD49f) yielded 6.7-fold increased human donor chimerism at 20 weeks in NOD/SCID IL2R $\gamma^{-/-}$ (NSG) mice compared with injection with the identical dose of CD34⁺CD38[−]CD45RA[−]Thy-1⁺CD49f⁺ cells.¹⁰⁰ Only the Thy-1⁺CD49f⁺ cells could be serially transplanted in this study, and the enrichment for LT-HSCs via limiting dilution analysis was estimated to be approximately one in 11 CD34⁺CD38[−]CD45RA[−]Thy-1⁺CD49f⁺ cells.¹⁰⁰ Further purification of this population of cells using Rh123 dye demonstrated that single-cell transplantation of Thy-1⁺Rh123^{lo}CD49f⁺ cells yielded long-term, multilineage engraftment in five of 18 transplanted recipients. Serial transplantation was also successful in two of four secondary mice, suggesting that at least some of the Thy-1⁺Rh123^{lo}CD49f⁺ cells undergo self-renewal.¹⁰⁰ Of note, because mice were transplanted via intrafemoral injection in these studies, it remained unknown whether this panel of markers equally identified human HSCs capable of homing properly to the BM after intravenous injection. Nonetheless, these studies revealed that the addition of CD49f⁺ to the panel of human LT-HSC markers provided an improved capability to isolate human HSCs at a level of purity that was comparable to that applied to murine HSC isolation.

Recently, two novel cell surface markers for human HSCs were identified, CD166 (activated leukocyte adhesion molecule) and protein tyrosine phosphatase-sigma (PTP σ).^{101,102} Human Lin[−]CD34⁺CD38[−]CD49f⁺CD166⁺ cells engrafted in primary and secondary NSG mice at a significantly higher level than Lin[−]CD34⁺CD38[−]CD49f⁺CD166[−] cells.¹⁰¹ Interestingly, CD166 is also expressed by BM osteoblasts and it was postulated that CD166 mediated HSC maintenance in vivo via hemophilic interactions between CD166 expressed on HSCs and osteoblasts.¹⁰¹ Quarmyne et al reported that NSG mice transplanted with human CB Lin[−]CD34⁺CD38[−]CD45RA[−]PTP σ [−] cells displayed 15-fold higher human hematopoietic cell engraftment at 16 weeks compared to mice transplanted with Lin[−]CD34⁺CD38[−]CD45RA[−] cells or Lin[−]CD34⁺CD38[−]CD45RA[−]PTP σ ⁺ cells.¹⁰² PTP σ was shown to negatively regulate both murine and human HSC repopulation following transplantation, via inhibition of the RhoGTPase, RAC1.¹⁰²

Functional Characterization

In Vitro Assays

The colony-forming cell (CFC) assay does not measure HSC content but rather committed myeloid progenitor cell content via a 14-day assay for colonies within methylcellulose media that is supplemented with specific growth factors.⁷⁸ The CFC assay measures colony-forming unit-granulocyte/macrophage (CFU-GM), burst-forming unit-erythroid (BFU-E) and CFU-granulocyte/erythroid/macrophage/megakaryocyte (CFU-GEMM). The CFU-GEMM, or CFU-mix colonies, represent a more immature progenitor cell population. B- and T-cell progenitor cell content can also be measured via in vitro assays but requires specialized coculture conditions, which are described elsewhere.^{78,103,104}

The long-term culture-initiating cell (LTC-IC) assay is a 6-week in vitro assay in which BM cells are cocultured with murine stromal cells for four weeks followed by replating of the entire culture system into methylcellulose and additional two-week assay for colony formation.^{78,105} The LTC-IC, unlike the CFC, measures a more immature stem/progenitor cell population, although the results of the LTC-IC are inherently dependent and limited by technical variabilities in stromal coculture experiments.⁷⁸ Importantly, the LTC-IC population lacks long-term repopulating cells because transplantation of LTC-ICs into mice in a competitive transplantation assay does not result in any long-term reconstitution.^{78,88,89}

The cobblestone area-forming cell (CAFC) assay also involves coculture of HSCs with preestablished stromal cell monolayers and relies on microscopic quantification of cobblestone-forming cells embedded underneath the stromal layer.^{105,106} It has been shown that

CAFC content correlates well with colony-forming unit-spleen (CFU-S) content on day 12 and marrow repopulating capacity.^{78,105} However, similarly to the LTC-IC, the CAFC assay does not measure LT-HSCs. An advantage of the CAFC and LTC-IC assays is that the estimate of stem/progenitor cell content is not confounded by the homing capacity of the cell population being tested. However, competitive transplantation assays provide a more physiologically relevant measure of functional HSC content and allow quantification of LT-HSC content as well as homing efficiency.^{64,78,107}

In Vivo Assays

Colony-Forming Unit-Spleen Assay

The first reproducible in vivo assay for hematopoietic progenitor cells (HPCs) was the CFU-S assay, which was developed by Till and McCullough.^{12,88} In this assay, BM cells are injected into lethally irradiated mice, and macroscopic spleen colonies are measured from one to three weeks after injection.⁷⁸ These colonies represent short-term repopulating cell and MPP activity but do not measure LT-HSC content.^{4,78}

Competitive Repopulation Assay

A significant advance in the study of hematopoiesis was the development of the competitive repopulating assay (Fig. 9.3).^{78,108} In this assay, an unknown population of hematopoietic cells is transplanted via intravenous injection into lethally irradiated syngeneic mice along with a competing dose of host-derived BM cells.^{78,109,110} This assay has been refined over time such that it is typically performed using a limiting dilution method in which several cell doses (typically more than three to five doses; $n = 10$ mice/dose level) of BM cells or purified HSCs (e.g., CD34⁺KSL cells) are injected into lethally irradiated mice along with a fixed dose of host competitor BM cells, such that a fraction of the recipient mice can be predicted to have nonengraftment.^{78,111,112} This approach allows the application of Poisson statistical analysis to provide an estimate of competitive repopulating units (CRUs) within the donor hematopoietic cell population.^{78,111–113} An important feature of the CRU assay is the potential to estimate the frequency of LT-HSCs in a given hematopoietic cell population. Donor cell engraftment that is detected within the first 8 to 12 weeks after transplantation, reflects the contribution of ST-HSCs, which extinguish at or beyond 12 weeks posttransplant. Therefore, the number of LT-HSCs cannot be convincingly estimated until more than 12–20 weeks posttransplantation.^{78,114} Dykstra et al¹¹⁵ showed that competitive transplantation of single, phenotypic HSCs results in stable donor cell engraftment in lethally irradiated mice beyond 16 weeks, and retroviral marking of HSCs revealed that stable donor-derived hematopoiesis was not observed in recipient mice until six months posttransplant.¹¹⁴

A commonly used and rigorous approach to estimate the presence of LT-HSCs is the performance of secondary, tertiary, and quaternary HSC transplants.⁷⁸ This approach is based on the principle that a singular feature of primitive LT-HSCs is the capacity to serially reconstitute multilineage hematopoiesis in vivo without exhaustion.^{78,116–118} In this method, whole BM is typically collected from primary recipient mice and then injected, along with host competitor BM cells, into lethally irradiated syngeneic mice. Donor cell repopulation is then measured at 12–20 weeks posttransplantation. Serial transplantation assays have the limitation of being potentially confounded by variables such as homing efficiency of the donor cells.^{78,119,120} Therefore, as pointed out by Purton and Scadden⁷⁸ in an excellent review of this subject, serial transplantation assays may be better suited to studies of wild type hematopoietic cell populations as opposed to mutant mice-derived hematopoietic cells, which may have alterations in homing or engraftment mechanisms independent of HSC content.⁷⁸ Utilization of whole BM avoids issues regarding the fidelity of phenotypic markers of HSCs in mutant mice and is perhaps more broadly feasible than FACS-isolated HSC populations at some centers.^{78,121–124} However, the use of purified HSCs avoids the potential confounding effects of accessory cells contained within the BM graft on donor cell repopulation and allows for precise

Fig. 9.3 COMPETITIVE REPOPULATION ASSAY. Bone marrow (BM) cells from donor mice carrying the CD45.2 allele are sorted by fluorescence-activated cell sorting (FACS) and transplanted with an excess of BM cells from CD45.1 mice into lethally irradiated CD45.1 recipient mice. In general, three to four months posttransplantation, peripheral blood cells are analyzed by flow cytometry to identify the fraction of donor CD45.2 BM cells that, if present, must have homed to and engrafted the myeloablated recipient mouse. While short-term hematopoietic stem cells (ST-HSCs) do not persist in the recipient mouse after four months, long-term (LT)-HSCs are defined by their presence in the recipient mouse after four months and the ability to repopulate secondary, tertiary, and quaternary recipients. (Adapted from <http://stemcellassays.com/2011/11/experimental-bone-marrow-transplantation-101-%E2%80%93-part-2-congenic-mouse-model/>.)

determination of effects of growth factors on HSC content in vitro compared with unmanipulated BM.^{103,125} Lastly, Poisson statistical analysis and estimation of CRU frequency is based on particular criteria for “positive” donor engraftment in recipient mice, typically 0.1–1% multilineage donor engraftment.^{103,126} Therefore, the estimation of CRU frequency can be substantially altered depending on what criteria for engraftment are established. Given the limitations of flow cytometric analysis for accurate multilineage engraftment of hematopoietic cells, it is recommended that greater than 1% multilineage engraftment is used as a criterion for evidence of donor cell repopulation using the competitive repopulating assay.⁷⁸

Clonal Dynamics of HSCs

Historically, the transplantation assay, in which prospectively purified cell populations are transplanted into myeloablated recipients, has served as the “gold standard” for testing BM compartments for HSC potential. A single HSC can reconstitute the entire hematopoietic system of the host under optimal conditions.^{63,69,80,115,127} Based on initial transplantation studies, HSCs have been fitted into a simple linear branching hierarchy.¹²⁸ Such a hierarchical model assumes that all HSCs have similar developmental potential and, when committed to differentiate, can give rise to both a myeloid and lymphoid progenitor with equal probability. However, tracking experiments with individual retrovirally marked HSCs have revealed extensive heterogeneity within the HSC pool,^{114,116,129,130} which was subsequently confirmed by limiting dilution transplantation.^{63,127,131–135} Several models have been put forth to explain how diversity in HSC functionality is generated. These are broadly separated into instructive and intrinsic regulation models. According to the instructive models, each HSC is provided with slightly different cues from the microenvironment in which it resides.^{136–138} On the other hand, intrinsic regulation of HSC heterogeneity is either completely unpredictable (stochastic)^{139–142} or “programmed” (deterministic).^{135,143}

The development of methods to obtain highly purified HSCs by FACS has permitted single-cell transplants that address the basis of heterogeneity.^{115,127,144–146} These studies demonstrate the existence of

myeloid and lymphoid “biased” HSCs and that long-term repopulation is dependent on sustained myeloid reconstitution, irrespective of a contribution to the lymphoid compartment. HSCs may also differ in their response to extrinsic signals such as transforming growth factor- β 1 (TGF- β 1).^{145,147} A striking observation is the stable propagation of HSC “heterogeneity” upon secondary transplantation.^{115,148,149} This finding argues for some intrinsic regulation in which all HSCs in a clone follow a predetermined fate that is preset earlier in development.

Hematopoiesis as analyzed by transplantation is generally oligoclonal, that is, only few of the transplanted HSC clones contribute to multilineage repopulation.^{114,116,150,151} These results have argued for a “clonal succession” model of stem cell activation which posits that a small number of HSCs are sequentially activated from a pool of otherwise noncycling quiescent cells, but that these HSCs exhaust and are replaced over time.^{114,152,153} In contrast, the “clonal stability” model states that many or all HSCs have a low but constant cell cycle activity allowing them to continuously contribute to an organism’s blood life-long. Support for this model is derived from experiments showing that after transplantation a few HSC clones persist for a long time.^{139,154,155} HSCs could also show both models’ behaviors as other studies have shown that HSCs may reversibly switch between the quiescent and self-renewal state in a homeostatic environment or when challenged by injury, respectively.^{156–158}

A general limitation to transplantation approaches is their dependence on HSCs that home to and engraft a niche, proliferate rapidly and tolerate the stress imposed by the engraftment and an unbalanced cytokine milieu in myeloablated niches. Novel studies have recently explored endogenous, unperturbed hematopoiesis in the mouse and demonstrated that steady-state hematopoiesis appears to rely predominantly on rather long-lived progenitors rather than HSCs.^{159,160} These studies argue for the dominant contribution of MPPs or ST-HSCs to hematopoiesis in the untransplanted mouse. Thus, in contrast to the transplantation setting, native hematopoiesis is highly polyclonal, supported by the successive recruitment of thousands of clones and as such fits the clonal succession model.

Why more restricted progenitors, such as ST-HSCs or MPPs, cannot repopulate the hematopoietic system after transplantation

is unknown but presumably relates to the ex vivo handling of cells for transplantation or the stress of increased proliferation following transplantation. Furthermore, while it is commonly thought that in myeloid malignancies the “cell of origin”, which acquires the first cancer-promoting mutation¹⁶¹ is an HSC because of their extended lifespan, these recent studies suggest that long-lived progenitors might be equally suitable candidates for tumor-initiating cells.¹⁶⁰

REGULATION OF HEMATOPOIETIC STEM CELL FATE

HSCs have the capacity to generate more stem cells, a process called self-renewal, and to produce cells that differentiate into the entire spectrum of mature hematopoietic cells. The balance between these fate choices is thought to be regulated by the type of cell division that HSCs undergo.¹⁶² Asymmetrical cell divisions result in one HSC (self-renewal) and one committed HPC, allowing the maintenance of the stem cell pool while concomitantly ensuring the supply of differentiated cells. However, during development and regeneration the stem cell pool must have the capacity to expand. This can be achieved by symmetrical cell divisions, which will lead to two daughter HSCs capable of self-renewing. Another outcome of symmetric division would be two HPCs, diminishing and ultimately exhausting the HSC pool. The fate decision governing this balance between self-renewal and differentiation is regulated by cell-intrinsic including transcriptional and epigenetic mechanisms that are intertwined with cell-extrinsic mechanisms from the microenvironment or by the action of systemic factors.

Extrinsic Regulation

The past three decades have yielded substantial progress in the discovery and characterization of intrinsic and extrinsic mechanisms that regulate HSC self-renewal and differentiation. Despite this, the translation of these discoveries into the development of translatable methods to expand human HSCs ex vivo or therapeutics to induce HSC expansion in vivo has proven to be difficult. Therefore, further dissection of the mechanisms governing HSC function continues to be a high priority. The following pathways are extrinsically controlled and reflect unique mechanistic targets for the development of therapeutics to amplify the human HSC pool.

NOTCH Signaling

The NOTCH signaling pathway has been shown to have an important role in regulating the development of the central nervous system, eye, muscle, hematopoietic system, and germline, among others.^{163,164} To date, four NOTCH receptors have been identified (NOTCH1–4) as well as five ligands for Notch receptors (JAGGED1 and 2 and DELTA1, 3, and 4).¹⁶⁵ Ligand receptor interaction on HSCs induces two NOTCH cleavage steps, the last of which is mediated by γ -secretase and releases the constitutively active NOTCH-intracellular domain (NICD). The NICD then translocates to the nucleus, interacts with the DNA-binding protein RBPJ (recombination signal binding protein for immunoglobulin kappa J region) and initiates transcription of target genes such as the transcription factors HES1 and HES5 (mammalian homologues of *Drosophila* hairy and Enhancer of split).^{166–169} Depending on the specific NOTCH ligand, different NOTCH receptors and thus different NOTCH target genes are activated, leading to diverse cellular outcomes. For example, NOTCH1 activation by Delta1 and 4 is required for T-cell differentiation while it inhibits differentiation of the B-cell lineage. Jagged2- or Delta1-mediated activation of NOTCH2 inhibits myeloid differentiation and induces the generation of LT-HSCs and MPPs.^{167,170}

Activation of NOTCH signaling is sufficient to induce ex vivo HSC expansion. Retroviral expression of the *Notch1* ICD in murine HSCs leads to the generation of an immortal, cytokine-dependent cell line with multilineage in vivo repopulating capacity,¹⁷¹ and immobilized Delta1 promotes a several-log expansion of murine

HSC cultures.¹⁷² Furthermore, Jagged2-mediated activation of NOTCH signaling inhibits the differentiation of human CB CD34⁺ cells,¹⁷³ and culture of human CB HSCs with soluble human Jagged1 induces HSC expansion ex vivo.¹⁷⁴ NOTCH ligands that are expressed in the surrounding BM niche are thought to be critical in promoting HSC maintenance through the activation of NOTCH receptors expressed on HSCs. For example, BM osteoblasts express *Jagged1* and blocking NOTCH activation with a γ -secretase inhibitor significantly decreases murine HSC expansion in BM osteoblast cocultures.¹⁷⁵ Similarly, sinusoidal ECs that express NOTCH ligands stimulate expansion of wild-type but not *Notch1*^{−/−}*Notch2*^{−/−} LT-HSCs in vitro.¹⁷⁶ However, although deletion of *Jagged1*, *Notch1*, or *Rbpj* results in impaired embryonic hematopoiesis in the mouse, the physiologic role of NOTCH signaling in the maintenance of the adult HSC pool in vivo is controversial.¹⁷⁵ Deletion of *Jagged1* was shown to have no effect on HSC content in mice,¹⁷⁷ and deletion of *Rbpj* caused no defect in HSC repopulating capacity.¹⁷⁸ Interestingly, while neither *Notch1* nor *Notch2* were found to be required for HSC function under homeostatic conditions in vivo,^{170,177} challenging the BM with chemotherapy or radiation in the presence of a conditional *Notch2* deletion resulted in more rapid myeloid differentiation at the expense of HSC self-renewal.¹⁷⁰

In keeping with the evidence obtained from mouse studies that activation of NOTCH signaling can induce HSC expansion, Delaney et al¹⁷⁹ showed that serum-free culture of human CB progenitor cells with immobilized Delta1 plus cytokines for three weeks yielded a 5.3-fold increase in human hematopoietic cell engraftment in transplanted NOD/SCID mice. This group subsequently completed a phase I clinical trial showing that transplantation of CB cells, which had been expanded with immobilized Delta1 along with an unmanipulated CB unit shortened the time interval to neutrophil recovery (median, 16 days) compared with a cohort that received two unmanipulated CB units (median, 26 days).¹⁸⁰ Of note, in this phase I study, the unmanipulated CB cells demonstrated dominant engraftment by day 80 after transplant and in seven of eight reported recipients, ex vivo expanded CB cells were not detectable in recipients by day 40 posttransplant.¹⁸⁰ The extinction of the Delta1-expanded CB units might be explained by T-cell depletion as donor CB CD8⁺ T cells of a successful graft have been shown to mediate the rejection of the other CB unit in the setting of double CB transplantation.¹⁸¹

WNT Signaling

WNT signaling is initiated by the interaction of WNT ligands with the so-called Frizzled/LRP (lipoprotein receptor-related protein) cell surface receptor complex. In the absence of ligand binding, the WNT signal transducer β -catenin is phosphorylated by kinases such as glycogen synthase kinase-3 beta (GSK-3 β), leading to its rapid degradation. Upon activation of the canonical WNT pathway, β -catenin is no longer phosphorylated and thereby stabilized, translocates into the nucleus and interacts with transcription factors of the T-cell factor/lymphoid enhancer factor (LEF/TCF) family to regulate expression of target genes.¹⁸² Several lines of evidence implicate WNT signaling in the regulation of HSC self-renewal and differentiation. First, WNT proteins have been shown to be expressed at sites of embryonic and fetal hematopoiesis, and WNT ligands, receptors and LEF/TCF transcription factors are expressed by adult HSCs as well as the BM microenvironment.^{183,184} Second, ample evidence suggests that activation of WNT signaling is capable of promoting HSC expansion, at least in vitro.^{185–189} Using mice transgenic for human *BCL2* enabling HSCs to survive in the presence of stem cell factor (SCF) alone,^{190,191} it was shown that BM KTLS cells treated with purified WNT3A protein or transduced with active β -catenin ex vivo resulted in their expansion and multilineage reconstitution of competitively transplanted recipients.^{185,189} In a related study, treating immune-deficient recipient mice with a GSK-3 β inhibitor after transplantation of lineage-depleted human CB HSCs increased their engraftment and repopulating capacity, which was accompanied by faster recovery from posttransplant cytopenia.¹⁹² Importantly,

WNT-mediated maintenance of the HSC pool was demonstrated to depend on intact NOTCH signaling,¹⁹³ suggesting a deterministic role for the NOTCH pathway in controlling the effects of WNT signaling on the undifferentiated HSC pool.¹⁹⁴ On the other hand, HSCs from mice engineered to conditionally express a stable form of β -catenin were blocked in differentiation and failed to self-renew leading to their exhaustion.^{195,196} These results raise the possibility that the prior report of HSC expansion in response to β -catenin overexpression may have been affected by the use of *Bcl2* transgenic mice.¹⁸⁵ Alternatively, WNT signaling might have a more pronounced role in vitro than in the more complex in vivo setting.¹⁸⁸

Some WNT ligands, e.g., WNT5A, are able to activate pathways other than the canonical WNT pathway, depending on the particular WNT receptor context.¹⁹⁷ In vivo activation of noncanonical WNT signaling via systemic administration of WNT5A was shown to induce a greater than threefold increase in human CB HPC repopulation in NOD/SCID mice.¹⁸⁶ More recent studies have demonstrated noncanonical WNT signaling in the BM niche to be required for HSC maintenance in vitro and in vivo.^{198,199} Interestingly, it was shown that *Wnt5a* expression is increased in ageing LT-HSCs. Induction of *Wnt5a* in young mice induced ageing-associated HSC phenotypes, including apolarity, decreased repopulation capacity and myeloid bias. Conversely, knocking down *Wnt5a* in old mice attenuated HSC ageing.²⁰⁰

Although activation of WNT signaling can induce HSC expansion, it is uncertain whether WNT signaling is indispensable for normal hematopoiesis to occur. Conditional deletion of β -catenin in adult BM progenitors did not impair their ability for multilineage reconstitution.²⁰¹ In support of these results, hematopoietic cell ablation of porcupine, a membrane-bound *O*-acyl transferase essential for WNT ligand secretion and receptor interaction, had no effect on proliferation, differentiation, and self-renewal of adult HSCs in vivo.²⁰² Conversely, embryonic conditional knockout of β -catenin caused a deficiency in self-renewal of murine LT-HSCs,²⁰³ and HSCs derived from *Wnt3a*^{-/-} mice failed to repopulate secondary recipients,²⁰⁴ suggesting that WNT signaling might have different roles in embryonic versus adult HSCs.

TGF- β and Hedgehog Signaling

The TGF- β pathway represents a signaling mechanism that can be activated by members of the TGF- β superfamily including TGF- β , activins and bone morphogenetic proteins (BMPs).²⁰⁵ Each of these ligands binds to a specific receptor heterodimer composed of a type I and II receptor, leading to the phosphorylation of a subset of the receptor-regulated SMAD proteins (R-SMADs: SMAD1, 2, 3, 5, and 8). Thus activated R-SMADs then form a complex with the common SMAD SMAD4, and translocate into the nucleus to co-regulate target gene transcription. Another class of SMADs, inhibitory SMADs (SMAD6 and 7) block TGF- β family signaling by binding to R-SMADs.

TGF- β is one of the most potent inhibitors of HSC proliferation in vitro, and neutralization of TGF- β releases HSCs from quiescence.^{206–208} It has been suggested that TGF- β mediates cell cycle inhibition in HSCs via upregulation of cyclin-dependent kinase inhibitors, p21, p27 and p57, as well as downregulation of cytokine receptors.^{209–213} The role of TGF- β in vivo appears to be more complex. TGF- β likely functions as a negative hematopoietic regulator in vivo as supported by the observation that deletion of TGF- β 1 results in extensive myeloiposis in mice²¹⁴ as well as defective homing of HSCs.²¹⁵ Moreover, HSCs from mice with a conditional deletion of the TGF- β type II receptor show increased cell cycling and impaired repopulation capacity.²¹⁶ Conversely, TGF- β type I receptor null mice display normal HSC self-renewal and regeneration in vivo, although these HSCs exhibited increased proliferation in vitro.^{217,218} The discrepancies between different knockout phenotypes could be caused by differences in expression levels of the TGF- β receptors in HSCs and thus different in vivo importance.²⁰⁹ Still, TGF- β is considered a critical signal for HSC quiescence also in vivo.²⁰⁹

BMP signaling is required for mesoderm formation and patterning, and BMPs are key regulators for the hematopoietic specification from mesoderm across different species (reviewed in²⁰⁵). BMP4 has been shown to modulate adult human HSC maintenance and proliferation in a concentration-dependent manner, with high BMP4 levels extending the survival of hematopoietic repopulating cells in ex vivo cultures.²¹⁹ However, in vivo, BMP signaling does not seem to be required for adult HSC function as determined in mouse knockouts for its signal transducers, SMAD1 and 5.²⁰⁵ On the other hand, complete inhibition of the SMAD network has demonstrated the importance of SMAD proteins in regulating HSC self-renewal in vivo. Conditional deletion of *Smad4* in mice led to a significantly reduced ability of HSCs to repopulate primary and secondary recipients.²²⁰ Also, retrovirus-mediated overexpression of the inhibitory *Smad7* promoted HSC self-renewal in vivo.²²¹ Taken together, these results have been interpreted to indicate that SMAD4 positively regulates HSC self-renewal independently from its role as a mediator of SMAD pathway signaling. This hypothesis is supported by evidence demonstrating that SMAD proteins can activate WNT signaling,^{222,223} which has been shown to promote HSC expansion as discussed earlier.

As in other species and developmental contexts,^{224,225,226} an intersection between BMP4 and Hedgehog signaling has been described in the human hematopoietic system. Hedgehog proteins play an essential role in the embryonic development of a wide variety of organs, and, like BMPs, they are required for mesoderm patterning.^{227,228} Culture of human CB progenitor cells with Sonic Hedgehog (SHH), one of three human Hedgehog proteins,^{229,230} promoted the expansion of cells capable of multilineage repopulation in NOD/SCID mice.²³¹ The addition of Noggin an endogenous inhibitor of BMP4, blocked the effect of SHH on CB stem cell proliferation in vitro, whereas Hedgehog inhibition did not block BMP4-induced hematopoietic stem and progenitor cell (HSPC) proliferation, suggesting that BMP4 acts downstream of SHH in the regulation of human HSC growth.²³¹ Several other studies suggest that hedgehog signaling regulates HSC growth. Mice heterozygous for the Hedgehog antagonist Patched1 (*Ptc1*) were shown to have an expanded HSC compartment²³² and their fetal HSCs exhibited increased colony-forming potential in serial plating assays.²³³ Interestingly, while conditional deletion of the Hedgehog effector Smoothened (*Smo*) resulted in a profound loss of LT-HSCs in the embryo,²³⁴ conditional deletion of *Smo* or pharmacologic inhibition of Hedgehog had no effect on HSC content or hematopoiesis in adult mice.^{235,236} Thus, Hedgehog signaling during embryogenesis might be required for certain aspects of HSC function important in adult life.²³⁷

CXCL12–CXCR4 Signaling

CXCL12 is a chemokine that is expressed by BM osteoblasts, ECs, and perivascular stromal cells in the BM microenvironment and regulates the homing and retention of HSCs.^{238–240} Expression of CXCL12 or its receptor, CXCR4, is necessary for HSC maintenance in vivo.^{239–241} Recently, Ding et al reported that deletion of *Cxcl12* from perivascular stromal cells or vascular ECs depleted HSCs in mice, whereas depletion of *Cxcl12* from nestin⁺ mesenchymal cells or osteoblasts had no effect on HSC numbers.²³⁹ Greenbaum et al also showed that deletion of *Cxcl12* in *Prx1*-expressing perivascular stromal cells led to HSC depletion,²⁴² confirming the importance of CXCL12 signaling in the perivascular niche for HSC maintenance. A more detailed review of CXCL12–CXCR4 signaling in the context of the BM microenvironment, as well as a comprehensive review of HSC–HSC niche signaling interactions²⁴³ are presented in Chapter 11.

INTRINSIC PATHWAYS

Transcription Factors

Transcription factors are proteins that bind specific sequences of DNA within promoter or enhancer regions to regulate the process of

transcribing DNA into RNA.²⁴⁴ Because the intrinsic phenotype or state of a cell is the result of its gene expression, it is governed by the concerted action of transcription factors (guided by the epigenetic landscape discussed further below). The balance between self-renewal and differentiation of HSCs is intricately regulated by transcription factors of many different classes.²⁴⁵ Several general principles have emerged. First, given the relative limited number of transcription factors, they are used at multiple stages in development, such that they may be required in HSCs and also subsequently in lineage differentiation.¹⁸ Second, the balance between self-renewal and lineage commitment is thought to be

regulated, at least in part, by the antagonism of lineage-specific transcription factors. To promote a given lineage, transcription factors need to actively counteract factor(s) supporting other cell fates. Third, and most relevant to clinical situations, most hematopoietic transcription factors are subject to somatic mutation and/or chromosomal translocation in one or more hematopoietic malignancies. Thus, malignancy can be viewed as a disruption of normal development. Fig. 9.2 depicts key transcription factors within the hematopoietic hierarchy, and Table 9.1 summarizes main roles of critical transcription factors in HSPCs and hematologic malignancies.

TABLE 9.1 Roles of Critical Transcription and Epigenetic Factors in Hematopoietic Stem and Progenitor Cells (HSPCs) and Hematologic Malignancies

Transcription Factor				
SCL (TAL-1)	Mesoderm-endothelial/hematopoietic lineage transition; MegE lineage differentiation	Chromosomal translocations involving <i>TCR</i> genes; <i>SIL-TAL1</i> fusion gene; aberrant expression for other reasons	T-ALL	245, 263, 533
LMO2	Primitive erythropoiesis; generation and maintenance of definitive HSCs	Chromosomal translocations involving <i>TCR</i> genes; interstitial deletion; aberrant expression for other reasons	T-ALL (B-cell lymphoma; B-ALL; X-SCID gene therapy associated T-cell leukemia)	533, 534
GATA2	EHT; HSC survival and self-renewal; MegE, mast cell, monocyte lineage differentiation	Mutations	MonoMAC, MDS, AML, CMML, Emberger syndrome	535
RUNX1 (AML1, CBF- α)	Formation of intraaortic clusters and HSCs during EHT; lymphopoiesis	<i>RUNX1-ETO</i> chromosomal translocations; mutations	AML	536, 299, 288
CBF- β (CBFB)	Emergence of HSCs from HE (in complex with RUNX1)	<i>CBF-β-MYH11</i> chromosomal translocations	AML	288, 537, 538
E2A (TCF3)	Maintenance of adult LT-HSC; LMPP, CLP, early thymocyte progenitor, pro-B-cell differentiation	<i>E2A-PBX1</i> chromosomal translocations; mutations	Pre-B-cell ALL; T-cell lymphoma	245, 539
ETV6 (TEL)	Maintenance/survival of adult LT-HSCs	<i>ETV6-RUNX1</i> chromosomal translocations; mutations	Pre-B-cell ALL; immature adult T-ALL	299, 539, 297, 540
MYB (C-MYB)	Self-renewal and multilineage differentiation of adult LT-HSCs	Chromosomal translocation involving <i>TCRβ</i> ; duplication	T-ALL	541–543
EVI1	Generation of definitive HSCs; Self-renewal of adult LT-HSCs	Aberrant expression; Chromosomal translocations involving <i>RUNX1</i> and <i>ETV6</i>	AML; MDS, CML blast crisis	246, 544
Epigenetic Factor				
MLL	Generation of definitive HSCs; adult HSC quiescence and self-renewal	Chromosomal translocations involving <i>AF4</i> , <i>AF9</i> , <i>ENL</i> , <i>AF10</i> , <i>ELL</i> , <i>AF6</i> , etc. (79)	ALL, AML	545, 546
DNMT3A	HSC differentiation	Mutations	AML, T-cell leukemia and lymphoma, MDS	348
TET2	HSC differentiation	Mutations, <i>IDH1/2</i> mutations	CMML, AML, MDS, T-cell lymphoma, DLBCL	547, 548
ASXL1	HSC differentiation	Mutations	CMML, AML, MDS	549, 359, 550

^aData from complete or conditional knockout studies in mice

AML, acute myeloid leukemia; B-ALL, B-cell acute lymphoblastic leukemia; CML, chronic myeloid leukemia; CMML, chronic myelomonocytic leukemia; DLBCL, diffuse large B-cell lymphoma; EHT, endothelial-to-hematopoietic transition; HE, hemogenic endothelium; HSC, hematopoietic stem cell; HSPCs, hematopoietic stem and progenitor cells; LMPP, lymphoid primed multipotent progenitors; MDS, myelodysplastic syndrome; MegE, megakaryocyte/erythrocyte; MLL, mixed-lineage leukemia; MonoMAC, monocytopenia and *Mycobacterium avium* complex infections; *SIL*, *SCL* interrupting locus; T-ALL, T-cell acute lymphoblastic leukemia; X-SCID, X-linked severe combined immunodeficiency.

Transcription Factors Required for the Specification of HSCs

As one of the few transcription factors known to be essential for the mesoderm-hemangioblast transition, the ETS class protein ETV2 is expressed in a subset of FLK1⁺ cells with enhanced endothelial and hematopoietic potential and downregulated thereafter.^{246,247} Together with the forkhead transcription factor FOXO2, it cooperatively induces the FLK1⁺ mesoderm by stimulating the expression of key endothelial and hematopoietic genes such as *Flk1*, *vascular endothelial (VE)-cadherin*, *Tie2*, *Scl* and *Notch4*.²⁴⁸

Before the emergence of HSCs, the bHLH protein SCL is required for the specification of the bipotent hemogenic endothelium within the hemangioblast during embryonic development.²⁴⁹ Its knockout in mice, as well as that of its binding partner LIM domain protein *Lmo2*,^{250–252} results in the lack of hematopoiesis with early embryonic lethality,^{253–256} and an absence of adult HSCs.^{257,258} SCL expression is regulated by three hematopoiesis-specific enhancers, one of which comprises an ETS/ETS/GATA motif that binds ETS transcription factors FLI1 and ELF1 as well as GATA2, revealing the transcriptional cascade at the top of the hematopoietic hierarchy.²⁵⁹ Interestingly, once emerged, HSCs require either SCL or the closely related bHLH factor LYL1 for function and survival.^{260–262} Elevated expression of *SCL* and/or *LMO2*, as well as *LYL1* is found in 35–65% of T-cell acute lymphoblastic leukemia (T-ALL), mostly because of chromosome translocations but also, in the case of *SCL*, intragenic deletions.²⁶³

GATA2, a zinc finger transcription factor, is expressed before HSC emergence in the paraaortic splanchnopleura and later in the AGM.²⁶⁴ GATA2 has been shown to be essential for the production of cells belonging to all lineages in definitive (or adult) hematopoiesis.^{265,266} Interestingly, it functions to preserve the pool of immature HSPCs by preventing the differentiation of hematogenic precursor cells.²⁶⁷ Thus, reduction of *GATA2* expression or activity is a prerequisite for HSC commitment. Heterozygous germline mutations in *GATA2* are the cause of several previously known clinical syndromes: MonoMAC (monocytopenia and *Mycobacterium avium* complex infections),^{268,269} which are also described as combined dendritic cell, monocyte, B and natural killer lymphoid or DCML deficiency.^{270,271} Individuals with MonoMac almost invariably progress to a distinct form of myelodysplastic syndrome (MDS) and in 14% and 8% to acute myeloid leukemia (AML) and chronic myelomonocytic leukemia (CMML), respectively.²⁷² Familial myelodysplastic and AML syndrome²⁷³ as well as Emberger syndrome (primary lymphedema with predisposition to AML)²⁷⁴ also belong to this group, and in some cases are caused by the identical *GATA2* mutation.

The core-binding protein RUNX1 and its obligate binding partner CBF- β are both required for the transition from hemogenic endothelium to definitive HSCs.^{275–278} *Runx1* expression is upregulated during the endothelial-to-hematopoietic transition (EHT) in the hemogenic endothelium, probably by GATA2, the ETS transcription factors FLI1 and PU.1 and the SCL complex (SCL, LMO2, LDB1).²⁷⁹ RUNX1 then induces expression of other critical transcription factors such as GFI1 and GFIB which in turn downregulate the endothelial markers TIE2, VE-cadherin and KIT.²⁸⁰ In addition, RUNX1 causes rapid global reorganization of transcription factors such as SCL, FLI1 and C/EBP β which is critical for the EHT and hematopoietic fate.²⁸¹ RUNX1 is also required to antagonize the effects of the homeobox transcription factor HOXA3, a negative regulator of specification of the hemogenic endothelium. HOXA3 represses a cascade of transcription factors that promote hemogenesis while at the same time inducing a set of genes critical for maintaining endothelial character.²⁸² *RUNX1* and *CBF- β* are the most common target of chromosomal translocations in acute leukemia. In particular, translocations resulting in *RUNX1-ETO* and *CBF- β -MYH11* cumulatively account for 15% of AML.²⁸³ Consistent with the fact that neither *RUNX1-ETO*²⁸⁴ nor *CBF- β -MYH11*²⁸⁵ induce leukemia by themselves in mouse models but rather require additional mutations, next-generation sequencing studies have identified both as preleukemic lesions.^{286,287} In addition,

mutations in *RUNX1* are observed in patients with various hematologic diseases including MDS, CMML, ALL, de novo and therapy-related AML and the autosomal dominant preleukemic syndrome familial platelet disorder with predisposition to AML (FPD/AML).²⁸⁸

Transcription Factors Required for HSC Homeostasis

Many transcription factors from different protein classes that play a role in setting up the hematopoietic hierarchy are necessary for HSC self-renewal in competitive transplantation assays.¹ For example, SCL is expressed much higher in LT-HSCs compared to ST-HSCs, and promotes their quiescence,²⁸⁹ which preserves the LT-HSC pool.²⁹⁰ In HSCs as well as differentiating progenitors, SCL exists in different complexes most of which include GATA2 (or GATA1 in the erythroid lineage), E2A and the non-DNA binding adaptor proteins LMO2 and LDB1.^{279,291} Loss of any of these SCL partners leads to defects in HSC maintenance.^{255,262,292–294} Apart from GATA2 and LMO2, also deregulation of E2A causes hematologic malignancies. Six percent of all pediatric ALLs, in particular pre-B cell ALL (23%) are caused by a chromosomal translocation that fuses the *E2A* gene with *PBX1* (pre-B-cell leukemia homeobox 1),^{295,296} which encodes an important HOX interacting factor discussed later.

The ETS-related transcriptional repressor TEL/ETV6 is specifically required for HSC survival but not their emergence.²⁹⁷ Like E2A, also ETV6 is involved in chromosomal translocations; the *ETV6-RUNX1* is the most common fusion gene in pediatric cancers, found in 22% of childhood ALL (of the pre-B-cell subtype).²⁹⁸ In contrast to the translocation generating the *E2A-PBX1* fusion gene most of the *ETV6-RUNX1* fusions seem to originate in utero.²⁹⁹

Another transcription factor associated with human malignancies, *EVII*, is specifically expressed in LT-HSCs. When overexpressed in mice *Evi1* boosts LT-HSC self-renewal, whereas its heterozygous loss leads to marked reduction of their self-renewal capacity.³⁰⁰ Aberrant expression of *EVII* isoforms is observed in 8–11% of AML,^{301,302} and 28% of mixed-lineage leukemia (MLL)-rearranged AML,³⁰³ and usually associated with a poor prognosis.³⁰² Furthermore, its translocation with *ETV6* or *RUNX1* is associated with progression to blast crisis in chronic myeloid leukemia (CML).^{304,305}

The HOX Cluster in HSC Self-Renewal

Homeobox (HOX) genes encode homeodomain-containing transcription factors critical for embryonic patterning, organized into four paralogous clusters (A, B, C, and D) on four chromosomes.³⁰⁶ Because of limited DNA sequence specificity and selectivity, HOX proteins function through interaction with DNA-binding cofactors, in particular, PBX and/or myeloid ectopic insertion site (MEIS) family members.^{307,308} At least 22 of the 52 HOX genes (none from the HOXD cluster) are expressed in mouse and human HSPCs and are subsequently downregulated to permit lineage commitment.³⁰⁹ Therefore, continuous HOX expression generally blocks differentiation and leads to rapid expansion of preleukemic HSPCs. In mice, overexpression of *HOXA10* has been shown to block myeloid and lymphoid differentiation leading to AML.³¹⁰ This is also the case for *Hoxa9*, in particular conjunction with *Meis1* or the *E2A-Pbx1* fusion gene.^{311–313} *HOXA9* overexpression belongs to a gene signature that distinguishes AML from ALL, and in AML patients highly correlates with treatment failure.³¹⁴

A number of leukemic chromosomal translocations, either directly or indirectly, lead to the overexpression of HOX genes. The nuclear pore complex protein NUP98 was first implicated in hematologic malignancies by the discovery of *NUP98-HOXA9* fusions in AML.^{315,316} Approximately half of all *NUP98* translocations involve HOX genes, most commonly *HOXA9* in AML, MDS, CML and CMML, but also *HOXA11* and *HOXA13* as well as their paralogues in the B and C cluster.^{317,318} While the overall prevalence of these fusions is low, they are associated with a poor prognosis.³¹⁹

In normal HSPCs, the expression of HOX genes is regulated by MLL1,³²⁰ as part of a multiprotein complex that regulates the chromatin structure at HOX clusters.^{321,322} MLL1 fusion proteins in *MLL1*-rearranged leukemias further induce the transcription of specific HOX genes including *HOXA5*, *HOXA9* and *HOXA10*.^{323,324} Indeed, HOX gene overexpression is essential for MLL1-fusion induced leukemogenesis as demonstrated by the dependence of transplanted AMLs induced by both *MLL1-ENL* and *MLL1-AF4* rearrangements on *HOXA9*.^{325,326}

Transcription Factor Networks

Transcription factors act within larger multiprotein complexes. In the setting of hematopoiesis, transcription factors often act positively to sustain their own expression, while simultaneously acting to cross-regulate other transcription factors, thereby establishing complex transcriptional networks. With the advent of genome-wide molecular studies, networks can be constructed computationally. Examples include a core heptad regulatory network consisting of SCL, LYL1, LMO2, ERG, FLI1, GATA2 and RUNX1 bound to over 1,000 genes in HSPCs,^{327,328} or a regulatory module composed of GATA1, GFI1 and GFI1B with a potentially important role in specifying early lymphoid cells.³²⁹ Also, profiling of transcription factors in single HSPCs combined with computational lineage progression analysis suggests a role for GATA2 in driving a network that specifies megakaryocytic and erythroid from lymphomyeloid lineage cells.³³⁰ As these constructed networks become more mature, in silico methods will predict developmental outcomes that can be tested experimentally by modulation of one or multiple transcription factors in a direct manner.³³¹ A comprehensive understanding of how gene regulatory networks are perturbed in hematologic malignancies may lead to new therapeutic approaches based on restoring normal regulatory patterns.

Epigenetic Regulation of HSC Self-Renewal

Epigenetic regulation leads to a “stably heritable phenotype resulting from changes in a chromosome without alteration in the DNA sequence”.³³² Epigenetic modifications include DNA methylation, covalent histone modification, chromatin remodeling and mechanisms involving noncoding RNAs which will be discussed further later. By modifying chromatin structure and accessibility, epigenetic mechanisms regulate the expression of genes involved in determining the balance between self-renewal and lineage commitment of HSCs, ultimately leading to all hematopoietic cell types. Epigenetic dysregulation has been implicated in the pathogenesis of virtually all hematologic malignancies.^{333,334} In contrast to genetic mutations, epigenetic alterations are in principle reversible, making epigenetic modifiers attractive targets for the innovative treatment of hematologic malignancies. Fig. 9.2 depicts key epigenetic factors within the hematopoietic hierarchy, and Table 9.1 summarizes main roles of critical epigenetic factors in HSPCs and hematologic malignancies.

DNA methylation plays a critical role in HSC self-renewal and commitment.^{335–338} Through recruitment of multiprotein complexes, methylated DNA results in transcriptional repression of nearby genes. In mammalian cells, DNA methylation occurs at cytidines, mostly in the context of CpG dinucleotides, dispersed throughout the genome and clustered (as CpG islands) within gene promoters. In a number of hematologic cancers, for example, the progression from MDS to AML, promoter CpG islands become hypermethylated and the affected genes, including tumor suppressor genes silenced.³³⁹ Furthermore, subgroups of AML can be defined by unique DNA methylation profiles, which can be used to stratify AML patients with respect to their overall survival.³⁴⁰ The family of DNA methyltransferases includes the de novo DNA methyltransferases DNMT3A and DNMT3B that establish methylation whereas another family member, DNMT1, maintains DNA methylation.^{341,342} DNA methylation is required for HSCs to differentiate. Conditional knockout

of *Dnmt3a*, further pronounced by ablation of *Dnmt3b*, leads to an accumulation of self-renewing HSCs in the BM which lose their differentiation capacity upon serial transplantation.^{343,344} Next-generation sequencing studies have identified *DNMT3A* mutations in most hematologic malignancies, in particular in patients with cytogenetically normal AML (over 30%),³⁴⁵ where they can be detected as preleukemic lesions,^{286,346} and T-ALL (16%)³⁴⁷; for a complete list see³⁴⁸). In contrast, *DNMT1* mutations have been rarely found in AML.³³⁴

Recently it was discovered that DNA methylation is in fact reversible,^{349,350} owing to the activity of ten-eleven translocation (TET) proteins (TET1, TET2, and TET3), which iteratively oxidize 5-methylcytosine present in methylated CpG dinucleotides.³⁵¹ Mice deficient for *Tet2*, the only TET expressed in the BM, show enhanced self-renewal of HSCs and develop a CMML-like disease.^{352–354} *TET2* is mutated in 49% of CMML³⁵⁵ and up to 23% of AML^{356–358} patients. Interestingly, gain-of-function mutations in isocitrate dehydrogenase 1 and 2 (*IDH1/2*) that indirectly impair TET2 function are mutually exclusive with *TET2* mutations in AML. *IDH1* and 2 are found mutated in 13–33% of AML cases and lead to similar methylation profiles as *TET2* mutations.^{359,360–363} *IDH1/2* enzymes catalyze the conversion of isocitrate to α -ketoglutarate (α -KG), but mutated *IDH1/2* further convert α -KG to 2-hydroxyglutarate, which inhibits the α -KG dependent TET2 enzyme.^{364,365}

The effects of histone modifications are combinatorial in nature, and there is crosstalk between DNA methylation and histone modifications.³⁶⁶ Histones have protruding flexible and charged NH₂-termini (“tails”) that can be posttranslationally modified in various ways, by methylation, acetylation, phosphorylation, ubiquitination and sumoylation, to name but a few.³⁶⁷ Many histone modifications have been implicated in HSC self-renewal by knockout or overexpression of chromatin regulators that function as their “writers”, “readers” or “erasers” (for a recent list, see³⁶⁸). Recurrent mutations of CREBBP and/or EP300, members of the histone acetyltransferase family that activate transcription, have been detected in several lymphoma types,³⁶⁹ and 18% of relapsed pediatric ALL patients exhibit mutations in the enzymatic domain of CREBBP, which are thought to contribute to drug resistance.³⁷⁰

Unlike histone acetylation, methylation of histones can have activating or repressive effects, dependent on the context and the targeted histone residue. With respect to active marks, most epigenetic studies have focused on lysine methylation carried out by lysine methyltransferases (KMTs) and removed by lysine demethylases (KDMs). The large multidomain KMT *MLL1* is essential for the generation of definitive HSCs in the mouse,³⁷¹ likely through its regulation of HOX cluster genes.³²⁰ The *MLL1* locus has been found to be frequently involved in chromosomal translocations in up to 70% of infant and childhood AML and ALL and in 5–10% of adult leukemia,³⁷² generally associated with a poor prognosis.³⁷³ 85% of *MLL1* translocations involve six proteins (AF4, AF9, ENL, AF10, ELL, and AF6), of which *MLL1-AF4* in ALL and *MLL1-AF9* in AML are most common.³⁷⁴ Many *MLL1* fusion partners belong to the super elongation complex (SEC); when fused to *MLL1* the aberrantly recruited SEC bypasses the normal transcription initiation-to-elongation checkpoints leading to high expression of *MLL1*-regulated genes such as HOX, WNT and leukemic stem cell target genes.³⁷⁵ Furthermore, almost all fusion proteins aberrantly recruit another KMT, DOT1L, which by methylating H3K79 induces the expression of *MLL1* target genes sufficient for leukemogenesis such as *HOXA9* and *MEIS1*.³¹¹ In addition, *MLL1* fusion proteins provoke a global loss of DNA methylation in AMLs.³⁷⁶ In fact, *Dnmt1* haploinsufficiency, while not perturbing normal HSC function, significantly delays leukemia progression in the *MLL-AF9* AML mouse model.³⁷⁷

At many lineage-specifying promoters in HSCs, epigenetic activators are balanced with repressive complexes, namely the polycomb repressive complex 1 (PRC1) and PRC2. The latter typically comprises the catalytically active EZH2, as well as EED and SUZ12, and is responsible for di- and trimethylation of H3K27, a repressive histone mark that is then “read” and maintained by PRC1 through

histone H2A ubiquitination.^{378,379} EZH2 also recruits DNA methyltransferases to its target genes, thereby enhancing its repressive effect.³⁸⁰ Overexpression of *Ezh2* in mice enhances LT-HSC self-renewal by silencing differentiation genes^{381,382} and causing a shift to the expression of proliferation genes.³⁸³ EZH2 has been described with either tumor suppressive or oncogenic roles, depending on the cellular context. *EZH2* gain-of-function mutations, resulting in overall “hyper-trimethylation”, occur in 7.2% and 21.7% of follicular lymphoma and diffuse large B-cell lymphoma, respectively. Loss-of-function mutations have been observed in 12% of myelodysplastic/myeloproliferative neoplasms and 18% of T-ALL cases but are rare in de novo AML (1–2%). PRCs do not bind to DNA directly but require the interaction with other proteins such as ASXL1. *ASXL1* is mutated in 6–30% of AML and 43% of CMML.³⁵⁹ These mutations hinder ASXL1 from recruiting PRC2 to and thus repressing target genes such as *HOXA9*.³⁸⁴

Regulation of HSCs by Noncoding RNAs

Sequencing the human genome revealed that less than 1.5% of the DNA encodes proteins³⁸⁵ but, remarkably, subsequent analyses discovered that still 76% of the genome is transcribed into RNA.³⁸⁶ Many noncoding RNAs (ncRNAs) are enriched in HSCs compared to hematopoietic progenitors.³⁸⁷ ncRNAs other than ribosomal RNAs and transfer RNAs are arbitrarily categorized into long ncRNAs (lncRNAs) and short ncRNAs if >200 or <200 nucleotides long, respectively. Among the short ncRNAs, microRNAs (miRNAs) are ~22-nucleotide regulatory ncRNAs that repress gene expression predominantly by binding to the 3′ untranslated region of protein-encoding mRNAs leading to their destabilization.³⁸⁸ A miRNA can target large numbers of mRNAs, and a single mRNA can be regulated by multiple miRNAs.³⁸⁹ HSCs depend on miRNA function for their survival as demonstrated by the finding that deletion of *Dicer* or *Ars2*, both essential factors for miRNA biogenesis results in HSC apoptosis and BM failure.^{390,391} More than 100 different miRNAs are specifically expressed during hematopoiesis, preferentially targeting and fine-tuning expression of transcription factors and their upstream activators.³⁹² Hematologic malignancies show characteristic changes in their miRNA expression profiles. For example, ALL samples can be classified into subtypes according to their miRNA expression patterns.³⁹³

Numerous miRNAs are specifically enriched in HSPCs, including miR-155,³⁹⁴ miR-125a,³⁹¹ miR-125b,^{395–397} miR-29a,³⁹⁸ miR-126, and miR-130a.³⁹⁹ Overexpression of the miRNA cluster miR-99b/let7e/125a or miR-125a alone is capable of expanding the HSC pool in mice,^{391,395,400} potentially by inhibiting apoptosis of HSCs mediated by the proapoptotic gene *Bak1*, which is a miR-125a target.³⁹¹ In addition, several miRNAs have been implicated in regulating HPC differentiation, including miR-155 (lymphoid and myeloid development),^{394,401} miR-223 (myeloid development)^{402,403} and the miR-181/miR-150/miR-17-92 cluster (lymphoid development).^{404–407} The example of miR-155 shows that, like transcription factors, some miRNAs are repurposed during hematopoietic ontogeny.⁴⁰⁸

Most of the miRNAs conferring a competitive advantage to the engrafted BM have been implicated in malignant transformation, and are therefore called oncomiRs.⁴⁰⁹ Overexpression of miR-125 family members causes myeloid and lymphoid malignancies in mice^{395,397,400,410,411} and they are upregulated in chromosomal translocations leading to MDS/AML and B-cell ALL.^{412–414} oncomiRs contribute to leukemic phenotypes by different mechanisms such as expediting cell cycle transitions,³⁹⁸ targeting tumor suppressors such as TET2,⁴¹⁵ or dysregulating the balance between lineage-specific transcription factors.⁴⁰¹ miR-155, the first miRNA shown to be sufficient to cause lymphoblastic leukemia or high-grade lymphoma in a transgenic mouse model,⁴¹⁶ is overexpressed in B-cell lymphomas⁴¹⁷ and AML.^{418,419} miR-196, which is upregulated specifically during the transition from quiescent LT-HSCs to ST-HSCs, targets several of its neighboring HOX genes important for self-renewal such as *HOXA9*.^{408,420–423} Like HOX genes, miR-196b is transcriptionally

regulated by MLL and highly induced in MLL-rearranged leukemias, contributing to an unfavorable prognosis.^{422,424} In this context, miR-196 has been shown to be necessary for *MLL-AF9* dependent immortalization of BM cells.⁴²⁴ miRNAs can also function as tumor suppressors, exerting their function by targeting oncogenes. For example, the miRNA cluster miR-15a/miR16-1 is deleted or epigenetically silenced in 68% of chronic lymphoid leukemia patients,⁴²⁵ resulting in the upregulation of its target oncogene *BCL2*.⁴²⁶

In contrast to miRNAs, little is known about the expression of lncRNAs in HSPCs and only a few lncRNAs have been further functionally characterized. Several recent studies have compiled lists of lncRNAs expressed in HSCs, some of which are downregulated in more differentiated progeny,^{338,387} and in leukemic cells.⁴²⁷ Knock-down of a lncRNA specifically expressed in mouse BM LT-HSCs increased self-renewal of HSCs in vivo and abolished recruitment of the transcription factor E2A, essential for the development of multi-lineage HPCs,²⁹² to chromatin.⁴²⁸ HSCs from female mice depleted for *Xist* lncRNA (responsible for X chromosome inactivation) were shown to have maturation defects and to be compromised in their repopulation capacity.⁴²⁹ Furthermore, all *Xist* mutant female mice developed highly aggressive mixed myeloproliferative neoplasms/MDS.⁴²⁹ With those relatively few studies the overall relevance of lncRNAs for the pathogenesis of hematopoietic diseases is not yet well understood.

HEMATOPOIETIC STEM CELL METABOLISM

The role of oxidative and nonoxidative glucose metabolism in regulating HSC and HPC function has recently been elucidated.⁴³⁰ Wang et al reported that deficiencies in either lactate dehydrogenase A (LDHA) or the M2 isoform of pyruvate kinase (PKM2), two enzymes which catalyze the fermentation of glucose to lactate, result in differential effects on HSC and progenitor cell function.⁴³⁰ Deletion of *Ldha* inhibited normal HSC and progenitor cell function, whereas deficiency in *Pkm2* impaired progenitor cell function without affecting HSCs.⁴³⁰ The authors further showed that deficiency of either *Ldha* or *Pkm2* inhibited leukemia initiation, suggesting that these metabolic enzymes may be therapeutically useful in targeting leukemia.⁴³⁰ Separately, Ito et al demonstrated that the loss of peroxisome proliferator-activated receptor δ (PPAR- δ) or inhibition of mitochondrial fatty acid oxidation induced the loss of HSC maintenance.⁴³¹ Interestingly, this PPAR- δ -FAO axis was considered to serve as a “metabolic switch” which regulated HSC symmetric versus asymmetric division.⁴³¹ The tumor suppressor gene, *Lkb1*, which encodes a serine/threonine kinase that regulates phosphorylation of AMP-activated protein kinase, was also shown to be essential for HSC maintenance.⁴³² *Lkb1* inactivation was shown to deplete quiescent HSCs associated with depletion of all hematopoietic subpopulations, coupled with mitochondrial defects, depletion of ATP and alterations in lipid and nucleotide metabolism.⁴³²

Not surprisingly, the metabolic state of HSCs is influenced by the hypoxic microenvironment in which HSCs reside.^{433,434} Specifically, hypoxia contributes to the maintenance of quiescent HSCs which have high expression of HIF-1 α and rely primarily on anaerobic glycolysis, rather than oxidative phosphorylation, to produce ATP.^{434–436} The therapeutic importance of understanding the cellular metabolic state of HSCs was recently highlighted by Liu et al,⁴³⁷ who showed that treatment of HSCs with alexidine dihydrochloride, a selective inhibitor of the mitochondrial phosphatase PTPMT1, reprogrammed HSC metabolism from aerobic to glycolysis, resulting in increased HSC maintenance in culture. Alterations in HSC metabolism have also been described with aging, thereby impacting HSC function. Mohrin et al recently reported that SIRT7, a histone deacetylase which regulates the expression of the mitochondrial master regulator, nuclear respiratory factor 1, was reduced in aging HSCs.⁴³⁸ SIRT7 inactivation was shown to increase mitochondrial folding stress and compromise the regenerative capacity of HSCs, suggesting that alterations in the mitochondrial unfolded protein response contribute to HSC aging.⁴³⁸

TABLE 9.2 Soluble Proteins and Small Molecules That Regulate Hematopoietic Stem Cell Self-Renewal

Growth Factor	Function in HSC Self-Renewal	Reference ^a
NOTCH ligands	Sufficient, not necessary	167, 171–173, 177, 178
WNT proteins	Sufficient, ? necessary	185, 189, 201, 203
BMPs	? Sufficient, <i>SMAD4</i> necessary	220
SCF	Necessary, not sufficient	439
TPO	Necessary, not sufficient	440
CXCL12	Necessary	239, 242
RAR- γ	Necessary	117
ANGPTL	Sufficient	441, 442
PGE ₂	Sufficient	445, 448
PTN	Necessary, sufficient	107, 454
AHR antagonist	Sufficient	456

^aReferences are representative, not all-inclusive.

AHR, aryl hydrocarbon receptor; ANGPTL, angiopoietin-like protein; BMP, bone morphogenetic protein; CXCL12, C-X-C motif chemokine 12; HSC, hematopoietic stem cell; PGE₂, prostaglandin E₂; PTN, pleiotrophin; RAR- γ , retinoic acid receptor γ ; SCF, stem cell factor; TPO, thrombopoietin. NOVEL GROWTH FACTORS FOR HEMATOPOIETIC STEM CELLS AND CLINICAL TESTING

Several novel proteins and small molecules have been reported to promote potent expansion of murine or human HSCs in culture (Table 9.2).^{107,439,440} Moreover, leveraging insights into the mechanisms which regulate HSC self-renewal and differentiation, several different approaches to expand human CB HSCs have been tested in early clinical trials. Zhang et al⁴⁴¹ reported the discovery of the proteins angiopoietin-like 2 (ANGPTL2) and ANGPTL3 in a fetal liver stromal cell line and demonstrated that the addition of ANGPTL2 or ANGPTL3 to cytokine cultures supported a 24- to 30-fold expansion of human BM cells capable of long-term repopulation in NOD/SCID mice. Subsequently, Zhang et al⁴⁴² demonstrated that the addition of ANGPTL5 and insulin-like growth factor binding protein 2 (IGFBP2) to the combination of SCF, TPO, and FGF1 supported up to a 20-fold increase in human CB cells capable of 8-week engraftment in NOD/SCID mice. Of note, because the addition of ANGPTL5 and IGFBP2 did not substantially increase total cell expansion compared with SCF, TPO, and FGF1 alone, it remains possible that treatment with ANGPTL proteins or IGFBP2 may enhance the homing of HSCs in immune-deficient transplant models.⁴⁴² Because of their potency in expanding human CB HSCs in preclinical models, ANGPTL proteins represent attractive targets for translation into the clinic. Recently, several ANGPTL proteins, including ANGPTL2 and ANGPTL5 have been found to bind and activate the immune-inhibitory receptor human leukocyte immunoglobulin-like receptor B2 (LILRB2).⁴⁴³ Interestingly, studies in zebrafish and human cells indicate that ANGPTL2, through its interaction with LILRB2, leads to cleavage and activation of the NOTCH receptor, ultimately inducing MYC target genes stimulating HSPC formation and expansion.⁴⁴⁴

North et al⁴⁴⁵ reported that prostaglandin E₂ (PGE₂) positively regulates HSC formation in the zebrafish model. These authors also demonstrated that short-term (2-hour) treatment of murine HSCs with PGE₂ produced a two- to threefold increase in donor cell repopulation in transplanted mice compared with mice transplanted with untreated cells.⁴⁴⁵ Subsequently, Goessling et al⁴⁴⁶ showed

that PGE₂ modulates WNT signaling via regulation of β -catenin degradation and PGE₂/WNT activation regulated both hematopoietic regeneration in the zebrafish and long-term HSC repopulation in mice. Hoggatt et al⁴⁴⁷ also showed that short-term exposure to PGE₂ promoted the enhanced homing and repopulation of human CB HSCs in immune-deficient mice caused by increased CXCR4 expression on PGE₂-treated CB HSCs. Ex vivo treatment with PGE₂ was subsequently shown to increase human CB CFC content and engraftment capacity after transplant into immune-deficient mice, and PGE₂-treated BM cells were also found to provide more than one year of multilineage reconstitution in a nonhuman primate model.⁴⁴⁸ Based on these encouraging results, a phase I clinical trial was undertaken, in which one unmanipulated CB unit and a second CB unit that was cultured for two hours in the presence of 16,16-dimethyl PGE₂ (dmPGE₂) were transplanted into adult patients after nonmyeloablative conditioning. dmPGE₂-treated CB cells resulted in accelerated neutrophil recovery (17.5 days versus 21 days) and long-term engraftment in 10 of 12 patients.⁴⁴⁹

Recently, screening strategies in human cells have been successfully used to identify novel growth factors, developmental factors and chemical compounds, for HSCs. Himburg et al identified pleiotrophin (PTN), a heparin binding growth factor, from a gene expression analysis of human brain-derived endothelial cells (ECs) that support human HSC expansion in vitro.^{450–453} Treatment of murine BM HSCs with PTN produced a 10-fold expansion of long-term repopulating HSCs in culture, and systemic administration of PTN to irradiated mice caused a 20-fold increase in the recovery of BM LTC-ICs in vivo.¹⁰⁷ Mechanistically, PTN signaling caused the upregulation of PI3K/AKT signaling and *Hes1* expression in HSCs, suggesting that activation of these signaling cascades may contribute to PTN-mediated HSC expansion.¹⁰⁷ Mice lacking *Ptn* had 11-fold less BM HSC content than their wild-type littermates.⁴⁵⁴ Interestingly, LT-HSC content, as measured in tertiary and quaternary transplants, was increased in chimeric mice with *Ptn* deletion in the BM microenvironment compared with wild-type mice.⁴⁵⁵ Taken together, these results suggest that PTN regulates BM HSC expansion and regeneration, and in the context of constitutive *Ptn* knockout, *Ptn* loss in hematopoietic cells may dominate over effects of *Ptn* loss in the niche.^{109,455} Further studies will be necessary to resolve these questions and define the potential therapeutic efficacy of PTN. Boitano et al⁴⁵⁶ described a screening approach of more than 100,000 heterocyclic compounds for the capacity to maintain human CD34⁺ cells in culture for five days. This screen yielded the discovery of the purine derivative StemRegenin 1 (SR1), which was shown to promote the expansion of human CB repopulating cells in vitro.⁴⁵⁶ Three-week cultures of human CB CD34⁺ cells with thrombopoietin, SCF, FLT3 ligand, interleukin-6 (IL-6), and SR1 promoted a 17-fold increase in SCID-repopulating cells compared with the progeny of cultures containing thrombopoietin, SCF, FLT3 ligand, and IL-6 alone.⁴⁵⁶ SR1 appears to mediate its effects via inhibition of the aryl hydrocarbon receptor. Aryl hydrocarbon receptors are expressed by HSCs, but the downstream signaling mechanism through which SR1 mediates HSC expansion remains unknown.⁴⁵⁶ Recently, Dahlberg et al reported that the combination of SR1 with the NOTCH ligand, Delta^{Ext-IgG}, caused a threefold increase in human CB-derived myeloid repopulation in NSG mice at two weeks compared to CB cells cultured with Delta^{Ext-IgG} or SR1 alone.⁴⁵⁷ Preliminary results from a phase I trial of transplantation with SR1-treated CB cells have demonstrated the feasibility and safety of this approach.⁴⁵⁸

In a recent analysis of growth factors elaborated by an AGM-derived stromal cell line, Wohrer et al reported that nerve growth factor and collagen 1, when added to a defined serum-free medium containing SCF and IL-11, produced fourfold expansion of murine long-term repopulating HSCs in seven-day cultures compared to SCF and IL-11 alone.^{459,460} Separately, treatment of human CB HSCs with a pyrimidoindole derivative, UM171, was shown to promote a 13-fold expansion of CB cells capable of repopulating NSG mice at 20 weeks posttransplantation.⁴⁶¹ Although the mechanism of action of UM171 has not been elucidated, preliminary analyses suggested that UM171 inhibited erythroid and megakaryocytic differentiation

of human HSCs in culture. Jaroscak et al.⁴⁶² tested the combination of FLT3 ligand, a GM-CSF/IL-3 fusion protein, and erythropoietin in a continuous perfusion culture system as a means to expand human CB cells before transplant. Similarly, Shpall et al.⁴⁶³ tested the capacity of SCF, granulocyte colony-stimulating factor (G-CSF), and megakaryocyte growth and differentiation factor to expand human CB cells that were then transplanted into adult CB transplant recipients. An alternative approach to cytokine-based expansion of human CB cells was suggested by Peled et al.^{464–466} who demonstrated a 159-fold increase in human CD34⁺ cells after seven-week culture with a copper chelator, tetraethylenepentamine (TEPA), and cytokines. Subsequently, de Lima et al.⁴⁶⁷ reported the safety and feasibility of culturing human CB cells with TEPA and SCF, FLT3 ligand, IL-6, and thrombopoietin followed by transplantation into patients in a phase I/II clinical trial. Although each of these clinical trials has shown the feasibility of transplanting ex vivo-cultured CB cells, none demonstrated substantial acceleration in hematopoietic cell engraftment in CB transplant recipients compared to historical controls. However, the TEPA plus cytokine strategy is being tested further in a phase II/III study in several countries, including the United States.¹⁶⁶

Several other clinical trials have recently indicated progress toward the clinical expansion of human CB HSCs for therapeutic purposes. De Lima et al. reported a median time to neutrophil engraftment of 15 days in recipients of one unmanipulated CB unit plus CB cells cultured with mesenchymal stromal cells, compared to 24 days in historical controls, although long-term donor hematopoiesis derived almost exclusively from the unmanipulated cord blood unit.⁴⁶⁸ Lastly, Horwitz et al. reported that transplantation of one unmanipulated CB unit and the progeny of 21-day culture of human CB cells with nicotinamide produced earlier neutrophil recovery (13 versus 25 days for historical controls) and dominant engraftment from the nicotinamide-treated CB unit in eight of 11 treated patients.⁴⁶⁹

GENERATING HEMATOPOIETIC STEM CELLS FROM PLURIPOTENT STEM CELLS AND BY REPROGRAMMING OF SOMATIC CELLS

Globally more than 50,000 patients per year receive allogeneic and autologous HSC transplantations as treatments for congenital and acquired hematopoietic diseases and other malignancies.⁴⁷⁰ At present, the only cell sources for HSC transplantations are BM, CB, or mobilized peripheral blood. However, insufficient numbers, shelf-life concerns as well as immunologic incompatibility leading to graft-versus-host disease, even in human leukocyte antigen-matched grafts, limits their availability.^{471,472} One option to generate more HSCs is by expanding existing HSCs in vitro as described earlier. Despite substantial efforts, this has proven difficult; because of their tendency to differentiate in culture, the expansion of HSCs is not very efficient and does often not lead to fully functional HSCs in terms of their migratory behavior and long-term multilineage reconstitution potential.^{461,473,474}

The observation in 1981 that embryonic stem cells (ESCs) could be derived from mouse or, later, human blastocysts^{475–477} fueled experiments to differentiate HSCs from ESCs. In 2006, the discovery that mouse or human fibroblasts could be reprogrammed to induced pluripotent stem cells (iPSCs) by retroviral transduction with the same four factors, OCT3/4, SOX2, KLF4, and c-Myc,^{478,479} opened the door for the possibility of autologous stem-cell based therapies in the clinic.^{480,481} Since its first report this technology has been constantly modified⁴⁸² and is allowing the generation of iPSC lines from patients with a variety of blood disorders (references in⁴⁸³). This approach presents a new opportunity for disease modeling and drug screening.

Numerous methods for directed differentiation of HSCs from ESCs or more recently iPSCs have been developed, but so far none yield long-lived cells with full HSC functionality. In a recent study, inducible expression of five transcription factors, *HOXA9*, *RORA*, *ERG*, *SOX4*, and *MYB* imparted human ESC- and iPSC-derived

progenitors with short-term myeloid and erythroid engraftment potential.⁴⁸³ This and similar approaches are characterized by the lack of robust lymphoid potential, likely because these progenitors are developmentally still too immature.⁴⁸⁴

In light of the obstacles in generating HSCs from ESCs or iPSCs, approaches to directly reprogram somatic cells into HSCs, or trans-differentiate them to hematopoietic cells are being explored as alternative strategies. The concept of direct reprogramming was first demonstrated with the conversion of embryonic fibroblasts into contracting myocytes by just the transcription factor MyoD.⁴⁸⁵ Pluripotency-related factors are upregulated during endogenous reconstitution of mouse hematopoiesis after irradiation.⁴⁸⁶ Thus, studies successfully reprogramming human skin fibroblasts directly into HSPC-like cells used the pluripotency factors OCT4 or SOX2 together with a specific cytokine cocktail.^{486,487} While these cells engrafted, they again lacked lymphoid potential. In contrast to these examples of indirect lineage conversion via a less differentiated state, direct lineage conversion (or transdifferentiation) attempts have included the enforced expression of transcription factors critical for normal hematopoiesis.⁴⁸⁸ In analogy to the HSC-producing hemogenic endothelium, human umbilical-vein ECs cultured on an artificial vascular niche and overexpressing four transcription factors (*FOSB*, *GFI1*, *RUNX1* and *PU.1*) yielded serially transplantable hematopoietic colonies.⁴⁸⁹ However, these cells did not differentiate into T cells. In another approach demonstrating the benefit of the niche, lymphoid or myeloid progenitors were transduced with a transcription factor cocktail (*HLF*, *LMO2*, *PBX1*, *PRDM5*, *RUNX1T1* and *ZFP37*) and matured in irradiated mice to yield serially transplantable HSCs producing all lineages.⁴⁹⁰ Despite this progress in mice, fully functional human HSCs have not yet been generated in vitro. In addition, future studies will have to focus on strategies to avoid the risk of malignant transformation inherent in any directed differentiation or cellular reprogramming method.⁴⁹¹

HEMATOPOIETIC STEM CELL REGENERATION

Although much is now known about the intrinsic and extrinsic mechanisms that regulate adult HSC self-renewal and differentiation,^{1,166,188} the process through which HSCs regenerate after injury (e.g., chemotherapy or radiation) remains less well understood. Successful delineation of the mechanisms that control HSC regeneration has significant therapeutic potential because a large proportion of patients with cancer receive myelosuppressive or myeloablative therapy during the course of their disease. Signaling through the BMP and WNT signaling pathways has been shown to be necessary for hematopoietic regeneration to occur in zebrafish after sublethal irradiation.⁴⁹² These authors further demonstrated that SMAD and TCF, the downstream effectors of BMP and WNT signaling, respectively, couple with master regulators of myeloid and erythroid differentiation (C/EBP α and GATA1) to drive lineage-specific regeneration.⁴⁹² In a murine model of hematopoietic injury, Congdon et al.⁴⁹³ showed that *Wnt10b* expression is increased in BM stromal cells in response to irradiation, and WNT signaling is activated in BM HSCs after irradiation. As discussed earlier, in a zebrafish model, activation of WNT signaling during hematopoietic regeneration is modulated by PGE₂.⁴⁴⁶ WNT reporter activity was responsive to PGE₂ treatment, and the effect of Wnt8 toward enhancing hematopoietic recovery after sublethal irradiation was inhibited by administration of indomethacin, a PGE₂ antagonist.⁴⁴⁶ NOTCH signaling has also been implicated in the regulation of hematopoietic regeneration after stem cell transplantation.²⁷⁹ Deletion of *Notch2*, but not *Notch1*, was shown to delay myeloid reconstitution in mice after stem cell transplantation.¹⁷⁰ These data suggest that the BMP, WNT, and NOTCH pathways are attractive mechanistic targets for strategies to augment hematopoietic regeneration after myelosuppressive therapy.

Additional signaling pathways have been implicated in regulating hematopoietic regeneration. Deletion of plasminogen (*Plg*), a fibrinolytic factor, was shown to prevent HPC proliferation and recovery after 5-fluorouracil (5-FU)-induced myelosuppression in

mice.⁴⁹⁴ Conversely, activation of PLG by administration of tissue plasminogen activator promoted HPC proliferation and differentiation after myelosuppression, and this effect was dependent on matrix metalloproteinase 9-mediated release of c-Kit ligand.⁴⁹⁴ Similarly, Trowbridge et al²³² reported that mice that were heterozygous for the hedgehog receptor *Ptc1*, displayed earlier recovery of hematopoiesis after 5-FU-induced myelosuppression compared with wild-type littermate mice. Hedgehog binding blocks PTC1-mediated inhibition of SMO, thereby promoting downstream Hedgehog signaling. Therefore, heterozygous *Ptc1* mice have enhanced Hedgehog signaling, and these results implicate Hedgehog signaling as positively regulating short-term hematopoietic regeneration after injury. However, this acceleration in hematopoietic recovery in mice heterozygous for *Ptc1* occurred at the expense of LT-HSCs, which were exhausted in these mice.²³² Genetic studies have similarly demonstrated that the homozygous deletion of *Ship* in mice (SH2-containing inositol phosphatase) is associated with increased loss of HSCs after 5-FU exposure compared with heterozygous *Ship* deletion.⁴⁹⁵ In a similar model of 5-FU-mediated myelosuppression, Nemeth et al⁴⁹⁶ reported that mice deficient in the high-mobility group box 3 (*Hmg3b*) DNA binding protein exhibited more rapid recovery of phenotypic HSCs compared with wild-type mice. The enhanced recovery of the stem/progenitor pool in *Hmg3b*-deficient mice was associated with activation of WNT signaling, again suggesting that activation of the WNT pathway may accelerate HSC recovery after myelosuppression. Of note, expression of a constitutively active form of the signal transducer and activator of transcription 3 (*Stat3*) in HSCs increases their regenerative capacity after transplant into lethally irradiated mice.⁴⁹⁷ In this study, it was not determined whether alteration in *Stat3* expression affected HSC regeneration after myelosuppression (e.g., 5-FU or irradiation).⁴⁹⁷

At the cellular level, increasing evidence suggests an important role for BM ECs in promoting hematopoietic regeneration after myelotoxic stress.^{498–501} Genetic deletion or antibody-based inhibition of VEGFR2, which is expressed by sinusoidal BM ECs, was shown to delay both BM vascular and hematopoietic recovery after total-body irradiation (TBI).⁴⁹⁹ Systemic infusion of syngeneic or allogeneic ECs has also been shown to significantly accelerate the recovery of both the HSC pool and overall hematopoiesis in mice after high-dose TBI.^{501,502} Salter et al⁵⁰¹ and Butler et al¹⁷⁶ further demonstrated that hematopoietic regeneration after irradiation is dependent on VE-cadherin-mediated vascular reorganization because administration of a neutralizing anti-VE-cadherin antibody caused significant delay in hematologic recovery in mice after TBI. While the precise mechanisms through which BM ECs regulate HSC regeneration in vivo remain unclear, it was shown that systemic administration of PTN, a heparin binding growth factor that is secreted by both BM and brain ECs, causes a rapid increase in recovery of the HSC pool in mice after high-dose TBI.¹⁰⁷ Taken together, these studies suggested that the BM vascular niche may be an important reservoir for the discovery of growth factors and membrane-bound proteins that mediate HSC regeneration. Additional studies have further validated the important role of the BM vascular niche in regulating HSC regeneration following myelosuppressive injury. Deletion of the proapoptotic proteins, BAK and BAX, from *Tie2*-expressing BM ECs was shown to protect HSCs from radiation-induced depletion in mice, independent of HSC-autonomous effects.⁵⁰³ Furthermore, Doan et al reported that EGF is expressed by BM ECs after TBI and that systemic administration of EGF improved HSC regeneration and survival after TBI.⁵⁰³ EC-specific deletion of the NOTCH ligand, Jagged1, has also been shown to cause delayed white blood cell recovery and decreased survival in mice following sublethal TBI.⁵⁰⁴ Interestingly, recent studies have suggested several novel mechanisms through which HSC regeneration can be augmented following radiation-induced myelotoxicity, including augmentation of the thrombomodulin-activated protein C pathway,⁵⁰⁵ administration of the bactericidal/permeability-increasing protein (rBPI₂₁),⁵⁰⁶ activation of nuclear factor erythroid-2-related factor 2⁵⁰⁷ or Ras/MEK/ERK signaling in HSCs.⁵⁰⁸ Interestingly, it was also recently shown that both HSCs and leptin receptor-expressing BM stromal

cells secrete Angiopoietin 1 (ANGPT1) and that deletion of *Angpt1* in these cell populations accelerated vascular and hematopoietic recovery in mice after irradiation.⁵⁰⁹ Taken together, these studies reveal the remarkable complexity and orchestration of molecular responses to myelotoxicity and also suggest several potential pathways that can potentially be exploited for the therapeutic regeneration of HSCs.

Lastly, the effect of age on the capacity for HSCs to regenerate after myelosuppressive challenge remains an important question.⁵¹⁰ Clinical studies have confirmed the impaired reconstitutive capacity of HSCs from older patients in autologous stem cell transplant settings.⁵¹¹ Not surprisingly, older mice with defects in DNA damage repair mechanisms (nucleotide excision repair, nonhomologous end-joining) and telomere maintenance displayed severe defects in their capacity to reconstitute hematopoiesis after transplantation into lethally irradiated recipient mice compared with age-matched control subjects that retained the DNA repair and telomerase genes.⁵¹² Furthermore, Flach et al recently showed that aging HSCs display heightened levels of replication stress during cell cycling as a result of decreased expression of mini-chromosome maintenance replicative helicase components and altered DNA replication forks.⁵¹³ Therefore, therapeutic targeting to accentuate these DNA repair and replication mechanisms may facilitate the recovery of the functional HSC pool after myelosuppression and may lessen the oncogenic risk incurred via repeated exposure to DNA-damaging therapies (e.g., alkylators and irradiation).^{512,513} Interestingly, prolonged fasting has been shown to ameliorate chemotherapy-induced HSC damage and age-dependent myeloid bias in mice, associated with reduction in IGF1 levels.⁵¹⁴ Further research into the HSC-autonomous and extrinsic mechanisms which regulate HSC aging and HSC regeneration during aging should be prioritized going forward and will hopefully yield therapeutic avenues to reverse some aspects of hematopoietic aging.

HEMATOPOIETIC STEM CELLS AND MALIGNANCY

Similar to the HSC at the apex of the hematopoietic hierarchy, an entity termed a leukemic stem cell (LSC) has been proposed to drive tumorigenesis because of its ability to self-renew and reinitiate leukemia upon transplantation in an experimental setting (e.g., mouse transplant; Fig. 9.4).^{515–517} A clonal origin of a hematopoietic malignancy was first demonstrated for CML where the presence of the characteristic Philadelphia chromosome in myeloid, erythroid, megakaryocytic and B-lymphoid cells suggested a common origin,^{518–520} which was later proven by molecular analysis.⁵²¹ Genetic analyses in a case of CML also provided the first proof for another important concept in cancer, that of clonal evolution (see Fig. 9.4),⁵²² which had already been hypothesized for solid tumors.⁵¹⁶ This model posits that a subclone within the initial LSC-derived clone acquires additional genetic or epigenetic alterations that convey a growth advantage and lead to heterogeneity within the tumor.⁵¹⁵ Whereas the HSC pool itself does not expand during progression of chronic phase CML to blast crisis, granulocyte-macrophage progenitors (GMPs) with increased expression of the continuously active tyrosine kinase fusion protein BCR-ABL and high self-renewal capacity driven by activation of nuclear β -catenin are amplified.⁵²³ Thus, the LSC may differ from the tumor-initiating “cell of origin”.^{161,523} While in CML the tumor-initiating HSC maintains the chronic phase of the disease, subsequent genetic events arising in the GMPs give rise to LSCs sustaining the blast crisis.

The first cancer stem cell to be identified in any malignancy was the LSC in AML.^{517,524} CD34⁺CD38[−] cells but not CD34⁺CD38⁺ cells derived from all known AML subtypes (except for the AML subtype M3) repopulated secondary NOD/SCID recipient mice and fully reproduced AML.^{524,525} Next-generation sequencing efforts have revealed the clonal evolution in primary and relapsed AML.^{287,334,345,526–529} While healthy and AML genomes contain hundreds of exonic mutations,²⁸⁷ as few as two key somatic “driver” mutations enable clonal expansion of a cell that takes along all the background “passenger” mutations.

Fig. 9.4 CLONAL DYNAMICS IN HEMATOLOGIC MALIGNANCIES. (A) The cancer stem cell (CSC) model assumes a hierarchical structure akin the normal hematopoietic hierarchy. The CSC can give rise to the hematopoietic lineage but usually results in a differentiation block leading to the accumulation of immature progenitor (blast) cells. (B) The clonal evolution model suggests that a carcinogen-induced change in a normal cell confers a growth advantage to that cell permitting its clonal expansion. Selective pressures are responsible for some mutant subclones to expand while others become extinct or dormant. A combination of both models is also possible. (A, Adapted from Wang J, Ma Y, Cooper MK: *Cancer stem cells in glioma: challenges and opportunities*. *Transl Cancer Res* 2, 429, 2013. B, Adapted from Greaves M, Maley CC: *Clonal evolution in cancer*. *Nature* 481, 306, 2012; Nowell PC: *The clonal evolution of tumor cell populations*. *Science* 194, 23, 1976.)

An additional driver mutation occurring in this clone then gives rise to the founding LSC.²⁸⁷ Mutations in either the LSC itself or again its subclones can evolve into the dominating clone in relapsed AML.⁵²⁶ Genomic profiling of AML patients has yielded strong evidence for the presence of nonmalignant preleukemic HSPCs^{286,346,530} that survive chemotherapy and produce mature lymphoid cells while at the same time generating new waves of mutant clones as the disease progresses. Mutations in epigenetic genes, for instance, *DNMT3A*, *IDH2* and *ASXL1*, are often identified in the ancestral clones, suggesting their early role in AML pathogenesis, whereas mutations in *NPM1* and signaling genes appear to be acquired later.^{286,346} Of note, *DNMT3A* and *ASXL1* are also among the three most recurrently mutated genes in clonal hematopoiesis (along with *TET2*) and present with a frequency of about 10% of healthy people over 65 years.^{531,532} Furthermore, these findings indicate that the LSC crucial for driving the progression to AML can be a downstream progenitor (in this case, a GMP and/or multilymphoid progenitor). Further support comes from mouse models: LSCs from leukemias initiated by forced expression of an *MLL-AF9* fusion gene (common in AML patients) in GMPs retain the identity of the progenitor cells, despite having acquired self-renewal potential.³²⁴ The identification of both tumor-initiating ancestral HSPCs and LSCs has important implications for the treatment of hematologic malignancies, as relapse-causing clones may be unrelated to the predominant clones at diagnosis in ~50% of patients with B-cell acute lymphoblastic leukemia (B-ALL), T-ALL and AML.³⁴⁶

STEM CELL MODEL OF HEMATOLOGIC DISEASES

Justin Taylor and Omar Abdel-Wahab

CELL OF ORIGIN STUDIES IN HEMATOLOGIC MALIGNANCIES

One of the prevailing models of cancer development proposes that a cancer is initiated and maintained through the function of cancer stem cells (CSCs), which represent a rare population of cells within a cancer that have an indefinite proliferative potential and are ultimately responsible for the generation of the bulk of cancer cells. This so-called cancer stem cell hypothesis has been best studied in hematopoietic malignancies. The ability to purify hematopoietic cells more easily than cells from other tissues, combined with the well-defined cell-surface markers of hematopoietic cells, has allowed the prospective isolation of nearly every hematopoietic cell subset from humans as well as mice.

The CSC hypothesis proposes that cancers are organized into hierarchical populations like normal tissues. At the apex of hierarchy are largely quiescent long-lived CSCs with marked self-renewal capacity that sustain the disease and give rise to the majority of the bulk cancer cells that constitute the disease. While identification of a single normal hematopoietic cell subset as the target of the malignant transformation and the cellular reservoir for disease has been possible for a variety of myeloid leukemias and lymphomas, pinpointing a single cell as the target of malignant transformation has not yet proven possible for other hematopoietic malignancies. In this chapter, we will discuss efforts to identify the malignant stem cell for each of the common forms of myeloid and lymphoid leukemias.

ACUTE MYELOID LEUKEMIA

The first evidence of a stem cell origin of malignancy came from studies in 1997 performed by Blair et al¹ as well as Bonnet and Dick² into acute myeloid leukemia (AML). These studies demonstrated that most leukemia cells were unable to proliferate extensively and that only a subset of cells was consistently clonogenic. In these studies a small subset of human Thy1⁺CD34⁺CD38⁺ AML cells (0.2–1.0%) was identified and shown to be the only cells capable of transferring human AML to immunodeficient mice. In humans, normal hematopoietic stem cells (HSCs) reside in the lineage-negative (Lin[−]) CD34⁺CD38[−]CD90⁺CD45RA[−] compartment and generate multipotent progenitors with lymphomyeloid potential (LMPPs) defined as Lin[−]CD34⁺CD38[−]CD90⁺CD45RA[−] cells, as well as more committed myeloid progenitors that are present in the CD34⁺CD38⁺ compartment.³ Among the myeloid progenitors, the common myeloid progenitors (CMPs), granulocyte–macrophage progenitors (GMPs), and megakaryocyte–erythroid progenitors (MEPs) can be discriminated based on differential expression of CD123 (IL3RA), CD110 (MPL), and CD45RA.

The initial observation that AML leukemia-initiating cells (LICs) reside within the CD34⁺CD38[−] compartment suggested that AML HSCs are rare cells that most closely resemble normal HSCs sharing a common limited immunophenotype and being in rare populations (Fig. 10.1). However, subsequent data have suggested that this conclusion is an oversimplification and that the cell of origin of any myeloid malignancy is likely dictated by a combination of the specific genetic and epigenetic alterations present in the individual patient as well as the cells in which these alterations occur. For example, the

aforementioned earliest studies of LICs in AML relied on their transplantation into immunodeficient nonobese diabetic/severe combined immunodeficient (NOD/SCID) mice (see box on [Evolution of Immunodeficient Mouse Models](#)) to assay the ability of a defined population of AML cells to give rise to AML in vivo. However, using more immunodeficient xenotransplant models, primary human cells from both CD34⁺CD38[−] and CD34⁺CD38⁺ compartments have been shown to have LIC activity. In addition, work by Vyas and colleagues has revealed that two expanded populations, both with LIC activity, exist in CD34⁺ AML (Fig. 10.1).⁴ One population shares the immunophenotype of normal LMPPs and the other mirrors the GMP population. The LMPP-like leukemic stem cell (LSC) population can give rise to the GMP-like LSC population but either can give rise to AML in immunocompromised mice in vivo.

As described in the box on [Functional Evaluation of Cell-of-Origin In Vivo](#), the leukemogenic effects of specific oncogenes directly depend on the specific oncogene as well as the target cell of expression. Based on these facts, consistent LICs may be most easily defined for specific genetically defined subsets of leukemias (such as specific chronic leukemias defined by specific translocations or point mutations) but are much more difficult to define for normal karyotype AML. For example, expression of the *AML1-ETO* fusion transcript, generated by the common t(8;21) translocation in AML, can be detected not only in leukemic cells but also in normal HSCs from patients in clinical remission from AML.⁸ However, these *AML1-ETO*-expressing HSCs are not leukemic and can differentiate into myeloid and erythroid cells in vitro in a manner similar to HSCs without the *AML1-ETO* fusion transcripts (Fig. 10.1). Similarly, analysis of mice expressing the *AML1-ETO* fusion from the endogenous *Aml1* locus in vivo has revealed that *AML1-ETO*-expressing HSCs have aberrant self-renewal capacity but do not develop overt leukemia unless additional genetic abnormalities are present. These data strongly suggest that acquisition of additional genetic abnormalities in a subset of HSCs or their progeny is required to give rise to overt leukemia. In these studies the HSCs bearing the *AML1-ETO* fusion reside within the Lin[−]CD34⁺CD38[−] subpopulation that is also the immunophenotype of normal human HSCs, suggesting that the initiating lesion must occur in a cell with an immunophenotype of normal HSCs. However, leukemic cells from 30% to 40% of patients with AML do not express CD34, and LICs from some patients with AML can actually be CD34[−]. Interestingly, prior work evaluating the location of the *PML-RARA* transcript present in acute promyelocytic leukemia (APL) revealed that the *PML-RARA* translocation is actually present in CD34[−]CD38⁺ populations and not in CD34⁺CD38[−] HSC-enriched populations⁹ (Fig. 10.1). These data clearly reveal that there is enormous heterogeneity in the cell-of-origin of AML.

Advancement in techniques to map genetic alterations in cancer have allowed for much finer tracking of somatic mutations in AML and other hematopoietic malignancies with a normal karyotype. It is now believed that an average of five coding mutations is present in adults with de novo AML. Several groups have now studied the occurrence of somatic mutations in bulk AML cells and the remaining seemingly nonaffected HSCs. This work has clearly shown that the HSC compartment in patients with AML contains HSCs with none of the mutations found in the AML as well as HSCs with various combinations of genetic alterations similar to that present in the bulk malignant cells (Fig. 10.1). These latter HSCs are now understood to be “preleukemic stem cells” that initiate AML and can

Fig. 10.1 SCHEMATIC MODELS DEPICTING THE ORIGIN OF LEUKEMIC STEM CELLS (LSCs) IN VARIOUS MYELOID MALIGNANCIES. (A) Genetic evidence from some forms of acute and chronic myeloid leukemias reveals that the inciting genetic event occurs in a cell type in which normal hematopoietic stem cells (HSCs) are enriched (lineage-negative (Lin⁻)CD34⁺CD38⁻). For example, the *AML1-ETO* and *BCR-ABL* translocations found in acute myeloid leukemia (AML) and chronic myelogenous leukemia (CML) are present in HSCs. In addition, the *JAK2V617F* mutation is present in HSCs. However, presence of these mutations alone may not be sufficient to generate overt AML and may be associated with aberrant self-renewal (as is the case with *AML1-ETO*) or chronic myeloproliferation (as with *BCR-ABL* and *JAK2V617F*) alone. (B) In contrast, other forms of AML appear to be generated due to acquisition of genetic alterations in a cell type more differentiated than HSCs. For example, *PML-RARA* translocations occur in Lin⁻CD34⁺CD38⁺ cells in patients with acute promyelocytic leukemia (APL). (C) In addition, in a proportion of patients with de novo non-APL AML, LSC activity may be present in a cell with an immunophenotype distinct from HSCs. In some cases, multiple populations of LSCs may be present, each with a distinct immunophenotype as shown. (D) Finally, most recently it has been proposed that genetic alterations may occur in a proportion of HSCs in patients with AML and that confer aberrant self-renewal properties to these cells. Further stepwise accumulation of genetic alterations then occurs in these preleukemic HSCs results in an overt malignant phenotype. As shown, mutations associated with the preleukemic HSCs include genes affecting DNA methylation and chromatin state whereas mutations associated with frank leukemia include genetic alterations associated with increased cell proliferation.

Evolution of Immunodeficient Mouse Models

Xenotransplantation of human hematopoietic cells into immunocompromised mice has been an important assay for studying normal and malignant human hematopoiesis for more than 50 years.⁵ The first breakthrough in xenograft modeling of human hematopoiesis was the discovery of the severe combined immune deficient (SCID) mouse. Transplantation of human bone marrow cells into the SCID mouse not only regenerated T and B cells, which the mice lacked genetically, but also continued to generate myeloid progenitors long-term. SCID mice are limited by high levels of innate immune function that impede human engraftment, however. To circumvent this limitation, SCID mice were back-crossed onto nonobese diabetic (NOD) mice harboring innate immune defects. NOD-SCID mice support higher levels of human engraftment but are limited by the development of thymic lymphomas and persistence of functioning natural killer (NK) cells. Both of these problems were addressed by deletion of the IL-2 receptor common gamma chain. Resultant NOD/SCID/gamma-null (NSG) mice have complete loss of B, T, and NK cells and their defective cytokine signaling also prevents lymphomagenesis. NSG mice support higher levels of human donor cell engraftment and serve as assays that functionally assess the ability of potential cancer stem cells to initiate a malignancy. Newer types of humanized mice, such as the MISTRG mouse, have been developed that express human cytokines that are not cross-reactive with murine cells and are able to stimulate the growth of more human cell types in vivo.⁶ Other humanization strategies include constitutive expression of HLA class I and II that strengthens T-cell function or constitutive expression of *Sirpa*, a transmembrane protein on macrophages that induces tolerance to human grafts. Loss of function mutations in KIT proto-oncogene receptor tyrosine kinase (KIT) have allowed for the creation of hematopoietic stem cell (HSC) xenografts without the need for irradiation of the recipient mouse.⁷

also be identified in remission samples, indicating that they are able to survive induction chemotherapy (see box on [Preleukemic Stem Cells](#)).^{11–13} Many of the mutations that occur in preleukemic HSCs confer growth properties that allow them to outcompete normal HSCs and presumably lead to relapse. Interestingly, mutations occurring in preleukemic HSCs are enriched in genes regulating DNA methylation, chromatin modifications, and the cohesion complex while genetic alteration activating signaling are often present in more downstream overt malignant cells and absent from preleukemic HSCs.

MYELODYSPLASTIC SYNDROMES

Much as in AML, tracking major chromosomal abnormalities allowed earlier investigators to establish that clonal hematopoiesis in MDS originated in HSCs. Studies performed in 2000 identified deletion of the long arm of chromosome 5 (del(5q)) in the HSCs of patients with del(5q)-MDS. Moreover, del(5q) CD34⁺CD38⁻ cells possessed MDS-initiating potential based upon in vitro and in vivo stem cell assay. Systems subsequently improved phenotypic identification of HSCs have allowed investigators to focus on Lin⁻CD34⁺CD38⁻CD90⁺CD45RA⁻ cells as candidate CSCs in MDS. These studies showed that in patients with del(5q)-MDS, 99% of Lin⁻CD34⁺CD38⁻CD90⁺CD45RA⁻ cells contained del(5q) and that they were molecularly and functionally distinct from clonally involved GMPs and MEPs.²⁰ By gene expression profiling and principle component analysis of RNA sequencing data, the three cell populations were shown to be distinctively different, with the Lin⁻CD34⁺CD38⁻CD90⁺CD45RA⁻ cells selectively expressing genes

Functional Evaluation of Cell-of-Origin in Vivo

The earliest studies of cancer stem cells in acute myeloid leukemia (AML) suggested that AML is initiated by genetic alterations that take place in hematopoietic stem cells (HSCs). Alternatively, however, there is clear evidence that some leukemias may be initiated by mutations arising in more committed progenitors that provide these cells with aberrant self-renewal capacity that they otherwise lack. Numerous studies have attempted to directly address each of these possibilities through selective expression of specific oncogenes in isolated HSCs, common myeloid progenitors (CMPs), granulocyte–macrophage progenitors (GMPs), and even more mature myeloid cells (Figure). Such experiments have been most thoroughly performed using expression of mixed lineage leukemia (MLL) fusion oncoproteins. *MLL* encodes an epigenetic enzyme required for normal hematopoiesis due to its role in maintenance of *HOX* gene expression. Translocation events fusing the N-terminus of *MLL* to over 50 different C-terminal partners are common in both AML and acute lymphoblastic leukemia (ALL). Overexpression of the *MLL-ENL*

fusion oncoprotein in self-renewing HSCs as well as myeloid progenitor populations with more restricted self-renewal potential including CMPs and GMPs result in the rapid onset of AML in vivo.¹⁰ Similar results have been seen with retroviral overexpression of a different MLL fusion oncoprotein, *MLL-AF9* as well as an unrelated AML-associated fusion, *MOZ-TIF2* (Figure). In contrast, overexpression of *BCR-ABL* is only able to transform HSCs but not committed downstream progenitors. These results unequivocally demonstrate (1) the ability of an MLL fusion oncoprotein to convert a myeloid progenitor cell population that is distinct from an HSC to acquire leukemogenic self-renewal activity and (2) that the cell-of-origin where a genetic alteration is expressed may regulate the resultant ability for a malignant disease to develop. It is also important to note that when the *MLL-AF9* fusion is expressed under endogenous regulatory control, *MLL-Af9* transforms HSCs but not GMPs. These data clearly reveal that the dosage of oncogene expression may also regulate cellular transformation.

Pink Box 10.1 Figure LEUKEMIC CELL-OF-ORIGIN DEPENDS ON THE GENETIC ALTERATION, THE CELLULAR CONTEXT, AND GENE DOSAGE. Schematic of experiments testing the leukemogenic effects of retroviral overexpression of a number of leukemogenic fusions in hematopoietic stem and progenitor cell populations from mice followed by their transplantation into recipient mice. Populations studied include the hematopoietic-stem cell enriched LSK cell population as well as the common myeloid progenitor (CMP) and granulocyte–macrophage cell progenitor population. While retroviral overexpression of *MLL-AF9* transforms LSK cells, CMP and GMP populations, expression of *MLL-AF9* from its endogenous locus efficiently transforms LSK cells but is only able to transform a proportion of CMP cells and unable to transform GMPs.

characteristic of normal HSCs. These candidate stem cells were the only cells able to sustain long-term generation of MDS myeloid progenitors in vitro that was never observed in GMPs, MEPs, or CMPs. Moreover, patients with del(5q)-MDS were found to have residual del(5q) clones in the CD34⁺CD38⁺CD90⁺ stem cell compartment during clinical remission.²¹ Over time, most of these patients experienced expansion of the clone, leading to cytogenetic and clinical progression.

The evidence for an MDS-initiating stem cell is not limited to isolated del(5q)-MDS, which may be a unique disease entity given its distinct clinical features. In fact, recent studies have shown that recurrent driver mutations occur at the HSC level in a broad panel of low to intermediate risk MDS and that the 5q deletion preceded any other identifiable recurrent driver mutations in isolated

del(5q)-MDS. The same was observed with *SF3B1* in MDS with ringed sideroblasts, where *SF3B1* mutations are thought to be early and potentially initiating events. Targeted screening for mutations in a large number of genes known to be frequently mutated in MDS and other myeloid malignancies on bulk bone marrow from patients with MDS was performed. After identifying the mutations specific to each patient, the different cell compartments (HSC, GMP, or MEP) were purified and the screen for mutations was repeated. It was hypothesized that if progenitor cells acquired self-renewal capacity allowing them to persist long enough for the mutations to be responsible for the MDS phenotype, then the mutations would be identifiable in progenitors but not within upstream HSCs. However, all of the mutations in MDS patients have been traced back to the HSC compartment (Lin[−]CD34⁺CD38[−]CD90⁺CD45RA[−] cells) and

Preleukemic Stem Cells

Hematopoietic stem cells (HSCs) are rare (~1–2 per 10^8 bone marrow cells) and quiescent cells that rarely divide. However, all blood cells originate from progenitor cells that in turn originate from HSCs and thus HSCs must replicate/self-renew to continue the cycle. Mutations in HSCs can therefore occur during cell division and accumulate, sometimes speeding self-renewal divisions and leading to clonal hematopoiesis. Although able to confer a growth advantage to clones derived from mutated HSCs, these single mutations alone are not sufficient to transform cells, resulting in an overt malignant phenotype. Because growth promoting gene mutations are common in cancer, it is thought that HSCs with mutations that cause clonal hematopoiesis might exist as preleukemic stem cells in patients with leukemia for months to years prior to diagnosis. Cooperative driver mutations are then acquired that cause cancer to develop. Recent publications have reported that somatic mutations causing clonal hematopoiesis exist in healthy persons and increase in frequency with age.^{14–16} The risk of a hematologic malignancy is higher in patients with clonal hematopoiesis compared with matched controls, providing evidence for leukemic predisposition. The most common mutations causing clonal hematopoiesis were found in the genes *ASXL1*, *DNMT3A*, and *TET2*, which are also known to be recurrently mutated in myeloid malignancies. These genes encode proteins involved in epigenetic modifications of chromatin and DNA. Functional experiments have shown that *DNMT3A* and *TET2* actually increase the number of HSCs in the bone marrow through impaired differentiation and increased self-renewal, respectively. Studies of a few patients with preleukemic stem cells who went on to develop leukemia were able to show that at least in some cases, the leukemia developed only after acquisition of another driver mutation such as mutations in *FLT3*.¹⁷ Additionally, different somatic mutations drive distinct patterns of clonal hematopoiesis, such as mutations in the splicing factors *SF3B1* and *SRSF2*, which exclusively occur in patients over the age of 70 and may only confer a growth advantage under the selection pressures of an aging hematopoietic system.^{18,19}

all of the mutations found in the Lin[−]CD34⁺CD38[−]CD90⁺CD45RA[−] MDS initiating cells have also been identified in downstream GMPs and MEPs.²⁰ These findings suggest that MDS is propagated by a stem cell that develops and acquires mutations at an early stage in the disease.

MYELOPROLIFERATIVE NEOPLASMS

The translocation between chromosomes 9 and 22, the so-called Philadelphia chromosome, is the hallmark of CML and gives rise to the *BCR-ABL* oncogene and its constitutively active protein tyrosine kinase product p210^{BCR-ABL}. In patients with CML, there is a clonal expansion of HSCs and the *BCR-ABL* translocation can be detected in HSCs from patients with CML as well as all myeloid as well as even committed lymphoid cells generated by these HSCs (Fig. 10.1). This data clearly identifies chronic phase CML as a stem cell disorder in which the target cell of transformation is a HSC. This is a finding that has direct therapeutic implications as ABL kinase inhibitors, which are used clinically for CML, do not consistently eradicate the quiescent *BCR-ABL*-positive CML LICs.

In contrast to the chronic phase of CML where the normal HSC appears to be the target cell-of-origin, transformation of CML to the myeloid blast crisis appears to be associated with expansion of a more committed myeloid progenitor population (which consists mostly of GMPs) rather than expansion of the HSC population. The GMPs from blast crisis patients with CML actually have the ability to serially replat in vitro, a proxy of aberrant self-renewal capacity not seen in normal GMPs. These data suggest that disease progression from chronic phase to myeloid blast crisis occurs due to aberrant acquisition of self-renewal potential within the committed GMP population, a possibility which has been directly studied in animal models (Pink Box 10.2).

The other chronic myeloproliferative neoplasm besides CML in which a specific genetic alteration is present in nearly 100% of

patients is polycythemia vera (PV); a single mutation results in the substitution of phenylalanine for valine at codon 617 of the Janus kinase 2 (*JAK2*) tyrosine kinase in nearly every patient. Targeted sequencing of *JAK2* in patients with PV showed that the *JAK2V617F* mutation is present in cells with an HSC phenotype²² (Fig. 10.1). Moreover, HSCs from patients with PV are skewed toward the erythroid lineage at the HSC level already and there is also an expansion of the CMP pool, suggesting that expression of the *JAK2V617F* mutation affects HSC and progenitor cell populations. Interestingly, early efforts to study the effects of JAK inhibition in PV revealed that JAK inhibition exhibited inhibitory effects on the erythroid potential of PV HSCs but did not result in preferential eradication of *JAK2V617F*-mutant HSCs versus normal HSCs. Thus this finding of an HSC origin for PV has direct therapeutic implications, as curative eradication of the disease would require therapy that eliminates rare quiescent bone marrow-based HSCs.

ACUTE LYMPHOBLASTIC LEUKEMIA

Unlike the myeloid malignancies, it has been less clear whether lymphoid malignancies also arise from an HSC or have a different cell-of-origin. In B-cell acute lymphoblastic leukemia (B-ALL), considerable effort has gone into answering this question (Fig. 10.2). Early studies in specific subtypes of B-ALL supported a preleukemic stem cell such as identified in AML. *TEL/AML-1* rearranged ALL has been particularly well studied and is associated with a good prognosis. These studies showed that *TEL/AML-1* alone is insufficient for leukemogenesis. In fact, the frequency of *TEL/AML-1* in healthy infants far exceeds the incidence of ALL, suggesting that the development of leukemia requires a second hit. This is evident from studies of pairs of twins, both with evidence of a preleukemic *TEL/AML-1* CD34⁺CD38[−]CD19⁺ population of cells, where one twin developed ALL and the other did not. The healthy twin retained the preleukemic population, which showed evidence of self-renewal and hierarchical differentiation. Later studies of high-risk ALL showed that leukemogenic potential may also be present in more differentiated cell populations, such as CD34[−]CD19⁺ cells (Fig. 10.2). Recent extension of this work to B-ALL cases with a variety of chromosomal abnormalities have found that even mature blasts expressing CD20 were able to establish leukemia upon transition into immunodeficient mice. Also, as many as 1 in 40 B-ALL blasts retained leukemogenic potential. Overall, B-ALL blasts do not seem to be hierarchically arranged in a similar fashion as AML and engraftment of further differentiated CD34[−] blasts can give rise to both CD34[−] and CD34⁺ populations in vivo.²³ Together, these data suggest that B-ALL arises in a committed lymphoid progenitor rather than only a small population of cells accumulating mutations and retaining stem cell properties, and that most or even all of the leukemic blasts retain the ability to propagate the malignancy.

In contrast to *TEL/AML-1*, those patients with ALL carrying the *BCR-ABL* fusion protein have much worse clinical outcomes. However, like *TEL/AML-1*, *BCR-ABL* is also thought to be a primary mutation that is necessary but not sufficient for ALL transformation. Interestingly, the two *BCR-ABL* transcripts, P190 and P210, caused by different break points in the t(9;22) translocation, show distinct patterns of HSC and committed B-cell progenitor involvement. In most cases, the P190 *BCR-ABL* originates in a CD34⁺CD38[−]CD19⁺ progenitor cell while P210 *BCR-ABL* originates in a multipotent HSC. When purified P210 *BCR-ABL* HSCs were transplanted into NOD/SCID mice, they exclusively reconstituted normal, *BCR-ABL*-negative multilineage hematopoiesis.²⁴ These data suggest that the purified HSC also contained normal HSCs that outcompeted the P210 *BCR-ABL* HSCs, which are not the leukemia stem cells. In contrast, more committed CD19⁺ P210 *BCR-ABL*-positive cells resulted in leukemic reconstitution upon transplantation into NOD/SCID mice that was enhanced following secondary transplant. These data complement recent findings suggesting that the primary *BCR-ABL* translocation in CML originates in HSCs, yet the leukemic transformation in blast crisis results in an LSC with a committed

Fig. 10.2 STAGES OF NORMAL EARLY B-CELL DIFFERENTIATION AND SCHEMATIC OF LEUKEMIC STEM CELLS IN B-CELL ACUTE LYMPHOBLASTIC LEUKEMIA (B-ALL). Based on several studies testing the ability of human B-ALL blasts to engraft in immunodeficient mice, it appears that multiple blast populations in B-ALL are able to establish the disease in immunodeficient mice. For example, CD34⁺CD19⁺ blasts as well as CD34⁺CD19⁻ blasts from individual patients have been shown to be able to transplant leukemia in vivo and to give rise to CD34⁺ and CD34⁻ leukemic cells. Thus B-ALL does not appear to follow a hierarchical model in which blasts with a more mature immunophenotype lose their stem cell capacity as has been seen in some cases of acute myeloid leukemia.

progenitor cell phenotype. This begs the question whether P210 BCR-ABL⁺ positive ALL represents *de novo* ALL or CML in lymphoid blast crisis.

MATURE B-CELL MALIGNANCIES

The classification of mature B-cell malignancies based on their histology and immunophenotypic resemblance to a particular stage of lymphoid differentiation has led to the theory that each lymphoma subtype originates within lymphocytes at distinct differentiation stages (Fig. 10.3). Another model predicts that cells acquire initial alterations at early stages, even at the HSC level, that may drive clonal expansion or resistance to apoptosis and that these cells then develop additional complementary alterations at a later stage that lead to overt malignancy. Recent studies have identified novel lymphoid associated mutations and alterations across large panels of lymphomas, creating the opportunity to define the clonal architecture and cell-of-origin in lymphoma subtypes.

CHRONIC LYMPHOCYTIC LEUKEMIA

Chronic lymphocytic leukemia (CLL) is a B-cell malignancy marked by the accumulation of clonal mature B cells in the lymph node, bone marrow, and/or blood. In nearly all cases, CLL is preceded by a preleukemic monoclonal B cell lymphocytosis (MBL), though not all cases of MBL continue on to CLL. The precise cell within B-cell development that gives rise to CLL has been debated for decades and two recent studies have implicated HSCs in the pathogenesis of CLL. Kikushige et al investigated the cellular origin of CLL by isolating distinct subpopulations of cells and assaying their ability to initiate disease in immunodeficient mice. Only the CD34⁺CD38⁻CD90⁺ fraction engrafted and this population, known to be highly enriched in HSCs, gave rise to both lymphoid and myeloid hematopoiesis. Interestingly, these engrafted mice showed an increased proportion of polyclonal B cells and a population of monoclonal B cells expressing CD5, akin to MBL.²⁵ Further examination determined that they

had different variable, joining and diversity segments (VDJ) rearrangement patterns compared to the prior CLL. The finding of aberrant HSCs in CLL suggest that they are primed to generate MBL cells, which are likely to accumulate additional mutations that eventually results in a clonal CLL disorder.

In a different approach, Damm et al investigated whether molecular alterations present in CLL cells could be traced to cells in the earliest stages of hematopoietic development before committed B-cell development. In fact, acquired mutations were detected in HSCs in the majority of the patients with CLL studied.²⁶ These findings support a preleukemic phase and the clinical implications imply that treatments with true curative intent in CLL might require approaches other than those focused solely on cell-surface antigens restricted to B cells or B-cell receptor signaling pathways.

HAIRY CELL LEUKEMIA

Hairy cell leukemia (HCL) is a chronic lymphoproliferative disorder characterized as a mature B-cell malignancy based on the expression of CD19, surface immunoglobulin, and the clonal rearrangement of immunoglobulin heavy and light chain genes. At the same time, HCL cells also express cell surface markers not present on normal B cells, including CD103 and CD11c, which are typically expressed by dendritic cells and monocytes. In addition, patients with HCL have long been known to have clinical features disparate from most mature B-cell malignancies, including the absence of lymph node involvement and frequent splenomegaly due to extramedullary hematopoiesis (EMH). Recent identification of BRAFV600E mutations in nearly 100% of patients with classic HCL provided genetic insight into the pathogenesis of HCL and a clonal marker to track the origin and propagation of HCL. The BRAFV600E mutation was found in purified (Lin⁻) CD34⁺CD38⁻CD90⁺CD45RA⁻ HSCs in primary samples from patients with HCL. These aberrant HSCs were also able to recapitulate BRAFV600E-mutant hematopoiesis after transplantation into NOD/SCID/gamma-null (NSG) mice. Additionally, conditional knock-in mice were generated expressing BRAFV600E in either HSCs or CD19⁺ cells. Those mice with BRAFV600E HSCs

B

Fig. 10.3 MODELS OF LYMPHOMA ONTOGENY. (A) The conventional model of lymphoma classifies lymphomas based on differentiation of mature peripheral B cells. This model is based on the presence of somatic hypermutation as well as immunophenotypic and gene expression analyses comparing the malignant cells to normal B-cell counterparts. (B) At the same time, mature B cells are derived from precursor B cells and earlier progenitor and hematopoietic stem cells (HSCs). In the conventional model (*left*), it is assumed that cells more primitive than the peripheral B cell depicted in (A) are not involved with the lymphoma disease process. However, there is increasing evidence that HSCs and/or more intermediate progenitors may harbor aberrancies directly linked to mature B-cell malignancies. *ABC DLBCL*, Activated B-cell-like diffuse large B-cell lymphoma; *CLL*, chronic lymphocytic leukemia; *FL*, follicular lymphoma; *GCB*, germinal center B cell-like DLBCL; *MCL*, mantle cell lymphoma.

showed an HCL-like phenotype of anemia, thrombocytopenia, and EMH; however, no phenotypic hairy cells were seen. In contrast, mice with BRAFV600E expression limited to lineage committed B cells did not have reduced survival or an overt phenotype. These data suggest that HCL is initiated within the HSC compartment but that the development of additional genetic alterations occurring along the course of hematopoiesis may be necessary to give rise to HCL cells. Indeed, in patients with genetic alterations in addition to BRAFV600E in HCL cells, these additional mutations were not found in the BRAF-mutated HSCs.²⁷

DIFFUSE LARGE B-CELL LYMPHOMA

High-resolution genomic analyses of a large number of human diffuse large B-cell lymphoma (DLBCL) samples identified copy number gain of chromosome 3q27.2 to be associated with the worst prognosis and the aggressive activated B-cell (ABC) disease subtype. The transcription factor BCL6 is likely the target oncogene affected by this copy number alteration at this locus given its propensity to be targeted by other alterations in DLBCL such as translocations and point mutations, which were mutually exclusive from the 3q27.2 gain. Other roles for BCL6 have been described in normal hematopoiesis and myeloid leukemia stem cells, prompting inquiries into whether BCL6 expression in HSCs has a role in the origins of DLBCL. This hypothesis was tested by the generation of a mouse model that expressed BCL6 only in HSCs, under the control of a stem cell-specific promoter so that BCL6 was no longer expressed by the differentiated progeny. These mice developed a form of lymphoma that resembled DLBCL with an ABC phenotype that did not overexpress BCL6.²⁸ This led to a proposed model of “hit-and-run” oncogenesis, wherein BCL6 expression in hematopoietic precursors is sufficient to produce DLBCL without requiring sustained overexpression.

FOLLICULAR LYMPHOMA

The most common subtype of lymphoma is follicular lymphoma (FL), which is so named because histologically the lymph node follicle B cell is affected. These aberrant B cells carry a hallmark translocation between chromosomes 14 and 18, resulting in juxtaposition of the immunoglobulin heavy chain gene (IGH) and the antiapoptotic protein BCL-2, thus driving overexpression of BCL2 and resistance to programmed cell death. This malignancy usually follows an indolent course and is more common in elderly patients. It has been shown that up to 25% of healthy individuals harbor BCL-2/IGH rearranged cells, yet do not have disease, indicating that the hallmark lesion is not sufficient to cause lymphoma and that additional genetic mutations must be required for lymphomagenesis. As in other hematologic malignancies, newer sequencing technologies have allowed identification of novel recurrent mutations in FL and some researchers have begun investigating the timing of those mutations. By taking the opportunity presented by an unfortunate but rare occurrence of donor-derived FL after hematopoietic stem cell transplantation, investigators have shown that some of these genetic mutations occur in hematopoietic precursors prior to the cells in which the BCL-2/IGH rearrangement occurs.

Hematopoietic stem cell donors are screened for signs and symptoms of malignancy but are not currently subjected to genetic testing for premalignant conditions. Often the donor is a brother or sister due to the 25% chance of being a complete HLA-match and the willingness of a sibling to donate. This inherently means that a sibling donor is at slightly higher risk of having a malignancy given their close relationship to someone with cancer (i.e., the recipient), yet it is still a rare occurrence that donor cells will transfer a malignancy to the recipient after stem cell transplantation. In the case mentioned previously,²⁹ the donor and the recipient both developed FL 7 years after the transplant. Both patients' FL had exactly identical BCL-2/IGH rearrangement breakpoints and the same VDJ recombination, indicating that they were derived from the same mutation. The

recipient had received a donor-lymphocyte infusion (DLI) 7 years prior, which also harbored the same BCL-2/IGH and VDJ rearrangements, thus confirming the donor-derived source. There was no sample left of the original stem cell transplant to test but the BCL-2/IGH rearrangement was not present in the cells other than CD19⁺ mature B cells in the DLI sample. However, there were mutations known to occur in lymphoma present in the CD34⁺CD10⁺CD19⁺ population that includes multipotent progenitors and HSCs.³⁰ These alterations presumably contributed to the development of FL prior to the acquisition of the hallmark translocation and occur in progenitors of the follicle B cell. These findings provide evidence of a possible role of stem cell progenitors in the development of mature B-cell malignancies.

CONCLUSION

The stem cell model of hematologic diseases has implications beyond a theoretical construct for the pathogenesis of disease. Not only does this model support stem cell transplant and gene therapy as curative treatments in some cases, but also has much broader application in the management of hematologic malignancies. Most of our current standard therapies are based on the principle of interrupting DNA replication in rapidly dividing cancer cells, yet stem cells are quiescent and spend little time in active cell cycle. Many of the new and developing therapies are targeted at cell surface markers or mutated genes whose expression may be restricted to the most mature malignant cells and may be lacking in the premalignant or malignant stem cells. It remains to be seen whether the same challenges will face immune response checkpoint modulators, but one could consider the possibility that neoepitopes recognized by activated T cells might have differential expression on different cell populations.

Remarkable progress has been made in the field of CSCs in hematologic malignancies due to the evolution of immunodeficient mouse models and the improvement of sequencing technologies that have allowed the mapping of clonal evolution and studies of mutational ontogeny. There are controversies from inside and outside of the field as to whether stem cells should be defined phenotypically, molecularly, or functionally but as the evidence accumulates there is broad agreement on the stem cell model of hematologic diseases.

HEMATOPOIETIC MICROENVIRONMENT

David Scadden and Lev Silberstein

EVOLUTION OF THE NICHE CONCEPT

In 1868, Ernest Neumann first suggested that blood cells are being replenished throughout postnatal life, and this proposal led to the attempts to localize the place of hematopoiesis. His hypothesis that blood cell production takes place in the bone marrow (BM) was experimentally validated by selective lead shielding of limbs in irradiated animals almost a century later. Notably these and other studies showed that differentiation pathways of immature blood cells are determined by their location and are different between the spleen and the BM. Based on this difference between BM and spleen, Schofield first proposed that there is a specialized place or niche where stem cells reside and are governed. He succinctly posed in 1978 that “stem cell is seen in association with other cells which determine its behavior.”

Trentin further clarified how different sites affected hematopoietic stem/progenitor cell (HSPC) differentiation. Although both spleen and marrow support multiple cell lineages (erythropoietic and granulocytopoietic, for example), the ratios of differentiating cells were distinct: spleen favored erythropoiesis, but BM predominantly supported granulopoiesis. This controlling influence of the surrounding cells was further illustrated by implanting BM stroma into the spleen and showing that hematopoietic cells abruptly changed from erythropoiesis to granulopoiesis at the spleen–BM demarcation. These observations suggest that immature differentiating progenitors require interactions with other specific cell types in a defined *microenvironment*.

This chapter reviews the current knowledge of the hematopoietic microenvironment during development and in postnatal life in normal hematopoiesis and in myelodysplasia and leukemia. The opportunities for therapeutic manipulation of the niche in the treatment of these disorders are also discussed. For the related topics on stem cell mobilization, hematopoietic cytokines and the role of microenvironment in lymphoid malignancies, plasma cell disorders, and myeloproliferative conditions, readers are referred to other chapters of this book.

HEMATOPOIETIC MICROENVIRONMENT DURING DEVELOPMENT

In mammals, hematopoiesis during development takes place in distinct extraembryonic and embryonic sites. Sequentially, it moves from the yolk sac to the aorta-gonad-mesonephros (AGM) region, fetal liver, placenta, and BM (for details, see [Chapter 26](#)).

The first definitive adult HSPCs emerge from the floor of the dorsal aorta, more precisely from AGM region in midgestation mouse embryo, and the HSPC clusters appear in close association with the aortic endothelium.¹ Recent reports indicate that phenotypically defined HSPCs (Sca1⁺ c-kit⁺ S⁺ CD41⁺) arise directly from ventral aortic endothelial cells and that fluid shear stress may be important for this process.² Although direct cellular interactions during the emergence of hematopoietic stem cells (HSC) in the embryo remain to be dissected, bone morphogenetic protein 4 (BMP4), fibroblast growth factor (FGF), transforming growth factor (TGF), and vascular endothelial growth factor (VEGF)-Flk1 signaling pathways are involved in early mouse hematopoiesis.

Recently placenta has been identified as a hematopoietic organ during development. Placenta is known to produce hormones that influence vascularization and therefore may affect blood cell production because hematopoiesis and vasculogenesis are tightly coupled.³

The hematopoiesis-promoting factors may be either produced by the placental trophoblast cells or enter via maternal circulation. Hematopoietic progenitors appear in the placenta at E9, but their number declines by E13. The cells and local factors providing placental hematopoietic support are currently unknown, but mesenchymal/stromal cells have been suggested as candidates. Placental microenvironment is thought to be geared toward supporting the expansion or maturation of HSPCs without their concomitant differentiation.

In the fetal liver, the HSPCs are first detected on day 9 of mouse embryonic development, and large expansion of the HSPCs occurs between days 12 and 15 before migration to the bone on day 18. Stromal cell lines obtained from the fetal liver are able to support primitive hematopoietic cells in ex vivo cultures. Some of these cells (termed *myelosupportive stroma*) are able to differentiate in vitro into mesenchymal components (osteoblasts, chondrocytes, and adipocytes). Although the nature of fetal liver cells participating in the HSPC niche remains enigmatic, recent studies point to a nonhematopoietic hepatic population that express Dlk-1, a member of delta-like family of cell surface transmembrane proteins, and stem cell factor, and can be prospectively isolated based on the expression of these molecules.⁴ These cells express angiopoietin ligand 3 and CXCL12, and in combination with stem cell factor, thrombopoietin, FGF1 and FGF2, and either angiopoietin ligand 2 or 3 are able to produce more than 30-fold expansion of the murine HSPCs in culture.

Despite the differences in the hematopoietic microenvironment between the sites of fetal and adult hematopoiesis, the key components of the molecular milieu are likely to be shared, as evidenced by successful (although limited) engraftment of HSPCs across developmental barriers. For example, AGM- or fetal liver–derived HSPCs are able to engraft in the adult BM. Notably, they have a competitive advantage over their BM-derived counterparts, with the long-term repopulating ability exceeding that of the BM by fivefold. Vice versa, BM HSPCs engraft in fetal liver when transplanted in utero, although at low efficiency (<5% for the whole BM and 0.43% for highly enriched HSPCs), which may be partly attributable to the absence of pretransplant conditioning.⁵

Multilineage hematopoiesis during development occurs largely by the virtue of sequential HSPC migration from the AGM region to the fetal liver and the BM, as opposed to de novo HSPC generation. Failure of migration to the “next niche,” as exemplified by the targeted disruption of the guanine-nucleotide-binding protein stimulatory α -subunit (GS- α), calcium-sensing receptor, or CXCL12/CXCR4 axis (discussed in detail in [Chapter 14](#) on HSPC migration) leads to severe impairment in hematopoiesis. This suggests even in the absence of cell-intrinsic HSPC defects, proper progression of blood cell production throughout development critically depends on the ability of the HSPC to sequentially move to the appropriate microenvironmental compartments.

ADULT BONE MARROW MICROENVIRONMENT

Niches for Hematopoietic Stem and Progenitor Cells

Location of the HSPC Niche

In mammals, BM is a major site of hematopoiesis throughout life. The niche preserves and dynamically regulates the HSPC pool by

providing signals required for maintenance, quiescence and retention of HSPCs in the BM. However, the location of HSPC niche within the marrow has been a subject of controversy.⁶ The endosteal surface has long been considered the zone in which HSPCs are preferentially located. In the setting of irradiation conditioning, this has been directly demonstrated by intravital imaging studies, which allow dynamic assessment of the interaction between transplanted HSPC and the niche. Currently, in vivo imaging is limited to calvarial BM, an area in the mouse skull where the bone is very thin, thus permitting penetration of the laser beam into the BM cavity. Using this technique and simultaneous multicolor fluorescent labeling of osteolineage cells (OLCs), HSPCs, and the vasculature, studies showed that in irradiated recipients, transplanted HSPCs home closest to the endosteal surface and individual OLCs as compared with more differentiated progenitors, and that they are “anchored” to their niches at least through 72 hours.⁷ Preferential localization of primitive hematopoietic cells to the endosteal surface under the homeostatic conditions has been also demonstrated, although this analysis was performed using immunostaining of histologic BM sections of either femoral bones or the sternum.⁸

However, other studies performed under steady state (not transplant) conditions indicate that most HSPC are located in the central marrow in a perivascular position, thus arguing in favor of more primitive mesenchymal cells and endothelial cells governing the niche.

Deletion of a key niche factor, such as stem cell factor (kit-ligand), from either endothelial or perivascular cells leads to decrease in the

HSPC number further supporting the notion of a perivascular niche.⁹ Although the debate about location of the HSPC niche, and consequently, cell types that serve as niche participants, continues it is important to bear in mind that HSPCs themselves are molecularly and functionally heterogeneous, and that several distinct niches may coexist to support this heterogeneity, particularly under different conditions such as the stress of transplantation.

Cellular Components of the HSPC Niche

Over recent years, animal studies revealed marked complexity in cellular and molecular organization of the HSPC BM niche. Major cellular components of the HSPC niche and the factors that they produce (summarized in Table 11.1) are discussed later.

Osteolineage Cells

OLCs are a heterogeneous population of mesenchymal cells that line the endosteal surfaces of flat and trabeculated bones at the interface between the bone and the BM and become embedded within the bone matrix upon terminal differentiation. OLCs are thought to originate from mesenchymal stem cells (MSCs) and gradually progress from the early immature progenitors that express OLC-specific transcription factors Runx2 and osterix to mature osteoblasts

TABLE 11.1

HSPC Niche Factors and Their Cellular Sources

Factor	Source	Effect
Membrane-bound SCF	Lepr ⁺ perivascular cells, Tie2 ⁺ endothelial cells	Maintenance of HSC in the bone marrow (Ding et al, 2012)
CXCL12	Lepr ⁺ perivascular cells, Tie-2 ⁺ endothelial cells Prx-1 ⁺ osteoprogenitors	Retention of HSC in the bone marrow (Ding and Morrison, 2013) Retention of HSC, myeloid and lymphoid progenitors in the bone marrow (Ding and Morrison, 2013; Greenbaum et al, 2013)
	Osx ⁺ osteoprogenitors and Col-2.3 ⁺ osteoblastic cells	Retention of lymphoid progenitors in the bone marrow (Ding and Morrison, 2013; Greenbaum et al, 2013)
Notch signaling (Jagged1)	VE-cadherin ⁺ endothelial cells, osteoblastic cells (in PPR model)	Maintenance of HSC and regeneration posttransplantation (Poulos et al, 2013) Expansion of HSC and progenitors (Calvi et al, 2003)
Wnt signaling (Canonical)	Col-2.3 ⁺ osteoblastic cells (Wnt inhibitor DKK1)	Maintenance of HSC and quiescence (Fleming et al, 2008)
Wnt signaling (Noncanonical)	N-cadherin ⁺ osteoblastic cells	Maintenance of HSC and quiescence (Sugimura, 2012)
E-Selectin	CD-31 ⁺ endothelial cells	Promotion of HSC cycling (Winkler et al, 2012)
Pleiotrophin	VEGFR3 ⁺ /VE-cadherin ⁺ endothelial cells and CXCL12 perivascular cells	Maintenance of HSC and retention in the bone marrow (Himburg et al, 2012; Himburg et al, 2010)
Thrombopoietin	Alkaline phosphatase ⁺ osteoblastic cells	Maintenance of HSC and quiescence (Qian et al, 2007; Yoshihara et al, 2007)
Osteopontin	Osteoblastic and other microenvironmental cells	Negative regulation of HSC numbers and maintenance of quiescence (Nilsson et al, 2005; Stier et al, 2005)
TGF- β	Nonmyelinating Schwann cells, megakaryocytes	HSC quiescence (Yamazaki et al, 2011)
Angiopoietin-1	Osteocalcin ⁺ osteoblasts	Promotion of HSC quiescence (Arai et al, 2004)
Robo-4 ligand(s) (Slit2 ^a)	Bone marrow stromal cells (^a Slit2 identified at the mRNA level)	Promotion of HSC homing to the bone marrow (Smith-Berdan et al, 2011; Smith-Berdan et al, 2012)
Junction adhesion molecule B (JamB)	Osteoblasts, MSCs, endothelial cells	HSC adhesion and quiescence (Archangeli Blood, 2011)
CXCL4	Megakaryocytes	Promotion of HSC quiescence

Updated and modified from Kfoury Y, Mercier F, Scadden DT: Snapshot: the hematopoietic stem cell niche. *Cell* 3;158(1), 2014.

expressing extracellular matrix (ECM) protein osteocalcin and eventually to osteocytes.

Several lines of *in vivo* evidence support a functional role of the OLCs in regulation of primitive hematopoietic cells. In the studies providing the first experimental evidence for a mammalian niche *in vivo*, mice with genetically modified OLCs had an increase in the number of activated OLCs and a corresponding increase in the number of HSPCs.^{10,11} This effect was associated with an increased trabecular bone area and an elevated number of trabecular osteoblasts that expressed the Notch ligand Jagged 1. When the OLCs were depleted, there was a reduction in the BM cellularity and migration of hematopoiesis to the extramedullary sites. Thus, OLCs play a role in regulation of HSPC pool size. In addition, OLCs participate in controlling HSPC quiescence through contributing to production of CXCL12, Angiopoietin 1, thrombopoietin, paninhibitor of canonical Wnt signaling Dickkopf1 (Dkk1), noncanonical Wnt ligands and ECM protein osteopontin. Finally, OLCs govern HSPC localization by controlling their egress into blood and return to the BM, a process that forms the basis for clinical peripheral blood stem cell collection for transplantation. When mature OLCs are deleted from bone, there is an increase in the number of circulating progenitors and a decrease in the mobilization of HSPC with granulocyte colony-stimulating factor (G-CSF) indicating that OLC-derived signals retain primitive hematopoietic cells in the marrow. Following G-CSF-induced mobilization, the OLCs in the trabecular bone adapt a flattened morphology with short projections, which is associated with HSPC egress from the niche. Similar changes are seen after treatment with nonsteroidal antiinflammatory drugs (NSAIDs), which are known to enhance G-CSF-induced HSPC mobilization. When CXCL12, a major HSPC chemoattractant and retention factor, is deleted from the osteoprogenitors using osterix-Cre promoter, increased HSPC mobilization is also observed. Thus, OLCs participate in the BM niche by regulating HSPC number, quiescence and retention in the BM space.

Despite the evidence presented earlier, several studies have argued against the role of OLCs in the niche, citing the absence of HSPC changes either in genetic models associated with reduced OLC number or following OLC-specific deletion of HSPC regulators such as kit-ligand or CXCL12. Several experimental factors are likely to account for this discrepancy, including developmental adaptation when the genetic modification is present throughout the ontogeny, or inability of genetic tools to target a specific subset within the OLC compartment that serves as a nodal point of the HSPC regulation: several studies suggest that immature OLCs are important for the niche function, whereas mature OLCs are dispensable.

Endothelial Cells

Endothelial cells are known to secrete hematopoietic cytokines and express several adhesion molecules such as E-selectin, P-selectin, vascular cell adhesion molecule 1 (VCAM-1), and intercellular adhesion molecule 1 (ICAM-1) which have been shown to participate in cellular interactions within HSPC niche. The existence of vascular niche for the HSPCs has been suggested by *in vivo* imaging studies showing early homing of transplanted BM progenitors to specific subdomains of the vascular tree as well as by histologic assessment of the BM using CD150 antibody when HSPCs were found to be in a close proximity to the BM sinusoids.

Endothelium-derived factors have diverse effects on HSPCs *in vivo*. For example, E-selectin (which is expressed exclusively in the endothelial cells) negatively regulates HSPC quiescence; consequently, HSPCs from E-selectin knockout (KO) mice are more quiescent and resistant to irradiation.¹² On the other hand, endothelial-specific deletion of stem cell factor or CXCL12 lead to the respective reduction of the HSPC pool and loss of repopulating capacity. Similar changes are seen upon endothelial-specific deletion of Notch ligand Jagged 1, which in contrast to E-selectin, promotes HSPC quiescence. The heparin-binding growth factor, pleiotrophin, which is produced

by sinusoidal endothelial cells also plays a role in the retention and self-renewal of HSPC in BM.¹³

Perivascular Cells

The observation that HSPCs colocalize with the marrow vasculature raised the possibility that perivascular cells may also play a role in the HSPC regulation by the niche. So far, three types of perivascular cells have been characterized: CXCL 12-abundant reticular cells (CAR cells), nestin-GFP^{dim}/leptinR⁺ MSCs and nestin-GFP^{bright}/NG2⁺ pericytes.

CAR cells were identified in a mouse model in which GFP was driven by *CXCL12* promoter. Similar to the other components of the niche, CAR cells are found in a close proximity to HSPCs. It is likely that they are genetically and phenotypically related to nestin-GFP^{low} cells (see later) because their ablation also severely impaired adipogenic and osteogenic differentiation of nonhematopoietic BM cells in addition to reducing the number of HSPCs. Notably, the effect of deletion was not limited to HSPCs but also affected mature lineages, such as lymphoid cells, indicating a wider role for these cells in hematopoietic support.

MSCs are located in the perisinusoidal BM space and have been initially defined by low expression of green fluorescent protein (GFP) driven by gene regulatory elements of intermediate filament protein Nestin (nestin-GFP^{low}).¹⁴ Nestin-GFP^{low} cells express the genes associated with HSPC retention in the niche (*Cxcl12*, *VCAM-1*), which are downregulated upon G-CSF mobilization. Selective deletion of Nestin-positive cells in mice resulted in 50% reduction in the number of long-term HSPCs and their relocation to the spleen, although it is not clear whether this effect was mediated directly by Nestin-positive cells or through their more differentiated downstream progeny. Subsequent studies revealed that a population that largely overlaps with nestin-GFP^{low} cells can be also defined by expression of leptin receptor. Specific deletion of known HSPC regulators (stem cell factor, CXCL12) specifically from MSCs using Cre-recombinase driven by leptin receptor gene regulatory elements lead to reduction in the HSPC number and long-term repopulating capacity, further delineating the functional significance of MSCs in the HSPC niche.

Careful analysis of HSPC distribution within BM sections led to discovery of another perivascular cell subset (termed nestin-GFP^{high}), which is closely associated with arterioles.¹⁵ Cell deletion experiments demonstrated the role for nestin-GFP^{high} in maintaining HSPC quiescence. Interestingly, nestin-GFP^{high} cells are preferentially found close to the endosteum leading to a model that denotes the endosteal surface as a quiescent niche and central BM (where nestin-GFP^{low} form the niches around sinusoidal vessels) as a proliferative niche, with the two being involved in a dynamic interaction with each other.

Adipocytes

An observation that adipocyte-rich vertebrae in mice contained significantly fewer cycling HSPCs compared with adipocyte-poor thoracic vertebrae led to the discovery of their role in HSPC regulation.¹⁶ In a genetic mouse model of lipodystrophy (i.e., a condition with reduced adipocyte number), posttransplant hematopoietic recovery was accelerated, although a concomitant increase in trabecular bone could have contributed to this result.

Osteoclasts

Osteoclasts are BM-derived cells that are located in close proximity to stem cell-rich endosteum and play a critical role in bone remodeling. During stress and G-CSF-induced mobilization, the activity of the osteoclasts increases and is accompanied by secretion of proteolytic enzymes and reduction in the endosteal niche components, as evidenced by downregulation of the osteopontin expression by the

OLCs.¹⁷ Conversely, inhibition of the osteoclasts leads to reduced HSPC and progenitor egress.

Bone Marrow Macrophages

During experiments investigating the mechanisms of G-CSF-induced HSPC mobilization, it was noted that in addition to previously reported reduction in the endosteal OLCs, BM macrophages were also decreased in number. In vivo depletion of this cell population by clodronate administration produced the same result.¹⁸ It therefore appears that macrophages play a critical role in supporting the OLC niche compartment. A similar role for the macrophages, but with regard to supporting nestin-GFP^{low} MSCs, has been suggested by another study that used clodronate-mediated macrophage ablation. Again, this resulted in HSPC egress from the BM, perhaps through the effect on nestin-GFP^{low}, which showed a marked downregulation of genes responsible for HSPC retention in the niche (see earlier discussion). Thus, macrophages appear to function at a level of regulation upstream of OLCs and nestin-GFP^{low} cells.

Megakaryocytes

Megakaryocytes are the most recent addition to a growing list of niche cell types and appear to be directly involved in regulation of HSPC quiescence, as shown by cell deletion studies. This effect is mediated by CXCL4, also known as platelet factor 4, and TGF- β .¹⁹ Overall, only 20% of immunophenotypically defined HSPCs are associated with megakaryocytes, and were spatially distinct from HSPCs that are located near the arterioles, suggesting the existence of specific megakaryocytic niche. The above findings also illustrate a feedback mechanism, by which mature hematopoietic cells may regulate HSPC number.

EXTRINSIC REGULATION OF THE HEMATOPOIETIC STEM CELL NICHE

Sympathetic Innervation

Sensory and autonomic innervation of the BM is critical for its ability to respond to hematopoietic stress. Increase in sympathetic tone promotes HSPC mobilization and downregulates the components of the endosteal niche, mainly through the activation of β_2 -adrenergic receptor.²⁰ Nestin-positive cells express both β_2 and β_3 receptors and act as another mediator between sympathetic signaling and HSPCs, again facilitating egress from the BM. In a mouse model of streptozotocin-induced diabetes, diabetic autonomic dysfunction was shown to disrupt this regulatory circuit, alter the function of Nestin-positive cells, and lead to impaired G-CSF-induced HSPC mobilization, providing a biologic explanation for a higher frequency of peripheral blood stem cell mobilization failure in diabetic patients. The sympathetic nervous system is also involved in regulation of HSPC egress from the BM as governed by circadian rhythms, a remarkable discovery based on a chance observation that continuous exposure to light (because of a broken light switch in the animal house) significantly altered the number of HSPCs mobilized after G-CSF administration. Thus, sympathetic niche innervation is essential for relaying and integrating extrinsic signals, and acts as a responsive and finely tuned tool, which regulates HSPC traffic between peripheral blood and the BM.

Not only sympathetic nerves, but also the glial cells that surround them can regulate HSPC behavior in the marrow, as exemplified by the studies of nonmyelinating Schwann cells.²¹ These cells ensheath the sympathetic nerves, come into contact with HSPCs and are responsible for activation of the latent form of TGF- β . Denervation experiments lead to significant reduction in the number of glial cells and associated increase in HSPC cycling.

Hypoxia

The niche for quiescent HSPCs is thought to be hypoxic. These observations are based on studies that use an intracellular marker of reducing equivalents, pimonidazole, or direct measurement of oxygen tension in the BM using intravital microscopy. By direct measurement of oxygen, it is apparent that the absolute level of PO_2 in the BM is quite low (<32 mmHg) and reduces to ~10 mmHg deeper into the marrow space.²² The vascular network in the marrow is extensive and it appears that the low PO_2 levels reflect high consumption by the action of hematopoiesis.

Hypoxia is associated with upregulation of stromal cell-derived factor 1 (SDF-1) expression in the endosteal region and HSPC traffic to the BM; in contrast, hyperbaric oxygen (exposure to 100% oxygen under increased atmospheric pressure) mobilizes HSPC and progenitors away from the BM. Hypoxic responses in the HSPCs are mediated through a family of hypoxia-inducible factors (HIFs). The best-studied species of HIFs is HIF1- α , which induces SDF-1 expression and directs metabolic circuits within HSPCs toward anaerobic metabolism. HIF1- α also stimulates secretion of VEGF, thereby promoting bone formation and angiogenesis. HIF1- α affects HSPC function, as HIF1- α deletion from HSPCs leads to HSPC exhaustion.

What is a physiologic role of hypoxia? Firstly, hypoxia is believed to protect HSPCs in the niche from oxidative stress. Indeed, HSPCs within the niche contain a lower level of reactive oxygen species. Moreover, it appears that hypoxic conditions are beneficial for the HSPC function because culturing human BM HSPCs under lower oxygen tension leads to an increase in their ability to engraft and repopulate nonobese diabetic/severe combined immune deficient (NOD/SCI) mice. Finally, hypoxia may also protect the HSPC pool from exhaustion by promoting cell cycle quiescence. Of note, when radiation or cytotoxic chemotherapy are used, the PO_2 levels in marrow go dramatically higher, raising the question of whether PO_2 levels participate in the hematopoietic regenerative response to injury.

LYMPHOID NICHES

BM is the site of *B-cell lymphopoiesis*. Several cell types involved in the HSPC niche also participate in formation of the lymphoid niches. Interestingly, B-cell niches correspond to maturation stages of the lymphoid cells: OLCs, osteoclasts, and CAR cells are necessary for the less mature stages of development, whereas interleukin-7 (IL-7) secreting cells and sinusoidal endothelial cells are important for more differentiated cells. These observations come from targeted deletion of each supporting cell population using genetic means and analyzing the effect on B-cell homeostasis. For example, deletion of the OLCs leads to a considerable decrease in pre-pro and pro-B cells. This process appears to be mediated by the heterotrimeric G protein α subunit because its deletion in the OLCs leads to 60% decrease in the percentage of B-cell precursors in the BM. A similar phenotype is seen upon deletion of CAR cells.

Naive recirculating B and T cells are located in the perisinusoidal space and colocalize with dendritic cells, which are thought to deliver supportive signals, because as their deletion leads to significant decrease in B-cell number and reduction in IgM production after immunization.

Plasma cells are the product of terminal differentiation of B cells after antigen exposure. In vitro and in vivo studies showed that plasma cells receive multiple extrinsic survival signals, including CXCL12, IL-6, BAFF (B-cell activating factor of the TNF family), and APRIL (a proliferation-inducing ligand), which may account for their longevity. Mice deficient in CXCR4 displayed impaired homing of plasmablasts, illustrating the involvement of CXCL12–CXCR4 axis in plasma cell trafficking. Eosinophil- and megakaryocyte-derived APRIL and BAFF appear to regulate the number of plasma cells, which is greatly reduced upon eosinophil or megakaryocyte deletion.

The majority of long-lived *memory T cells* reside in the BM and appear to require a close contact with IL-7 secreting stromal cells to

ensure that they remain quiescent in the absence of antigen stimulation. The BM also contains a large proportion of *regulatory T cells*, which have recently been found to exclusively protect HSPCs and early progenitors from rejection after allogeneic transplantation, arguing that the endosteal surface acts as an immune privileged site. Surprisingly, BM harbors specific niche cells (osteocalcin⁺ OLCs) which provide instructive cues to T-competent progenitors that migrate from the BM to the thymus, since deletion of the osteocalcin-expressing cells leads to decreased intrathymic T-cell precursors and impaired generation of mature T-cells in the presence of normal thymic function. Specific OLCs therefore appear to be important in T-lymphopoiesis. Their damage in the settings of conditioning for transplantation or graft-versus-host disease (GVHD) may compromise the ability of BM to provide the early T-lineage cells for thymocyte and ultimately, T-cell production.²³

ERYTHROID NICHES

Erythroblastic islands were first described by a French hematologist Marcel Bessis more than 50 years ago and consist of developing erythroblasts surrounding a central macrophage. They are present in the BM, fetal liver, and the spleen and in *in vitro* long-term BM cultures. The number of erythroblasts per island ranges from 10 cells observed in sections of rat femur to 5 to 30 erythroblasts seen in human BM. Some islands are located adjacent to the BM sinusoids, and the others are scattered throughout the BM cavity. Within erythroid islands, the macrophage functions as a “nurse cell” providing iron to the developing erythroblasts and phagocytosing the extruded nuclei at the end of erythroid differentiation.

Adhesion between maturing erythroblasts and central macrophage is mediated by several molecules, including erythroblast macrophage protein (Emp via homophilic binding), $\alpha 4 \beta 1$ integrin (VCAM-1), and αv integrin (ICAM-4); antibody-mediated blockade of each of these molecule results in disruption of the islands. The most striking effect is seen with the blockade of Emp, which causes significant increase in proliferation, maturation, and apoptosis of maturing erythroblasts *in vitro*. Of note, Emp-null fetuses die *in utero* from severe anemia.

In addition to interaction within macrophages, maturing erythroblasts adhere to ECM proteins, fibronectin, and laminin for the maturation to proceed. Fibronectin protects erythroblasts from apoptosis, partly through antiapoptotic bcl-xL, and laminin is thought to localize reticulocytes to sinusoids as the initial step before their release into circulation.

MEGAKARYOCYTIC NICHES

Megakaryocytes localize to BM endothelial cells *in vivo* and release platelets into the marrow intravascular–sinusoidal space or the lung capillaries. Although CXCL12 induces platelet production by megakaryocytes if preceded by migration through endothelial cells, this is not observed in the absence of endothelial cells, suggesting that megakaryocyte interaction with specific molecules present on the endothelial cells is necessary for thrombopoiesis. FGF4 and CXCL12 enhance the interaction of megakaryocytes with endothelial cells and restore thrombopoiesis in mice deficient in thrombopoietin or its receptor c-mpl. Thus, chemokine-mediated localization of megakaryocytes within a specific vascular microenvironment is necessary for their maturation and platelet production.

HUMAN BONE MARROW MICROENVIRONMENT

Because direct mechanistic studies of human BM microenvironment cannot be undertaken, the bulk of our knowledge comes from experiments in xenotransplantation models. These initially involved fetal sheep and heavily irradiated or nude mice as recipients, but only very low level of human hematopoietic engraftment was observed. The

discovery of SCID mice led to development of two powerful models. The first, known as SCID-hu mouse, was generated by engrafting human thymus and fetal liver. This model was most informative for the study of human lymphoid development and is still used for testing novel HIV drugs. The second model, hu-SRC (for SCID-repopulating cell), through the pioneering work of John Dick and colleagues, enabled investigation of human HSPC engraftment and differentiation. Further modifications of the SCID model led to generation of NOD/SCID–IL2 receptor γ chain knock-out (NSG) strain, which supports robust normal human multilineage (myeloid and lymphoid) hematopoietic engraftment, as well as engraftment of acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL) cells from patients. The sensitivity of the transplant assay is further increased by direct intrafemoral injection into the BM cavity; remarkably, in NSG recipients, human hematopoietic engraftment can be detected after intrafemoral transplantation of a single highly purified human HSPC. Further advance in the field of xenotransplantation is the development of mouse strains that express several human hematopoietic cytokines, thereby enabling support of innate immune cells (myeloid and NK cells).

Similar to mouse HSPCs, human HSPCs transplanted into mouse recipients preferentially traffic to the trabecular bone and home next to the endosteal surface.²⁴ They are guided to their niches by the CXCL12–CXCR4 pathway and cell adhesion molecules such as very late antigen-4 (VLA-4), very late antigen-5 (VLA-5), and lymphocyte function-associated antigen-1 (LFA-1); of note, CXCL12 is expressed by human OLCs, mesenchymal stromal, Nestin-positive, and endothelial cells. CD44 and hyaluronic acid cooperate with CXCL12 in human HSPC homing. Recent experiments identified $\alpha 6$ integrin CD49f as a novel marker for human HSPCs, alluding to functional importance of HSPC anchorage within BM microenvironment.^{25,26} The cellular components of the human HSPC niche are yet to be identified. One potential candidate is a population of mesenchymal subendothelial cells expressing CD146, which can be prospectively isolated from human BM.²⁶ These perivascular cells were able to establish both bone and hematopoietic microenvironment upon subcutaneous transplantation; had a documented self-renewal capacity; and produced angiopoietin 1, a cytokine known to induce HSPC quiescence. CD271 has been suggested as another marker for human hematopoiesis-supporting mesenchymal population; in addition to CD146⁺ perivascular cells, it labels CD146–endosteal population, which colocalizes with hematopoietic CD34⁺ cells in human BM.

The limitations of our knowledge of human hematopoietic microenvironment restrict our ability to accomplish *in vitro* stem cell expansion. The potential benefits of doing so are especially evident in the context of cord blood transplantation when the number of donor cells is small and in the setting of gene modified stem cells where gene transduction efficiencies are low. Several molecules have been tested. One of them is Sonic hedgehog protein, which has been shown to induce proliferation of primitive human hematopoietic cells when added to highly purified CD34⁺ CD38[−] lineage human cells; this effect translated into increased level of progenitor expansion in NOD/SCID mice. The aryl hydrocarbon receptor antagonist, SR-1 also appears to increase HSPC. An engineered Notch ligand Delta 1 and pleiotrophin have both been shown to increase HSPC. Prostaglandin E₂ enhances murine HSPC localization in the BM after brief *in vitro* exposure. This resulted in a two- to threefold increase in the number of HSPCs compared with control (vehicle-exposed) cells. A phase 1 study in transplant recipients concurrently receiving PGE₂-treated and vehicle-treated cord blood units showed that PGE₂-treated cells generated durable multilineage engraftment and displayed greater efficacy, as evidenced by accelerated neutrophil recovery.²⁷ These results are encouraging but require validation in larger studies.

HEMATOPOIETIC MICROENVIRONMENT IN ACUTE LEUKEMIA AND MYELODYSPLASIA

Given a critical role of hematopoietic microenvironment in safeguarding cellular homeostasis in the BM, it is not surprising that alterations

within it—either primary or induced by the presence of malignant cell population—have been proposed to contribute toward tumor initiation, maintenance, and resistance to treatment. Here, we will summarize the data related to the role of microenvironment in the pathogenesis of acute leukemia and myelodysplasia. For the review of this topic in other hematologic neoplasms, readers are referred to disease-specific chapters of this book.

Early *in vitro* studies alluded to significant contribution of nonhematopoietic BM cells (collectively termed *stroma*) to the pathogenesis of acute leukemia. For example, fibroblastic stromal cells from patients with AML were unable to support normal granulocytic-macrophage (GM) colony formation in contrast to those obtained from normal individuals. However, when the stromal cells were tested from patients in remission, they maintained growth of GM colonies similar to normal stroma. Strikingly, when the patients relapsed, this GM colony-supporting ability was lost. In another series of observations, when nonadherent cells from continuous marrow cultures or GM-CSF-dependent progenitor cell lines were cocultured with mouse stromal cells that had been previously irradiated, they developed factor-independence and multiple distinct karyotypic abnormalities; upon subcutaneous injection, these newly transformed cell lines produced granulocytic monomyeloid tumors that spread to spleen, lymph nodes, and BM. Although by no means definitive, these studies suggested that either the altered stromal cells may contribute to the emergence of leukemia, or leukemia itself may affect the nonhematopoietic compartment. Both of these hypotheses found confirmation in the later studies reviewed later.

Niche Contribution to Leukemia Development

The idea of “niche-induced oncogenesis,” or contribution of the microenvironment to the emergence of malignant disease, stems from the clinical observation of donor-induced leukemia. In this condition, which has a reported incidence between 0.12% and 5%, the leukemic clone arises from an apparently normal donor hematopoietic cells after allogeneic BM transplantation.²⁸ Although the etiology is clearly multifactorial, damage to the BM microenvironment, either because of previous chemotherapy or pretransplant conditioning, may be an important contributing factor. In keeping with this notion, several experimental mouse models illustrate that microenvironmental alterations, either alone or in conjunction with corresponding molecular lesions in the hematopoietic compartment, can play a critical role in the initiation of malignant disease. For example, the mice with deficiency of phosphatase and tensin homologue (PTEN) both in the microenvironment and HSPC developed a myeloproliferative disorder, but PTEN deficiency in HSPCs alone did not result in the disease. Similarly, widespread deletion of retinoblastoma protein or retinoic acid receptor led to the development of myeloproliferative disorder, in the latter case purely because of gene deletion in the microenvironment. Using a cell type-specific approach, it was found that targeted deletion of the microRNA processing enzyme Dicer 1 in immature OLCs resulted in development of myelodysplasia and acute leukemia associated with independent complex genetic changes.²⁹ The effect of Dicer-1 deletion was entirely attributable to the microenvironment because transplantation of Dicer 1-deleted BM into normal microenvironment resulted in reversal of the myelodysplastic phenotype. Remarkably, hematopoietic abnormalities were observed when Dicer-1 was deleted in very immature OLCs (osterix⁺) but not in those at a more mature differentiation stage (osteocalcin⁺). Deletion of Shwachman-Diamond-Bodian syndrome gene in immature OLCs recapitulated the key features of the Dicer-1 deletion phenotype and implicated their role in its pathogenesis. In another striking example, niche involvement in leukemia generation, mice carrying an OLC-specific mutation of constitutively activated beta-catenin developed AML. The leukemic process was microenvironment-dependent and mediated by Notch signaling. Genetic or pharmacologic inhibition of Notch signaling lead to reversal of the leukemic phenotype. The findings of this study are clinically relevant, as 38% of patients

with MDS and AML showed nuclear (activated) beta-catenin in osteoblasts.

Altogether, the above studies illustrate that perturbed BM microenvironment can act as a source of signals that promote malignant change in the hematopoietic compartment, and highlight their potential role as therapeutic targets.

Niche Alterations by Leukemia

Just as the microenvironment can contribute to disordered hematopoiesis, it can be disrupted and modified by leukemic cells leading to competitive advantage over normal counterparts. Visualization of BM niches by intravital microscopy studies revealed that primary ALL and AML blasts are able to downregulate CXCL12 expression in the BM, causing the egress of normal CD34⁺ HSPCs from the BM and impairment of normal hematopoiesis. This process was mediated by the stem cell factor (SCF) secreted by leukemic blasts and reversed upon SCF neutralization.³⁰ Similarly, in myeloproliferative disorders such as chronic myeloid leukemia (CML), it is thought that microenvironmental changes that are induced by malignant cells result in formation of self-reinforcing loop leading to preferential expansion of leukemic cells at the expense of their normal counterparts. Leukemia can also affect the niches indirectly, i.e., through perturbation of sympathetic innervation: both in CML and AML, “sympathetic neuropathy” promotes leukemogenesis through either reduction in quiescence-inducing nestin⁺ cells or altering their differentiation properties and frequency relative to nestin-GFP^{high}/NG2⁺ cells.³¹ The “niche-modifying” ability of the leukemic cells *in vivo* is an area of ongoing investigation because it suggests that the leukemic niche can be molecularly distinct from the normal thus creating an opportunity for altering the leukemic niche as a means of reducing persistence of leukemia-initiating cells.

Therapeutic Targeting of Leukemic Niche

The CXCR4–CXCL12 pathway is critical for homing and subsequent adhesion of not only normal, but also leukemic stem cells (LSCs) to the BM microenvironment. Of note, the level of CXCR4 is elevated in patients with AML and is associated with a poor outcome. The presence of Flt3 internal tandem duplication (a poor prognostic factor in AML) is in turn associated with increased CXCR4 expression. Experimentally, treatment of NOD/SCID mice transplanted with primary human AML cells using a neutralizing antibody against CXCR4 reduced the leukemic burden. Follow-up studies confirmed the antileukemic effect of blocking CXCL12–CXCR4 axis using competitive antagonists of CXCR4 (AMD3100 and AMD3254) in mouse models of AML. These findings formed the basis for ongoing clinical trials of CXCR4 antagonist AMD3100 (Plerixafor) as a chemosensitizing agent in AML.³² So far, these studies have confirmed safety and tolerability of this drug in combination with chemotherapy, but the effect on response rate and survival has not been demonstrated.

Another example of LSC niche dependence is a cell adhesion molecule CD44, which is present on the surface of leukemic cells and interacts with hyaluronan on the endosteal surface. Blocking the interaction between CD44 and hyaluronan using activating CD4 antibody had significant effect on LSC eradication and even cured some mice.³³ The therapeutic effect of the antibody was more marked when it was administered soon after injection of human leukemic cells compared with the animals with established disease, suggesting that it acts predominantly at the stage when LSCs engage their respective niches. It is also possible that some of the effect of the CD44 antibody was attributable to differentiation induction in the LSCs. Nevertheless, this study provided a proof-of-principle demonstration that LSCs interaction with the niche is required for their survival and leukemia progression and thereby raised the potential for targeting therapy.

Other molecular mediators of LSC–microenvironment interaction have also been identified. B4 integrin (also known as very late antigen 4).³⁴ mediates lodgment of leukemic cells in the BM and interacts with fibronectin to confer resistance to cytosine arabinoside-induced apoptosis. Integrin ligation triggers prosurvival pathways, and the blocking antibody leads to reduction in the level of leukemic burden and a modest prolongation of the lifespan in human AML-transplanted animals. Similar protective role for AML blasts has been observed for $\beta 1$ and $\beta 2$ integrins. IL-3 receptor α chain (CD123).³⁵ also contributes to LSC survival, at least partly through being involved in controlling LSC homing to the BM; CD123 blocking antibody demonstrated considerable antileukemic activity, which was also attributable to promoting immune-mediated destruction of leukemic cells. This idea that has been explored further in the studies of blocking a macrophage-associated molecule CD47. Expression of CD47 on LSCs appears to protect the LSCs from phagocytosis.³⁶ CD47 expression is associated with Flt3-ITD mutation and independently predicts worse prognosis. Mechanistically, CD47 acts as a “do not eat me” signal for the macrophages. Blocking CD47 antibody produces depletion of AML in xenotransplantation models and specific eradication of LSCs. Phase 1 study of CD47 antibody in hematologic malignancies and solid tumors is ongoing.

Emerging experimental evidence (using the chemical marker of hypoxia pimonidazole) suggests that leukemic BM niches are hypoxic and that leukemic cells adapt to hypoxic conditions. Although low oxygen tension within the leukemic niche remains to be directly demonstrated, the findings of overexpression of the key hypoxia-response factor HIF1- α in clusters of ALL cells, together with increased angiogenesis and production of VEGF by the ALL blasts support this hypothesis. Hypoxia-activated dinitrobenzamide mustard, PR-104, prolonged survival of NSG mice engrafted with ALL cell line Nalm-6 and lead to transient cytorreduction in some patients with refractory AML in a Phase 1 study. Although very preliminary, these results identify hypoxia as another potential avenue for niche-based antileukemic therapy.

FUTURE DIRECTIONS

Although the concept of specific microenvironment for different hematopoietic compartments was first proposed more than 100 years ago, it was not until recently that the existence of the “niches” has been experimentally proven and the molecular factors involved in cellular interactions have been discovered.

Our current knowledge of the hematopoietic microenvironment has been evolving in parallel and often leading that in other stem cell systems. It appears that fundamental components and molecular pathways are highly conserved among evolutionary diverse species, although their role in specific niches may vary. These include supporting stromal cells secreting soluble molecules regulating stem cell self-renewal (bone morphogenic protein and Wnt signaling), ECM proteins that serve as stem cell anchors (integrin ligands), blood vessels that are responsible for nutritional support and transit of stem cells in and away from the niche, and neural inputs for integrating signals from different systems. It is therefore likely that future studies in spatial and molecular organization of other stem cell niches will inform the knowledge of hematopoietic niches and vice versa.

With a rapidly increasing number of cell types known to be involved in hematopoietic niches (and the number of different cytokines they produce, which will inevitably follow), it will be important to use a “network” approach—similar to the one used for analysis of transcriptional networks—to understand how these multiple factors act in concert to control location, proliferation, and trafficking of HSPCs and more mature cells in the BM. It is possible that these factors work in combinatorial manner, ultimately creating a “niche code” that is designed to suit a specific physiologic situation.

A particularly notable development over the recent years has been our improvement in understanding of the role of microenvironment in initiation and maintenance of malignant disease, although many

questions remain. We still know very little about the molecular mediators of “niche-induced oncogenesis” and those involved in microenvironment-induced chemoresistance. Recent advances in xenotransplantation assay using highly immunocompromised mouse strains for the study of normal and leukemic hematopoiesis, together with further molecular insights into biology of leukemic stem cells, will provide an opportunity to address these issues.

Therapeutic manipulation of the hematopoietic microenvironment remains an ultimate goal of ongoing research. Clearly, the effort of the next several years will be focused on translating the wealth of data obtained from the animal models into human biology and the clinic. This work has already started with the clinical trials of ex vivo HSPC expansion before cord blood transplantation. A number of clinical trials are also underway to examine the efficacy of niche-directed therapies in hematologic malignancies. Although the animal data suggest that targeting the niche alone is often insufficient to achieve cure, especially in an established disease, this approach has been successful in regaining leukemia chemosensitivity to commonly used agents and may become a valuable component of future treatment protocols, particularly in the setting of low tumor burden, such as minimal residual disease. Gaining a deeper insight into the molecular distinctions between normal and malignant niches will enable better understanding of “niche competition” between normal and leukemic populations and lead to development of novel approaches based on eradication of leukemic cells and fostering normal hematopoiesis through manipulation of niche-derived signals.

CELL ADHESION

Rodger P. McEver and Francis W. Luscinskas

Cell adhesion is essential for the development and maintenance of multicellular organisms. Cell-to-cell and cell-to-matrix adhesion provide a mechanism for intercellular communication and to define the three-dimensional architecture of organs. The regulated nature of cell adhesion is particularly evident in the hematopoietic system, where blood cells routinely make transitions between nonadherent and adherent phenotypes during differentiation, and in response to stimuli in the circulation or extravascular space.

In the bone marrow (BM), hematopoietic stem cells reside in a specialized microenvironment called the *stem cell niche*, and their proliferation and differentiation are controlled not only by soluble growth factors but also by adhesion to stromal cells and matrix molecules (see [Chapter 9](#) for more detailed discussion). Weakening of these adhesive interactions is required for mature blood cells to enter the circulation. Circulating erythrocytes normally remain nonadhesive until they become senescent and are finally cleared by the reticuloendothelial system (see [Chapter 33](#) for more discussion). Other circulating blood cells often participate in regulated adhesive events during their lifespan. For example, prothymocytes adhere to thymic stromal cells where they undergo guided movement from the cortex to the medulla during maturation before reentering the circulation. T cells regularly stick to the specialized high endothelial venules of lymphoid tissues, migrate into these tissues for sampling of processed antigens, and then exit via the lymphatics to recirculate in the blood (see [Chapter 13](#) for more discussion). During inflammation, specific classes of leukocytes roll at very low velocity on the endothelium that line all blood vessels, then adhere more tightly, and finally emigrate between endothelial cells into the tissues. There, neutrophils and monocytes phagocytose invading pathogens, and lymphocytes adhere to antigen-presenting cells, such as dendritic cells, B cells, and macrophages (see [Chapter 123](#) for more discussion). During hemorrhage, platelets stick to exposed subendothelial matrix components, spread, and recruit additional platelets into large aggregates that serve as an efficient surface for thrombin and fibrin generation. This is discussed in more detail later in [Chapter 124](#). Leukocytes also adhere to activated platelets and to other leukocytes, and platelets roll on the endothelium. When activated, endothelial cells increase expression of molecules that affect the adhesiveness of platelets or leukocytes. Tight contacts between adjacent endothelial cells also regulate access of blood cells to the underlying tissues.

ADHESION MOLECULES

Cells adhere through noncovalent bond formation between macromolecules on cell surfaces with macromolecules on other cell surfaces or in the extracellular matrix (ECM). These interactions involve either protein–protein or protein–carbohydrate recognition. Although some adhesion molecules are expressed only by blood or endothelial cells, most also are synthesized by other cells. Many adhesion molecules can be grouped into families according to related structural and functional features.

EXTRACELLULAR MATRIX PROTEINS

The ECM provides structural and mechanical support for many tissues and spatial cues that enable cell–cell communication and

signaling. The principal constituents of the ECM are adhesive proteins and proteoglycans. The major proteins are collagens, von Willebrand factor (vWF), thrombospondin, elastin, fibronectin, laminin, and vitronectin. These proteins are large and often highly extended, and consist of multiple domains with different binding functions. In some proteins such as fibronectin, alternative splicing can increase diversity by producing molecules with variable numbers of domains. In addition, stretching of fibronectin can expose cryptic binding sites. The many binding domains allow adhesive proteins to interact with each other as well as with cell-surface receptors, resulting in multipoint contacts that stabilize matrix structure. One adhesive protein, fibrinogen, is found predominantly in plasma but also may be deposited in exposed subendothelial matrix after vascular injury. Fibronectin, vitronectin, thrombospondin, and vWF are located predominantly in the ECM but also are found in plasma in lower amounts. Several adhesive proteins also are stored in α -granules of platelets, where they are secreted after platelet activation at sites of vascular injury. Similarly, the endothelium stores adhesive proteins in cytoplasmic storage granules, called *Weibel–Palade bodies*, that are released upon injury or activation.

Proteoglycans contain protein cores to which are covalently attached many glycosaminoglycans—long linear polymers of repeating disaccharides. Most proteoglycans are in the ECM, but some are anchored on cell surfaces through a core protein that contains a membrane-spanning domain. Hyaluronan is a unique glycosaminoglycan that forms polymers with molecular masses up to several million daltons that are not covalently attached to a protein. Hyaluronan forms noncovalent interactions with globular domains on the protein core of proteoglycans and with a small molecule called *link protein*. The resultant hyaluronan–proteoglycan complexes can become very large, contributing to the structural stability of the matrix and function as space fillers during embryonic development. Hyaluronan can also bind to cell-surface receptors and is also abundantly produced during wound healing.

INTEGRINS

Integrins are a broadly distributed group of cell-surface adhesion receptors that consist of noncovalently associated α - and β -subunits ([Fig. 12.1](#) and [Table 12.1](#)). There are 18 α -chains and eight β -chains that pair in many, but not all, of the possible combinations. All blood cells have several different integrins. The four β_2 integrins, each paired with a unique α -subunit, are expressed only by leukocytes, and the $\alpha_{IIb}\beta_3$ integrin (glycoprotein IIb–IIIa [GPIIb–IIIa]) is expressed only by megakaryocytes and platelets. Multidomain adhesive proteins of the ECM are ligands for many integrins. Integrins are unusual adhesion molecules because they usually reside in an inactive state on the cell surface until they receive an activating signal. Some integrins bind to specific domains of several different proteins, and some adhesive proteins bind to several different integrins. These interactions generally mediate cell–matrix and cell–cell adhesion. A unique feature of integrins is transmission of signals in both directions across the cell plasma membrane. Integrin binding to matrix informs the interior of the cell (outside-in), and intracellular signals or conditions inside cells transmit signals outward (inside-out) that regulate binding to matrix or to adhesion receptors on the surface of adjacent cells. Force can also regulate integrin adhesive function.

Fig. 12.1 SCHEMATIC DIAGRAMS OF SEVERAL TYPES OF CELL SURFACE ADHESION RECEPTORS. Integrins consist of noncovalently linked α - and β -subunits, both of which contribute to ligand binding. The platelet α IIb β 3 integrin is illustrated at *far left*. Ig-like receptors contain a variable number of Ig homology domains, of which some bind ligands and others extend the ligand-binding domains from the membrane. Shown *second from left* is VCAM-1, which contains seven Ig domains; the two domains that bind to integrins are *shaded*. The platelet GPIb-IX-V complex, depicted in the *middle diagram*, consists of several leucine-rich protein subunits. CD44, illustrated next, contains an amino-terminal (*N*-terminal) domain that binds to hyaluronan. Each of the selectins contains an *N*-terminal carbohydrate recognition domain that binds sialylated and fucosylated oligosaccharides on specific cell-surface GP ligands. Illustrated at *far right* is P-selectin, the largest of the three selectins. *GP*, Glycoprotein; *Ig*, immunoglobulin; *VCAM-1*, vascular cell adhesion molecule-1.

TABLE 12.1

Integrins on Blood Cells

Integrin Designation	Other Name(s)	Expressed by	Ligand(s)	Function(s)
$\alpha_1\beta_1$	VLA-1	Leukocytes, other cells	Collagens, LM	Adhesion to ECM
$\alpha_2\beta_1$	VLA-2 GPIa/IIa	Leukocytes, platelets, other cells	Collagens, LM	Adhesion to ECM
$\alpha_3\beta_1$	VLA-3	Leukocytes, other cells	Collagens, LM, FN	Adhesion to ECM
$\alpha_4\beta_1$	VLA-4	Monocytes, lymphocytes, eosinophils	VCAM-1, FN	Adhesion to cells, ECM
$\alpha_5\beta_1$	VLA-5 GPIc/IIa	Leukocytes, platelets, other cells	FN	Adhesion to ECM
$\alpha_6\beta_1$	VLA-6 GPIc/IIa	Leukocytes, platelets, other cells	LM	Adhesion to ECM
$\alpha_9\beta_1$		Neutrophils	VCAM-1	Adhesion to ECs
$\alpha_4\beta_2$	LFA-1 CD11a/CD18	Leukocytes	ICAM-1, -2, -3	Leukocyte aggregation and adhesion
$\alpha_M\beta_2$	MAC-1 CR3 CD11b/CD18	Neutrophils, monocytes	ICAM-1, FIB, CR for iC3b	Neutrophil aggregation and adhesion to ECs
$\alpha_X\beta_2$	P150,95 CD11c/CD18	Neutrophils, monocytes	CR for iC3b	Adhesion to ECs
$\alpha_E\beta_2$	CD11d/CD18	Eosinophils, monocytes, lymphocytes	VCAM-1, ICAM-3	Adhesion to leukocytes and to ECs
$\alpha_{IIb}\beta_3$	GPIIb/IIIa	Platelets	FIB, FN, vWF, VN, TSP	Platelet adhesion and aggregation
$\alpha_v\beta_3$	VN receptor	Platelets, ECs	FIB, FN, vWF, VN, TSP, collagens	Platelet adhesion, angiogenesis
$\alpha_4\beta_7$	LPAM-1	Lymphocytes	VCAM-1, MAdCAM-1, FN	Lymphocyte adhesion to ECs and ECM

CR, Complement receptor; EC, endothelial cell; ECM, extracellular matrix; FIB, fibrinogen; FN, fibronectin; GP, glycoprotein; LFA-1, leukocyte function-associated antigen; LM, laminin; LPAM-1, lymphocyte Peyer patch adhesion molecule; MAdCAM-1, mucosal addressin cell adhesion molecule-1; TSP, thrombospondin; VCAM-1, vascular cell adhesion molecule-1; VLA, very late-appearing antigen; VN, vitronectin; vWF, von Willebrand factor.

The application of tension to integrins can increase ligand binding, and a reduction in tension lessens integrin adhesiveness. Cell–cell interactions result from integrin recognition of cell-surface members of the immunoglobulin superfamily. Binding of fibrinogen to α IIb β 3 integrins on adjacent platelets creates a molecular bridge that promotes platelet aggregation. Furthermore, fibrinogen simultaneously binds to the α M β 2 integrin on leukocytes and to an immunoglobulin-like receptor on endothelial cells, promoting leukocyte adhesion to the endothelium.

IMMUNOGLOBULIN-LIKE RECEPTORS

Immunoglobulin superfamily members contain a variable number of disulfide-stabilized motifs similar to those in antibodies, which are linked to transmembrane and cytoplasmic domains (Table 12.2; see also Fig. 12.1). The immunoglobulin-like motif provides a framework on which specific recognition structures for other proteins can be added. Some of these motifs also recognize glycoconjugates. The immunoglobulin-like molecules, intercellular adhesion molecule 1 and 2 (ICAM-1 and ICAM-2), and vascular cell adhesion molecule 1 (VCAM-1), expressed on endothelial cells, as well as ICAM-3, expressed on leukocytes, mediate cell–cell contact through recognition of specific integrins on leukocytes. ICAM-4, expressed on erythroid precursors, binds to integrins on stromal cells of BM, which may regulate erythropoiesis. ICAM-5 is restricted to neural tissues. The immunoglobulin-like GPVI on platelets promotes cell activation by binding to collagen exposed on damaged blood vessels. Interactions between immunoglobulin-like molecules help to mediate adhesion between T cells and antigen-presenting cells. Thus, whereas the immunoglobulin-like molecules CD8 and CD4 on T cells bind to the conserved membrane-proximal domains of class I and class II major histocompatibility complex (MHC) proteins, respectively, the α - and β -chains of the T-cell receptor (TCR) bind to the polymorphic antigen-presenting domain. In addition, the immunoglobulin-like proteins CD2 and CD28 on T cells bind to the immunoglobulin-like

protein leukocyte function-associated antigen-3 (LFA-3) and B7-1 (CD80) and B7-2 (CD86), respectively, on antigen-presenting cells. The immunoglobulin-like receptor, platelet and endothelial cell adhesion molecule-1 (PECAM-1; CD31) uses homotypical interactions to promote contacts between adjacent endothelial cells and to mediate adhesion of leukocytes to platelets and endothelium. The immunoglobulin-like junctional adhesion molecules (JAMs), expressed on endothelial and epithelial cells and leukocytes, regulate endothelial and epithelial cell junctions, paracellular permeability, and leukocyte trafficking between endothelial and epithelial cells by homotypical interactions or by heterotypical interactions with integrins. JAM-A, the founding member of this family, functions as a homodimer and transmits intracellular signals critical for its function in regulation of endothelial and epithelial permeability.

OTHER ADHESION RECEPTORS THAT MEDIATE PROTEIN–PROTEIN INTERACTIONS

Cadherins are cytoskeletally linked type 1 transmembrane proteins that mediate cell–cell contact in many organs through homotypical binding to cadherins on adjacent cells (Table 12.3). Cadherins have not been described on blood cells but are found on endothelial cells, where, similar to PECAM-1 and JAMs, they help form cell junctions and participate in the process of leukocyte migration across endothelial cell-to-cell borders, termed *diapedesis* or *transendothelial migration*. Cadherins are also expressed in the epithelium and help form cell-to-cell junctions.

The GPIb–IX–V complex on platelets consists of leucine-rich protein subunits (see Fig. 12.1). Under conditions of high shear stress such as those found in arterial circulation, this complex promotes the initial platelet adhesion to injured vessels by binding to vWF exposed in the subendothelium. It also may assist interactions with other platelets or with endothelial cells by binding to P-selectin, which normally binds to glycoconjugates, and it may assist platelet adhesion to leukocytes by binding to the integrin $\alpha_m\beta_2$.

TABLE 12.2 Immunoglobulin-Like Receptors

Name	Other Name	Expressed by	Ligand	Function(s)
ICAM-1		Macrophages, EC, other cells	$\alpha_M\beta_2$, $\alpha_L\beta_2$, FIB	T-cell responses, leukocyte adhesion to EC
ICAM-2		EC	$\alpha_L\beta_2$	Leukocyte adhesion to EC
ICAM-3		Leukocytes	$\alpha_L\beta_2$	T-cell responses, leukocyte aggregation
ICAM-4		Erythroid precursors	$\alpha_4\beta_1$, $\alpha_v\beta_3$, $\alpha_{IIb}\beta_3$	Regulate erythropoiesis
GPVI		Platelets	Collagen	Platelet adhesion and activation
PECAM-1	CD31	Leukocytes, platelets, EC	PECAM-1	EC junctions, leukocyte transmigration, cell signaling
VCAM-1		Activated EC, smooth muscle cells	$\alpha_4\beta_1$, $\alpha_4\beta_7$	Mononuclear cell adhesion to EC
MAdCAM-1		EC of Peyer patches	$\alpha_4\beta_7$	Lymphocyte homing
Siglecs		Leukocyte subsets	Sialylated glycans	Regulates B-cell activation, innate immunity?, hematopoiesis?
JAMs		EC	JAMs, $\alpha_L\beta_2$, $\alpha_4\beta_1$	EC junctions, leukocyte transmigration
CD2		T cells	LFA-3 ^a	T-cell responses
CD4		T cells	Class II MHC ^a	T-cell responses
CD8		T cells	Class I MHC ^a	T-cell responses
CD3	T-cell receptor	T cells	Antigen on MHC ^a	T-cell responses
CD28	Costimulatory molecule	T cells	B7-1 (CD80)	T-cell responses

^aLFA-3 and classes I and II MHC molecules are also immunoglobulin-like receptors.

ICAM-1, -2, -3, -4, Intercellular adhesion molecules; JAM, junctional adhesion molecule; MHC, major histocompatibility complex; PECAM-1, platelet and endothelial cell adhesion molecules-1. For other abbreviations, see Table 12.1 footnotes.

TABLE 12.3**Other Adhesion Receptors**

Name	Other Name	Expressed by	Ligand	Function(s)
Cadherins		EC, many other cells	Homotypic binding	Formation of EC junctions
GPIb/IX/V		Platelets	vWF	Platelet adhesion to ECM under shear
CD36	GPIV	Platelets, many other cells	Collagens, TSP	Platelet adhesion to ECM
CD44		Leukocytes, other cells	Hyaluronan, serglycin	Lymphopoiesis, lymphocyte activation
DC-SIGN		Dendritic cells	Mannosylated glycans, other glycans	Regulate T-cell–dendritic cell interactions, recognize pathogens
NK cell receptors		NK cells	MHC molecules	Recognition of virus-infected or other foreign cells

DC-SIGN, Dendritic cell-specific ICAM-3 grabbing nonintegrin; MHC, major histocompatibility complex; NK, natural killer. For other abbreviations, see Table 12.1 footnotes.

TABLE 12.4**Selectins**

Name	Other Name	Expressed by	Ligand	Ligands Expressed by	Function(s)
P-selectin	CD62P GMP-140 PADGEM	Thrombin-activated platelets and ECs, cytokine-activated ECs	PSGL-1, GPIb α	Leukocytes, platelets	Leukocyte adhesion to activated ECs and platelets
E-selectin	CD62E ELAM-1	Cytokine-activated ECs	PSGL-1, other sialylated and fucosylated GPs	Leukocytes	Leukocyte adhesion to activated ECs
L-selectin	CD62L LECAM-1 LAM-1	Leukocytes	PSGL-1, also GlyCAM-1, CD34, and other mucins on ECs of lymph nodes	Leukocytes, ECs or lymph nodes	Leukocyte adhesion to other leukocytes; lymphocyte homing to lymph nodes

The selectins bind to sialylated, fucosylated, and (in some cases) sulfated oligosaccharides on specific glycoproteins, of which only some have been identified. EC, Endothelial cell; ELAM-1, endothelial leukocyte adhesion molecule-1; Gly-CAM-1, glycosylation-dependent cell adhesion molecule-1; GMP-140, granule membrane protein-140; LAM-1, leukocyte adhesion molecule-1; LECAM-1, leukocyte endothelial cell adhesion molecule-1; PADGEM, platelet activation-dependent granule external membrane protein; PSGL-1, P-selectin glycoprotein ligand-1. For other abbreviations, see Table 12.1 footnotes.

CD36 is a receptor with at least two membrane-spanning domains that is expressed on many cell types. On platelets, it has been implicated as a receptor for collagen and for thrombospondin; both interactions could facilitate adhesion to the subendothelial matrix at sites of hemorrhage.

LECTIN ADHESION RECEPTORS

CD44 is an unusual transmembrane GP expressed to variable degrees on many subsets of leukocytes (see Fig. 12.1). It has a membrane-distal domain that is structurally related to link protein of the ECM, and similar to link protein, can bind to hyaluronan. CD44 also binds to serglycin, a proteoglycan secreted by hematopoietic cells. The hyaluronan-binding function of CD44 may modulate a number of leukocyte responses. The most clearly demonstrated function is in lymphopoiesis, where maturation of lymphocyte precursors requires contacts with BM stromal cells bearing surface hyaluronan. CD44–hyaluronate interactions also may promote lymphocyte entry to and transit through organized lymphoid tissues. The membrane-proximal regions of CD44 are structurally diverse because of the insertion of variable numbers of domains through alternative splicing. These insertions may regulate the ability of CD44 to bind hyaluronan and may mediate postbinding events that affect cell signaling.

The selectins are a group of three receptors that terminate in a membrane-distal carbohydrate-recognition domain related to those in Ca^{2+} -dependent (C-type) animal lectins such as the hepatic asialoglycoprotein receptor (see Figs. 12.1 and 12.2). L-selectin is expressed on leukocytes, E-selectin on cytokine-activated endothelium, and P-selectin on macrophages, platelets, and endothelial cells exposed to secretagogues such as thrombin or histamine (Table 12.4). The selectins mediate leukocyte adhesion to platelets, endothelium, or other

Fig. 12.2 PLATELET ADHESION AND AGGREGATION. In response to arterial injury under high shear forces, platelets rapidly adhere to the subendothelial matrix of injured vessels. The initial contacts are made between GPIb–IX–V on platelets and von Willebrand factor (vWF) in the matrix. These molecular interactions help activate platelets, thereby increasing the affinity of several platelet integrins for other adhesive matrix proteins such as fibronectin, laminin, and collagen. GPVI further activates platelets by binding to collagen. CD36 also interacts with both collagen and thrombospondin. Fibrinogen cross-links activated platelets into aggregates by binding to $\alpha_{\text{IIb}}\beta_3$ integrins. The platelet plug then serves as an efficient surface for generation of thrombin and fibrin. GP, Glycoprotein.

leukocytes through Ca^{2+} -dependent interactions of the carbohydrate-recognition domains with cell-surface carbohydrates on apposing cells. High-affinity binding appears to require specific carbohydrate structures displayed on a limited number of membrane GPs. The best-characterized GP ligands for selectins are mucins, which have large numbers of clustered, sialylated *O*-linked oligosaccharides. Site-specific construction of *O*-glycans with specific sialylated, fucosylated, and (in some cases) sulfated moieties is required for these mucins to bind optimally to selectins. In the case of one mucin, P-selectin GP ligand-1 (PSGL-1), sulfation of tyrosine residues near a specific *O*-glycan is required for binding to P- and L-selectin.

Dendritic cells and related macrophages express a novel group of C-type lectins, of which the best characterized is dendritic cell-specific ICAM-3-grabbing nonintegrin (DC-SIGN). DC-SIGN binds to particular oligosaccharides on ICAMs, thereby regulating T-cell and dendritic cell function during antigen presentation. It also binds to glycans on a variety of pathogens, which may have critical roles in innate immunity. Natural killer cells express a different group of proteins, with some containing membrane-distal C-type lectin-like domains (e.g., NKG2D). Although these receptors are important for interactions of natural killer cells with target cells, they may bind to proteins rather than to glycoconjugates.

Siglecs are a subgroup of membrane proteins of the immunoglobulin superfamily that bind to carbohydrates instead of to proteins (see Table 12.2). The first two amino-terminal (*N*-terminal) domains appear to be necessary and sufficient for carbohydrate recognition. The *N*-terminal domain is a V-type structure that includes an unusual disulfide bond that is not found in the more common C-type immunoglobulin domains. Siglecs bind well to sialylated glycans on some but not all GPs. Different siglecs preferentially recognize sialic acid that is linked $\alpha 2,6$ -, $\alpha 2,8$ -, or $\alpha 2,3$ - to an underlying galactose residue. Most siglecs have immune receptor tyrosine-based inhibitory motifs and transmit inhibitory signals. Siglecs can form *cis* interactions with other GPs on the same cell or *trans* interactions with GPs on another cell. The best-characterized example is CD22, which negatively regulates B-cell activation when it engages sialylated GPs. Sialoadhesin, expressed on BM macrophages, may regulate hematopoietic cell differentiation.

LIGAND BINDING VERSUS CELL ADHESION

As with all noncovalent macromolecular interactions, adhesion molecules bind to each other with equilibrium affinities that are defined by their association and dissociation rates. However, the efficiency of cell adhesion is not simply a function of the solution-phase equilibrium affinities of adhesion molecules for one another. Adhesion molecules in cell membranes and matrix are limited primarily to two dimensions, and even low-affinity molecular interactions may stabilize adhesion if there is time for sufficient bonds to form along the plane of cell contact. The efficiency of cell attachment and the ensuing strength of adhesion reflect multiple factors that dictate the probability of formation of bonds between adhesion molecules on cell or matrix surfaces. The kinetics of bond formation and dissociation are especially important for certain kinds of cell adhesion. Furthermore, interactions between cell adhesion molecules are subjected to force, which affects the lifetimes of adhesive bonds. This is particularly true in the circulation, where platelets and leukocytes must rapidly adhere to the blood vessel wall and withstand forces applied by the wall shear stresses of flowing blood. Other factors that affect bond formation include the number of adhesion molecules on a cell or matrix surface, the distance the binding domain of an adhesion receptor protrudes from the cell membrane, the lateral mobility of receptors, receptor dimerization, and the clustering of receptors on microvilli or other membrane domains. Cell adhesion can be further stabilized by events that occur after the initial interactions of adhesion molecules. For example, the cytoplasmic domains of many adhesion molecules bind to cytoskeletal components, allowing clustering of receptors into surface patches that strengthen adhesion, thereby promoting cell spreading or migration.

TABLE 12.5 Regulation of Adhesion Receptors

Mechanism	Example
Synthesis	Erythroid precursor synthesis of $\alpha_5\beta_1$ Lymphocyte synthesis of CD44 Cytokine-induced synthesis of E-selectin, P-selectin, ICAM-1, and VCAM-1 by endothelial cells
Surface expression	Proteolytic cleavage of L-selectin from leukocytes Redistribution of P-selectin from granule membranes to plasma membrane of platelets and endothelial cells Endocytosis of P- and E-selectin on endothelial cells
Ligand affinity	Activation-induced increased affinity of many integrins for their ligands Activation-induced increased affinity of CD44 for hyaluronan

For abbreviations, see Table 12.1 footnotes.

REGULATION OF ADHESION RECEPTORS

To prevent inappropriate interactions of cells with each other or with the ECM, the expression and function of adhesion receptors must be tightly controlled. Three primary control mechanisms are used: (1) the rate of synthesis of the receptor, (2) the time during which the receptor is displayed on the cell surface, and (3) the binding affinity or avidity of the receptor for ligands (Table 12.5). All of these mechanisms are used to control interactions of blood and vascular cells.

REGULATION OF SYNTHESIS

The synthesis of many adhesion receptors is regulated. Erythroid precursors synthesize integrins that mediate their interactions with stromal cells and with ECM in the BM. As the precursors mature, synthesis ceases, resulting in loss of expression of cell-surface integrins by the time a mature erythrocyte enters the circulation. Lymphocyte precursors synthesize CD44 during differentiation in the BM, stop synthesis before release, and resume synthesis during maturation in the thymus. On exposure to antigens, immunologically naive lymphocytes synthesize increased amounts of several adhesion receptors and chemokine receptors during their conversion to the effector phenotypes; this process presumably allows these cells to become more adhesive in response to a subsequent antigenic challenge. Endothelial cells in postcapillary venules of the peripheral vasculature express very low, if any, levels of adhesion molecules that bind leukocytes. When exposed to inflammatory cytokines such as tumor necrosis factor- α and interleukin-1 (IL-1) or bacterial endotoxin, endothelial cells transiently increase synthesis of E- and P-selectin, ICAM-1, and VCAM-1, resulting in an adhesive surface for leukocytes.

REGULATION OF SURFACE EXPRESSION

The surface expression of some adhesion receptors is tightly controlled. L-selectin is present on the plasma membrane of leukocytes, where it is available to bind to ligands on the endothelial cell surface. Stimulation of the leukocyte causes L-selectin to be shed into the plasma by proteolytic cleavage. P-selectin is constitutively synthesized by megakaryocytes (where it is incorporated into platelets) and by endothelial cells. Rather than being directly delivered to the plasma membrane, it is sorted into secretory storage granules: the α granules of platelets and the Weibel–Palade bodies of endothelial cells. On stimulation of these cells by agonists such as thrombin, P-selectin is rapidly transported to the cell surface during fusion of granule membranes with the plasma membrane. When they are on the surface of the endothelium, both E-selectin and P-selectin are internalized and delivered to lysosomes for degradation. The cytoplasmic domain of

P-selectin contains signals that direct sorting into secretory granules, internalization through coated pits of the plasma membrane, and movement from endosomes to lysosomes; the latter two signals are probably also present in the cytoplasmic domain of E-selectin. The net result of these events is to control the duration of exposure of E- and P-selectin on the endothelium, where they can mediate adhesion of leukocytes. Activation of leukocytes also mobilizes a pool of β_2 integrins from storage compartments to the plasma membrane, although some of these molecules are also constitutively expressed on the cell surface. Finally, platelet activation redistributes a portion of the GPIb-IX-V complexes from ligand-accessible positions on the plasma membrane to sequestered, invaginated membrane domains known as the *surface-connected canalicular system*. This process, which requires interactions of the cytoplasmic domain of GPIb-IX-V with the cytoskeleton, may serve to downregulate GPIb-mediated adhesion of platelets to immobilized vWF.

REGULATION OF BINDING AFFINITY

Regulation of binding affinity is an important control mechanism for other adhesion receptors. Many integrins are constitutively present on the cell surface but interact poorly with their ligands. Cell activation by a number of agonists induces conformational changes in integrins so that they effectively recognize their ligands. An example is the $\alpha_{IIb}\beta_3$ integrin, which requires platelet stimulation to bind fibrinogen; if this binding affinity were not regulated, circulating platelets would indiscriminately aggregate in the fibrinogen-rich plasma milieu. The cytoplasmic domains of integrins can exert both positive and negative influences on binding affinity. Binding of specific cytoplasmic proteins to these domains may propagate structural changes to the extracellular ligand-binding regions of the integrins. Three-dimensional structures of integrins suggest that the integrin “headpiece” that contains the ligand-binding site faces down toward the membrane in the inactive conformation and rapidly extends upward in a “switchblade”-like opening motion on activation. Low-affinity ligand binding may stabilize some active conformations of integrins, perhaps explaining why integrins on unactivated cells will sometimes bind to immobilized, multivalent adhesive proteins but not to the same proteins in solution. Cellular activation may also regulate the binding avidities of CD44, L-selectin, P-selectin, and some integrins through changes in membrane distribution engineered by interactions of their cytoplasmic domains with the cytoskeleton or with clathrin-coated pits.

CELL SIGNALING THROUGH ADHESION MOLECULES

In addition to their roles in cell-cell and cell-matrix contacts, adhesion molecules may cause cell signaling through indirect or direct mechanisms. Proteoglycans in the ECM can sequester growth factors that can be released to bind to surface receptors on nearby cells. Some chemoattractants bind to proteoglycans on the surface of endothelial cells, where they can activate adherent leukocytes. Binding of adhesive ligands to cell-surface integrins, GPIb-IX-V, CD44, cadherins, CD36, PECAM-1, selectins, ICAM-1 and VCAM-1, and perhaps other receptors can directly trigger intracellular events. The consequences of such signaling include changes in affinity or avidity of other adhesion receptors for their ligands, shape change, secretion, proliferation, synthesis of cytokines and other molecules, and migration. In some cases, binding of a monovalent adhesive ligand to a receptor may induce a signal. More commonly, signaling requires cross-linking of several receptors through interactions with multivalent ligands in matrix or on apposing cells.

Many studies of adhesion receptor signaling have focused on integrins. Binding of the same ligand to different integrins can mediate different responses in the same cell. Furthermore, ligand binding to the same integrin expressed in different cells can result in different signals. These data suggest that very specific interactions occur between ligand-occupied integrins and intracellular components. The cytoplasmic domains of integrins are essential for initiating signaling.

Tyrosine kinases have been localized at the interaction zones between integrins, the cytoskeleton and several adaptor and effector molecules, and tyrosine phosphorylation of a number of proteins accompanies integrin-mediated cell signaling. Tyrosine phosphorylation initiates a cascade of signaling events, including the activation of serine/threonine kinases, which cause a variety of cellular responses. Ligand binding to integrins also results in generation of lipid second messengers, alkalization of the cytoplasm, and influxes of Ca^{2+} .

COOPERATIVE INTERACTIONS BETWEEN SIGNALING AND ADHESION MOLECULES

Signaling and adhesion molecules frequently function cooperatively in sequential cascades to enhance the specificity of cell adhesion. Three examples of how these cooperative interactions facilitate blood cell responses are described next.

Platelet Adhesion and Aggregation

At sites of blood vessel injury in the arterial circuit, platelets rapidly tether to and then translocate or roll along the damaged vessel through reversible interactions of GPIb-IX-V receptors with immobilized vWF exposed in the subendothelial matrix of injured vessels (Fig. 12.3). These interactions are facilitated by arterial flow, perhaps because of complex effects of high wall shear stresses on the lifetimes of bonds between GPIb and vWF. An important feature of this initial reversible adhesive event is that prior activation of the platelets is not required. After adhesion, however, the interaction of immobilized vWF with GPIb receptors triggers intracellular signals that lead to platelet activation. These signals synergize with those produced by engagement of the collagen receptor GPVI. Platelet activation, in turn, increases the affinity of platelet integrins for collagen and fibrinogen, which stabilizes adhesion. Binding of these ligands transduces signals that propagate further activation responses such as spreading, secretion of granule contents, and recruitment of additional platelets through cell-cell contact mediated by binding of fibrinogen to activated $\alpha_{IIb}\beta_3$ integrins. This adhesion cascade allows

Fig. 12.3 NEUTROPHIL ROLLING, SPREADING, AND EMIGRATION. At sites of tissue injury or infection, neutrophils first roll on the endothelial cells in postcapillary venules. These transient adhesive interactions are mediated by activation-induced transcription-dependent expression of E- or P-selectin on the endothelial cell surface. E- and P-selectin bind to carbohydrate ligands on the neutrophil. These molecular bonds can form under the shear forces in the venular circulation. The rolling neutrophils are then activated by locally generated inflammatory mediators that increase the affinity of β_2 integrins for immunoglobulin-like receptors such as intercellular adhesion molecule-1 (ICAM-1) on the endothelium. These bonds slow rolling and then promote firm adhesion to the endothelium. Neutrophil migration between endothelial cells into tissues at the site of infection requires disengagement of old adhesive bonds and formation of new bonds among integrins, PECAM-1, and their respective ligands. *PECAM-1*, Platelet and endothelial cell adhesion molecule-1.

unstimulated platelets to home to the site of vascular injury and then be activated by locally generated mediators.

Neutrophil Rolling, Spreading, and Migration

Near sites of extravascular bacterial infections, neutrophils first tether to and roll on the endothelial surface of venules through the interactions of selectins with cell-surface carbohydrate ligands (Fig. 12.3). Little, if any, leukocyte adhesion occurs in nearby arterioles. Neutrophil rolling on the endothelium occurs under shear forces, just as platelets adhere to subendothelial matrix under shear forces, although the shear flow in postcapillary venules is lower than that in arterioles. Rolling requires a balance between the formation of selectin–ligand bonds at the leading edge of the cell and the dissociation of bonds at the trailing edge of the cell. Whereas shear forces affect the lifetimes of selectin–ligand bonds, lower forces prolong lifetimes (catch bonds) and higher forces shorten lifetimes (slip bonds). Catch bonds help explain why a minimum shear force is required to support leukocyte rolling, particularly through L-selectin. Just as the initial adhesion to vWF does not require prior activation of platelets, selectin-mediated rolling does not require prior activation of neutrophils. Instead, locally generated inflammatory mediators induce expression of E- or P-selectin on the endothelial cell surface. The requirement for activation of endothelial cells rather than leukocytes allows the latter to adhere to vessels only at the site of vessel inflammation. After being situated on the vessel wall through selectin-mediated contacts, however, the neutrophils become exposed to activators such as platelet-activating factor, a phospholipid signaling molecule, activated complement proteins, and interleukin-8 (IL-8), a potent chemoattractant cytokine or chemokine, both of which are presented on the surface of activated endothelial cells. These signals cooperate with others directed by engagement of selectin ligands and promote very slow rolling of neutrophils on the surface of activated endothelium. Neutrophil activation increases the affinity of β_2 integrins for immunoglobulin counterreceptors on the endothelial cell surface such as ICAM-1. Although flowing cells cannot form these bonds, neutrophils rolling on selectins can do so because of their slower velocities. The integrin–ICAM interactions further slow rolling and then arrest the cells on the endothelium. The leukocytes then migrate, presumably because of disengagement of integrin–ICAM bonds and redistribution of integrins to the leading edge of the cell, where new bonds form. Interactions of leukocytes with JAMs and PECAM-1 and other molecules at interendothelial cell junctions facilitate transendothelial migration of the neutrophils into the underlying tissues. Adhesion of leukocytes to the endothelium disrupts cytoskeletal tethers to the endothelial cadherins; this disruption leads to dissociation of homotypic cadherin interactions that normally prevent passage of leukocytes. Both the integrin- and the PECAM-1-mediated adhesive events may signal cytoskeletal redistributions in leukocytes that enhance migration toward chemotactic molecules released in the vicinity of the infection. When leukocytes enter in the tissues, integrin recognition of ECM protein ligands may trigger secretion of proteolytic enzymes and production of superoxide anions, both required for optimal bactericidal function.

Adhesion of T Cells to Antigen-Presenting Cells

The initial engagement of T cells with antigen-presenting cells requires that the TCR ($\alpha\beta$ TCR) recognize antigen presented by the polymorphic domain of MHC molecules (Fig. 12.4). Subsequent interactions include the binding of CD8 or CD4 to MHC class I or II molecules, respectively, plus the binding of CD2 to LFA-3 and CD28 binding to B7 molecules. These molecular contacts are all of low affinity but are highly specific because they first require specific antigen presentation to the appropriate T cell. The combination of these binding events triggers inside-out signals that increase the affinity of LFA-1 ($\alpha_1\beta_2$), a β_2 integrin on T cells, for its ligand ICAM-1 on antigen-presenting cells, strengthening and prolonging the length of time cells stably adhere. During this time, the T cell is further

Fig. 12.4 ADHESION BETWEEN T LYMPHOCYTES AND ANTIGEN-PRESENTING CELLS. The initial contact is mediated by the TCR, or CD3, which binds with low affinity but high specificity to a specific antigen presented by a MHC molecule. Additional contacts, also of low affinity, are between CD4 (on helper cells) or CD8 (on cytotoxic cells) and MHC, and between costimulatory molecules CD2 and LFA-3 and CD28 and CD80 (B7-1) and CD86 (B7-2). These interactions signal the T cell to transiently increase the affinity of the β_2 integrin LFA-1 for ICAM-1 on the antigen-presenting cell. These bonds strengthen adhesion, and the costimulatory molecules transduce sustained and additional signals to the T cell that cause increased gene transcription, proliferation, and cytokine secretion. Not shown is the redistribution of these adhesion molecules into different regions of the contact zone as adhesion strengthens. Additional signals result from binding of β_1 integrins on the T cell to adhesive proteins in the extracellular matrix. LFA-3, Leukocyte function-associated antigen-3; MHC, major histocompatibility complex; TCR, T-cell receptor.

activated by a second or costimulatory signal delivered by T-cell CD28 binding to B7 molecules expressed by antigen-presenting cells. Together these interactions drive TCR-induced gene activation (IL-2 production) and cell proliferation and differentiation into different effector T cells that exit the secondary lymph node and migrate to immune reactions (see Chapter 21 for detailed discussion of T-cell–antigen-presenting cell activation).

The first principle of these three responses is that the initial adhesive event, although relatively limited, is highly specific. Thus, platelets bind to exposed subendothelial matrix in injured vessels, neutrophils bind to hyperadhesive endothelium near the site of infection, and T cells bind to cells presenting specific antigen in secondary lymph nodes. The second principle is that subsequent activation events strengthen cell adhesion and lead to further responses such as secretion, fibrin formation, cellular migration, and release of cytotoxic mediators or cell activation and proliferation. Activation often results from cooperative signaling by soluble agonists and by binding of ligands to adhesion receptors. Costimulation by multiple signals can amplify and provide specificity to cellular responses by mechanisms not always feasible for individual mediators. Thus, adhesion and cell signaling are highly interrelated processes.

The process of reversing cell adhesion, although less well understood, is equally important for the control of cell behavior. Some molecules such as the selectins can be proteolytically cleaved or internalized. The activation-induced increases in affinity of integrins and CD44 for their ligands are generally transient, but the mechanisms for return to the inactive conformation are obscure.

ALTERED EXPRESSION OF ADHESION MOLECULES

The highly regulated nature of adhesive events by hematopoietic cells suggests that defects in or excessive expression of adhesion molecules may contribute to the pathogenesis of disease. A variety of clinical observations support this hypothesis.

TABLE 12.6 Genetic Deficiencies in Adhesion Molecules

Molecule	Disease	Laboratory Finding(s)	Clinical Finding(s)
$\alpha_{IIb}\beta_3$	Glanzmann thrombasthenia	Impaired platelet aggregation	Mucocutaneous bleeding
GP1b-IX-V	Bernard-Soulier syndrome	Impaired platelet adhesion to vWF	Mucocutaneous bleeding
β_2 integrins	Leukocyte adhesion deficiency-1	Impaired adhesion of activated leukocytes to EC	Frequent infections
Selectin ligands	Leukocyte adhesion deficiency-2	Impaired fucose metabolism resulting in defective carbohydrate ligands for selectins, impaired rolling of leukocytes on venules	Frequent infections
β_1 , β_2 , β_3 integrins	Leukocyte adhesion deficiency-3	Impaired platelet adhesion and aggregation and impaired adhesion of activated leukocytes to EC	Mucocutaneous bleeding and frequent infections

For abbreviations, see Table 12.1 footnotes.

Genetic Deficiencies in Adhesion Molecules

Genetic deficiencies in platelet adhesion receptors such as the GPIb complex (as in Bernard-Soulier syndrome) and the $\alpha_{IIb}\beta_3$ integrin (as in Glanzmann thrombasthenia) result in hemorrhagic symptoms similar to those in patients with thrombocytopenia (Table 12.6). Genetic deficiencies in the leukocyte β_2 integrins (as in leukocyte adhesion deficiency-1) are associated with frequent severe bacterial infections and a failure of neutrophils to enter the infected tissues. Similar symptoms are seen in patients with a congenital defect in fucose metabolism that prevents synthesis of the carbohydrate ligands for selectins (leukocyte adhesion deficiency-2). A recently identified set of patients has both hemorrhagic symptoms and life-threatening infections (leukocyte adhesion deficiency-3). The molecular mechanism is attributable to mutations in an intracellular protein kindlin-3, which binds to β_1 , β_2 , and β_3 integrin cytoplasmic tails upon cell activation. These patients have normal levels of integrin surface expression (see Table 12.6).

Dysregulated Expression of Adhesion Molecules

Inappropriate expression of adhesion molecules has been implicated in thrombotic and inflammatory disorders and in tumor metastasis. For example, erythrocytes from patients with sickle cell anemia adhere to each other, to leukocytes, and to the endothelium, contributing to vasoocclusive crises. These adhesive events may reflect, in part, the expression of integrins and selectin ligands not normally found on mature erythrocytes. Inappropriate adhesion and activation of platelets on exposed atherosclerotic plaques may contribute to thrombosis and acute ischemic coronary artery syndromes. Dysregulated expression of selectins on the endothelium of ischemic blood vessels during myocardial infarction or shock may contribute to neutrophil-mediated tissue necrosis after reperfusion of the vessel. Mediators released while the neutrophils are adherent in the reperfused vessels may activate integrin function, strengthening adhesion and generating further signals that release destructive oxygen radicals and proteases within the vasculature. Finally, malignant cells appear to use molecules normally used for adhesion of blood cells to promote metastatic spread through interactions with platelets, endothelial cells, and extracellular matrix.

These examples underscore the importance of proper regulation of adhesion molecule expression in the physiology of blood cells.

CHEMOKINES AND HEMATOPOIETIC CELL TRAFFICKING

Antal Rot, Steffen Massberg, Alexander G. Khandoga, and
Ulrich H. von Andrian

The mammalian immune system has evolved to mount multifaceted molecular and cellular microbicidal responses tailored and custom-adapted to eliminate an endless variety of infectious agents and, at the same time, remain tolerant to self-antigens. Accomplishing these tasks requires continuous movement of billions of motile immune cells that roam throughout the body along distinct nonrandom traffic routes from one tissue to another using blood and lymphatic vessels as avenues for rapid access. Migratory pathways characteristic for distinct immune cell subsets are integral parts of their functional make-up determined in the process of cell differentiation and activation. During development in the bone marrow (BM) or thymus, or following stimulation by antigens or pathogen-associated molecules, immune cells acquire the expression of characteristic repertoires of cell surface molecules that enable and restrict their migration to defined tissues and microenvironments. For example, naive lymphocytes largely disregard inflammatory tissue sites, but migrate efficiently into secondary lymphoid organs. Conversely, innate immune cells and antigen-experienced lymphocytes can respond to inflammation-induced traffic cues, although some subsets also enter noninflamed lymphoid and nonlymphoid target tissues.^{1–4} Notably, not only mature leukocytes but also hematopoietic stem cells (HSCs) and progenitor cells, and other rare cell subsets recirculate throughout the body.^{5–13} The characteristic trafficking routes of leukocyte subpopulations are determined by their expression of cell surface adhesion molecules and chemoattractant receptors. Chemoattractants are generated in target sites and signal through their cognate receptors on leukocytes to induce their emigration and directed locomotion within the tissues. Leukocyte chemoattractants include a number of lipid mediators, microbial factors, complement fragment 5a and, most importantly, members of the chemokine family. This chapter discusses chemokines as master navigation signals for leukocyte trafficking and then focuses on specific trafficking pathways that direct leukocyte subsets to distinct target tissues.

CHEMOKINES IN CONTROL OF LEUKOCYTE TRAFFICKING

Chemokines (a clipping blend of *chemotactic cytokines*) are critical molecular messengers in the complex cellular communication network used by the immune system. Almost 50 human chemokines have been identified to date (Table 13.1).^{14–18} However, due to the existence of different splice variants and enzymatically processed forms the number of individual functionally distinct chemokine molecules is much higher. The two major subclasses of chemokines are designated CC- or CXC-, depending on the relative position of the two proximal to the N-terminus canonical cysteines, being either adjacent or separated by a single amino acid, respectively. XCL1 and XCL2, and CX3CL1 constitute two additional structural chemokine forms with one cysteine and three amino acids between the two canonical cysteines, respectively. CX3CL1 and another chemokine, CXCL16, are associated with a cell membrane via a long spacer sequence and anchored by a transmembrane domain; however, both these chemokines can be cleaved of their stalks and give rise to functional soluble molecules. All other chemokines are secreted proteins of 67 to 127 amino acids. Historically, chemokines have been grouped into functional subfamilies termed *inflammatory* and *homeostatic* chemokines. The former are induced by inflammatory

signals and control the recruitment of effector leukocytes in infection, inflammation, tissue injury, and malignancies, whereas the latter navigate leukocytes during hematopoiesis in the BM and in the thymus during initiation of adaptive immune responses in secondary lymphoid organs and in immune surveillance of healthy peripheral tissues. However, it is now clear that such functional distinction is largely blurred, as many “inflammatory” chemokines are produced under physiologic conditions and the expression of “homeostatic” chemokines is upregulated in inflammation.

Chemokine signals are transmitted through specific cell-surface G protein-coupled receptors (GPCRs) with seven transmembrane domains.^{19–23} The human chemokine receptor repertoire identified at present consists of 20 different GPCRs (Table 13.2).²⁴ The tremendous specificity and plasticity of leukocyte homing and tissue localization is largely determined by the interactions of chemokines with their cognate receptors. Individual leukocyte subsets express characteristic fingerprints of chemokine receptors, and each chemokine receptor binds defined sets of chemokines, albeit with various binding affinities and resulting in a spectrum of downstream responses, from agonism to antagonism.^{25,26} Chemokine receptors function as allosteric molecular relays where chemokine binding to the extracellular portion modifies the tertiary structure of the receptor. This allows the intracellular domain of the engaged receptor to bind to and activate heterotrimeric G proteins. In response, the activated G proteins exchange GDP for GTP, and in the process dissociate into $G\alpha$ and $G\beta\gamma$ subunits. The dissociated $G\beta\gamma$ subunits mediate most chemokine-induced signals by activating different phosphatidylinositol 3-kinase (PI3K) isoforms, leading to the formation of phosphatidyl-3,4,5-triphosphate (PIP_3). PI3K and its product PIP_3 then translocate to the pseudopod at the leading edge of migrating leukocytes, where they colocalize with the small GTPase Rac.^{27–30} PIP_3 activates Rac through specific guanine nucleotide exchange factors.^{31,32} Rac in turn acts through the downstream effectors p21-activated kinase and the Wiskott-Aldrich syndrome protein homologue WAVE, which stimulate actin-related protein 2/3. Together, this process induces focal polymerization, required for the development and forward extension of the pseudopod, a critical step in leukocyte chemotaxis.³³ The importance of PI3K-dependent signaling for leukocyte chemotaxis is evidenced by the lack of migration of myeloid leukocytes to chemokines in mice lacking PI3K γ .^{34–39} Notably, though, distinct signaling pathways or at least other PI3K isoforms appear to be involved in the trafficking of immune cells. For example, neutrophil and B-cell migration requires PI3K δ ^{42–45}, whereas T-cell chemotaxis is not impaired in PI3K-deficient mice, but depends on the Rac guanine exchange factor DOCK2.^{40–42}

Different pathways have been identified that can terminate chemokine signaling through their GPCRs. The $G\alpha$ subunit possesses an intrinsic GTPase activity to hydrolyze GTP. In a negative-feedback loop this GTPase activity allows the $G\alpha$ subunits to reassociate with the $G\beta\gamma$ subunits, thereby restoring the heterotrimeric G protein to its inactive state. In addition, another class of molecules, known as regulators of G protein signaling (RGS), also modulates signaling through chemokine GPCRs. RGS are a large and diverse protein family initially identified as GTPase-activating proteins of heterotrimeric G protein $G\alpha$ -subunits.^{43,44} At least some RGS can also influence $G\alpha$ activity through either effector antagonism by competing with effector molecules for GTP-bound $G\alpha$ -subunits or by acting as

guanine nucleotide dissociation inhibitors.⁴³ To date, over three dozen genes have been identified within the human genome that encode proteins containing an RGS or RGS-like domain.

An additional mechanism of termination of chemokine signaling involves ligand-induced internalization of GPCRs from the cell membrane into intracellular vesicular compartments. Receptor internalization is triggered by intracellular domains of GPCRs associating with beta arrestins, which together with other potential intracellular effectors, is involved in G protein-independent signaling of GPCRs.⁴⁵ Internalized chemokines are targeted for lysosomal degradation, whereas GPCRs may be recycled onto the cell membrane.

In addition to GPCRs, most chemokines also bind to one or two of the four “atypical” chemokine receptors (ACKRs) identified to date.⁴⁶ Like GPCRs, these are serpentine membrane receptors with seven transmembrane domains. However, unlike GPCRs, ACKRs lack or have an altered DRYLAIV consensus motive in the second intracellular loop, which is required for G-protein coupling. Therefore upon chemokine binding ACKRs do not trigger signaling events characteristic of GPCRs and cannot mediate cell migration. However, ACKRs internalize chemokines and may target them either into lysosomes or alternatively into transcytotic pathways.⁴⁷ ACKRs may also transmit intracellular signals, independently of G proteins, for example, through triggering biochemical cascades downstream of beta arrestin or affect signaling through classical chemokine GPCRs

expressed by the same cell, possibly through receptor heterodimerization. Based on the chemokine-scavenging activity of ACKRs, it has been postulated that the main role of ACKRs is to reduce the overall chemokine levels in the tissues. However, because ACKRs are expressed in discrete and often sparse cellular microenvironments, they cannot affect chemokine availability in the tissues globally, but only at the immediate sites of their cellular expression. Thus, the key role of ACKRs may be only to determine in which tissue microenvironments chemokines may or may not exert their activities.⁴⁸ This is achieved either through chemokine scavenging or chemokine transport. Currently four ACKRs have been included in the nomenclature (Table 13.3) and shown to bind a broad range of chemokine ligands.⁴⁹

Additional fine-tuning of chemokine communication is achieved by proteolytic cleavage and inactivation of chemokines, generating truncated chemokines with either increased or decreased receptor affinities and an altered spectrum of agonistic activities on different receptors. This adds a further layer of plasticity to the chemokine system. Proteases, such as dipeptidyl peptidase CD26, elastase, the ADAM (a disintegrin and metalloproteinase) family, as well as matrix metalloproteases (MMPs), have been implicated in the control of chemokine-mediated navigation of leukocyte trafficking.^{50–53} MMPs are a family of more than 20 enzymes with important functions in matrix degradation. They also act on chemokines to regulate varied aspects of inflammation and immunity.⁵⁴ In fact, the ADAM family of disintegrins and metalloproteinases has been identified as

CCR1	CCL3 (MIP-1 α), CCL5 (RANTES), CCL7 (MCP-3), CCL8 (MCP-1), CCL14 (HCC1), CCL15 (HCC2, MIP-1 δ), CCL16 (HCC-4), CCL23 (MPIF)	T cells, monocytes, eosinophils, basophils
CCR2	CCL2 (MCP-1), CCL8 (MCP-2), CCL7 (MCP-3), CCL13 (MCP-4), CCL16 (HCC4)	Monocytes, dendritic cells (immature), memory T cells
CCR3	CCL11 (eotaxin), CCL13 (eotaxin-2), CCL7 (MCP-3), CCL5 (RANTES), CCL8 (MCP-2), CCL13 (MCP-4), CCL24 (eotaxin-2), CCL26 (eotaxin-3), CCL28 (MEC)	Eosinophils, basophils, mast cells, Th2, platelets
CCR4	CCL17 (TARC), CCL22 (MDC)	T cells (Th2), dendritic cells (mature), basophils, macrophages, platelets
CCR5	CCL3 (MIP-1 α), CCL4 (MIP-1 β), CCL5 (RANTES), CCL11 (eotaxin), CCL14 (HCC1), CCL16 (HCC4), CCL8 (MCP-2)	T cells, monocytes
CCR6	CCL20 (MIP-3 β , LARC)	T cells (T regulatory and memory), B cells, dendritic cells
CCR7	CCL19 (ELC), CCL21 (SLC)	T cells, dendritic cells (mature), antigen-experienced B cells
CCR8	CCL1 (I309), CCL18 (PARC)	T cells (Th2), dendritic cells
CCR9	CCL25 (TECK)	T cells, IgA ⁺ plasma cells
CCR10	CCL27 (CTACK), CCL28 (MEC)	T cells
CXC Family		
CXCR1	CXCL8 (interleukin-8), CXCL6 (GCP2)	Neutrophils, monocytes
CXCR2	CXCL8, CXCL1 (GRO α), CXCL2 (GRO β), CXCL3 (GRO γ), CXCL5 (ENA-78), CXCL6, CXCL7 (NAP-2)	Neutrophils, monocytes, microvascular endothelial cells
CXCR3-A	CXCL9 (MIG), CXCL10 (IP-10), CXCL11 (I-TAC)	Th1 helper cells, mast cells, mesangial cells
CXCR3-B	CXCL4 (PF4), CXCL9 (MIG), CXCL10 (IP-10), CXCL11 (I-TAC)	Microvascular endothelial cells, neoplastic cells
CXCR4	CXCL12 (SDF-1)	Widely expressed
CXCR5	CXCL13 (BCA-1)	B cells, T _{FH}
CXCR6	CXCL16 (SR-PSOX)	CD8 ⁺ T cells, natural killer cells, memory CD4 ⁺ T cells
CXCR8	CXCL17	Monocytes, T cells, neutrophils, dendritic cells
CX₃C Family		
CX ₃ CR1	CX3CL1 (fractalkine)	Macrophages, endothelial cells, smooth muscle cells
XC Family		
XCR1	XCL1 (lymphotactin), XCL2	T cells, natural killer cells

TABLE 13.3**Atypical Chemokine Receptors**

Receptor	Chemokine Ligands	Cell Types
ACKR1	CCL2 (MCP-1), CCL5 (RANTES), CCL7 (MCP-3), CCL8 (MCP-2), CCL11 (eotaxin), CCL13 (MCP-4), CCL14 (HCC1), CCL17 (TARC) CXCL1 (GRO α), CXCL2 (GRO β), CXCL3 (GRO γ), CXCL5 (ENA-78), CXCL6 (GCP-2), CXCL7 (NAP-2), CXCL8 (interleukin-8), CXCL11 (I-TAC)	Erythrocytes, blood endothelial cells, Purkinje neurons
ACKR2	CCL2 (MCP-1), CCL3 (MIP-1 α), CCL4 (MIP-1 β), CCL5 (RANTES), CCL7 (MCP-3), CCL8 (MCP-2), CCL11 (eotaxin), CCL13 (MCP-4), CCL14 (HCC1), CCL17 (TARC), CCL22 (MDC), CCL23 (MPIF-1, SCYA23), CCL24 (eotaxin-2)	Lymphatic endothelial cells, placenta syncytiotrophoblast, innate-like B cells, marginal zone B cells, dendritic cells, monocytes, tissue-resident mast cells, macrophages
ACKR3	CXCL11 (I-TAC), CXCL12 (SDF-1)	Blood endothelial cells in the brain, embryonic, and neonatal tissues, marginal zone B cells
ACKR4	CCL19 (ELC), CCL21 (SLC), CCL25 (TECK), CXCL13 (BCA-1)	Lymphatic endothelial cells lining the ceiling of the lymph node subcapsular sinus, thymic epithelial cells

BCA-1, B-cell chemoattractant 1; CTACK, cutaneous T cell-attracting chemokine; ELC, Epstein Barr virus-induced molecule 1 ligand chemokine; ENA, epithelial cell-derived neutrophil-activating peptide; GCP, granulocyte chemotactic protein; GRO, growth-regulated oncogene; HCC, hemofiltrate chemokine; IgA, immunoglobulin A; IP-10, interferon-inducible protein 10; I-TAC, interferon-inducible T-cell alpha chemoattractant; LARC, liver and activation-regulated chemokine; MCP, monocyte chemoattractant protein; MDC, macrophage-derived chemokine; MEC, mammary-enriched chemokine; MIG, monokine induced by interferon- γ ; MIP, macrophage inflammatory protein; SDF-1, stromal cell-derived factor-1; SLC, secondary lymphoid-tissue chemokine; SR-PSOX, scavenger receptor for phosphatidylserine-containing oxidized lipids; TARC, thymus and activation-regulated chemokine; TECK, thymus-expressed chemokine; T_{FH}, follicular helper T cells.

the most relevant group of proteases implicated in the shedding of L-selectin, VCAM, as well as CX3CL1 and junctional adhesion molecule (JAM)-A, and thereby involved in facilitating the detachment of leukocytes.⁵⁵ In addition, chemokines such as CCL2, CXCL10, and CXCL12 are cleaved and inactivated by MMP-2 and MMP-9.^{56,57} Apart from MMPs, proteases stored in neutrophil granules, in particular cathepsin G and elastase, inactivate chemokines such as CXCL12 and its receptor CXCR4 that regulate not only the migration of mature leukocytes but also the mobilization and homing of immature HSCs.^{58,59} Hence, proteases by means of their chemokine-modifying properties must be regarded as integral components in the control of trafficking of mature leukocytes and their precursors.

In general, leukocyte trafficking can be classified into three distinct patterns of migration (1) entry into tissues from the circulation; (2) migration within tissues; and (3) exit from tissues. The following sections will discuss each of these steps in leukocyte trafficking.

LEUKOCYTE ENTRY INTO TISSUES

In order to leave the circulation and enter target tissues, leukocytes must engage in several sequential steps of adhesion to the endothelial cells, which most often take place in the venular segment of the circulatory tree.^{27,60–65} Discrete individual adhesion steps are mediated by binding interactions of pairs of adhesion receptors and their counter-ligands expressed in trans-geometry by leukocytes and endothelial cells. The initial tethering of leukocytes to the endothelial cell is induced by adhesion molecules, which are able to rapidly bind their ligands with high tensile strength. The most important initiators of leukocyte tethering are selectins, expressed on leukocytes (L-selectin), endothelial cells (E- and P-selectin), and platelets (P-selectin). The most important selectin counter-ligands are sialomucins, which are decorated with oligosaccharides related to sialyl-Lewis^x, including P-selectin glycoprotein ligand (PSGL)-1 and the peripheral-node addressin (PNAd). Selectin-mediated adhesion bonds that are formed in the bloodstream are transient and do not allow prolonged, firm leukocyte arrest. As tethered leukocytes are pushed along the vessel wall by the blood flow, selectin bonds continuously dissociate at the upstream end of the cells and new ones form downstream, resulting in the slow rolling motion characteristic of leukocyte tethering. To undergo firm adhesion the rolling leukocyte must engage additional adhesion receptors that belong to the integrin family, particularly CD11a/CD18 (leukocyte function-associated antigen-1 [LFA-1]) and the $\alpha 4$ integrins, $\alpha 4\beta 1$ (very late antigen [VLA]-4) and $\alpha 4\beta 7$. Without exception, individual integrins are expressed by the subsets of leukocytes and their counter-ligands by the endothelial cells.

Whereas selectins are constitutively active, integrins first need to be activated to assume a high-affinity state that promotes efficient adhesion to endothelial ligands. Integrin activation is induced by chemoattractant signals that trigger a reversible change in integrin conformation (leading to enhanced ligand-binding affinity) or in integrin clustering (enhancing avidity), or both.²⁰ Some (but not all) chemokines presented on the luminal surface of microvascular endothelial cells can trigger rapid integrin activation and efficiently induce leukocyte arrest. The retention of chemokines on the vessel endothelium is mediated through binding to glycosaminoglycans (GAGs) in the luminal glycocalyx. Chemokines that are produced in the extravascular space can be transported across the endothelial barrier to the luminal surface.⁶⁶ This process is triggered by chemokine binding to the atypical chemokine receptor ACKR1 (previously known as *Duffy antigen receptor for chemokines* [DARC]), which is also involved in luminal immobilization of chemokines.⁴⁷ ACKR1 expression by the endothelial cells characterizes only the venular but not the capillary or arterial segment of the circulatory tree.⁶⁷

Chemokines signal through the G α_i subfamily of large heterotrimeric G proteins, which can be inhibited by pertussis toxin (PTX). Consequently, intravital microscopy studies have shown that lymphocytes treated with PTX undergo normal tethering and rolling

interactions in high endothelial venules (HEVs) in lymph nodes (LNs) and Peyer patches (PPs), but unlike control cells, the PTX-treated cells are unable to undergo integrin-dependent firm arrest. Chemokine receptor activation precipitates a cascade of intracellular signaling and adapter proteins, including Kindlin-3 and RAP-RAPL, which are involved in the so-called *inside-out signaling* that results in integrin activation. Modifications at the cytoplasmic tails of the integrin α and β chains are critical to regulate leukocyte adhesion to integrin ligands, such as the binding and spreading of neutrophils on intercellular cell adhesion molecule (ICAM)-1 and the complement C3 activation product, iC3b.⁶⁸ Once arrested, the adherent leukocytes rapidly polarize and slowly migrate within the vessel in random directions.^{69–71} The intraluminal crawling is thought to be essential to enable leukocytes to find exit points within the vessel through which they can leave the vasculature.²⁷ A subset of monocytes crawl within uninfamed microvessels under steady-state conditions.^{62,72,73} These patrolling monocytes are poised to provide immune surveillance of the endothelial cell surfaces and clear the intravascular debris,⁷³ but may also enter the extravascular space in response to damage and infection. Once emigrated, some monocyte cells may differentiate into macrophages or dendritic cells (DCs). In some tissues and organs, such as the intestine, monocyte emigration contributes throughout life to the replenishing of the resident macrophage pool.^{72,74,75} In other tissues, macrophage and DC precursors home only during the embryonic period from either the liver or yolk sack, and the resident mature cells proliferate in situ to give rise to their progeny.^{76,77}

The interactions between the $\beta 2$ -integrins LFA-1 and Mac-1 with endothelial ICAMs are required for intravascular adhesion and crawling. However, the specificity of these interactions differs between different leukocytes, such as neutrophils and monocytes.^{69,72} Neutrophil luminal crawling is mainly mediated by Mac-1,⁶⁹ whereas monocytes and T cells use LFA-1.^{1,72} Recent studies using blocking antibodies against Mac-1 and LFA-1 showed that crawling patterns of monocytes and neutrophils differ at steady state compared with those under inflammatory conditions; both LFA-1 and Mac-1 contribute to monocyte crawling; however, the LFA-1-dependent crawling in unstimulated venules becomes Mac-1 dependent upon inflammation. By contrast, Mac-1 alone is responsible for neutrophil crawling in both unstimulated and cytokine-stimulated venules.⁷⁸ This indicates that differences in monocyte and neutrophil crawling behavior result from involvement of different $\beta 2$ integrins and consequently affect the next step of the leukocyte migration cascade: transendothelial migration.

Transendothelial migration or diapedesis is a critical event allowing leukocytes to cross the vascular wall and enter their target tissue. Two routes of leukocyte diapedesis have been observed: a paracellular route that dominates most extravasation processes, and a transcellular route reported for neutrophils and some T cells.^{79–85} Both routes involve the action of apical and junctional endothelial ICAM-1, and, at least in some settings, vascular cell adhesion molecule-1 (VCAM-1). In inflammatory conditions, additional junctional endothelial ligands such as PECAM-1, vascular endothelial (VE)-cadherin, ESAM, CD99, CD99L2, and junctional adhesion molecule (JAMs) can contribute to leukocyte diapedesis.^{80,86–92}

After penetration of the endothelial barrier, leukocytes may move further within the interstitium toward their target destinations in the tissue. This locomotion is considered to reflect in vivo chemotaxis, increased rate-directed cell locomotion driven by the putative gradients of chemotactants.^{93,94} Several signaling pathways have been proposed to be involved in this gradient-driven process, the most predominant being the PI3K pathway.³⁵ Thereby, leukocytes use an “internal compass” for sensing the direction of chemotactic gradients, and undergo polarization characterized by the formation of lamellipodia at the leading edge of the cell and an uropod at the trailing edge.^{95,96} Chemokines released by a broad range of tissue cells, epithelial cells, stromal cells, mast cells, smooth muscle cells, fibroblasts, myocytes, and tissue-resident immune cells may form gradients and mediate the leukocyte chemotaxis in the interstitium. In this context, the spatiotemporal formation of chemokine gradients in the

interstitial tissue may be supported by GAGs, which immobilize chemokines and, thus, determine the position and temporal persistence of chemokine gradients.^{97,98} It has been shown that immobilized, substrate-bound chemokines are effective in inducing directed leukocyte migration, which is called *haptotaxis*.⁹⁹ It has also been suggested that efficient development of tissue chemokine gradients also requires, in addition to the free diffusion of chemokines from their cellular sources, scavenging of chemokines by their atypical chemokine receptors expressed by cells in apposition to chemokine sources.¹⁰⁰ Leukocytes moving within the interstitial tissue receive signals from neighboring cells as well as from the extracellular matrix, activate intracellular processes, release inflammatory mediators, and upregulate adhesion molecules and release enzymes.¹⁰¹ Although neutrophils display enhanced expression of $\beta 1$ -integrins upon transmigration, it remains unclear whether integrins are relevant for interstitial leukocyte migration. According to this, the involvement of integrins seems to be rather different in 2D versus 3D settings. In contrast to 2D migration, the 3D tissue network confines and mechanically anchors cells from all sides so that they intercalate alongside and perpendicular to tissue structures. Importantly, 2D but not 3D leukocyte migration seems to be integrin dependent.¹⁰² In this context, proteolytic enzymes (proteases) such as heparase, elastase, and matrix metalloproteinases (MMP-2 and MMP-9) provide for degradation of the components of the basement membrane and the ECM, and thus play an important role in leukocyte interstitial migration.^{52,103}

All consecutively occurring steps of (1) leukocyte tethering and rolling, (2) exposure to a chemotactic stimulus, (3) firm arrest, (4) postadhesive strengthening and intraluminal crawling, (5) diapedesis, and (6) interstitial migration are essential for leukocytes to migrate to sites of inflammation. Accordingly, genetic defects in any of the molecules involved in either step lead to compromised host defenses. Patients with leukocyte adhesion deficiency (LAD) syndrome may have a genetic defect in $\beta 2$ integrins (type 1) or in fucosylated selectin ligands (type 2), and neutrophils either cannot stop or cannot roll, respectively.^{104–106} Type 3 LAD involves the deficiency of kindlin-3, a molecule regulating integrin activation and leukocyte adhesion reinforcement.^{107,108} LAD syndrome is characterized by marked leukocytosis and frequent and severe soft-tissue infections.

Chemokine Control of Lymphocyte Homing to Secondary Lymphoid Organs

Migration of blood-borne lymphocytes to secondary lymphoid organs is the best-characterized example of leukocyte trafficking from the circulation into distinct target tissues.^{2,4,109–114} Lymphocytes constantly survey secondary lymphoid organs, which include the spleen, tonsils, appendix, PPs, and LNs. Such homing allows lymphocytes to encounter antigen that may pose a threat to the organism. Antigens are collected and presented to T cells by DCs, in conjunction with signals by costimulatory molecules and cytokines. In contrast to the spleen, where the molecular mechanisms of leukocyte homing are still not entirely clear and differ from all other lymphoid organs, the rules that govern homing of immune cells to LNs are well understood. Mature DCs, which have acquired antigen in peripheral tissues, and some memory cells reach the LNs through afferent lymph vessels.^{115–117} In contrast, circulating T and B lymphocytes gain access to LNs and PPs through specialized postcapillary microvessels lined with cuboid endothelial cells that are known as *high endothelial venules* (HEVs).^{118–121} HEVs in different secondary lymphoid organs express distinct patterns of trafficking molecules to serve as tethering platforms for defined subsets of lymphocytes. For example, HEVs in LNs express PNAd, whereas HEVs in PPs express mucosal addressin-cell adhesion molecule (MAdCAM-1). Other mucosa-associated lymphoid organs, such as mesenteric LNs, express both MAdCAM-1 and PNAd. Although T and B lymphocytes are recruited by similar multistep cascades to home to secondary lymphoid organs, the roles of individual traffic molecules are not necessarily identical, even when both subsets interact with the same microvessel.²

The first step in the homing cascade in LNs is mediated by L-selectin/CD62L expressed on all lymphocytes, except effector/memory cells. PNAd, an O-linked sulfated core 1 carbohydrate moiety that is exclusively found in HEVs, is the major endothelial L-selectin ligand.^{122–126} Binding of L-selectin to PNAd initiates lymphocyte rolling in HEVs and slows down and marginates the free-flowing lymphocytes.^{2,65,125} While the L-selectin–PNAd interaction is required, it is not by itself sufficient to promote firm leukocyte adhesion. The subsequent firm arrest of rolling T and B lymphocytes is mediated by the $\alpha 4 \beta 1$ integrin, $\beta 2$ -integrin CD11a/CD18 (LFA-1), CD11b/CD18 (Mac-1), and $\beta 7$ -integrin, which bind ICAMs, in particular ICAM-1 and ICAM-2, VCAM-1, or MAdCAM-1 on high endothelial cells.^{125–130}

Chemokines that are presented in the lumen of HEV function as triggers of integrin activation.^{131,132} On naive T cells integrin activation is primarily mediated by CCL21 (previously known as *SLC*, *TCA4*, *exodus 2*, or *6-C-kine*), which is constitutively expressed and secreted by HEVs. The secreted chemokine is noncovalently bound to GAGs on the surface of HEVs. Here it activates rolling lymphocytes through binding to CCR7, which is expressed on naive B and T cells. Another CCR7 ligand, CCL19 (previously termed *ELC* or *MIP3 β*), also supports T-cell homing to LNs.¹³² CCL19 is not expressed by high endothelial cells themselves. However, CCL19 and other chemokines may be released by extravascular cells in LNs or in tissues that discharge lymph to a local LN. Lymph-borne chemokines can be transported to the luminal aspect of HEVs. Correspondingly, chemokines, including CCL2, CCL19, and CCL21, injected under the skin of mice accumulate on the luminal surface of the HEV in draining LNs, where they promote integrin activation on rolling leukocytes bearing the cognate receptors.^{133–135} In this context, endothelial heparan sulfate has been shown to be essential for controlling chemokine presentation on the endothelium and thereby for recruitment of lymphocytes and DCs to lymph nodes.¹³⁶

B cells use largely the same trafficking molecules as naive T cells to home to LN. However, B-cell–HEV interactions are only moderately affected by the absence of CCR7 or its ligands.¹³⁷ Correspondingly, LNs of mice lacking CCR7 contain few T cells, while the B-cell compartment (and the memory T-cell compartment) is less affected.^{138,139} Similar observations were made in *pl1/pl1* mice, which have a spontaneous genetic defect resulting in deletion of CCL19 and the HEV-expressed form of CCL21 (mice, unlike humans, have a second *ccl21* gene that is only expressed in lymph vessels of peripheral tissues), demonstrating that B cells are not absolutely dependent on CCR7 to adhere to HEVs.¹³⁷ In fact, rolling B cells can be induced to arrest in HEVs by either CCR7 agonists or by CXCL12 (previously called *stromal cell–derived factor* [*SDF-1*] α), the ligand for CXCR4.¹⁴⁰ An additional chemokine pathway involving CXCL13 (also called *BLC*) and its receptor CXCR5 has also been implicated in B-cell homing to secondary lymphoid tissues.¹⁴¹ Of note, although B cells encounter several distinct integrin-activation signals in HEVs, B-cell homing to LNs is nonetheless less efficient than that of T cells. A likely reason is that the B cells express only approximately half the number of L-selectin molecules expressed on T cells, which greatly affects their ability to initiate the adhesion cascade in HEVs.^{121,142}

The requirement for a sequence of distinct molecular steps that each leukocyte must undergo to arrest within microvessels explains why only certain leukocyte subsets gain access to lymphoid tissues, while others are excluded. Granulocytes, for example, express LFA-1 and L-selectin, but not CCR7. Consequently, although granulocytes can roll in HEVs (via L-selectin), these leukocytes do not perceive an integrin-activating stimulus and, therefore, fail to accumulate in LNs or PPs. Likewise, mature DCs express CCR7 and CD11a/CD18, but not L-selectin. Because these cells are thus incapable of rolling in HEVs, they fail to home to noninflamed LNs from the blood (although mature DCs readily access LNs via afferent lymph). Hence, the GPCR-mediated integration activation step is critical for imparting specificity to the process of lymphocyte homing to LN.

In HEVs of PPs, similar homing mechanisms are encountered as described earlier for LNs. However, the levels of L-selectin ligands

(which are immunologically distinct from PNAd) expressed by HEVs in PPs are considerably lower when compared with LNs.^{143,144} As a result, L-selectin itself is not sufficient to initiate a successful homing cascade for most lymphocytes in PPs.¹⁴³ Indeed, HEVs in PPs (and also in mucosa-associated LNs) additionally express MAdCAM-1, a ligand for the $\alpha 4 \beta 7$ integrin.^{143–145} The $\alpha 4 \beta 7$ heterodimer, which comprises an $\alpha 4$ integrin chain (CD49d) linked to the $\beta 7$ integrin chain, is expressed at low levels by naive T and B cells, and is required for the successful homing of these cells in PP HEVs.¹⁴³ Following formation of an initial L-selectin-dependent tether, the $\alpha 4 \beta 7$ –MAdCAM-1 pathway stabilizes and slows the rolling lymphocytes without requiring chemokine activation. Once a chemokine signal has been transmitted, both $\alpha 4 \beta 7$ and LFA-1 become activated and jointly mediate firm arrest.¹⁴³

Of note, $\alpha 4 \beta 7$ is strongly upregulated on gut-homing effector/memory lymphocytes, but completely absent on skin-homing memory T and B cells; these differential levels of $\alpha 4 \beta 7$ integrin expression allow certain antigen-experienced lymphocyte subsets to acquire tissue selectivity.¹⁴⁶ The mechanisms underlying this specificity and plasticity of lymphocyte homing will be addressed later. Like in LNs, chemokines are essentially involved in promoting integrin activation and allowing firm lymphocyte arrest in HEVs of PPs. Thus, CXCR4, CXCR5, and CCR7 have been implicated in B-cell homing, while CCR7 seems exclusively responsible for T-cell homing. Interestingly, while T and B cells are recruited across the same HEVs in LNs, there is segmental segregation of T- and B-cell recruitment in PPs. HEVs supporting B-cell accumulation in PPs are concentrated in or near B follicles and present CXCL13, but not CCL21, whereas T cells preferentially accumulate in interfollicular HEVs (i.e., within the T-cell area), which express high levels of CCL21 but not CXCL13.

Trafficking of Leukocytes From Blood Into Nonlymphoid Tissues

As outlined previously, naive lymphocytes migrate most efficiently into secondary lymphoid organs, from which innate immune cells are excluded. However, both innate immune cells and subsets of lymphocytes can respond to inflammatory and/or activation signals by modulating the expression and/or activity of traffic molecules, which allows them to migrate to nonlymphoid tissues.⁴ For example, in response to inflammatory stimuli, granulocytes, including neutrophils, eosinophils, and basophils, are rapidly recruited into the affected site and provide the first line of antimicrobial defense. Thereafter, additional immune cells, including monocytes, DCs, and effector as well as memory lymphocytes, may be recruited. Essentially, all of these different recruitment events depend on distinct multistep adhesion cascades.

Many of the inflammation-associated traffic molecules required for access into nonlymphoid tissues are shared by the different leukocyte subsets. The key receptors that initiate capture and mediate rolling of neutrophils, monocytes, natural killer cells, eosinophils, and effector T and B cells at peripheral sites of injury and inflammation are the three selectins, the leukocyte-expressed L-selectin as well as P- and E-selectin, which are induced on both acutely and chronically stimulated endothelial cells.^{147–151} In addition, interactions between leukocytes involving PSGL-1 and L-selectin can also support the accumulation of immune cells in inflamed tissues.^{150,152–154} Subsequent to rolling, firm arrest of leukocytes in nonlymphoid tissues involves integrins, including CD11a/CD18 (and its counter-ligand ICAM-1 and possibly also ICAM-2), VLA-4 (and its counter-ligand VCAM-1), as well as CD11b/CD18 (and its counter-ligand ICAM-1).^{1,27,155} As discussed above for lymphoid tissues, chemoattractants, including chemokines and other GPCR agonists, such as formyl peptides, complement fragment 5a, and lipid mediators (e.g., PAF and LTB₄), contribute essential integrin-activation signals for leukocytes at sites of inflammation. The molecular diversity of chemoattractants and their restricted temporal and spatial expression patterns combined with leukocyte subset-specific fingerprints of chemoattractant receptor expression provide

a crucial mechanism for the fine-tuning of the migratory cellular responses.^{65,156,157}

In contrast, the migratory properties acquired by T and B lymphocytes in response to activation are diverse depending on the strength, the quality, and the context of the antigenic stimulus.¹⁴⁶ Specifically, antigen stimulation of naive lymphocytes results in the generation of effector and memory cells that express specific repertoires of trafficking molecules that guide them back to tissues containing the stimulatory antigen.^{158–160} Thus, a cutaneous challenge generates preferentially a skin-tropic memory response, whereas orally ingested antigens induce preferentially gut-homing effector and memory cells. Recent studies have broadened our understanding of the molecular events that induce the generation of tissue-specific memory cells.

In addition to presenting antigen, DCs in different lymphoid organs are endowed with information characteristic for the tissue in which the antigen was obtained. DCs in mucosa-associated lymphoid tissues, but not other lymphoid organs, possess the enzymatic machinery to synthesize retinoic acid (RA) from vitamin A.¹⁶¹ Exposure of activated T cells to RA induces the expression of gut-homing receptors (i.e., $\alpha 4 \beta 7$ and CCR9) and suppresses skin-homing molecules.^{159,162} In the absence of RA, T-cell stimulation induces few or no gut-homing molecules, but instead promotes the expression of P- and E-selectin ligands, as well as CCR4, which are needed for homing to the skin. Additionally, when activated T cells are exposed to IL-12 and high levels of vitamin D₃, which is physiologically induced by sunlight in the skin, they upregulate CCR10, the receptor for the epidermal chemokine CCL27.¹⁶³ This organ-specific information can reprogram and “imprint” the tissue-tropic memory cells as they differentiate from naive lymphocytes.¹⁶⁰

Like T cells, B-cell subsets also express homing receptors that permit their selective trafficking to specific tissues. For example, distinct B-cell subsets produce the immunoglobulin isotype IgA, which is present in secreted body fluids, including tears, breast milk, and mucus. IgA⁺ B cells are characterized by their expression of CCR10.^{164,165} The ligand for CCR10, MEC/CCL28, is expressed predominantly in mucosal tissues that secrete IgA.¹⁶⁶ Hence, CCR10 may function as a homing receptor that allows IgA-secreting B cells to migrate to tissues where IgA is required. A large subset among the IgA-secreting B cells are those in the small intestine, which in addition to CCR10 express the gut-homing receptors $\alpha 4 \beta 7$ and CCR9. When naive B cells are activated in the presence of intestinal DCs, they upregulate not only these two traffic receptors, but also undergo class switching to IgA. This imprinting effect is dependent upon RA, which is sufficient to induce gut-homing receptors, but must be combined with DC-derived IL-5 or IL-6 to promote IgA class switching.¹⁶² More than 50 different subtypes of lymphocytes have been characterized in human blood and it is likely that multiple similar associations between homing receptors, immunologic effector function, and tissue specificity will be revealed in future.

Migration of Hematopoietic Stem Cells to the Bone Marrow and Mobilization in the Niche

The BM is the principal site of hematopoiesis in the adult body. Correspondingly, most HSCs are lodged in the BM cavity. Within the BM, maintenance of HSCs and regulation of their self-renewal and differentiation is thought to depend on the specific microenvironment, which has historically been termed *stem cell niche*.^{6,8,167–169} The central role of stem cell niches for HSC function has been recognized with the discovery that *Sl/Sl^{fl}* (steel-Dickie) mice bearing a mutation in the gene encoding membrane-bound stem cell factor (SCF; also known as *KIT ligand*) show failure of BM HSC maintenance.¹⁷⁰ However, the exact localization as well as the composition of BM HSC niches and the molecular cross-talk that controls the retention of HSC within the niches are the subject of intense ongoing research.^{171–174}

Notably though, not all HSCs reside within the BM. In fact, it has been known for almost four decades that a small amount of

hematopoietic precursors are also present in peripheral blood.^{10–13} Blood-borne HSCs continuously migrate back to the BM cavity, presumably to fill any vacant stem cell niches.¹³ Although the exact physiologic relevance of blood-borne HSCs remains to be determined, the intrinsic capacity of HSCs to home to the BM compartment is the prerequisite for successful clinical BM and stem cell transplantation. Homing of HSCs to the BM is a rapid process, as intravenously injected murine and human progenitors are quickly cleared from the recipient's circulation.^{13,175,176} Like mature lymphocytes, HSCs and hematopoietic progenitor cells (HPCs) interact through a multistep adhesion cascade with BM microvessels.^{7,176–180} Initially, HPCs tether and roll along BM microvessels.^{181,182} This process involves $\alpha 4 \beta 7$ integrin on HSCs/HPCs, which binds VCAM-1, as well as E- and P-selectin on BM sinusoidal endothelial cells, which bind $\alpha (1-3)$ -fucosylated ligands including CD44 and PSGL-1 on the surface of HPCs.¹⁷⁶ The subsequent firm arrest is mediated by activated $\alpha 4 \beta 1$ and VCAM-1, which is constitutively expressed in BM sinusoids. In addition to $\alpha 4 \beta 1$ integrin, the integrins $\alpha 4 \beta 7$, $\alpha 5 \beta 1$ and $\alpha 6 \beta 1$, and CD44 as well as JAM-B have recently been implicated in HSC homing to the BM.^{180,183–186} Integrin-mediated adhesion is important for HSPC movement not only in adulthood but also during embryogenesis. Thus, HSPCs in the yolk sac, aorto-gonad-mesonephros region, and placenta express CD41 (GPIIb integrin encoded by the gene *Itga2b*). Expression gradually decreases during development, and adult HSPCs express little or no CD41.^{7,187} In addition to CD41, $\beta 1$ integrins tune the migration of fetal HSPCs. The use of chimeric mice generated with $\beta 1$ integrin-deficient fetal HSPCs has revealed that fetal HSPCs lacking $\beta 1$ integrins form and differentiate but they cannot colonize the follicular lymphoma, suggesting an essential role of $\beta 1$ integrins in fetal HSPC trafficking. The role of the $\beta 2$ -integrins LFA-1 (CD11a/CD18) and Mac-1 (CD11b/CD18) is controversially discussed. Although some studies have reported their involvement in HSPC retention,^{188,189} others have indicated that the effect of $\beta 2$ integrins becomes apparent only in synergy with $\alpha 4 \beta 1$.¹⁹⁰

The chemokine CXCL12, the ligand for CXCR4 expressed by most hematopoietic cells including HSCs, is thought to play a pivotal role in BM homing of HSCs. BM endothelial cells (in addition to immature osteoblasts and other stromal cells) constitutively express and secrete CXCL12.^{177,191–194} However, alternate pathways appear to exist because fetal liver-derived mouse HSCs home to the BM of adult recipients independent of CXCR4,¹⁹⁵ and adult HSCs treated with a CXCR4 antagonist are still able to home sufficiently to the BM.¹⁹⁶ This indicates that HSCs may use different receptors and/or respond to distinct integrin-activation signals. In this context, the recent description of CXCR7, an alternate receptor for CXCL12, may explain some of the seemingly contradictory findings.¹⁹⁷

Of note, the CXCL12/CXCR4 axis is not only involved in the homing process of HSCs to the BM, but (among others) has also been linked to the retention of HSCs within stem cell niches and to the regulation of the maturation of more committed HPCs (in particular, B-cell progenitor cells).^{59,198–202} Correspondingly, disruption of the CXCL12/CXCR4 pathway leads to premature release of HPCs into the peripheral blood.^{203,204} HPCs lacking CXCR4 accumulate in the circulation and fail to undergo normal lymphopoiesis and myelopoiesis, most likely because the cells do not receive the required maturation signals. Interestingly, upregulation of metalloproteinases (see earlier), which cleave and inactivate CXCR4 and CXCL12, has recently been implicated in HSC mobilization.^{205–208} Mechanisms that modulate the CXCR4/CXCL12 axis are also thought to play a role in the coordinated mobilization of HPCs in response to cytokines that are used for this purpose in clinical practice.⁵⁸

In addition to CXCL12, the egress from BM niches has been recently shown to be critically dependent on the nervous system. Thus, it was found that the mouse line exhibiting aberrant nerve conduction (UDP-galactose ceramide galactosyltransferase-deficient [*Cgt*^{−/−}] mice) was characterized by the absence of HSPC egress from BM following granulocyte colony-stimulating factor (G-CSF) or fucoidan administration.²⁰⁹ Interestingly, norepinephrine signaling-controlled bone CXCL12 downregulation and HSPC mobilization,

whereas administration of a beta(2) adrenergic agonist enhanced HSPC mobilization. Therefore, the sympathetic nervous system regulates the attraction of stem cells to their niche via transduction of circadian information from the central pacemaker in the brain, the suprachiasmatic nucleus, to the BM microenvironment.²¹⁰ Recent data show that circadian regulation is regulated by beta-2 and beta-3 adrenergic receptors (beta-ARs) expressed on HSCs, osteoblasts, and mesenchymal stem/progenitor cells. Moreover, beta(2)-ARs and beta(3)-ARs have specific roles in stromal cells and cooperate during progenitor mobilization.²¹¹ Whereas activation of beta(3)-ARs down-regulates Cxcl12, beta(2)-AR stimulation induces clock gene expression.²¹¹ In addition, double deficiency in beta(2)-ARs and beta(3)-ARs compromises enforced mobilization. Therefore, these data demonstrate that HSC trafficking and hematopoiesis do not escape the circadian regulation that controls most physiologic processes. For the clinical settings, the timing of stem cell harvest or infusion may influence the yield or engraftment, respectively, and may result in better therapeutic outcomes.²¹⁰

LEUKOCYTE MIGRATION WITHIN TISSUES

Trafficking Patterns of Lymphocytes

After a leukocyte has accessed a tissue, it must migrate to specific interstitial positions. As discussed earlier, homing typically requires that the blood-borne leukocyte completes a complex tissue- and subset-specific multistep adhesion cascade. One exception to this rule is the spleen, where most blood-borne lymphocytes can leave the circulation even in the absence of multiple traffic molecules. However, chemokines are essential in all lymphoid organs, including the spleen, to guide the newly arrived lymphocytes to their proper position within the organ.

Multiphoton intravital microscopy was used as a tool to decipher the mechanisms that control the extravascular traffic patterns of homed lymphocytes within lymphoid and nonlymphoid tissues.^{212–220} For example, imaging experiments have shown that T cells that have entered an LN move incessantly within the paracortex (T-cell area). Here, they query the resident DCs for the presence of antigens that activate their T-cell receptor. B cells that home to LNs migrate to the more superficial B-cell-rich follicles, where they may detect antigens presented by follicular DCs. Activated B cells that encounter antigens then move to the margins of the B- and T-cell zones.²¹⁵ Here, they can receive help from antigen-specific CD4 T cells. Analogous specific microenvironments for T and B cells also exist in the other lymphoid tissues.

Migration of T Cells to T Zones Within Secondary Lymphoid Organs

After homing to secondary lymphoid organs, T cells migrate within the T zones. They engage in highly motile amoeboid movement (average speed ~12 $\mu\text{m}/\text{min}$) and undergo multiple brief encounters with resident DCs.^{221–223} In this context, the fibroblastic reticular cell (FRC) network regulates naive T-cell access to the paracortex and also supports and defines the limits of T-cell movement within this domain.^{224,225} As a consequence of high T-cell motility, it has been estimated that every DC in an LN touches as many as 5000 naive T cells within 1 hour. When T cells encounter a specific antigen, they progressively decrease their motility, become activated, and form long-lasting stable conjugates with DCs. Finally, antigen-experienced T cells start to proliferate and resume their rapid migration while contacting DCs only briefly.^{223,226}

The positioning and high motility of T cells in the T-cell area is dependent on CCR7 and its ligands CCL19 and CCL21.^{110,158,159,212,227,228} Both ligands are abundantly expressed in T zones by radiation-resistant stromal cells. Notably, ectopic expression of CCL21 induces the formation of LN-like structures in the pancreas of mice.²²⁹ The expression of CCL19 and CCL21, but also

of CXCL13, which attracts B cells to B-cell follicles (see later), by lymphoid stromal cells is strongly dependent on the cytokine lymphotoxin (LT)- α 1 β 2 heterotrimer signaling via the LT β receptor.^{230–232} Correspondingly, mice deficient in LT have no morphologically detectable LNs or PPs.²³³ Moreover, CCL21 and CXCL13 have been shown to be transiently downregulated by a mechanism controlled by the cytokine interferon- γ . This modulation alters the localization of lymphocytes and DCs within responding lymphoid tissues. As a consequence, priming of T-cell responses to a second distinct pathogen after chemokine modulation became impaired. Therefore, transient chemokine modulation may help orchestrate local cellularity, thus minimizing competition for space and resources in activated lymphoid tissues.^{234,235}

The differential ability of T-cell subsets to migrate in response to interstitial chemokine gradients is also an important determinant of immunologic memory.²³⁶ For example, LNs harbor not only naive T cells, but also a major subset of antigen-experienced cells, the central memory T cells (T_{CM}). In steady-state LNs, both T-cell subsets localize in the deep T-cell area and interact dynamically with antigen-presenting DCs. However, upon entry of a lymph-borne virus into an LN, virus-specific T_{CM} relocate rapidly toward the outermost LN regions where virally infected cells are concentrated. This rapid peripheralization of T_{CM} is coordinated by a cascade of cytokines and chemokines, particularly ligands for CXCR3 that diffuse from the outer cortex toward the T-cell area. Antiviral T_{CM} express high levels of CXCR3 and are responsive to the virus-induced chemokine gradient. By contrast, naive T cells do not express CXCR3 and remain initially sequestered in the T-cell zone. This delayed T-cell response in nonimmune hosts allows more time for the viral infection to spread than in immune individuals. Thus, early antigen detection afforded by intranodal chemokine guidance of T_{CM} is essential for efficient antiviral memory.²³⁶

Positioning of B Cells Within Secondary Lymphoid Organs

Similar to T cells, B cells enter secondary lymphoid organs from the blood to search for their specific antigens.²³⁷ As previously outlined, the homing and entry of B cells into secondary lymphoid organs such as the LNs and PPs depends on chemokine/receptor interactions that finally result in firm integrin-mediated adhesion on the surface of HEVs. This adhesion is followed by cell movement into lymphoid tissue.^{140,234,238,239} After entering secondary lymphoid organs, the naive B cells travel to B cell-rich areas, the B-cell follicles. This migration depends on the presence of CXCR5 on the surfaces of B cells and the localized expression of CXCL13 by follicular stromal cells.^{109,232,239} Follicular B cells are also highly motile, migrating on a network of follicular DCs (FDCs), a process that is thought to be necessary to ensure optimal surveillance of the FDC for surface-displayed antigen. After a period of random migration within follicles, those B cells that have not encountered a cognate antigen return to the circulation via the lymph or, in case of the spleen, via the blood. In contrast, B cells that become stimulated by antigen relocate to the B–T boundary area to receive help from T cells, which is necessary for further differentiation. To achieve this repositioning, activated B cells rapidly upregulate CCR7. This permits their chemotaxis toward CCR7 ligands expressed in the T cell-rich zones of the secondary lymphoid organs.²¹⁵ Real-time imaging revealed that antigen-stimulated follicular B cells initially reduce their migration velocity upon antigen exposure. About 6 hours later the activated B cells move toward the follicle border with the T cell-rich zone and undergo highly dynamic interactions with helper T cells during the following several days.²¹⁵

In the spleen, a subpopulation of “innate” B cells is present in the marginal zone (MZ) immediately adjacent to the marginal sinus that surrounds the white pulp cords. The exact extent to which chemokine-induced attraction and adhesion affect the positioning of MZ B cells is still unclear. However, recent studies indicate that the localization of B cells in the MZ is dependent upon interactions of α L β 2 and α 4 β 1 on MZ B cells with their ligands (ICAM-1 and VCAM-1,

respectively).^{240,241} As with follicular B cells in LN, antigen encounter of MZ B cells causes their rapid repositioning to the B–T boundary area. The retention of naive B cells in the MZ and their relocation to the B–T boundary area upon antigen encounter is thought to involve signaling through the phospholipid sphingosine-1 phosphate (S1P) and its receptor S1P₁.²⁴²

LEUKOCYTE EXIT FROM TISSUES

Although the coordinated role of adhesion molecules and chemokines governing lymphocyte entry into tissues has been examined in great detail, less is known about the exit of these cells from tissues. The final sections of this chapter will discuss examples of emerging research on the diverse mechanisms that regulate exit of distinct leukocyte subsets from tissues.

Reprogramming Dendritic Cells to Exit Tissues Toward Secondary Lymphoid Organs

Lymphocyte homing remains without consequence unless lymphocytes encounter DCs that present their cognate antigen. DCs capture and present antigen to T cells more efficiently than any other antigen-presenting cell. In general, two routes of antigen delivery to LNs have been described to date. (1) Antigenic material becomes lymph borne and is taken up by DCs that reside in the LN a priori; (2) antigen is acquired by DCs that reside in peripheral tissues and then transport the material to the draining LN. DCs constitutively patrol all tissues and engulf microorganisms, dead cells, and cellular debris. In the absence of inflammatory stimuli, the cells remain in an immature state that is only weakly immunogenic and often stimulates T-cell tolerance, rather than activation. However, multiple signals associated with infection or tissue damage can induce DC maturation. Immature DCs express a variety of chemokine receptors, including as CCR1, CCR5, and CCR6, which are believed to result in the constitutive homing of immature DCs into tissues, particularly sites of inflammation where ligands for these receptors are abundant.^{4,115,243–245}

After exposure to a maturation stimulus, such as Toll-like receptor agonists (e.g., lipopolysaccharide, bacterial lipoproteins, peptidoglycans or CpG dinucleotides), which often originate from infectious pathogens,^{246,247} DCs lose CCR1, CCR5, and CCR6, while expression of GPCRs for lymphoid chemokines, in particular CCR7 and CXCR4, are upregulated.²⁴⁸ Lymphatic endothelial cells in peripheral tissues express CCL21, the ligand for CCR7.²⁴⁹ The loss of chemokine receptors that keep the DCs within the tissue together with the increased expression of CCR7 results in the exit of the mature DCs via the lymphatic drainage system.^{138,250} Recently, using a microfluidic device that allows rapid establishment of stable gradients in three-dimensional matrices, it was shown that CCL21 is a more potent directional cue for DC migration than CCL19.²⁵¹ DC migration into the draining lymphatics also requires β 2 integrin binding to ICAM-1 expressed by lymphatic endothelial cells. Moreover, JAM-A, which is expressed by DCs and the lymphatic endothelium, also affects DC migration to lymph nodes, because the absence of JAM-A expression by DCs facilitates their migration to lymph nodes.^{117,252} The expression and activation of β 1-integrins, which mediate the interaction of DCs with extracellular matrix components, might favor retention of DCs in the periphery.¹¹⁷

While traveling to the draining LN, DCs upregulate the expression of molecules for efficient antigen presentation and T-cell stimulation, and begin to generate chemokines and other cytokines that allow them to attract and stimulate T cells.^{250,253,254}

Egress of Lymphocytes From Secondary Lymphoid Organs

When naive lymphocytes do not encounter antigen on antigen-presenting DCs after a period of random walk, they exit secondary

lymphoid organs through efferent lymph vessels or, in the case of the spleen, by directly returning to the blood. Several adhesion receptors have been implicated in the egress of lymphocytes into lymphoid sinusoids, including PECAM-1 (CD31); the mannose receptor, which interacts with L-selectin; and common lymphatic endothelial and vascular endothelial receptor 1 (CLEVER-1).²⁵⁵

We still have very limited information about the signals that determine the dwell time of lymphocytes in secondary lymphoid organs (~12–24 hours for T cells). However, the recent observation that the egress of both T and B cells from LNs can be prevented by the immunosuppressant molecule FTY720 has revealed some of the principal mechanisms underlying lymphocyte egress. FTY720 is a synthetic derivative of myriocin, a metabolite of the fungus *Isaria sinclairii*, which has been used in Chinese traditional medicine. FTY720 induces lymphocyte sequestration in LNs and causes profound lymphopenia. In animal models of transplantation and autoimmunity FTY720 causes immunosuppression, and it has recently been shown to exert significant therapeutic effects in a placebo-controlled clinical trial of relapsing multiple sclerosis.^{256–258} Although lymphocyte sequestration in LNs and lymphopenia in response to FTY720 have been reported some time ago, the underlying molecular mechanisms were uncovered only recently.¹¹⁴ Upon in vivo administration FTY720 becomes rapidly phosphorylated and then binds to four of the five known S1P receptors (S1P₁ and S1P_{3–5}).^{109,259–261} Naive B and T cells express substantial levels of S1P₁, and it appears to be this receptor that plays a predominant role in lymphocytes egress from lymphoid tissues into the efferent lymph vessels. Studies using gene-targeted mice have shown that T lymphocytes deficient in S1P₁ cannot exit secondary lymphoid organs (and in the case of T cells, also the thymus).^{262,263} Reports using FTY720 and S1P₁-selective agonists also supported a role for S1P–S1P₁ signaling in the regulation of lymphocyte egress from secondary lymphoid organs. Notably, S1P₁ receptors not only regulate lymphocyte exit from tissues but also modulate lymphocyte homing capacity.¹²⁰

The sphingolipid S1P is abundant in blood and lymph, while low levels of S1P are maintained within lymphoid tissues. This S1P gradient is established by the action of the S1P degrading enzyme S1P lyase.^{264–266} Based on these findings, it has been proposed that S1P gradients between blood, lymphoid tissue, and lymph fluid together with cyclical ligand-induced modulation of S1P₁ on recirculating lymphocytes regulates lymphocyte egress and determines the lymphoid organ transit time of lymphocytes.^{6,267} Indeed, recent observations support that concept by showing that S1P₁ on lymphocytes is downregulated in the blood, upregulated in lymphoid organs, and downregulated again in the lymph.²⁶⁵ Notably, CD69, which is rapidly induced when T cells become activated, negatively regulates S1P₁ and thus promotes lymphocyte retention in lymphoid organs.^{268,269}

Besides chemokines, other factors are also involved in the migration patterns of lymphocytes. By combining confocal, electron, and intravital microscopy, it has been found that the FRC network regulates naive T-cell access to the paracortex, whereas a distinct follicular DC network served as the substratum for movement of follicular B cells.²²⁵ These results highlight the central role of stromal microanatomy in orchestrating cell migration within the LN.

Although the mechanism of HSPC homing into the BM is well investigated, little is known about the signals regulating the exit of HSPCs out of tissues other than the BM. HSPCs arrive in peripheral organs via blood, but leave them predominantly via the draining lymphatics.^{6,270} Interestingly, it has been shown that, as on lymphocytes, S1P and S1P receptors mediate the egress of HSPCs from peripheral tissues.^{6–8} The inhibition of S1P–S1P receptor signaling decreases the number of HSPCs in tissue-draining lymph due to impaired egress from the tissue. Stress signals that mimic an infection (induced by administration of a Toll-like receptor [TLR]4 agonist) reduce S1P₁ expression on HSPCs, leading to prolonged retention in peripheral organs, and thus providing necessary time for HSPCs to differentiate into immune cells that are required to eliminate the danger. Tuning of HSPC retention in peripheral tissues could support innate immune responses by fostering a local and versatile supply of effector cells.

SUMMARY

In this chapter we have outlined three distinct aspects of leukocyte trafficking: (1) leukocyte entry into tissues from the circulation; (2) migration within tissues; and (3) exit from tissues. Migration of leukocytes throughout the body is essential for the development of lymphocyte subsets and underpins their functions in immune surveillance and responses of effective adaptive immunity. The molecular reactions involved in leukocyte migration are tightly regulated and involve chemoattractants and adhesion molecules. Leukocyte migration is characterized by a considerable plasticity and specificity, because different leukocyte subsets express unique patterns of traffic molecules that enable their navigation into and within target tissues. Our expanding knowledge of the mechanisms that control leukocyte trafficking will likely influence the development of multiple therapeutic strategies, including the use of stem cells, cell immunotherapy of cancer, and autoimmune, inflammatory, and infectious diseases.

INTERACTIONS BETWEEN HEMATOPOIETIC STEM AND PROGENITOR CELLS AND THE BONE MARROW: CURRENT BIOLOGY OF STEM CELL HOMING AND MOBILIZATION

Eman Khatib-Massalha, Kfir Lapid, Karin Golan, Orit Kollet, Shiri Gur-Cohen, Menachem Bitan, Anju Kumari, and Tsvee Lapidot

The hallmarks of hematopoietic stem and progenitor cells (HSPCs) are their migration, bone marrow (BM) homing, and repopulation potential. These primitive cells are continuously released at low levels from the BM to the circulation as part of steady-state homeostasis, and at accelerated rates during stress hematopoiesis situations such as injury or inflammation as part of host defense and repair mechanisms. Migration of hematopoietic stem cells from the blood, across the endothelial vasculature to their BM niches, requires active navigation, a process termed *homing*. The ability of HSPCs to home to the BM is the first and essential step for clinical transplantation. Physiologic stress caused by bleeding, injury, or infection induces massive proliferation and differentiation of HSPCs in the BM, which is accompanied by increased progenitor cell egress and recruitment to the circulation. This process is mimicked in clinical mobilization protocols, to increase the HSPC pool in the circulation and to harvest stem cells for clinical transplantation protocols. The transplanted stem cells actively home to the recipient BM and repopulate it by extensive proliferation and differentiation, while maintaining their self-renewal potential and motility capacity, enabling them to egress back to the circulation. These processes involve the stromal chemokine SDF-1 (also termed CXCL12) and its major receptor CXCR4, which regulate stem cell motility and proliferation, as well as their adhesion, retention, and quiescence. HSPC mobilization can be clinically induced by a variety of cytokines, such as the myeloid cytokine granulocyte colony-stimulating factor (G-CSF), the CXCR4 antagonist AMD3100, and by DNA-damaging chemotherapy drugs, such as cyclophosphamide (Cy).

HSPCs in the BM continuously replenish the blood with new maturing myeloid and lymphoid immune cells with a finite life span throughout life. Some of the circulating leukocytes are short lived, in particular neutrophils, which rapidly age within a few hours and home back to the BM across the physical blood–BM barrier, resulting in their apoptotic cell death. SDF-1/CXCR4 signaling is also involved in neutrophil retention in the BM, while the CXCL2/CXCR2 signaling pathway is involved in neutrophil trafficking from the BM to the circulation.

This chapter discusses recent findings concerning the biology of HSPCs and mature leukocyte (especially neutrophil) homing and mobilization, emphasizing the major roles of the SDF-1/CXCR4 and CXCL2/CXCR2 signaling cascades in their dynamic retention and mobilization.

HEMATOPOIETIC STEM AND PROGENITOR CELL HOMING

Migration of HSPCs from the circulation and their extravasation across the physical barrier of the blood vessels to the BM require an active navigation, a process termed homing. HSPC homing is the critical first step leading to successful clinical engraftment in the ablated BM of transplanted recipients, which is the predominant physiologic site of hematopoiesis.

The BM endothelium is the first anchoring site for homing cells, exposing them to presented adhesion molecules and stimulating

chemokines. The small blood vessels in both human and murine BM, the sinusoids, in which transendothelial migration is thought to take place, are composed of specialized cell structures that regulate cell trafficking.

The homing process is initiated by a SDF-1/CXCR4 guiding signal, leading to firm adhesion and docking to the vascular sinusoidal wall (Fig. 14.1), which induces cytoskeleton rearrangement and activation of integrins (e.g., VLA-4) and metalloproteinases (e.g., MMP-2/9). These cellular alterations are followed by transmigration across the physical BM–blood endothelial cell and extracellular matrix barriers (reviewed by Lapidot et al²).

HSPCs are localized and anchored in special stromal niches via adhesion interactions, which provide them with signals that prevent their motility, proliferation, and uncontrolled differentiation. Stromal CXCL12 abundant reticular (CAR) cells express the highest levels of SDF-1, which is essential for murine stem cell quiescence and maintenance; they serve as stem cell niche cells. While murine stem cell homing can be investigated in genetically matched recipient mice without rejection of donor cells, functional preclinical immune-deficient animal models have been developed to study human stem cell homing and engraftment.

Mechanisms Regulating HSPC Homing: The Essential Role of the SDF-1/CXCR4 Axis

As discussed by Cottler-Fox et al,^{2a} SDF-1/CXCR4 interaction and downstream signaling have been implicated in retention, migration, homing, and mobilization of HSPCs during steady-state homeostasis, as well as during injury (reviewed by Lapidot et al²). Both human and murine BM stromal cells, including endothelial cells and endosteal bone-lining osteoblasts, express and secrete high levels of SDF-1, observed in regions rich in HSPCs.

Concomitantly, the expression of CXCR4 on circulating HSPCs is very dynamic and allows their direct chemoattraction toward high levels of SDF-1 found in the BM endothelium, thus facilitating the homing process (see Fig. 14.1). CXCR4-dependent homing is also observed in aging neutrophils, which express high levels of CXCR4 and migrate back to the BM across the mechanical barrier in order to engage cell death. Genetic overexpression of CXCR4 or cytokine-induced increased surface expression of CXCR4 (e.g., by hepatocyte growth factor [HGF]) enhanced the homing capacity of transplanted human HSPCs, while Kollet et al^{2b,2c} showed that administration of neutralizing anti-CXCR4 antibodies impaired the homing of immature human CD34⁺ stem and progenitor cells to the BM of transplanted immunodeficient mice. Given the important clinical challenge of improving HSPC engraftment and repopulation, upregulation of CXCR4 expression is a promising approach.

Murine BM stem cell niches contain a rare population of mesenchymal stem and progenitor cells (MSPCs), which express the highest levels of SDF-1 in the BM microenvironment. Depletion of stromal-supporting niche cells results in defective hematopoiesis and

Homing of transplanted HSPC

Fig. 14.1 HOMING OF TRANSPLANTED HEMATOPOIETIC STEM AND PROGENITOR CELLS TO THE BONE MARROW. Following transplantation, navigating HSPCs from the circulation roll and adhere (1) to BM endothelial cells. This process is followed by transendothelial migration across the physical blood–BM barrier (2). HSPCs interact with MSPCs via surface SDF-1/CXCR4 signaling, which is a key regulator of stem cell homing and adhesion to the BM-supportive niche, an essential process for HSPC lodgment and retention (3). *BM*, Bone marrow; *HSPC*, hematopoietic stem and progenitor cell; *MSPC*, mesenchymal stem and progenitor cell.

reduced homing of transplanted HSPCs to the BM, demonstrating the crucial role of SDF-1 in homing of HSPCs.³

Administration of high doses of SDF-1 induce cell survival and quiescence, whereas low doses promote cell motility, proliferation, and migration (reviewed by Lapidot and Kollet⁴). Accordingly, Cashman et al showed that in vivo treatment with high doses of SDF-1 increased engraftment of human repopulating cells (reviewed by Lapidot and Kollet⁴).

A single injection of human SDF-1 to nonirradiated $\beta 2m^{null}$ NOD/SCID mice increased homing of transplanted human mobilized peripheral blood and cord blood (CB) CD34⁺ cells to the murine BM. It was found that the noncleaved active form of SDF-1 can cross the BM endothelium to the BM in a CXCR4-dependent manner. This increase in SDF-1 level in the BM functionally enhances the homing capacity of transplanted human CD34⁺ progenitors of NOD/SCID mice (reviewed by Lapidot et al²). According to this data, enhanced CXCR4 expression as well as inhibition of SDF-1 degradation is important to enable a stable chemotactic response, directing the homing of HSPCs to the BM.

Another important cytokine regulating progenitor cell homing is stem cell factor (SCF; also termed c-Kit ligand), which plays an important role in hematopoiesis. Prestimulation of human or murine HSPCs with SCF improved their in vivo homing abilities through

increased migration and adhesion via very late antigen (VLA)-4 and VLA-5 integrins. Moreover, the homing of murine progenitor cells to the BM of mice deficient in P- and E-selectin was impaired, demonstrating the crucial role of adhesion interactions for proper homing, allowing HSPC rolling on the BM endothelium and retention in their stromal supportive niches. Interestingly, SDF-1 is not the only chemoattractant factor for HSPC homing; previous studies have shown that the chemoattractant lipid sphingosine-1-phosphate (S1P) has a role in inducing murine HSPC homing to the BM by increasing progenitor adhesion to stromal cells.⁵ S1P, together with SDF-1, was indeed reported to have a synergistic effect on the migration of hematopoietic progenitor cells; however, this finding was later refuted by Ryser et al, showing no additive effect when both chemoattractants are added to the same plate. In contrast, this group showed that overexpression of S1P₁ (S1P receptor) on immature human CD34⁺ cells strongly reduces their migration toward a gradient of SDF-1 and in vivo homing via inhibition of CXCR4 signaling (reviewed by Golan et al⁶).

Taken together, manipulation of SDF-1 levels in the target organ and CXCR4 on the surface of transplanted stem cells can be used to navigate stem cells in vivo. Enhanced SDF-1 production by BM stromal cells after host preconditioning, crossing the blood–BM barrier, and activation of the adhesion machinery are required for HSPC attachment to BM-supporting niches, allowing their subsequent self-renewal and differentiation (see Fig. 14.1).

HEMATOPOIETIC STEM AND PROGENITOR CELL MOBILIZATION: A DYNAMIC MULTIFACETED PROCESS

HSPCs are actively retained in the BM via adhesion interactions with their stromal microenvironment. In the BM, they undergo extensive proliferation and differentiation, giving rise to all mature leukocyte and erythrocyte reservoirs, and replenishing the blood with new cells. Interestingly, in addition to mature leukocytes, low levels of HSPCs are also released to the blood as part of steady-state homeostasis. During stress situations and upon demand of accelerated hematopoiesis, HSPC egress is dramatically augmented in a process termed *recruitment*.⁷ Enhanced HSPC egress occur as part of host defense and repair mechanisms following various stress situations, such as inflammation (mimicked by lipopolysaccharides [LPS]; endotoxins found in the outer membrane of Gram-negative bacteria, or endotoxin administration), bleeding, and administration of cytotoxic agents, such as chemotherapy.

Stem and progenitor cell recruitment is achieved by clinical mobilization protocols, such as repeated G-CSF stimulations, which are used to expand the HSPC pool and to harvest the cells from the blood for clinical transplantation.

Stress-induced HSPC recruitment and mobilization is a complex process involving essential motility mechanisms, activities of various cytokines, chemoattractants (e.g., SDF-1), proteolytic enzymes, and other extrinsic factors that enable detachment of HSPCs from their BM niches. These BM niches prevent HSPC migration and proliferation via adhesion interactions, and therefore disconnecting such interactions are essential for HSPC motility, leading to their egress. Recent evidence for the involvement of other cellular players, such as neutrophils, macrophages, and osteoblasts, in the regulation of stress-induced HSPC recruitment will be discussed.

This part of the chapter summarizes insights regarding mechanistic aspects of mobilization, as well as recent data on steady-state and rapid HSPC mobilization mechanisms. Currently, new rapid mobilization protocols using CXCR4 antagonists, such as AMD3100, together with G-CSF, lead to higher levels of HSPC mobilization.⁸

The SDF-1/CXCR4 Axis in Hematopoietic Stem and Progenitor Cell Mobilization

As noted earlier in this chapter (in the section [Mechanisms Regulating HSPC Homing: The Essential Role of the SDF-1/CXCR4](#)

Axis), SDF-1 has important roles in HSPC homing, retention, survival, and quiescence. Impairment SDF-1 or CXCR4 levels in murine embryos results in multiple lethal defects, including lack of stem cell seeding of the BM.⁹ In order to circumvent lethality, conditional knock-out models were established. Induced deletion of CXCR4 in the hematopoietic system of the adult mouse or ablation of SDF-1 in the BM stroma led to severely reduced BM cellularity and hematopoietic stem cell (HSC) numbers, as well as impaired repopulation capacity.¹⁰ Conditional deletion of CXCR4 or SDF-1 also results in dramatically increased HSPC numbers in the peripheral blood and spleen,¹⁰ suggesting that blocking CXCR4 hampers their retention in the BM. Selective chemical antagonists of CXCR4, such as AMD3100, were originally developed to block CXCR4-mediated HIV infection, without any success in blocking *in vivo* infection. Nevertheless, serendipitous research shows that upon AMD3100 administration, mouse and human HSPCs undergo rapid mobilization within hours¹¹ and the mobilized HSPCs demonstrate increased repopulation potential *in vivo*.

AMD3100 synergistically augments G-CSF-induced mobilization. AMD3100 is the only chemokine receptor antagonist utilized clinically for inducing mobilization, either alone or in combination with G-CSF administration.¹¹ AMD3100 has been shown to be an effective mobilizing agent in murine and human clinical models,¹² which are known to be poor mobilizers in response to G-CSF. Mechanistically, AMD3100-induced SDF-1 release from BM stromal cells to the circulation, together with an inhibitory effect *in vivo*, induces rapid mobilization of HSPCs.

The essential role of SDF-1/CXCR4 signaling in HSPC retention can be inferred from the observations that following G-CSF administration, SDF-1 levels in the BM are transiently increased followed by their downregulation at both protein^{7,13} and mRNA levels, enabling transient and local SDF-1 gradients toward the blood. In addition, CXCR4 upregulation is observed in immature murine BM cells following G-CSF treatment, as well as on immature human CD34⁺ cells and primitive CD34⁺CD38⁻ cells resident in the BM of G-CSF-treated chimeric mice.⁷ Blocking CXCR4 or SDF-1 reduces G-CSF-induced mobilization, thus demonstrating an essential role for SDF-1/CXCR4 in mobilization of murine progenitors.⁷

Christopherson et al reported that, compared with continuous SDF-1 expression in the BM, SDF-1 in the peripheral blood is short-lived and is prone to proteolysis by proteases, such as CD26, and metalloproteases, for example MMP-9 (reviewed by Lapidot et al²). SDF-1 can directly activate the metalloprotease MMP-9, which in turn cleaves and degrades this chemokine, participating in the enhanced migration capacity and recruitment of HSPCs to the periphery.¹⁴ These observations suggest that SDF-1 levels in the peripheral blood are dynamically regulated during homeostasis in addition to its major role in retention of HSPCs in the BM. Repetitive daily administrations of SDF-1 for 5 consecutive days induce murine HSPC mobilization.¹⁵ Hampering SDF-1/CXCR4 signaling in the BM results in loss of retention, because active SDF-1/CXCR4 signaling is required for stem cell adhesion and quiescence in the BM.

The Dynamics of Hematopoietic Stem and Progenitor Cell Niches and Bone Marrow Microenvironment During Mobilization

Coupling of bone degradation and bone formation, carried out by monocyte-derived osteoclasts and MSPC-derived osteoblasts, respectively, is part of the complex process of bone remodeling. Noteworthy, osteoblasts and osteoclasts maintain bone equilibrium by also acting in the endosteum in the vicinity of HSPCs.¹⁶ Thus the endosteal stem cell niche is dynamically altered during bone remodeling, affecting HSPC function and maintenance. Furthermore, accumulating evidence supports dynamic alteration of the HSPC microenvironment upon stress-induced mobilization procedures. G-CSF or cyclophosphamide injections, as part of a clinically oriented HSPC mobilization procedure, lead to the disappearance or altered morphology of bone-lining osteoblasts, resulting

in their reduced function, which is also associated with reduced transcription of SDF-1.^{17,18} Of interest, upon G-CSF administration, osteoblasts rapidly expand, promoting HSPC proliferation prior to their apoptosis, which in turn enables loss of HSPC retention. The importance of BM stromal cells in the retention of HSPCs can be illustrated, for example, by the conditional deletion of the cell cycle regulator Retinoblastoma protein (Rb). Absence of Rb in the murine hematopoietic system, as well as in the BM stroma, is sufficient to increase the numbers of circulating HSPCs, in addition to a myeloproliferative-like disease and extramedullary hematopoiesis.¹⁷

Involvement of Monocytes/Macrophages

Chow et al (2011) found that depletion of mononuclear phagocytes in mice is sufficient to mobilize HSPCs, suggesting that BM macrophages promote retention of HSPCs in the BM (reviewed by Ludin et al¹⁸). Because macrophages play a crucial role in osteoblast growth and survival, it has been proposed that their depletion mobilizes HSPCs by disruption of the osteoblastic niche.¹⁹ By using a variety of approaches to abrogate monocytes and macrophages from the BM, previous studies have reported that G-CSF-stimulated recruitment of HSPCs to the peripheral blood is dependent on direct activation of the monocyte lineage (Chow et al, 2011, and Christopher et al, 2011, reviewed by Ludin et al¹⁸). Christopher et al (2011) supported the important role of BM-resident macrophages in regulating the osteoblastic niche by utilizing chimeric mice that expressed the G-CSF receptor only in CD68⁺ macrophages. Upon G-CSF administration, HSPC mobilization and SDF-1 downregulation in the BM were completely restored in these chimeric mice (reviewed by Ludin et al¹⁸). BM-resident macrophages may therefore regulate SDF-1 production by BM osteoblasts and other stromal cells, which generate factors that are yet to be determined. Of interest, cholesterol efflux pathways within mouse BM-resident macrophages are necessary to mediate this function, as a lack of cholesterol transporters in macrophages and dendritic cells leads to osteoblast suppression, elevated plasma G-CSF levels, and reduction in SDF-1 production in the BM, including by MSPCs.²⁰ As a result, these mice demonstrated increased numbers of circulating HSPCs and extramedullary hematopoiesis.²⁰ Intriguingly, Ludin et al (2012) has demonstrated the existence of an additional type of BM-resident myeloid niche cell that regulates the maintenance of primitive murine HSPCs. These rare, activated α SMA⁺ monocytes/macrophages, which are located near small blood sinuses, produce high levels of prostaglandin E₂ (PGE₂) in a COX2-dependent manner; they apparently act to protect the HSPC pool from exhaustion in steady state and upon stress by direct intercellular contact and reactive oxygen species (ROS) inhibition, preventing stem cell migration and differentiation (reviewed by Ludin et al¹⁸). BM monocytes/macrophages emerge as central players in driving HSPC retention, probably via osteoblast maintenance, stromal SDF-1 expression, and PGE₂ production; however, other immune cells of the innate immune system play additional roles, as discussed later.

Bioactive Lipid-Induced Mobilization

Other potential chemoattractants responsible for egress of HSPCs into the peripheral blood include heat-resistant bioactive lipids, in particular S1P, which was previously shown by Ratajczak et al (2010) to directly induce chemoattraction of human and murine HSPCs (reviewed by Golan et al⁶). Alvarez et al (2007) showed that S1P is a bioactive lipid implicated in cell migration, survival, proliferation, and angiogenesis, as well as immune and allergic responses (reviewed by Golan et al⁶). Human and murine HSPCs, and BM stromal and endothelial cells have been shown to express functional S1P receptors, which also cross-talk with SDF-1/CXCR4 signaling, affecting migration, adhesion, homing, mobilization, development, and engraftment capacities. It is proposed that S1P is a crucial chemoattractant for BM-residing HSPCs, increasing ROS levels and leading

to recruitment of HSPCs to the circulation (reviewed by Golan et al⁶). Accordingly, S1P concentrations in the plasma were rapidly increased following both G-CSF and AMD3100 treatments in mice, as well as expression of its receptor S1P₁ on HSPCs (reviewed by Golan et al⁶). By utilizing mice with reduced S1P levels, or lacking the S1P₁ receptor, Golan et al (2012) showed a reduced capacity to mobilize upon G-CSF or AMD3100 treatments.⁵ Bendall et al (2013) found that manipulation of the S1P/S1P₁ axis may be used to improve clinical mobilization protocols. As suggested by Bendall and colleagues, activation of S1P₁ by a specific agonist during AMD3100 administration led to increased levels of mobilized stem cells that are harvested for BM transplantation (reviewed by Golan et al⁶). Furthermore, S1P was shown to induce SDF-1 secretion from BM MSPCs and endothelial cells, followed by SDF-1 release from the BM to the peripheral blood, adding another regulatory aspect for HSPC mobilization (reviewed by Golan et al⁶). Altogether, recent data suggest that additional chemoattractive compounds, such as S1P, mediate egress and recruitment of HSPCs from the BM to the circulation by regulating the SDF-1/CXCR4 axis.

The Dynamic Brain–Bone–Blood Triad

The *brain–bone–blood triad* is composed of the nervous system, bone-lining osteoblasts, and the hematopoietic system. The nervous system, a major regulator of the mammalian body that interacts with the immune system directly as well as indirectly, influences both bone- and blood-forming stem and progenitor cells. The mammalian nervous system regulates the immune system during homeostasis as well as acute physiologic conditions, for example, during mental stress as part of the “fight-or-flight” response.²¹ The importance of the nervous system for HSPC mobilization has been determined by establishing mice lacking catecholaminergic activity, which display an inability to induce HSPC mobilization by G-CSF.²² Adrenergic stimulation suppresses bone-lining osteoblasts, causing a significant reduction in SDF-1 production and leading to detachment of HSPCs from their BM niches. Katayama et al (2006) showed that G-CSF administration in mice lacking catecholaminergic activity does not result in osteoblast suppression, BM SDF-1 downregulation or subsequent HSPC mobilization. Concomitantly, Spiegel et al (2008) have also shown a role for the nervous system in hematopoiesis, not only indirectly through its effects on bone-lining osteoblasts,²² but also through a direct effect on HSPC (reviewed by Spiegel et al²³). In this regard, it was demonstrated that primitive human progenitor cells express β_2 adrenergic receptors as well as dopamine receptors. These receptors are upregulated during G-CSF-induced mobilization of immature human CD34⁺ cells, as well as on primitive CD34⁺CD38[−] cells, suggesting a role of sympathetic stimulation in inducing HSPC mobilization. β_2 -Adrenergic stimulation by norepinephrine administration in mice results in increased numbers of circulating HSPCs, while administration of β_2 -adrenergic antagonists reduced peripheral blood numbers⁸ (reviewed by Spiegel et al²³). Interestingly, there are daily oscillations of circulating murine HSPCs, peaking 5 h after the initiation of light in parallel to reduced BM SDF-1 levels.²⁴ Thus the physiologic egress of BM HSPCs into the circulation is not random but follows daily circadian oscillations. These oscillations are dependent on the sympathetic neurotransmitter, norepinephrine, through the β_3 -adrenergic receptors expressed by BM stromal cells, leading to downregulation of SDF-1 in the BM, and subsequently reducing HSPC BM retention.²⁴ Although all players of the brain–bone–blood triad are linked and mutually regulated, much is unknown with regard to the specific molecular mechanisms of this dynamic regulation (reviewed by Spiegel et al²³).

Involvement of Bone Marrow Neutrophils in Stem and Progenitor Cell Mobilization

Neutrophils are the most abundant myeloid leukocytes in mammals and are an essential component of the innate immune system, as

they are the first line of defense upon pathogen infiltration. During steady-state homeostasis, mobilization of neutrophils from the BM occurs at a dramatic rate of about 10^{11} cells in humans and 10^7 in mice per day, and they are characterized by a very short life span of about 12 h in mice. At baseline, the great majority (>98% in mice) of neutrophils are located in the BM, given a reservoir of neutrophils to respond to stress conditions such as infections (reviewed by Day and Link²⁵). During the acute phase of inflammation, neutrophils are the first leukocytes to migrate from the circulation to sites of infection following a gradient of inflammatory stimuli, where they eradicate the pathogens and are eventually cleared by macrophages. During homeostasis, neutrophils are maintained through a balance between their production in the BM, release through the endothelial barrier to the circulation, and clearance from the circulation.²⁶ Neutrophils are key regulators of HSPC mobilization via HGF secretion, ROS signaling, and proteolytic enzymes. The chemokine CXCL2 is a potent chemoattractant of neutrophils, and it is known to play a crucial role in the emigration of activated neutrophils from the BM, indirectly inducing HSPC mobilization. In addition, the major mediators of neutrophil driving power for HSPC mobilization are proteolytic enzymes (e.g., MMP9), which are released by activated neutrophils into the BM microenvironment and periphery. These proteolytic enzymes interfere with the SDF-1/CXCR4 retention signal that preserves HSPCs in their BM niches,¹³ enabling their subsequent recruitment from the BM to the blood. The requirement of neutrophils and G-CSF-induced HSPC mobilization was supported by a study in 2012 showing that G-CSF mediated neutrophil expansion in the BM of mice. In addition, G-CSF induced apoptosis of MSPCs and osteoblasts through increased ROS production and reduced expression of retention factors in the BM, including SDF-1.²⁷ Depletion of activated neutrophils in mice by administration of neutralizing antibodies led to attenuation of G-CSF–mobilization effects.²⁷ Although ROS generation in neutrophils is critical during eradication of pathogens and is involved in the apoptotic processes, it also serves as a common signaling mediator. Except for ROS generation in activated neutrophils, ROS signaling is a key intrinsic cellular mechanism during HSPC differentiation and recruitment to the periphery. Dar et al (2011) demonstrated that inhibition of ROS by the antioxidant *N*-acetyl cysteine could preferentially attenuate AMD3100-induced mobilization of murine HSPCs,⁸ suggesting that ROS signaling is involved in rapid HSPC motility and egress. Tesio et al (2011) found that granulocytes (e.g., neutrophils), activated by repeated G-CSF stimulations, release HGF. HGF in turn binds to its receptor c-Met on the HSPCs themselves, triggering mTOR/ROS signaling as part of the HSPC mobilization process (reviewed by Ludin et al¹⁸). It is therefore not surprising that blocking c-Met, mTOR, or ROS leads to inhibition of G-CSF-induced HSPC mobilization, while HGF administration induces their mobilization. Of note, Dar et al (2011) showed that inhibition of ROS by *N*-acetyl cysteine not only reduces AMD3100-induced mobilization of HSPCs, but also reduces the induction of SDF-1 release by BM stromal and endothelial cells.⁸ These studies identified a cross-talk between SDF-1/CXCR4 via ROS signaling, which is essential for HSPC egress and mobilization⁸ (reviewed by Ludin et al¹⁸). Collectively, results taken from different studies support the claim that neutrophils are key elements in G-CSF-induced HSPC mobilization, as shown by HGF secretion, release of proteolytic enzymes, suppression of osteoblasts, and increased ROS generation. The mechanism of HSPC and neutrophil mobilization is summarized in Fig. 14.2.

Neutrophil Retention and Egress: The Essential Role of SDF-1/CXCR4 and CXCL2/CXCR2 Signaling

Accumulating evidence suggests that the SDF-1/CXCR4 axis regulates neutrophil retention. SDF-1 is a chemoattractant not only for HSPCs, but also for many hematopoietic cell types, including neutrophils. BM neutrophils and neutrophil precursors express low but visible levels of surface CXCR4 and high intracellular levels, suggesting an internalization of CXCR4 *in vivo* (reviewed by Day

Fig. 14.2 NEUTROPHILS AND HEMATOPOIETIC STEM AND PROGENITOR CELL RETENTION AND MOBILIZATION FOLLOWING G-CSF TREATMENT. (A) During steady state, HSPCs are localized in specific bone marrow (BM) stromal niches associated with MSPCs and osteoblasts via SDF-1/CXCR4-induced adhesion and retention. The balance between the chemokine stromal SDF-1 and endothelial CXCL2 favors neutrophil retention, with only a small fraction of neutrophils released to the blood. (B) Repeated G-CSF administration increases SDF-1 secretion from MSPCs, leading to HSPC mobilization to the blood. G-CSF also alters the balance of BM chemokines by increasing endothelial CXCL2 expression and decreasing SDF-1 expression by BM osteoblasts and other stromal cells, leading to neutrophil activation and mobilization to the blood. The activated neutrophils in the BM secrete ROS, HGF and proteolytic enzymes (e.g., MMP-9), which interfere with retention signals. These inflammatory signals induce detachment of HSPCs from BM MSPCs and osteoblasts, leading to their enhanced proliferation, differentiation, and mobilization to the circulation. *HGF*, Hepatocyte growth factor; *HSPC*, hematopoietic stem and progenitor cell; *MMP-9*, matrix metalloproteinase-9; *MSPC*, mesenchymal stem and progenitor cell; *ROS*, reactive oxygen species.

and Link²⁵). Previous studies have shown neutrophilia and impaired neutrophil mobilization in response to G-CSF in mice carrying a myeloid-specific deletion of CXCR4. In addition, conditional deletion of SDF-1 is also related to neutrophilia. Finally, treatment with AMD3100 in humans or mice results in rapid neutrophil mobilization.¹¹ Another major player in neutrophil activation and egress is the chemokine CXCL2 (also termed macrophage inflammatory protein 2 [MIP-2]), which is known to play an essential role in their egress from the BM to the circulation or to sites of inflammation (reviewed by Day and Link²⁵). CXCL2 is expressed by endothelial cells and megakaryocytes in the BM, and induces neutrophil egress by binding to its correspondent receptor CXCR2 on neutrophils. It has been demonstrated that neutrophils in CXCR2-deficient mice are retained in the BM, leading to a myelokathexis-like phenotype (reviewed by Day and Link²⁵). These data provide strong evidence that CXCL2/CXCR2 signaling plays a major role in neutrophil egress from the BM to the circulation. Under steady-state conditions, the balance of SDF-1 and CXCL2 chemokines favors neutrophil retention in the BM, with a relatively small population of neutrophils egressing to the circulation (reviewed by Day and Link²⁵). On the contrary, under stress situations (e.g., infections) the expression of inflammatory cytokines, in particularly G-CSF, is upregulated and leads to massive neutrophil egress into the circulation. Link et al (2005) showed that after G-CSF administration there is a suppression of osteoblasts, resulting in decreased SDF-1 expression in the BM (reviewed by Day and Link²⁵). In addition, G-CSF causes cleavage of surface CXCR4

on neutrophils, disrupting SDF-1/CXCR4 signaling, which leads to their mobilization.²⁸ G-CSF administration also elevates CXCL2 expression by BM endothelial cells, increasing the interaction between CXCL2 and CXCR2, followed by activation of neutrophils and egress to the circulation. Taken together, administration of G-CSF alters the balance of chemokine production in the BM by stromal and endothelial cells, thereby regulating neutrophil mobilization from the BM (see Fig. 14.2). There is evidence for cross-talk between CXCR4 and CXCR2, and disruption of one signaling pathway may enhance another chemokine's receptor signaling. Martin et al (2003), Suratt et al (2004), and Wengner et al (2008) showed that pharmacologic blockade of CXCR4 signaling results in enhanced CXCR2 ligand-induced neutrophil mobilization in mice (reviewed by Day and Link²⁵). Previously, Eash et al (2009) demonstrated that neutrophils lacking both CXCR4 and CXCR2 receptors exhibit increased neutrophil egress, similar to mice lacking only the CXCR4 receptor in neutrophils. In accordance, administration of CXCL2 does not induce neutrophil mobilization in mice lacking CXCR4 expression in neutrophils (reviewed by Day and Link²⁵).

WHIM Syndrome

WHIM syndrome is an autosomal-dominant combined immunodeficiency disease caused by mutations in the receptor CXCR4, resulting in increased BM retention and severe reduction in circulating

neutrophils. The term *WHIM* is an acronym for the main signs of the syndrome: warts, hypogammaglobulinemia, infections, and myelokathexis; myelokathexis refers to impaired egress of mature neutrophils and other myeloid cells from the BM, causing neutropenia. Al Ustwani et al (2014), Beaussant et al (2012), and Dotta et al (2011) reported that the signature pathogen in WHIM syndrome is human papillomavirus (HPV), which causes warts that cannot be controlled with standard medical treatment and may progress to cancer. Prophylactic antibiotics and G-CSF are often used to reduce the frequency of infections; however, their specific efficacy has not been established. This syndrome confirms a crucial role for CXCR4 signaling in neutrophil trafficking from the BM. In the majority of cases, WHIM syndrome is caused by truncation mutations in a domain important for CXCR4 downregulation (reviewed by Day and Link²⁵). These mutations confer enhanced responsiveness to SDF-1, suggesting a model in which increased CXCR4 signaling leads to increased retention of neutrophils in the BM. Dale et al (2011) and McDermott et al (2011) demonstrated safety and preliminary evidence of clinical efficacy in phase I studies of the specific CXCR4 antagonist AMD3100 (plerixafor [Mozobil]) in WHIM syndrome, which increases the numbers of neutrophils in the circulation (reviewed by Link²⁹). Spontaneous remission or cure of WHIM syndrome has been reported in 2015. McDermott et al (2015) describe chromothripsis (chromosome chattering) in one patient with WHIM syndrome that deleted one copy of chromosome 2, including deletion of the disease allele CXCR4^{R334X} in a single HSC. Because CXCR4 regulates stem cell quiescence and the cell cycle, this led to their increased proliferation and differentiation due to a missing copy of CXCR4. This clone took over the BM and resorted normal immune function, which resulted in cure of the disease. This study suggests that partial CXCR4 inactivation might enhance clinical BM repopulation in transplanted patients.³⁰

CONCLUDING REMARKS

This chapter discusses the mechanisms and pathways involved in the regulation of HSPC homing, egress, and mobilization, emphasizing the major roles of the SDF-1/CXCR4 axis in the regulation of these complex interactive processes. In addition, this chapter discusses the

essential role of SDF-1/CXCR4 and CXCL2/CXCR2 signaling in the regulation of neutrophil egress and retention.

Successful BM reconstitution requires directed stem cell migration from the circulation across the blood–BM barrier, and lodgment in the specialized BM niches wherein stem cells proliferate and differentiate, while maintaining a small pool of primitive stem cells (see Fig. 14.1).

Currently, there are multiple hypotheses regarding the defined entity of the HSPC niche. SDF-1, which has a prominent role in homing, mobilization, retention, and quiescence of HSPCs, is highly expressed by endosteal osteoblasts, MSPCs, and other stromal cell types, implying the importance of regulating the niche in order to induce mobilization. The retention capacity of HSPCs in the BM during mobilization is altered due to several signaling events, chemotactic gradients (e.g., SDF-1 and S1P), as well as breakdown of adhesion interactions. Proteolytic enzymes that degrade adhesion molecules or extracellular matrix components, thus promoting adherence to the BM niches, are a key mechanism that enables egress of cells to the peripheral blood. Mimicry of this process by mobilizing agents leads to HSPC mobilization, and therefore such procedures can be utilized to clinically harvest repopulating HSPCs from the blood. Various BM-resident cellular players, including neutrophils, osteoclasts, and osteoblasts, play significant roles in mediating physiological cell egress and stress-induced mobilization to the peripheral blood (see Fig. 14.2). Mutual interactions and effects between these players result in a complex microenvironmental niche that regulates HSPC function, retention, and migration. Suppression of osteoblasts, MSPCs, or both, resulting in decreased SDF-1 expression in the BM, seems to be a major mechanism by which detachment of HSPCs is enabled as part of their recruitment to the peripheral blood. Hence, BM niches are dynamic and undergo alterations on demand, directly affecting hematopoiesis and motility. Additionally, there exist significant data implying a major contribution of innate immunity in mobilizing HSPCs (e.g., by neutrophils; see Fig. 14.2). This interplay is evident by studies showing activation of neutrophils upon administration of mobilizing agents, such as G-CSF. Disruption of CXCR4 signaling is an important mechanism by which neutrophils and HSPCs are mobilized into the circulation under stress conditions. CXCL2 is a secondary chemokine that, together with SDF-1, controls neutrophil trafficking from the BM.

Relevance to Clinical Hematology

Optimal HSPC migration from the BM to the circulation (mobilization) for donor cell transplant harvest and from the recipient blood into the BM (homing) for stem cell lodgment is an essential prerequisite for successful BM reconstitution in clinical transplantation. As discussed in this chapter, experimental systems involving human and murine HSPCs enable dissection of these migration processes to identify regulatory mechanisms to improve clinical settings. Current understanding of HSPC biology reveals that these cells home to the BM homeland, where they proliferate and differentiate, giving rise to multilineage hematopoietic cells while maintaining a small pool of primitive stem cells. The majority of HSPCs remain confined to the BM cavity in a nonmotile mode, adjacent to niche-supportive cells that preserve them in a quiescent, nonproliferative mode, but a very low level of primitive progenitors and stem cells also continuously egress to the circulation as part of homeostasis. The levels of these rare migrating HSPCs are dramatically enhanced during alarm situations caused by injury and inflammation as part of the host defense and repair mechanism. The physiologic process of enhanced HSPC recruitment from the BM has been used clinically to accelerate stem and progenitor cell migration to the circulation. Thus collection of HSPCs from the donor's peripheral blood, rather than from their BM, became the most common clinical protocol for BM transplantation (BMT).

Clinical BMT has gained immense success within the past four decades in the treatment of malignant hematologic diseases and immunodeficiency states by providing long-term immune recovery after high-dose chemotherapy. The basic premise in BMT is either using a patient's own stem cells (i.e., autologous BMT), which are used primarily as stem cell support for myeloma or lymphoma while undergoing intensive

chemotherapy; or alternatively, allogeneic BMT, performed for the most part in the setting of marrow-infiltrating malignancies such as leukemia, which uses donor stem cells infused to a patient, thus capitalizing on the graft-versus-leukemia effect, which affords a significant reduction in relapse rate. One of the major clinical obstacles facing BM transplant experts today is the mobilization of the so-called "difficult mobilizers," who fail to mobilize the required amount of CD34 progenitors. Known risk factors for insufficient numbers of HSPCs after mobilization include older age, previous failed mobilization, heavy BM infiltration by tumor cells, and previous chemotherapy and radiotherapy, to name just a few. Several strategies have attempted to address this clinical problem using optimized current mobilization protocols, among them high-dose G-CSF regimens, erythropoietin, SCF, and chemomobilization achieved by chemotherapy treatment combined with G-CSF. Despite the wide gamut of therapeutic strategies used, most of them have either failed to show a clear advantage compared with standard mobilization regimens or were associated with substantial adverse effects (chemomobilization). With the recent introduction of the CXCR4 antagonist AMD3100 (also termed plerixafor [Mozobil]), there is renewed optimism in the management of difficult-to-mobilize patients. AMD3100 mediates rapid secretion of SDF-1 from BM stromal cells and its release to the circulation, resulting in CD34⁺ progenitor mobilization. Treatment with AMD3100 exhibits marked synergism with G-CSF, suggesting their different and complementary mechanisms of action to induce HSPC mobilization. Several studies have shown its success in mobilization of previously failed myeloma in non-Hodgkin lymphoma and Hodgkin lymphoma patients.

Relevance to Clinical Hematology—cont'd

Clearly, because BMT is used increasingly in elderly adults and patients previously exposed to intense chemotherapy, novel approaches for optimizing mobilization are warranted. Several promising approaches are looming over the clinical horizon; among them are novel mobilization agents such as AMD3465, SB-251353, T140, and PTH acting in its capacity as a pivotal regulator of hematopoietic niches. Additional avenues to be explored in this area include the use of cord blood, which at present is limited to pediatric patients and adults of low body weight because of the low number of CD34⁺ progenitors contained in each CB unit. For this reason, the major disadvantage of CB transplantation in adult patients is delayed engraftment. Approaches aimed at overcoming delayed engraftment with CB transplantation include double-CB transplants or, together with mobilized or BM-derived CD34⁺ cell infusion from a matched donor,

to achieve transient engraftment until the CB cells reconstitute the BM. In addition, circumventing this inherent limitation of CB use may be achieved by improving HSPC homing potential. For instance, inhibition of CD26 allows augmented engraftment of stem cells to the recipient's BM. Upregulation of CXCR4 by PGE₂ stimulation increases SDF-1 chemoattraction to the BM. Another pathway is activated by CD44 glycosylation, which may enhance navigation of treated MSCs to the BM. Taking into consideration bone and BM niche integrity, influencing factors such as age, timing of mobilization, and interplay among different mobilizing agents may be crucial in optimizing HSPC yield after mobilization, as well as their homing after transplantation. This approach might lead to advanced development of new safe and efficient therapeutic strategies for HSPC transplantation protocols.

VASCULAR GROWTH IN HEALTH AND DISEASE

Janusz Rak

HEMOSTATIC, HEMATOPOIETIC, AND VASCULAR SYSTEMS AS A FUNCTIONAL CONTINUUM

Although specific demands of practice, concepts, and methodologies define the unique scope of current hematology, the underlying biologic processes do not occur in isolation. Thus it is increasingly obvious that diseases affecting bone marrow and peripheral blood are closely intertwined with the state of the vascular system,¹ which acts as a niche, conduit, and regulator of many of these events.² This is exemplified by the anatomic proximity and interactions among several related cellular populations, including hematopoietic progenitors, their derivatives, endothelial cells and their precursors, platelets, perivascular tissues, and other components involved in blood vessel formation, repair, homeostasis, and patency.^{2,3} The remarkable recent progress in understanding the molecular mechanisms involved in communication between these cells increasingly informs medical practice and drug discovery efforts.^{2,4,5} For instance, agents designed to block vascular growth (antiangiogenics) in solid tumors also elicit hematologic perturbations,⁶ and are being considered for treatment of hematopoietic malignancies.⁷ Indeed, hematopoietic, hemostatic, and vascular compartments can be viewed as a functional continuum, both in health and in disease.

CONSTITUENTS OF THE VASCULAR SYSTEM

The hematopoietic and vascular systems emerge from a common progenitor cell (hemangioblast) early during embryogenesis. Subsequently, the vascular lineage evolves to form a network of channels that integrate, control, and reflect the structure and function of the tissues (parenchyma) and organs that they supply.⁸ Local characteristics of the vascular system are superimposed on a more general, hierarchical branching pattern (arborization) and arteriovenous directionality essential for the function of the circulation. Structurally, distinct lymphatics emerge from the venous system to return extravascular (interstitial) fluid and extravasated cells to the venous circulation.²

Blood vessels are not only the essential supply routes of nutrients and oxygen to tissues (parenchyma), but also conduits of long-range regulatory signals (hormonal/endocrine), and an important source of paracrine cues that act on surrounding cells in a perfusion-independent (angiocrine) manner.^{2,9,10} The latter influence may constitute a regulatory niche to either stimulate or inhibit the activity of parenchymal cells, including subsets of normal and cancer stem cells.^{11,12} Postnatal tissue maturation imposes a quiescent phenotype throughout the vascular system, a state that is only rarely and transiently interrupted by posttraumatic tissue regeneration, wound healing, vascular repair, or cyclic changes in reproductive organs. This quiescent state may be chronically compromised in certain pathologies (inflammation, hyperplasia, or cancer), which can lead to unscheduled or abnormal vascular growth.² Out of several forms of such growth, vasculogenesis, angiogenesis, and vascular remodeling stand out as fundamentally important and distinct. In vasculogenesis, endothelial progenitor cell self-assembly results in the formation of new vascular channels (e.g., during embryogenesis). In contrast, angiogenesis is a process whereby preexisting vascular channels are extended to form additional capillary loops (e.g., during tissue

remodeling and in cancer). Structural changes leading to enlargement or shrinkage of such structures are referred to as vascular remodeling.²

Cells Involved in Vascular Growth

Specialized endothelial cells (ECs) constitute the crucial structural and functional element of the adult vasculature. ECs create anti-thrombotic luminal surfaces within all blood vessels, produce an active interface between the blood and the surrounding tissues, control the transmural flux of fluids and macromolecules (permeability), and are the key component of vascular growth processes (see Chapters 122 and 123). Such growth not only involves cessation of the quiescent state in subsets of resident endothelial cells, but is also associated with multiple systemic events, such as release of cytokines into the circulation and mobilization of cells from the bone marrow, including endothelial progenitor cells (EPCs), hematopoietic stem cells (HSCs), and myeloid (bone marrow-derived) cells (BMDCs).² These cells serve as surveillance and regulatory mechanisms that control and coordinate the responses of the peripheral vasculature (Fig. 15.1).¹³ In established blood vessels the functionality of the endothelial tube is dependent on the support of the abluminal basement membrane, which is shared between these cells and one or more layers of contractile mesenchymal cells of the blood vessel wall (mural cells). Among those cells, sparse networks of pericytes (PCs) are associated with capillary endothelium, while continuous sheaths of smooth muscle cells (SMCs) cover the pre- and post-capillary vascular segments (arterial and venous, respectively).² The thickness and complexity of the vessel wall differ between veins and arteries, and increase with vascular hierarchy, so much so that the multilayered walls of large arteries contain their own capillary networks (vasa vasorum). The growth of the vasa vasorum can be induced in and contributes to the formation of atherosclerotic plaques, a process also involving metabolic abnormalities and increasingly well-characterized molecular pathways.¹⁴ Blood vessel integrity and growth are also dependent on platelets and the hemostatic system (tissue factor, thrombin, thrombin receptor/PAR-1, the fibrinolytic system, and other effectors), all of which play important roles in the regulation of vascular continuity, patency, and permeability.² Coagulation proteases not only regulate clot formation upon injury, but also elicit signals within the surrounding vascular, inflammatory, and parenchymal cells, thereby modulating the related biologic responses and gene expression patterns.^{9,15}

Molecular Regulators of Vascular Responses

The state of the vascular networks is controlled by a web of intercellular communications, which are executed by soluble growth factors, adhesion molecules, extracellular matrix (ECM) molecules, cell–cell contacts, the hemostatic system, various proteases, and the intercellular exchange of molecules (proteins, mRNA, and microRNA). A part of this circuitry entails the emission/uptake of extracellular vesicles (EVs), including exosomes.^{2,16,17} Of the involved mediators, some are essential for vascular growth and homeostasis, while others play more pleiotropic and context-dependent roles (Table 15.1).^{1,2}

Fig. 15.1 CELL POPULATIONS INVOLVED IN VASCULAR GROWTH AND TUMOR ANGIOGENESIS. Cells involved in blood vessel formation include endothelial cells, their progenitor cells, mural cells (pericytes), several populations of bone marrow–derived cells, as well as angiogenic fibroblasts, platelets, cancer cells, stem cells, and immune effectors not included in this diagram (based on Carmeliet and Jain², Kerbel⁴, and De Palma and Naldini¹³). *VEGFR*, Vascular endothelial growth factor receptor.

Vascular Endothelial Growth Factors

Vascular endothelial growth factor-A (VEGF-A), which is also known as VEGF or vascular permeability factor (VPF), is indispensable for vascular development.^{2,3,5} VEGF is the key member of a larger family of related polypeptides, which includes VEGF-B, VEGF-C, VEGF-D, VEGF-E, VEGFR-F, and placental growth factor (PlGF).² Upon dimerization, these factors bind to their tyrosine kinase receptors (RTKs/VEGFRs), including VEGFR1/Flt-1, VEGFR2/KDR/Flk-1, and VEGFR3/Flt-4, often in conjunction with their neuropilin coreceptors (NRP1, NRP2),² as depicted in Fig. 15.2. For instance, VEGF-A interacts with VEGFR2, VEGFR1, and VEGFR3, while PlGF is selective for VEGFR1. The distribution of different VEGFRs on vascular (VECs) and lymphatic (LECs) endothelial cell subsets, as well as among EPCs, hematopoietic, myeloid, and certain tumor cells, defines the known biologic activities of various VEGF ligands. The effects of VEGF include stimulation of endothelial mitogenesis, migration, survival, morphogenesis, and vascular permeability (e.g., through formation of intercellular gaps or transcellular structures known as *fenestrae*).³ The signaling activity of VEGFR2 is crucial for these processes, whereas VEGFR1 is often expressed as a soluble splice variant (sFlt-1) that neutralizes VEGF (acts as VEGF “sink”), thereby inhibiting angiogenesis.²

VEGF activity is also regulated by splicing of the corresponding mRNA, which results in the generation of several protein isoforms, including VEGF121, VEGF145, VEGF165, VEGF189, and VEGF206 (designations based on the number of amino acids).^{2,5} These variants differ in their cell association, solubility, and their ability to bind heparinoids or to interact with neuropilins, all of which define the formation of extracellular gradients and related biologic responses. In this regard, VEGF165 is an especially potent inducer of angiogenesis (Fig. 15.3). VEGF-C and VEGF-D stimulate the growth of lymphatics (lymphangiogenesis) via activation of VEGFR3, while VEGF-B and PlGF interact with VEGFR1 and are involved in vascular pathologies and inflammation.²

Platelet-Derived Growth Factors

This family of VEGF-related growth factors consists of four members: PDGF-A, PDGF-B, PDGF-C, and PDGF-D, the

homo- or heterodimers of which interact preferentially with one of the three known cellular RTKs, namely PDGFR α , PDGFR β , and PDGFR γ , each endowed with different cellular functions. For example, PDGF-BB is expressed by endothelial cells and mediates their capacity to attract mural cells harboring PDGFR β .²

Prokineticins

This group of factors consists of the endocrine gland vascular endothelial growth factor/prokineticin 1 (EG-VEGF/PK1) and the protein 8/prokineticin 2 (Bv8/PK2) secreted by *Bombina variegata*, both of which interact with their respective G-protein–coupled receptors on endothelial cells (PK-R1 and PK-R2). These mediators induce VEGF-like effects in endothelial cells and may render tumors resistant to VEGF inhibition.⁵

Angiopoietins and Tie Receptors

Angiopoietins (Ang1, 2, and 4) interact with the Tie2/TEK receptor (RTK), which is preferentially expressed by endothelial cells and some myeloid cells (see Figs. 15.1 and 15.2). A related orphan receptor, known as Tie1, remains poorly characterized and likely acts by modulating Tie2 activity.² Ang1 emanates from perivascular tissues and serves as the main Tie2 agonist to stabilize endothelial–mural cell interactions and to promote endothelial cell survival, vascular quiescence, and the nonpermeable state. Ang2, which is produced by VEGF-stimulated endothelium, exerts the opposite effect and stimulates pericyte detachment, permeability, vascular growth, or regression, as well as lymphangiogenesis.²

Notch Pathway

Delta-like (Dll1, 3 and 4) and Jagged (1 and 2) are membrane-bound ligands that activate Notch receptors (Notch 1–4) on adjacent cells. During vascular development and growth Dll4 and Jagged 1 are expressed by subsets of endothelial and mural cells, respectively, and regulate their distinct functions within the capillary outgrowths

TABLE 15.1**Molecular Regulators of Vascular Growth and Remodeling**

Regulator	Main Receptor(s)	Biologic Activity
Angiogenic Effectors Central to Endothelial and Mural Cell Function		
VEGF-A/VEGF	VEGFR2 (VEGFR3, VEGF1), NRP1	Stimulator of angiogenic functions, migration and survival of ECs, including formation of tip cells
VEGF-C	VEGFR3 (VEGFR2)	Stimulator of angiogenesis (ECs) and lymphangiogenesis (LECs)
Ang 1	Tie2	Positive regulator of endothelial–mural interactions, EC survival, and vessel maturation
Ang 2	Tie2	Negative regulation of endothelial–mural interactions, stimulator of lymphangiogenesis
Dll4	Notch	Inhibitor of tip cell formation
Jag1	Notch	Stimulator of tip cell formation
EphrinB2	EPHB4	VEGFR internalization/signaling, arterial identity, tube formation
PDGF-B	PDGFR β	Recruitment of mural cells, vessel maturation
TGF β 1	TGF β RII	Differentiation of mural cells, ECM formation
Integrins (α v, β 1, β 5)	ECM proteins	EC survival, migration morphogenesis
Stimulators Involved in Pathologic Angiogenesis		
PlGF	VEGFR1	Stimulates angiogenesis by interaction with ECs and BMDCs
Acidic FGF (FGF-1)	FGFRs 1–4	Stimulator of EC mitogenesis, survival, and angiogenesis
Basic FGF (FGF-2)	FGFRs 1–4	Stimulator of EC mitogenesis, survival, and angiogenesis
FGF-3	FGFRs 1–4	Stimulator of EC mitogenesis, survival, and angiogenesis
FGF-4	FGFRs 1–4	Stimulator of EC mitogenesis, survival, and angiogenesis
IL-8	CXCR1	Stimulator of ECs and inflammatory cells
IL-6	IL-6R	Stimulator of inflammatory angiogenesis
TNF α	TNFR1 (p55)	EC stimulator and VEGF inducer
Bv8	GPCR	Stimulator of endocrine and tumor ECs
PD-ECGF/TP	Unclear	Stimulator of angiogenesis
Angiogenin	170-kDa receptor	Stimulator of angiogenesis and tRNAse
MMP9	ECM proteins	Matrix metalloproteinase that breaks down the ECM and releases angiogenic growth factors
Endogenous Angiogenesis Inhibitors		
Inhibitor	Biologic Activity	
TSP-1	Interacts with the CD36 receptor, integrins, and other proteins, causing growth inhibition and apoptosis of angiogenic ECs	
Endostatin	Proteolytic fragment of collagen XVIII with antiangiogenic activity	
Angiostatin	Proteolytic fragment of plasminogen with antiangiogenic activity	
Tumstatin	Proteolytic fragment of collagen IV alpha 3 chain	
sFlt-1/sVEGFR1	Soluble splice variant of VEGFR1 neutralizing VEGF and blocking VEGFR2 signaling	
VEGF165b	Splice variants of VEGF with antiangiogenic activity	
PEX	Inhibitor of EC invasion and MMP activity	
IFN α (β)	Inhibits release of angiogenic growth factors	

Ang (1,2), Angiopoietin; Bv8, *Bombina variegata* protein; Dll4, delta-like 4; FGF, fibroblast growth factor; GPCR, G-protein-coupled receptor; IFN, interferon; IL-6, interleukin 6; IL-8, interleukin 8; Jag1, Jagged 1; MMP9, matrix metalloproteinase 9; PD-ECGF/TP, platelet-derived endothelial cell growth factor/thymidine phosphorylase; PDGF, platelet-derived growth factor; PlGF, placenta growth factor; TNF α , tumor necrosis factor alpha; TSP-1, thrombospondin 1; VEGF, vascular endothelial growth factor. See text and references for details.²

(sprouts), as depicted in Figs. 15.2 and 5.3.⁵ Dll1 is also involved in circumferential vascular enlargement (arteriogenesis; Fig. 15.4).²

Ephrins and Eph Receptors

The arterial or venous identity of endothelial cells in the evolving microcirculation is preprogrammed by the expression of transmembrane guidance molecules, especially ephrin B2 and its EPHB4 receptor. Bidirectional signals emanating from these molecules, together with mechanosensory cues, govern the arteriovenous vascular arborization that is essential for, and maintained by, proper blood flow.

Other ephrins are implicated in endothelial–pericyte interactions, and communication between blood vessels and tumor cells. They may also cooperate in VEGFR2 endocytosis and signaling.²

Vascular Integrins, Cadherins, and Cell Adhesion Molecules

Quiescent endothelial cells are anchored to the basement membrane, a structured layer of ECM composed mainly of laminin and collagen type IV. In contrast, growing (angiogenic) endothelial cells are surrounded by provisional ECM containing fibrin, vitronectin, fibronectin, and

Fig. 15.2 ELEMENTS OF THE SIGNALING CIRCUITRY INVOLVED IN BLOOD VESSEL FORMATION AND TUMOR ANGIOGENESIS. Receptors and co-receptors involved in angiogenic, lymphangiogenic, and regulatory signaling. *Bottom panel:* Outline of signaling pathways and their effector mechanisms downstream of VEGF-A/VEGF. *Dll4*, Delta-like 4; *eNOS*, endothelial nitric oxide synthase; *HSPG*, heparan sulfate proteoglycan; *MAPK*, mitogen-activated protein kinase; *NRP*, neuropilin; *PI3K*, phosphatidylinositol 3-kinase; *PLC*, phospholipase C; *PIGF*, Placental growth factor; *PKC*, protein kinase C; *PM*, plasma membrane; *VE-cadherin*, vascular endothelial cadherin; *VEGF*, vascular endothelial growth factor; *SRC*, Rous sarcoma virus-related proto-oncogene.

partially degraded collagens. Growth factors upregulate the expression of dimeric integrin receptors ($\alpha v\beta 3$, $\alpha v\beta 5$, $\alpha 1\beta 1$, $\alpha 2\beta 1$, $\alpha 4\beta 1$, $\alpha 5\beta 1$), which recognize specific motifs in ECM molecules (often the RGD sequence). Angiogenic growth factor receptors require integrin interactions for their signaling function, while integrin $\alpha v\beta 3$ is one of several antiangiogenic targets under investigation.^{2,4}

Vascular endothelial cadherin (VE-cadherin/CD144) is selectively expressed by endothelial cells and contributes to their barrier function, homotypic adhesion, and growth regulatory signals. Other cadherins, as well as claudins (e.g., endothelial claudin 5) and connexins, contribute to homo- and heterotypic endothelial cell interactions, and the formation of gap and tight junctions, as well as transmission of intercellular signals.⁵ On the other hand, interactions between endothelium and circulating immune, myeloid, inflammatory, and progenitor cells, and platelets are mediated by selectins (e.g., P-, L- and E-selectin), integrins ($\alpha 4\beta 1$ /VLA4), and members of the immunoglobulin family of cell adhesion molecules (ICAM-1/2

and VCAM1), all of which play distinct roles in the regulation of angiogenesis and vascular homeostasis.^{2,5}

Proteases

Proteases regulate remodeling, growth, and invasion of new blood vessels; liberation of ECM-bound angiogenic growth factors; generation of regulatory peptides (e.g., angiogenesis inhibitors); clotting and fibrinolysis; intracellular signaling; and numerous other steps involved in vascular maintenance and remodeling. For example, matrix metalloproteinases (MMPs) and their tissue inhibitors (TIMPs 1–4) participate in the controlled ECM/basement membrane breakdown that is required for invasiveness of the angiogenic endothelium.^{2,18} The key enzymes in this group include: MMP-1, MMP-2, MMP-9, and MMP-14, coagulation factors (VIIa and thrombin) and their receptors (tissue factor and PAR-1), plasminogen activators (uPA)

Angiogenic gradient formation (“switch”)

Hypoxia, inflammation, oncogenic transformation
Increased expression of stimulators (VEGF)
Decreased expression of inhibitors

Endothelial (phalanx) cell stimulation

Basement membrane dissolution
Pericyte “drop out”
Circumferential extension (mother vessels)

Formation of endothelial tip cells

VEGF gradient sensing
Expression of tip cell markers
Metabolic adaptation (glycolysis)

Formation of endothelial sprouts

Directional migration of tip and stalk cells
Blockade of VEGFR2 expression on stalk cells
by tip cells via the DII4/Notch pathway
Tip guidance (semaphorins, neuropilins, plexins, Robo4)

Extension of sprouts

Growth and migration of stalk cells and lumen formation

Myeloid cell–dependent anastomosis

Signalling by Tie2, Ang2, PlGF, PHD2, SDF-1 α

Formation of new vascular loops

Connection and anastomosis of sprouts

Vascular maturation

Pericyte recruitment/vessel maturation (PDGFR β , Ang1)
Restoration of basement membrane (TIMPs, PAI-1)
Endothelial quiescence–phalanx cells (Notch)
Junction formation (VE-cadherin)
Anticoagulant surfaces

Blood flow

Resolution of hypoxia

Fig. 15.3 SPROUTING ANGIOGENESIS. The change in balance between angiogenesis stimulators and inhibitors (angiogenic switch) and especially the gradient of VEGF leads to sprouting angiogenesis. This process begins with changes in the vessel wall (endothelial phalanx cells), resulting in the formation of enlarged mother vessels, endothelial tip cells, proliferating stalk cells, capillary loops, and eventually anastomoses, as depicted (details in the text and in Carmeliet and Jain³). *Ang*, Angiopoietin; *DII4*, delta-like 4; *PAI-1*, plasminogen inhibitor; *TIMP*, tissue inhibitor of MMP; *VEGF*, vascular endothelial growth factor; *VEGFR*, vascular endothelial growth factor receptor.

and their inhibitors (PAI-1), members of the disintegrin and metalloproteinase domain, and thrombospondin motif-containing families (ADAM and ADAMTS).

Angiogenesis Stimulators and Inhibitors

In addition to “professional” angiogenesis regulators, a number of molecules with more pleiotropic biologic activity serve as stimulators or inhibitors of vascular growth, either directly or indirectly (e.g., as inducers of VEGF). Examples of these diverse effectors are listed in Table 15.1 and include certain cytokines (FGF1, FGF2, HGF, TGF β), chemokines (IL-8/CXCL8, SDF-1/CXCL12), secreted ECM proteins (TSP1, TSP2), proteolytic ECM fragments (tumstatin, angiostatin),

phospholipids (sphingosine 1 phosphate [S1P]), and several other entities.¹ The effects of angiogenesis regulators are mediated by intracellular signaling pathways, including GTP-ases (Ras), kinases (src, Akt, PKC), transcription factors (ERG, HIF, MYC), microRNA species (miR17-92, miR155), and other effectors (see Fig. 15.2).²

PROCESSES INVOLVED IN BLOOD VESSEL FORMATION

The vascular system is programmed to rapidly respond to changes in the microenvironment. Although these responses may be provoked by local factors (e.g., tissue injury or hypoxia), they are regulated at several levels, including locally, regionally, and systemically, and with the involvement of perivascular, vessel wall–associated, circulating,

Fig. 15.4 PROCESSES OF VASCULAR GROWTH AND REMODELING IN CANCER. Neoplastic growth can serve as a paradigm for cellular programs regulating the proximity between parenchymal (cancer) cells and the vascular lumen^{2,24} (see text for details). *Angiogenesis*, Recruitment of new capillary vessels through paracrine effects of angiogenic factors on endothelial cells of the preexisting vasculature; *Vascular cooption*, recruitment of cancer cells to the proximity of preexisting blood vessels; *Vasculogenesis*, recruitment of bone marrow–derived endothelial progenitor cells (EPCs) to the sites of vascular growth or repair (although EPC are essential during embryogenesis, postnatally their role is more limited as they lodge in, and contribute to, fragments of the newly formed vascular wall, or participate in the repair at sites of endothelial denudation); *Arterio/venogenesis*, retrograde circumferential enlargement and remodeling of feeding vessels that supply expanding capillary networks with blood, a process involving bone marrow derived myeloid cell recruitment through tissue-related stimuli and shear forces; *Vasculogenic mimicry*, contribution of cancer cells to the vascular wall involving adoption of some endothelial-like features; *Endothelial differentiation (or trans-differentiation) of cancer stem cells*, certain types of multipotential tumor-initiating (stem) cells may activate programs of endothelial or pericytic transdifferentiation and form segments of the newly formed vasculature^{22,23}; *Intussusception*, division of the vascular lumen into smaller tubes by ingrowth of external tissue pillars; *Glomeruloid vessel formation*, formation of bundles of vascular loops through forces (arrows) generated by endothelial, pericyte, and parenchymal cell interactions.^{2,4,20,24}

and bone marrow–derived cells.² Cancer-related neovascularization exemplifies the diversity of processes that control cellular access to the perfused vascular space and the related terminology (see Fig. 15.4). Indeed, an increase in vascular density or the presence of endothelial structures or blood within the tissue or tumor mass is not necessarily related to angiogenesis,¹ a process defined as the formation of new capillaries from preexisting ones (see Figs. 15.1, 15.3, and 15.4). Instead, the vascular density and architecture represent a combination of parenchymal and vascular cell responses to metabolic demands and regulatory circuits operative in a given context (see Fig. 15.4). As mentioned earlier, these processes may include vasculogenesis, recruitment, and assembly of undifferentiated endothelial progenitor cells (EPCs).^{2,4} These cells may also mediate vascular repair in response to endothelial damage (i.e., denudation) in larger vessels.¹⁹ Extravascular tissues may actively increase their vascular access through processes of vascular cooption or intussusception, whereby blood vessels may respectively become actively ensheathed or divided (split) by advancing external cellular masses. Glomeruloid vessels, or tufts, may also increase the proximity between the parenchyma and the vascular space through increased capillary looping directed by forces generated by pericytes.²⁰ The vascular wall may also undergo different forms of physiologic and pathologic remodeling, including circumferential lumen enlargement through growth, dilatation, or both. This is exemplified by capillary mother vessel formation prior to the onset of proper angiogenesis (see Fig. 15.3). The vascular wall thickening and diameter expansion, involving both endothelial and mural cells, and occurring during the formation of larger “feeding vessels” (or collaterals) upstream to tissue growth or ischemic regions, is often referred to as *arteriogenesis* or *arterio/venogenesis*.^{18,21} Recruitment of pericytes to the newly assembled capillary endothelial tubes signifies the process of vascular maturation or stabilization.¹⁸ Distinct mechanisms also regulate the programmed regression (pruning) of superfluous capillaries (e.g., during vascular arborization). Moreover in cancer, new vascular structures are postulated to emerge as a consequence of differentiation of cancer stem cells into endothelial-like or pericyte-like cellular populations.^{22,23} Cancer cells may also replace endothelial cells within the capillary walls of certain tumor types, giving rise to a pseudoendothelial lining (vasculogenic mimicry).²⁴ Each of these processes is driven by specialized cellular and molecular circuitry, and plays a unique role in vascular growth, homeostasis, and pathology, as outlined briefly below^{2,4,5,24} (see Fig. 15.4).

Vasculogenesis and vascular repair involve the recruitment of endothelial precursors, such as angioblasts or EPCs, and their self-assembly, differentiation, and/or structural integration within the endothelial lining. Vasculogenesis is central to the origin of the vascular system (primary capillary plexus formation) during embryogenesis prior to the onset of angiogenesis.⁸ Although EPC-like cells can be detected during postnatal life, especially in the bone marrow, in walls of large vessels, and as circulating endothelial progenitors (CEPs) in peripheral blood, they have a more restricted role, which is mainly regulatory and reparative in nature. For instance, EPCs may accumulate at sites of angiogenesis, but they rarely form complete vascular segments. However, EPCs may contribute to the endothelialization of denuded luminal surfaces, inner surfaces of vascular grafts, damaged lining of larger vessels (vascular repair), or to the recanalization of occlusive thrombi.¹⁹ Several molecular mechanisms control the recruitment of EPCs and their retention at sites of vascular growth, including high levels of circulating VEGF, stromal-derived factor 1 (SDF-1), expression of certain integrins, and other regulators.^{2,4}

Angiogenesis occurs under conditions of tissue growth, wound repair, inflammation, hypoxia, or proliferative disease (e.g., cancer). The new vascular structures emerge from preexisting endothelial channels mainly through a mechanism known as *sprouting angiogenesis* (see Fig. 15.3). In this case, the triggering event involves the formation of a gradient of proangiogenic activity around hypoxic or activated cells. The resulting cascade of responses within the wall of the nearest capillary begins with local capillary distension to form an enlarged mother vessel. Although high concentrations of VEGF are sufficient to induce these changes,³ the underlying molecular events usually involve a more global shift in levels of multiple angiogenesis inhibitors and stimulators

(“angiogenic switch”).¹ Some of these factors may upregulate VEGF in parenchymal, stromal, and inflammatory cells, or act directly on the endothelium. Inflammatory cells often cluster at sites of angiogenesis prior to the formation of new blood vessels, where they contribute to the consolidation of the proangiogenic microenvironment, or trigger vascular growth via VEGF-dependent and independent mechanisms.^{2,5} Efficient sprouting involves metabolic reprogramming of endothelial cells, including the activation of glycolysis and upregulation of phosphofructokinase isoenzyme 3 (PFKFB3).²⁵

VEGF plays a central and indispensable role in normal angiogenic sprouting. After exposure to this potent stimulator, there is upregulation of Ang2 expression in endothelial cells residing within the continuous monolayer of the capillary or mother vessel wall (phalanx cells). Endothelial Ang2 blocks tonic activation of the Tie2 receptor by the constitutive presence of Ang1, and by disrupting the key mechanism maintaining capillary structure leads to the detachment of pericytes. This is followed by local dissolution of the basement membrane (by MMPs), increase in vascular permeability, and extravasation of plasma proteins into the interstitium. The extravascular deposition of fibrin and the formation of a provisional ECM provide the scaffold for the formation of new capillaries.²

These processes liberate endothelial cells and initiate their directional migration in the form of a cellular column (angiogenic sprout) toward the source of the angiogenic stimulus (e.g., VEGF-expressing cells). Each sprout is composed of a single, specialized leading endothelial cell (tip cell) equipped with hair-like, sensing projections (filopodia), which contain high concentrations of VEGFR2 and are rich in other regulators (e.g., PDGF-B, SDF-1, Apelin, and Dll4). In their gradient-seeking movement, tip cells are followed by a cohort of proliferating endothelial stalk cells, which express VEGFR1 and Notch. Stronger stimulation by VEGF results in VEGFR2-dependent upregulation of Dll4 in tip cells, allowing them to instruct their stalk cell counterparts (via Notch) to retain their phenotype, refrain from independent branching, and to maintain VEGF signaling at lower levels. The latter is mediated, at least in part, by upregulation of soluble VEGFR1, acting as a “VEGF sink.” Consequently, exogenous blockade of the Dll4/Notch pathway leads to excessive generation of tip cells and sprouts (from stalk cells), resulting in the formation of an overly branched, hyperdense, nonperfused, and dysfunctional capillary network (“nonproductive angiogenesis”).²⁶ Stimulation of Notch receptor by the Jagged 1 ligand modulates the effects of Dll4 on stalk cells and fine-tunes the capillary branching patterns. The neighboring sprouts eventually connect (anastomose) to form new capillary loops. This process is mediated by interaction with myeloid cells expressing Tie-2 and NRP1 receptors.²⁷ Subsequent generation of the vascular lumen and resumption of blood flow occur through the formation of intercellular spaces between endothelial stalk cells.²

Vascular maturation involves a buildup of a mural cell layer around the newly formed endothelial tube, which is essential for its functional integrity.² This process entails secretion of PDGF-BB by endothelial tip cells, which attracts regional pericytes; a source of structural support and vessel-stabilizing, pro-survival Ang1 activity.²⁸ S1P regulates N-cadherin, which further links endothelial cells and pericytes. Upon their attachment to the endothelial tube, pericytes assume a more mature phenotype under the influence of transforming growth factor beta 1 (TGFβ1).²⁸ Endothelial prolyl hydroxylase 2 (PHD2), an oxygen-sensing enzyme, also regulates pericyte recruitment. These mechanisms restore vascular integrity, mechanical resistance, endothelial cell survival, diminished dependence on VEGF, and restricted permeability.²

Lymphangiogenesis and lymphatic dilatation represent key responses of specialized lymphatic endothelial cells (LECs) to external stimuli. LECs express distinct molecular markers (VEGFR3, Prox-1, LYVE-1) and respond to VEGF-C, VEGF-D, VEGF, and Ang2 (which acts as a Tie2 agonist in LECs and a Tie2 antagonist in their blood vessel counterparts—VECs). Even though LECs exhibit up to 98% molecular similarity to VECs and originate from vascular endothelium, they form separate networks of thin-walled vessels that serve as conduits for the collection of interstitial fluid and cells, including inflammatory cells and metastatic cancer cells.²⁹

Vasculogenic mimicry and endothelial differentiation of cancer stem cells are processes whereby nonendothelial cells adopt endothelial-like phenotypes and line vascular channels.³⁰ Vasculogenic mimicry occurs during normal placentation and in tumors, such as melanoma, or mouse teratoma, and results in positioning of parenchymal cells (e.g., cancer cells) within the layer of endothelium or around blood-containing channels. Such cells may adopt some of the morphologic and antigenic attributes of proper endothelium.²⁴ In human glioblastoma, cancer stem cells were reported to undergo a more profound endothelial or pericytic transdifferentiation, including the expression of corresponding lineage markers and some contribution to the vascular wall. The scope and functional role of these processes remain unclear and controversial.^{22,23,30}

Vascular cooption occurs when cancer cells actively adopt a growth and invasion pattern around preexisting blood vessels.³¹ This process is observed in highly vascular organs, such as the lungs and brain, resulting in a nonangiogenic form of tumor neovascularization. Coopted vessels may undergo secondary structural alterations, which may result in their remodeling, formation of occlusive thrombi, and regression that can lead to ischemia.³²

MECHANISMS TRIGGERING ANGIOGENESIS

Vascular growth may occur in response to hypoxia, metabolic stress, expression of growth factors, emission of inflammatory mediators, or after activation of the coagulation system or malignant transformation. These mechanisms are interdependent and often converge upon the regulation of the VEGF gene,² but may also involve additional (or alternative) complex networks of molecular effectors. Although angiogenic responses may be morphologically similar, they exhibit context-dependent degrees of regulatory and functional redundancy.³ The most studied in this regard is the regulation of VEGF, which is transcriptionally controlled by dimeric hypoxia-inducible factors 1 and 2 (HIFs). Normally, the HIF alpha subunit (HIF-1 α) is constitutively degraded by a pathway involving oxygen-dependent prolyl and asparaginyl hydroxylases, von Hippel-Lindau (VHL) ubiquitin ligase, and the proteasome.³³ Hypoxia blocks this process, resulting in elevated HIF activity and VEGF production by parenchymal, stromal, and inflammatory cells. Several other mechanisms of proangiogenic, hypoxic responses have also been described (e.g., NF κ B, EGR1).³³ Likewise, the exposure of cells to growth factors (EGF, FGF, HGF) and inflammatory cytokines (IL-6) may upregulate VEGF, and some of these effectors may also directly stimulate endothelial cells.² Activation of oncogenes (e.g., ras) and loss of tumor suppressors (VHL) lead to upregulation of VEGF and may also affect other angiogenic growth factors in cancer cells, even under conditions of normoxia.⁹ Oncogenic transformation also shuts down some of the angiogenic inhibitors, contributes to coagulopathy (through upregulation of tissue factor and thrombin receptors), and enhances proangiogenic cellular vesiculation (biogenesis and emission of extracellular vesicles loaded with vascular mediators). Indeed, oncogenic pathways often mimic, distort, or exacerbate the effects of hypoxia, inflammation, or microenvironmental stress.⁹

THERAPEUTIC IMPLICATIONS OF ANGIOGENESIS IN HEMATOLOGY

Vascular events associated with cancer, hemangioma, or vascular malformations have the potential to trigger hematologic consequences, either spontaneously or during therapeutic angiogenesis or antiangiogenesis. These linkages are poorly understood, but often include one or more of the following factors: (1) endothelial cell activation associated with intravascular upregulation of procoagulant tissue factor, adhesion molecules, and other mediators; (2) disruption of vascular wall continuity; (3) recruitment of inflammatory cells; (4) enhanced vascular permeability resulting in the extravasation and activation of circulating coagulation factors; (5) platelet activation; (6) contact between procoagulant cell surfaces (e.g., metastatic cancer cells) and

circulating blood; (7) flow perturbations and stasis; (8) indirect external effects (e.g., indwelling catheters or administration of chemotherapy); and (9) shedding of procoagulant, anticoagulant, or bioactive extracellular vesicles (microparticles), and soluble factors into blood.⁹ A better understanding of blood vessel-directed therapies and their capacity to modulate or exacerbate some of these events represents an emerging challenge in hematology (see Chapter 149).

Therapeutic Inhibition and Stimulation of Angiogenesis

Excessive, protracted, or aberrant activation of vascular growth may represent a correlative and/or a causative factor in several pathologies (often referred to collectively as *angiogenesis-related diseases*).¹ These include chronic inflammation, certain forms of blindness, metabolic diseases, atherosclerosis, and cancer.¹ In some of these disorders (e.g., macular degeneration, certain malignancies) antiangiogenic therapies, especially inhibitors of the VEGF pathway (Table 15.2), already represent the standard of care. Numerous clinical trials are ongoing to explore other agents and indications.²

Conversely, pathology may also arise due to insufficient angiogenesis, arteriogenesis, or regulatory/repopulating activity of bone marrow-derived cells, as is the case in the myocardium postinfarction, in limb ischemia, and in other hypovascular states, especially in the elderly. In these disorders, stimulation of vascular growth may provide a therapeutic benefit, notably through delivery of angiogenic cells (EPCs), growth factors (VEGF, FGF), or gene therapy vectors into the affected site. Several such (proangiogenic) strategies are under investigation.²

Tumor Angiogenesis and Antiangiogenesis

The disorganized signaling cues during tumor angiogenesis may produce highly abnormal, leaky, tortuous, prothrombotic, and poorly perfused vasculature (vessel “abnormalization”), which may contribute to aberrant hemostasis.² Antiangiogenic agents may cause further perturbations by selective destruction of tumor-associated endothelial cells or by inhibition of their stimulatory circuitry.¹ Several classes of antiangiogenic compounds have been evaluated to date, including derivatives of natural angiogenesis inhibitors (e.g., endostatin or tumstatin), inhibitors of proangiogenic signaling pathways (antibodies, small-molecule agents), and agents that block proangiogenic inflammatory pathways (e.g., thalidomide analogs). Anticancer drugs may also be administered in low but frequent doses (metronomic chemotherapy) to target endothelial immune and regulatory cells preferentially (Table 15.2).^{1,4,34}

Bevacizumab (Avastin), a humanized monoclonal anti-VEGF antibody, was the first antiangiogenic agent to be approved (in 2004) for cancer treatment, and the drug is now used to treat colorectal, lung, kidney, and recurrent brain tumors.^{2,34} Several tyrosine kinase inhibitors (TKIs) with anti-VEGFR or multikinase activity (sunitinib, sorafenib, pazopanib) are also in common use, as are inhibitors of oncogenic pathways that drive the production of VEGF.⁹ The latter include inhibitors of epidermal growth factor receptor (EGFR) and HER2 (cetuximab and trastuzumab, respectively), and other oncogene inhibitors.⁹ These VEGF/VEGFR antagonists are mostly used in combination with chemotherapy, which suggests that they serve as chemosensitizers or mediators of vascular normalization.^{2,4} Studies are underway to develop drugs that specifically target pathologic angiogenesis (e.g., blockers of PIFG), or established tumor blood vessels (e.g., vascular disrupting agents [VDAs]).⁴

The overall objectives of antiangiogenic therapy in cancer are at least threefold: (1) to induce tumor hypovascularity, thereby causing hypoxic damage to cancer cells; (2) to deprive cancer (stem) cells of the paracrine growth stimulation and support rendered by angiogenic endothelial cells (anti-angiocrine effect)^{3,10}; and (3) at lower doses, to induce vessel “normalization,” resulting in the improved tumor perfusion associated with increased sensitivity to chemotherapy and radiation.²

TABLE
15.2

Blood Vessel–Targeting Therapeutics

Drug	Type	Target	Stage of Development
Targeted Agents Designed to Obliterate Defined Angiogenic Pathways			
Bevacizumab (Avastin)	Neutralizing huMoAb	VEGF	Approved for human use
Ramucirumab (Cyramza)	Neutralizing huMoAb	VEGFR2	Approved for human use
Sunitinib (Sutent)	TKI	VEGFR1-3, PDGFR α/β , KIT, FLT3, RET, CSF1R	Approved for human use
Sorafenib (Nexavar)	TKI	VEGFR2-3, C-Raf, B-Raf, VEGF-C, FLT3, FGFR1, PDGF β , KIT, p38	Approved for human use
Pazopanib (Votrient)	TKI	VEGFR1-3, PDGFR α/β , KIT, FGFR1,3,4, FMS,	Approved for human use
Vandetanib (Caprelsa)	TKI	VEGFR2, EGFR, RET	Approved for human use
Axitinib (Inlyta)	TKI	VEGFR1-3, PDGFR, KIT	Approved for human use
Regorafenib (Stivarga)	TKI	VEGFR-1, -2, -3, TIE2, PDGFR, FGFR, KIT, RET, RAF, BRAF, BRAFV600E	Approved for human use
Cabozantinib (Cometriq)	TKI	VEGFR2, MET, RET	Approved for human use
VEGF-trap Ziv-aflibercept (Zaltrap)	Soluble “VEGFR-body”	VEGF-A, -B, PIGF	Approved for human use
Cilengitide	Cyclic peptide	$\alpha v\beta 3/\beta 5$ integrin	In clinical trials
Agents With Direct Antiangiogenic Activity			
Endostar	Protein fragment	Unclear	In human use (China)
ABT510	Peptide	Endothelial CD36	Investigational agent
2ME2	Sterol	HIF-1 α , tubulin	Investigational agent
TNP470 (Lodamin)	Small molecule (slow release)	Complex activity	Investigational agent
Indirect-Acting Agents Designed to Block Oncogenic Pathways Driving Angiogenesis			
Trastuzumab (Herceptin)	Neutralizing huMoAb	HER-2	Approved for human use
Cetuximab (Erbix)	Neutralizing huMoAb	EGFR	Approved for human use
Gefitinib (Iressa)	TKI	EGFR	Approved for human use
Erlotinib (Tarceva)	TKI	EGFR	Approved for human use
Lapatinib (Tykerb)	TKI	EGFR, HER-2	Approved for human use
Imatinib (Gleevec)	TKI	ABL, PDGFR β , KIT	Approved for human use
PF00299804	TKI	Irreversible pan-Erb inhibitor	In development
Tipifarnib	FTI	Ras, farnesylated proteins	In clinical development
Agents With Antiangiogenic and Non-antiangiogenic Activities			
Chemotherapy (metronomic)	Various agents (CTX, VBL, TMZ, TAX)	Stress response pathways, DNA, cytoskeleton	Under clinical exploration
Celecoxib (Celebrex)	Small molecule	COX-2	Under clinical exploration
Thalidomide and analogues (Lenalidomide)	Small molecule	Inflammatory pathways	Approved in multiple myeloma, under investigation
Antivascular Agents/Vascular-Disrupting Agents			
ASA404	Flavonoid	EC survival	Clinical trials
CA4P	Tubulin binding	Tubulin assembly	Clinical trials
AVE8062	Tubulin binding	Tubulin assembly	Clinical trials
ABT-751	Tubulin binding	Tubulin assembly	Clinical trials
OXi4503	Tubulin binding	Tubulin assembly	Early clinical trials

2ME2, 2-Methoxyestradiol; CTX, cyclophosphamide; EC, endothelial cell; EGFR, epidermal growth factor receptor; FTI, protein farnesyltransferase inhibitor; huMoAb, humanized monoclonal antibody; TAX, paclitaxel; TKI, tyrosine kinase inhibitor; TMZ, temozolomide; VBL, vinblastin; VEGFR, vascular endothelial growth factor receptor. See text and references for more details^{2,34} (<http://www.angio.org>).

Angiogenesis and Antiangiogenesis in Hematopoietic Malignancies

The vascular bone marrow stroma plays a pivotal role in leukemogenesis.⁷ Indeed, angiogenesis, increased vascular density, and increased levels of angiogenic growth factors have all been observed in the bone marrow of patients with hematopoietic malignancies.⁷ VEGF may play multiple roles in this context, including as (1) vascular growth stimulator; (2) paracrine growth factor for leukemic stem cells⁷; and (3) inducer of angiocrine interactions between these cells and the endothelium.¹⁰ Consequently, a wide spectrum of antiangiogenic agents, including VEGF antagonists (bevacizumab, sorafenib, sunitinib, cediranib), are under investigation for the treatment of hematologic disorders, such as acute myelogenous leukemia, chronic myelogenous leukemia, acute lymphoblastic leukemia, myelodysplastic syndrome, non-Hodgkin lymphoma, multiple myeloma, and others.⁷ Additional agents with antiangiogenic activity have also been explored, including bortezomib and antiinflammatory antiangiogenics (thalidomide and lenalidomide), some of which are already in human use in hematologic malignancies (e.g., in mantle cell lymphoma, multiple myeloma, and myelodysplastic syndrome; see Medinger and Mross⁷ for review, also [Chapter 55](#)).

Hematologic Complications Associated With Blood Vessel-Directed Agents

Manipulation of endothelial and mural cells in the course of pro- and antiangiogenic therapy creates the potential for side effects.³⁵ The

most extensive clinical experience is in the area of cancer, where some toxicities (e.g., hypertension, proteinuria, fatigue, hypothyroidism) have been observed in this setting, along with hematologic side effects, mainly thrombosis and/or bleeding. While cancer patients are prone to thrombosis,³⁶ antiangiogenic therapy increases the risk of venous thromboembolism or arterial thrombosis.⁶ The risk varies depending on the agent and the type of cancer, and is exacerbated by accompanying chemotherapy or hormonal therapy.³⁶ Thrombosis is of particular concern in patients with multiple myeloma who receive thalidomide derivatives in combination with anthracyclins and dexamethasone. In this case the reported risk of thrombosis may be as high as 75%.³⁶ Bevacizumab may increase the risk of arterial thrombosis up to twofold in patients with solid tumors, especially in the elderly with additional risk factors. These estimates are variable, however (0.9% to 19.4% according to different studies), and drug specific, because small-molecule tyrosine kinase inhibitors acting on VEGFR are less likely to trigger venous thromboembolism (0% to 3%; also see [Chapters 126](#) and [149](#)).³⁶

Bleeding complications were also recorded with several of these agents, ranging from minor to life threatening.³⁷ In general, however, antiangiogenic agents are relatively well tolerated, and their side effects are usually manageable with careful monitoring and standard supportive care.⁶

SUMMARY

The functional integration of the vascular system, bone marrow, and circulating blood results in a high degree of biologic interdependence in health and disease ([Fig. 15.5](#)). While this may not always be

Fig. 15.5 THE RECIPROCAL INTERDEPENDENCE OF VASCULAR, NONVASCULAR, AND BLOOD CELLS IN HOMEOSTASIS AND DISEASE. In multicellular organisms blood flow connects all constituent cells to each other and to the external environment (oxygen supply, nutrition, regulation, migration). The ubiquitous presence of blood vessels, vascular cells, circulating cells, soluble mediators, and blood components defines and integrates multiple functions of organs and tissues in health and disease. Examples of processes, disease states, and therapies that epitomize this web of relationships are described in this chapter.

clinically obvious, the existence of these subtle links necessitates a greater consideration of blood vessel-regulating processes in the pathogenesis and therapy of hematologic disorders.

CYTOKINE/RECEPTOR FAMILIES AND SIGNAL TRANSDUCTION

Montaser Shaheen and Hal E. Broxmeyer

CYTOKINE/RECEPTOR FAMILIES AND SIGNAL TRANSDUCTION

Cytokines are secreted biologically active molecules that regulate cell growth and metabolism and cellular interactions through their specific binding to defined receptors and the subsequent induction of intracellular signaling. Cytokines are classified based on the primary structural features of the extracellular domains of their receptors.¹ Most of what is known of cytokine actions and their intracellular signaling is based on the effects of purified natural or recombinant cytokines on either a factor-dependent cell line or an isolated population of primary target cells. It is however, becoming clear that cytokines can be functionally modified *in vivo* by specific enzymes, and these modifications, which are not usually taken into consideration when analyzing intracellular signaling can elicit different signaling events. Moreover, it has also recently become clear that removing cells from the body for analysis can change their metabolism and activity, and perhaps how these cells may signal in response to intact or enzyme-truncated cytokines.

Class or type I cytokines (often referred to as hematopoietins) regulate development, differentiation, and activation of hematopoietic and immune cells. Their receptors are type I membrane proteins with an N-terminal extracellular and C-terminal intracellular orientation. Type I cytokine receptors include those for colony stimulating factors (CSFs), interleukins (ILs), erythropoietin (EPO), thrombopoietin (TPO) (Fig. 16.1), and hormones such as growth hormone (GH) and leptin.

Class II cytokines consist of type I interferons (IFNs), which include 16 members that are produced by almost every nucleated cell with approximately 20% to 60% sequence identity including 12 subtypes of IFN- α , IFN- β , IFN- ϵ , IFN- κ , and IFN- ω . Type I IFNs initiate signaling by binding to the same receptor composed of two subunits called IFNAR1 and IFNAR2. Type II IFN consists of the single IFN- γ , which signals through a heterodimeric receptor composed of IFNGR1 and IFNGR2. Type III IFNs include IFN- λ 1 (IL-29), IFN- λ 2 (IL-28A), and IFN- λ 3 (IL-28B). Some place the IL-10 family of cytokines (IL-10, IL-19, IL-20, IL-22, IL-24, IL-26) within this group. Type III IFN receptor is composed of IL-10R β and IL-28R (Fig. 16.2).

The structural similarities of type I cytokines were not initially recognized. Cloning of their receptors, however, revealed significant homology in that the extracellular regions contain a common domain with four conserved cysteines (C4) in the N-terminal segment and a tryptophan-serine doublet near the C-terminal end.² Mutagenesis studies revealed an essential structural role for these amino acids in maintaining the tertiary structure of the receptor without being involved in cytokine interactions. There is a 200 amino acid region evolutionarily derived from a tandem of two ancestral fibronectin-like domains, which has been named the hematopoietin receptor domain or cytokine-binding homology region (CHR) because it mediates the interactions with cytokines. The α receptors of IL-2 and IL-15 of the γ_c family are atypical cytokine receptors in that they do not contain a CHR, but rather they contain sushi domains. Two conserved Box 1/Box 2 regions are located in the proximal intracytoplasmic segment (Fig. 16.3). By contrast, type II cytokine receptors contain two cysteine doublets (C2-C2) located in the C-terminal end of both fibronectin-derived domains. They retain Box 1/2 regions but lack the tryptophan-serine-x-serine-tryptophan motif. Both types of receptors bind ligands that display common spatial four α -helix bundle

organization and use intracellular signaling mediators of the Janus kinase (JAK) and signal transducer and activator of transcription (STAT) families. In this regard type I and II cytokine receptors represent a homogeneous structural group of proteins. However, sequence homology is observed in a limited number of cases, such as for the GH/prolactin (PRL) family and for the IL-6 family. Nonetheless, evidence of the common derivation of cytokines can be observed in the common four-helix bundle structure, in addition to the similar intron-exon relationship and the clustering observed for certain cytokine genes such as genes of the IL-4 family.³ The receptors can be composed of dimers of a single chain (granulocyte-CSF receptor (G-CSFR), EPO receptor (EPOR), TPO receptor (c-MPL), or can be heterodimeric with a common signaling subunit and a unique ligand-binding chain. These heterodimeric receptors can be grouped into families based on whether they share the common β -chain (granulocyte-macrophage [GM]-CSFR α , IL-3R α , IL-5R α), or those that share the gp130 receptor (IL-6R α , leukemia inhibitory factor (LIF) receptor β , ciliary neurotrophic factor receptor α , IL-11R α , IL-12R, IL-23R, oncostatin M receptor α , Ciliary Neurotrophic Factor R α [NTFR α]) and those that share the common γ -chain (IL-2R α , IL-2R α , IL-4R α , IL-7R α , IL-9R α , IL-13R α , IL-15R α and IL-21R α ;) (see Fig. 16.1). Cytokine binding triggers receptor homodimerization (e.g., G-CSFR⁴) or heterodimerization/oligomerization of receptor subunits (e.g., GM-CSFR) or it induces a conformational change in preformed receptor dimers (EPOR) resulting in the activation of the JAKs (Fig. 16.4). Unlike other receptors with intrinsic enzyme activity (e.g., receptor tyrosine kinases [RTK] such as Flt3 and c-Kit), most cytokine receptors are constitutively associated with kinases. These cytoplasmic kinases comprise the four members of the JAK family: JAK1, JAK2, and Tyk2, which bind to a wide range of receptors, whereas JAK3 binds to only one receptor, the common gamma chain (γ_c).⁵ This binding is mediated by interactions between the 4.1, ezrin, radixin, moesin (FERM) domain of JAK (Fig. 16.5), and the Box 1 membrane proximal intracytoplasmic region of the receptor. Upon ligand binding, JAKs come into juxtapositioning and phosphorylate themselves and their associated receptors. Mutagenesis studies have shown that there are distinct regions of individual phosphorylated receptors that transmit signals for cell survival, proliferation, differentiation, and/or activation via interaction with adaptor molecules. Phosphorylation of certain residues generates docking sites for the Src homology 2 (SH2) domains of the STATs. Once bound to the receptor/JAK complex, STATs themselves become phosphorylated, which induces a conformational change that generates active STAT dimers via reciprocal phosphotyrosine and SH2 domain interaction (see Fig. 16.4). The dimers translocate to the nucleus, where they bind to DNA sequences in the promoters of target genes to activate transcription.

Other posttranslational modifications beside tyrosine phosphorylation occur. These include acetylation, sumoylation and ubiquitylation that modulate cytokine signaling through modifying protein-protein or protein-DNA interactions and protein stability. Multiple mechanisms exist to attenuate cytokine signaling, which ensures controlled cellular responses to cytokines and prevents pathologic hyperactivation. Because the signaling is mediated by extensive phosphorylation, phosphatases have emerged as important negative regulators. Examples of these include the SH2 containing phosphatase (SHP) proteins. Other regulators have been identified including protein inhibitors of activated STAT (PIAS), suppressor of cytokine signaling (SOCS) proteins and cytokine inducible

Fig. 16.1 CLASS OR TYPE I CYTOKINES (OFTEN REFERRED TO AS HEMATOPOIETINS) REGULATE DEVELOPMENT, DIFFERENTIATION, AND ACTIVATION OF HEMATOPOIETIC AND IMMUNE CELLS. Simple depiction of type 1 cytokine receptor subfamilies. IL-3R, IL-5R, and GM-CSFR share a common βc chain that place them in one group. IL-12 family members include four cytokines. IL-12 and IL-23 share the IL12R β 1 unit, while IL-12 and IL-35 share the IL12R β 2 unit. IL-27 share the gp130 with the IL-6 family. Multiple cytokines (IL-2, IL-4, IL-7, IL-9, IL-15, IL-21) share the common $R\gamma$ chain, which is mutated in a subset of patients with SCID. IL-4R shares a subunit with IL-13R. Both IL-4 and IL-13 drives Th2 response. IL-7R shares one subunit with the thymic stromal lymphopoietin (TSLP). This sharing of receptor subunit may explain why deletion of the gene encoding IL-7R affects the lymphoid system more severely than deleting the IL-7 gene. The IL-6 family includes multiple cytokines that all have the signal transducer gp130. Deleting gp130 results in embryonic lethality. Some IL-6 family members activate more than one receptor. Oncostatin M (OSM) can work through a heterodimer receptor consisting of gp130 with OSMR β or gp130 with leukemia inhibitory factor-receptor (LIF-R). Ciliary neurotrophic factor (CNTF), cardiotrophin-like cytokine (CLC), and neuropoietin (NP) engage the receptor composed of gp130, LIFR and CNTFR. Cardiotrophin-1 (CT-1) uses a receptor composed of gp130, LIF-R and another, yet to be identified subunit. IL-27 shares gp130 with its specific receptor unit. IL-31 receptor is composed of gp130 like receptor (GPL) and OSMR β .

SH2-domain-containing proteins (CIS). We will discuss the proposed mechanisms of inhibition of these proteins in some detail later. Expression of receptors is also regulated at the level of gene transcription, protein translation, internalization, and degradation.

MODELS OF LIGAND-RECEPTOR BINDING AND ACTIVATION

Cytokines usually bind with high affinity to their cognate receptors, although low-affinity binding has been documented. The presence and the density of the receptors determine biologic responses in

hematopoietic stem and progenitor or more mature cell populations.⁶ The crystal structures of cytokines bound to the receptors have been illustrated for multiple cytokine families. For most cytokine-receptor couples, more than one cytokine molecule engages more than one receptor unit at one time to form a complex. For example, two IL-6 molecules aggregate with four receptor chains to form a hexameric and interlocking assembly mediated by a total of 10 symmetry-related, thermodynamically coupled interfaces (Fig. 16.6).⁷ The assembly of this hexameric complex occurs sequentially: IL-6 is first engaged by IL-6R α and then is presented to gp130 in the proper geometry to facilitate a cooperative transition into the high-affinity, signaling-competent hexamer. This structure also reveals that gp130

Fig. 16.2 SCHEMATIC DIAGRAMS OF IL-1, IL-17, AND TYPE II CYTOKINE FAMILY MEMBERS AND RECEPTORS. IL-1 family and receptors. The IL-1 family is associated with acute and chronic inflammation and plays an essential role in the host response to infection. IL-1 α and IL-1 β share the same receptor. IL-33 and the IL-36 subfamily share with IL-1 and the IL-1R3 receptors (*top panel*); IL-17 family and receptors. IL-17 secretion defines the Th17 cells that mediate host defensive mechanisms to various infections and that are involved in the pathogenesis of many autoimmune diseases. The five IL-17 receptors are not homologous to any known receptors and show considerable sequence divergence. They harbor extracellular domains composed of fibronectin type III domains and cytoplasmic SEF-IL-17R domains that show loose homology to toll-IL-1R domains (*middle panel*); and type II cytokine receptor family. These include receptors for IFNs and the IL-10 family (*lower panel*).

is bent such that the membrane-proximal domains of gp130 are close together at the cell surface, enabling activation of intracellular signaling. Variation in the receptor bend angles suggests a possible conformational transition from open to closed states upon ligand binding.⁸ Reconstruction of full-length JAK1 in conjunction with gp130/IL-6/IL-6R α complex reveals a three-lobed structure of JAK1 possessing extensive intersegmental flexibility that likely facilitates allosteric activation (Fig. 16.7).⁹ Single-particle imaging of the gp130/IL-6/IL-6R α /Jak1 holocomplex shows JAK1 associated with the membrane proximal intracellular regions of gp130, abutting the would-be inner leaflet of the cell membrane. JAK1 association with gp130 appears to be enhanced by the presence of a membrane environment. Mutated JAK proteins can transmit a signal independent of the receptor, but a recent line of investigation revealed that manipulating the receptor by surrogate ligands, such as diabodies to mimic dimeric receptor-ligand system, can attenuate the mutant JAK2 downstream signaling, which may have therapeutic implications.

It has been debated how the 16 human type I IFN molecules signal through the same receptors, IFNAR1 and IFNAR2, yet they can evoke different physiologic effects. Structural analysis of this family in complexes with this single receptor complex indicates that the receptor-ligand cross-reactivity is enabled by conserved receptor-ligand “anchor points” interspersed among ligand-specific interactions that “tune” the relative IFN-binding affinities, in an apparent extracellular “ligand proofreading” mechanism that modulates biologic activity.¹⁰ This differential binding leads to variable conformational change in the receptor complex resulting in different STAT phosphorylation profiles, receptor internalization rates, and downstream gene expression patterns.

Signaling networks are typically measured in either their basal (minimum) or hyperstimulated (maximum) states, but there is a cytokine signal “dynamic range,” in which the responsiveness of cell outcomes to incremental changes in signal activation is more important for biologic outcome than signal strength per se.¹¹

Fig. 16.3 CYTOKINE RECEPTOR SUPERFAMILY. The general structure of cytokine receptor superfamily. In the extracellular cytokine receptor module, four conserved cysteine residues exist and are involved in disulfide bonds. A WSXWS (Tre, Ser, any, Tre, Ser) motif that is essential for receptor processing, ligand binding, and activation of the receptor is also located in the extracellular domain. In the intracellular portion, two short domains termed *Box 1* and *Box 2* are important for JAK binding. Tyrosine residues are present on the intracellular part to be phosphorylated upon receptor activation.

Janus Kinases

JAK proteins are tyrosine kinases of approximately 1000 amino acids. They have clear nonredundant *in vivo* functions defined by analysis of gene deletion in mice, and mutations of JAK3 or Tyk2 in humans that lead to primary immunodeficiency syndromes (severe combined immunodeficiency [SCID] and autosomal-recessive hyperimmunoglobulin E syndrome [AR-HIES], respectively).⁵ In addition, somatic mutations of JAKs are seen in human neoplastic conditions. The following is a brief description of JAK functions in cytokine signaling. Fig. 16.5A depicts the general structure of the JAK proteins.

JAK1

JAK1 is widely expressed and associates with the IFN receptors and receptors that use gp130 or the γ_c . JAK1^{-/-} mice have grossly normal nonlymphoid organogenesis¹²; however, they die perinatally of a poorly characterized defect that may be neurologic. It is believed that this morbid phenotype is caused by the failure of cytokine signaling that promotes neuronal cell survival via gp130. Defective cytokine signaling is observed with class II cytokine receptors (IFNs), IL-2, IL-6, and IL-7 families. JAK1^{-/-} mice manifest a SCID phenotype, consistent with the fact that JAK1 binds to the ligand-specific receptor subunit of γ_c . Somatic JAK1 activating mutations have been described in occasional cases of acute leukemia and solid tumors.

JAK2

JAK2 is widely expressed and is involved in signaling by single chain hormone receptors, the common β chain family, and certain members of the class II receptor cytokine family. JAK2 deficiency is lethal at day 12.5 caused by failure of erythropoiesis,¹³ which explains the lack of reports of individuals with germline loss-of-function JAK2 mutations. Receptor stimulation by EPO induces tyrosine phosphorylation of JAK2, which is required for EPO function. Defective responses of cells from JAK2^{-/-} mice also reveal its essential role in the signaling of IL-3, GM-CSF, IL-5, TPO, and IFN- γ , but not IL-6 and IFN- α/β .¹⁴ Transfer of JAK2^{-/-} fetal liver cells into irradiated JAK3^{-/-} recipients resulted in normal thymic subsets, arguing that JAK2 is not essential for T cell development. Multiple groups have identified acquired activating mutations in JAK2 as the etiology for virtually all cases of polycythemia vera, and in a significant percentage of cases of essential thrombocythemia and primary myelofibrosis. JAK2 mutations have also been described in other hematopoietic neoplasms. JAK2 inhibitors have shown efficacy at least in decreasing spleen size and constitutional symptoms in patients with myeloproliferative neoplasms irrespective of whether they harbor a JAK2 mutation.

JAK3

In contrast to the ubiquitous expression of the other JAKs, JAK3 is predominantly expressed in hematopoietic tissues. JAK3 selectively associates with only the γ_c , which is a component of multiple cytokine receptors. Accordingly, mutation of γ_c or JAK3 results in a SCID disorder in man, characterized by a lack of T and NK cells, with preservation of B cells, hence the designation T^{B+} NK⁻ SCID. Mice homozygous for JAK3 null mutation show severe defects in lymphoid cells. B cell precursors in bone marrow, thymocytes, and both T and B cells are drastically decreased,¹⁵ although these defects can improve as aging occurs.¹⁶ Peripheral lymph nodes, NK cells, dendritic epidermal T cells, and intestinal intraepithelial gamma delta T cells are absent in these mice. Normal numbers of bone marrow hematopoietic progenitor cells with a similar capability to generate myeloid and erythroid colonies as wild-type mice indicates specific defects in lymphoid progenitor cells. Thymus progenitors are severely deficient. This phenotype is attributable to failure of IL-7 and IL-2 signaling, which explains the T-cell deficiency while the absence of natural killer cell development has been attributed to the impairment in IL-15 signaling. There is an increased apoptotic rate in the lymphocytes generated in these mice, and this is consistent with the identified function of JAK3 in regulating Bcl-2 and Bax.

Activation of JAK3 because of gain-of-function mutations is found in human hematologic malignancies, including acute megakaryoblastic leukemia and cutaneous T-cell lymphoma.

Given the essential role of JAK3 in cytokine signaling through γ_c and given its limited tissue expression, inhibition of JAK3 activity has emerged as a promising strategy for immunosuppression in autoimmune disorders and immune rejection.

Tyk2

Tyk2 was the first JAK family member identified that plays a role in cytokine signaling. Tyk2 was discovered as an essential component in a screen for mutants in IFN- α signaling.¹⁷ Type I IFN receptors require Tyk2 and JAK1, while IFN- γ signaling depends on the combination of Tyk2 and JAK2. The combination of Tyk2 with JAK2 is not only required for IFN- γ signaling but also for the differentiation of IFN- γ -producing Th1 cells from naive Th cells. Lymphocyte development and proliferation are not affected in Tyk2-deficient mice, but signaling by cytokines that are important for host defense is impaired. The IL-12 receptor (IL-12R) is associated with Tyk2 and JAK2 and activates mainly the transcription factor STAT4. IL-12 signaling is markedly impaired in the absence of Tyk2, and

Fig. 16.4 CYTOKINE RECEPTOR SIGNALING. A general depiction of signal transduction by cytokine receptor superfamily. Ligand binding leads to dimerization or oligomerization of the receptor, which brings into proximity the associated JAKs, which phosphorylate tyrosine residues on the receptor and JAKs. This phosphorylation creates docking sites for proteins containing SH2 domains such as STATs. The latter heterodimerize or homodimerize and translocate to the nucleus where they affect transcription of target genes. Several mechanisms exist to reverse this cytokine-activated state. STATs trigger a negative feedback loop by inducing transcription of suppressors of cytokine signaling (SOCSs). There are eight SOCS members. SOCS1 interacts directly with JAK1 and inhibits its catalytic activity. CIS (another SOCS) binds the receptor and blocks binding and phosphorylating of STATs. SOCS3 binds the receptor before inhibiting JAK. SOCS proteins contain SOCS box that leads to proteosomal degradation of the SOCS associated molecules. SHP-1 is a tyrosine phosphatase that negatively regulates the cytokine transduction process by dephosphorylating JAKs and the cytokine receptors. CD45 is a transmembrane phosphatase that inactivates JAKs. PIAS family members interact with STAT dimers and inhibit their functions as described in the main text.

downstream activation of STAT3 and STAT4 is clearly reduced, resulting in the inability of IFN- γ production by T cells. Both STAT3 and STAT1 activation by type I and type II IFNs are reduced in Tyk2-deficient mice, although at high concentrations IFN- α can fully transduce its signal in the absence of Tyk2. IL-10 signaling is essentially normal. Because of all the above, Tyk2-deficient mice are susceptible to viral and bacterial infections.¹⁸ This susceptibility can be explained not only by impaired Th1 lineage development, but also

impaired Th17 differentiation. Since IL-4 is essential in generating Th2 cells, and since its signaling is independent of Tyk2, there is no disruption of Th2 in Tyk2-deficient mice. Th2 cell differentiation can however be inhibited by Tyk2-mediated signals occurring in response to IL-12 or IFNs. As anticipated, Th2-induced diseases such as allergic bronchitis are enhanced in the background of Tyk2 deficiency. One example is a mouse asthma model where pronounced lung inflammation is observed because of an enhanced Th2 response

Fig. 16.5 GENERAL STRUCTURE OF JAK AND STAT PROTEINS. (A) JAK protein consists of 4.1, ezrin, radixin, moesin (FERM) domain (which modulates the kinase activity), SH2 domain for phosphotyrosine binding, pseudokinase (which can exert inhibitory function), and kinase domain. (B) STAT protein consists of a N-terminus domain, coiled-coil domain for protein interaction, DNA binding domain (DBD), linker domain, SH2 domain, a conserved tyrosine, and trans-activation domain (TAD), which binds transcription regulators.

Fig. 16.6 IL-6 COMPLEX STRUCTURE. (A) The complex is a hexamer consisting of IL-6, the IL-6 α -receptor (IL-6R α), and the shared signaling receptor gp130. (B) 3.65 angstrom-resolution shows a hexameric, interlocking assembly mediated by a total of 10 symmetry-related, thermodynamically coupled interfaces. (C) Assembly of the hexameric complex occurs sequentially: IL-6 is first engaged by IL-6R α and then presented to gp130 to activate the downstream signaling. (Reproduced with permission from Boulanger MJ et al: Hexameric structure and assembly of the interleukin-6/IL-6 α -receptor/gp130 complex. *Science* 300:2101–2104, 2003.)

The orientations of the reconstructions in the left column represent the particles face-on, while the orientations to the right are rotated 90 degrees, reflecting the flatness of the surface on which JAK1 is lying. It is uncertain whether the open or the closed conformation what represents the active state. FERM, 4.1, ezrin, radixin, moesin; SH2, Src homology 2. (Reproduced with permission from Lupardus PJ et al: Structural snapshots of full-length Jak1, a transmembrane gp130/IL-6/IL-6R α cytokine receptor complex, and the receptor-Jak1 holocomplex. Structure 19:45–55, 2011.)

associated with an increase of IL-4 production, increased immunoglobulin E (IgE) levels, and recruitment of eosinophils.

Signal Transducers and Activators of Transcription

There are seven STAT family members that share similar structure, but mediate distinct biologic functions.¹⁸ Fig. 16.5B shows the general structure of the STATs. STAT1, for example, harbors an N-terminal domain, followed by α -helical coiled-coil and DNA-binding domains and a linker that connects to the C terminus. The C terminus contains an SH2 domain, followed by a short region containing a tyrosine residue, which is critical for the activation by JAK-mediated phosphorylation, and a transactivation domain that is the most divergent region within the STAT family. STAT proteins can be tyrosine phosphorylated by receptor-associated JAKs, by growth factor RTK, or by non-RTK. Latent STATs diffuse freely in the cytoplasm. Upon STAT phosphorylation and dimerization with a partner, the dimer quickly translocates to the nucleus (Fig. 16.8). This is achieved through an active process mediated by the nuclear transport machinery. For example, phosphorylated STAT1 transport is facilitated by the importin- α 5/importin- β 1 heterodimer.¹⁹ This nuclear movement culminates in DNA binding and transcriptional

activity. For example, IFN- γ binding to its receptor leads to tyrosine phosphorylation of STAT1. The STAT1 dimer was originally called the IFN- γ activated factor. It recognizes a DNA sequence termed the IFN- γ activated sequence, which contains an inverted repeat of GAAA residues spaced by two to four nucleotides. Later, we briefly discuss the biologic activities of STAT proteins largely inferred from gene targeting experiments.

STAT1

STAT1 mediates IFN signaling. STAT1-deficient mice do not have significant developmental abnormalities, but display a complete lack of responsiveness to either IFN- α or IFN- γ and are highly sensitive to infection by microbial pathogens and viruses.²⁰ The induction of IFN-inducible genes is disrupted. A missense mutation of *Stat1* was initially identified in a patient suffering from atypical mycobacterial infections, similar to individuals with mutations of IFNGR subunits. However, this *Stat1* mutation was not associated with susceptibility to viral infections. Since then, other families have been described with mutations in STAT1 that lead to viral and mycobacterial infections. Families with muco-cutaneous candidiasis with STAT1 mutations have been reported.²¹ These families have defective Th1 and Th17

Fig. 16.8 DEMONSTRATION OF STAT PROTEIN LOCATION IN RESPONSE TO CYTOKINE SIGNALING. U3A cells expressing STAT1–GFP were untreated (A) or treated (B) with IFN- γ for 30 minutes. One can observe the migration of STAT1 from the cytoplasm to the nucleus. (Reproduced with permission from McBride KM et al: Nuclear export signal located within the DNA-binding domain of the STAT1 transcription factor. EMBO J 19:6196–6206, 2000.)

responses. Not all IFN-dependent signaling is regulated by STAT1 since, as there is a large number of STAT1-independent genes that are induced by IFN- γ , which may explain the observations that STAT1^{−/−} mice are less susceptible to infection than mice lacking both IFN- γ and IFN- α/β receptors. Other, less pronounced defects have been described in STAT1-deficient mice such as a subtle decrease in bone marrow erythroid progenitors. STAT1 regulates other cytokine/growth factor signaling. One example is its role in the inhibitory activity of fibroblast growth factor on chondrocytes mediated by transcriptional activation of cell cycle inhibitors. Another example of IFN-independent activity of STAT1 is the more severe impairment of natural killer cells caused by STAT1 deficiency than observed with deficiencies of both IFN- γ and IFN- α/β receptors.

Because IFNs have antineoplastic activities, a role for STAT1 in tumor suppression has been suspected, and indeed, STAT1-deficient mice have a higher incidence of tumor formation in response to chemical carcinogens and also on a background of P53 deletion. However, given the involvement of STAT1 in other cellular pathways such as myc regulation and apoptosis, it cannot be concluded with certainty that this tumor-promoting phenotype is completely caused by the lack of immune surveillance.

STAT2

The main function of STAT2 is to mediate IFN- α/β signaling. STAT2 is constitutively associated with a non-STAT protein, IFN regulatory factor 9 (IRF-9). Tyrosine phosphorylated STAT1-STAT2-IRF-9 multimeric complex is called the IFN stimulated gene factor 3. This complex binds to a specific DNA sequence in type I IFN induced genes called the IFN stimulated response element. Because of the impaired IFN- α/β responsiveness, STAT2 knockout mice are susceptible to viral infections.²² As it is the case with STAT1-deficient mice, STAT2-deficient mice are viable and develop normally. The absence of STAT2 results in reduced tyrosine phosphorylation and activation of STAT1 because of the fact that STAT2 facilitates recruitment and activation of STAT1 by the IFN- α/β receptor complex.

STAT3

STAT3 mediates signaling from multiple cytokines. It was originally cloned as an acute-phase response factor, activated by IL-6. Murine embryos deficient in STAT3 die at postcoital day 7.5. One potential

explanation for this early embryonic death is failure of extraembryonic trophoblast development caused by impaired LIF signaling. Cell line specific conditional STAT3 deletions have been reported for multiple lineages with no major developmental abnormalities.²³ However, mouse hematopoietic-cell targeted STAT3 deletion leads to defects in hematopoietic stem and progenitor cells that are associated with dysfunction in mitochondria, overproduction of reactive oxygen species, and a rapid aging process.²⁴ STAT3-deficient T cells and hepatocytes have poor responses to IL-6. Deletion of STAT3 in macrophages results in constitutively activated cells and increased sensitivity to lipopolysaccharide. This is attributed to the role for STAT3 in the antiinflammatory responses induced by IL-10. CD4⁺ T cells can differentiate into the Th17 cells whose development and function are critically dependent on STAT3. These cells produce the inflammatory cytokine IL-17, and they are responsible for recruitment and activation of neutrophils and other inflammatory cells. Th17 cells can be generated from naive CD4⁺ T cells by IL-6 and TGF- β but can also produce another cytokine IL-21, which promotes IL-17 production in an autocrine-paracrine manner. Another cytokine, IL-23, also acts to expand and maintain Th17 cells. The importance of IL-23 signaling in inflammation is exemplified by recent discoveries that polymorphisms in *IL23R* are associated with increased risk of inflammatory bowel disease, ankylosing spondylitis, and psoriasis. IL-6, IL-21, and IL-23 all activate STAT3 by binding to their cognate receptors. The importance of STAT3 in Th17 cell development and function is appreciated in patients with Job syndrome, an autosomal-dominant disorder caused by STAT3 mutations, who fail to make Th17 cells (Chapter 21).

STAT3 deficiency in multiple types of T cells results in decreased IL-21 production, which is required for hematopoietic progenitor proliferation. STAT3 promotes optimal Th2 cell differentiation and cytokine production in the presence of activated STAT6.

Selective targeting of the STAT3b isoform has been reported and such mice exhibit diminished recovery from endotoxemic shock. STAT3 deletions in other cell lineages have been described. For example, Stat3 deletion in mammary glands results in a delay in involution after weaning, arising from a decrease in apoptosis. STAT3-deficient epidermal cells show defective wound healing and in vitro migration of epidermal cells.

STAT3 is activated in multiple tumor types. This activation enhances tumor cell survival mediated by multiple mechanisms including enhanced levels of prosurvival genes (e.g., *Bcl-2* and *Bcl-X_L*). STAT3 is also frequently activated in cells that are transformed by a variety of oncogenes (e.g., *v-src* and *BCR-abl*). The

enforced expression of a constitutively active STAT3 homodimer is sufficient to transform immortalized fibroblasts. STAT3 inhibitors are in early clinical trials for advanced malignancies.

STAT4

STAT4 is predominantly activated in response to IL-12, which drives T-helper cell differentiation towards the Th1 and Th17 pathways. The phenotype of STAT4-deficient mice is very similar to that of mice lacking IL-12. IL-12 promotes differentiation of naive CD4⁺ T cells to Th1 cells, which produce IFN- γ and augment cell-mediated immune responses. Th1 cells are critical in host defense against intracellular pathogens and tumors and in the pathogenesis of autoimmune diseases. Thus the phenotype of STAT4-deficient mice includes impaired Th1 differentiation, IFN- γ production, and cell-mediated immunity.²⁵ IL-12-, IL-12 receptor-, and STAT4-deficient mice have increased susceptibility to infection with intracellular organisms. STAT4-deficient mice are resistant to autoimmune diseases characterized by a Th1 response. A common haplotype of *STAT4* gene has been shown to be associated with susceptibility to rheumatoid arthritis, systemic lupus erythematosus, and primary Sjögren syndrome.²⁶ In acute sepsis, STAT4 deficiency is associated with improved survival, whereas STAT4^{-/-} mice had *increased* lethality in a noninfectious sepsis model. It appears that STAT4 may have either proinflammatory or antiinflammatory effects, depending upon context.

STAT4 is also activated by IL-23. In addition, in humans, but not in mice, IFN- α/β induces STAT4 phosphorylation. This is notable because IFN- α/β can promote Th1 differentiation in humans and not in mice. This has been attributed to STAT4/STAT2 dimer being recruited to the human type I IFN receptor via the carboxy terminus of STAT2. STAT4 also mediates IFN- γ production by dendritic cells and macrophages induced by IL-12, which may explain the mechanisms by which dendritic cells (DC) promote Th1 differentiation.

STAT6

STAT6 is primarily activated by IL-4 and IL-13. STAT6-deficient mice lack most of the physiologic functions associated with IL-4, in particular the ability of IL-4 to induce the *in vitro* differentiation of Th2 cells.²⁵ STAT6 is critically involved in several distinct aspects of allergic inflammatory disease, like airway hyperresponsiveness, eosinophilic infiltration, and responses of mast cells. B cells of STAT6-deficient mice cannot undergo class switching to produce IgE against helminthes and allergens. As expected, STAT6^{-/-} mice have impaired expulsion of helminthic parasites and reduced pathology in models of asthma. STAT6^{-/-} mice have increased lethality, inflammation, and cytokine production in a noninfection induced model of endotoxemia, but reduced lethality and enhanced clearance of bacteria in an infection model.

STAT6 induces expression of GATA3, which is considered the Th2 cell master regulator. Transgenic mice expressing IL-4 or constitutively active STAT6 are characterized by the development of spontaneous allergic inflammation. Certain chemokines such as CCL11, CCL17, CCL22, and CCL26 have been reported to be regulated in a STAT6-dependent manner and are involved in allergic disorders. Although a number of pathways, including the mitogen-activated protein kinase and the phosphoinositide-3-kinase pathways, are involved in signal transduction because of IL-4, IL-4-induced T cell differentiation appears to occur almost exclusively via STAT6. IL-4 also antagonizes Th1 responses through STAT6. In fact, residual STAT4-independent Th1 differentiation becomes apparent in doubly deficient STAT4/STAT6 knockout mice. A study of murine mast cells demonstrated IL-15-inducible STAT6 phosphorylation, involving Tyk2, although IL-15 was less potent than IL-4.²⁷

Functional deletion of STAT4 or STAT6 led to the determination that Th1 cells regulate hematopoietic progenitor cell homeostasis mediated by the production of oncostatin M.²⁸

STAT5

The genes encoding STAT5A and STAT5B are juxtaposed, and the transcriptional start sites are within 10 kb of each other. Although *Stat5a* and *Stat5b* gene promoters might share certain regulatory elements, lineage specific expressions have been reported. The highly related STAT5 proteins (A and B) are activated in response to a variety of cytokines and tyrosine kinase receptors. Mice lacking STAT5A,²⁹ STAT5B,³⁰ or STAT5A/B,³¹ display distinct phenotypes suggesting discrete functions for these proteins. STAT5A deficiency results in the loss of PRL-dependent mammary gland development, which is necessary for lactation. STAT5B-deficient mice are sexually dimorphic with growth retardation. In contrast, a good portion of STAT5A/B double knockout mice die within a few weeks of birth, are infertile with defective corpus luteum development, and have defective mammary gland development. Both male and female STAT5A/B-deficient mice are small with smaller fat pads and reduced levels of insulin-like growth factor-1 (IGF-1). STAT5A/B double knockout mice have hypocellular bone marrows, lymphopenia, neutrophilia, and modest anemia and thrombocytopenia. Moreover, the hematopoietic progenitors of STAT5A/B-deficient have defective bone marrow repopulating potential. Myeloid development is grossly normal in STAT5A/B knockout mice, but *in vitro* cytokine dependent proliferation, survival, and migration of myeloid cells are impaired. With respect to T- and B-cell development, complete deletion of the STAT5A/B locus results in severely impaired lymphoid development and differentiation with abrogated T-cell receptor γ rearrangement and survival of peripheral CD8⁺ T. In other words, complete STAT5 deficiency results in SCID, similar in lymphoid phenotype to deficiencies of IL-7R, γ_c , and JAK3. Deficiency of both STAT5A and STAT5B results in loss of CD4⁺ regulatory T (Treg) cells that express the transcription factor Foxp3, whereas constitutive activation of STAT5B enforces Foxp3-positive Treg cell development, bypassing the requirements for upstream cytokine or costimulatory signals to activate Foxp3 transcription. STAT5 deficiency abrogates transformation by Tel-JAK but not by v-Abl or BCR-abl. Mutations in the *Stat5b* gene has been documented in a few patients with severe growth retardation. Loss of functional STAT5B is associated with severe IGF-1 deficiency, indicating that this pathway is responsible for most of the GH-induced IGF-1 production.

Negative Regulators of Cytokine Signaling

Whereas the JAK-STAT pathway activation is important for homeostasis, its inactivation prevents excessive responses to cytokine stimulation. In addition to protein tyrosine phosphatases (PTPs), other factors are involved in downregulating this pathway as discussed later.

Src-Homology 2 Containing Phosphatase 1 (PTPN6)

The expression of SHP-1, a cytoplasmic phosphotyrosine phosphatase is limited to the hematopoietic system. SHP-1 was identified as the protein encoded by the mutated locus (*Hcph*) in the *moth-eaten* (*me*) mice.³² These mice that are characterized by reduced SHP-1 display severe immunologic dysfunction; enhanced proliferation of macrophages and neutrophils in the lungs, which leads to pneumonitis; and patchy dermatitis that results in the “moth-eaten” phenotype. SHP-1 associates with cytokine receptors and dephosphorylates JAK kinases. For example, it downregulates EPO-induced signaling by binding to the EPOR and dephosphorylating JAK2 associated with it. SHP-1 also dephosphorylates JAK1, because IFN- α -induced phosphorylation of JAK1 is enhanced in SHP-1-deficient macrophages. SHP-1 also interacts with JAK3. This interaction may explain the activation of JAK3/STAT3 pathway in some cases of ALK (+) anaplastic large cell lymphoma where SHP-1 appears to be suppressed by promoter methylation. The expression of an inactive SHP-1 in the cytokine-dependent cell line Ba/F3 increased the proliferative

response to IL-3, STAT5 phosphorylation, and cell survival following IL-3 withdrawal.

Consistent with the negative role of SHP-1 on the JAK/STAT pathway, silencing of SHP-1 by promoter methylation is often associated with various kinds of leukemia and lymphomas, myeloma, and acute myeloid leukemia. On the other hand, in a limited number of cases, SHP-1 has been described to have a positive role in promoting JAK/STAT signaling. For example, epidermal growth factor- and IFN- γ -induced STAT activation was suppressed by expressing a catalytically inactive form of SHP-1 in HeLa cells, while this pathway was essentially unaffected by the expression of wild-type SHP-1. There is no known molecular explanation for this observation.

Src-Homology 2 Containing Phosphatase 2 (PTPN11)

SHP-2 is a protein-tyrosine phosphatase that is widely expressed, with high levels of expression in hematopoietic cells. It contains two tandem SH2 domains (N-SH2 and C-SH2), a PTP domain and a C-terminal tail. SHP-2 has low basal enzymatic activity caused by autoinhibition of the PTP domain by the N-SH2 domain. SHP-2 directly or indirectly (via adaptor proteins) associates with activated receptor protein tyrosine kinases or cytokine receptors via its two SH2 domains. Binding of SH2 domains to phosphotyrosine sites of these receptors alters the conformation of the N-SH2 domain, releasing its binding to PTP domain and causing catalytic activation.³² Despite being a phosphatase, SHP-2 promotes activation of the Ras and ERK pathway by cytokines. Its catalytic activity is required for cytokine activation of phosphatidylinositol 3-kinase pathway. SHP-2 plays an essential role in hematopoietic cell development. Embryonic lethality is observed at day 8.5 in mice with a truncated version of SHP-2 because of severe defects in gastrulation and mesodermal patterning. Complete loss of SHP-2 causes embryonic death in the periimplantation period and SHP-2 is required for trophoblast stem cell survival. HSCs from SHP-2 haploinsufficient mice display a competitive repopulating defect. Embryonic stem (ES) cells lacking SHP-2 exhibit severely decreased differentiation to erythroid and myeloid lineages in chimeric mice derived from SHP-2^{-/-} ES cells and wild-type embryos. SHP-2 loss-of-function causes an early block of lymphocyte development before Pro-T and Pro-B stages. The exact mechanisms by which SHP-2 regulates cytokine signaling and hematopoiesis are uncertain. SHP-2 both enhances and inhibits the JAK/STAT pathway depending on the context. It functions as a negative regulator of the IFN-stimulated JAK1/STAT pathway and it dephosphorylates STAT1 and STAT5. At the same time SHP-2 is required for optimal JAK2 activation.

Activating germline mutations of *PTPN11* (the gene encoding for SHP-2 protein) are seen in patients with Noonan syndrome while loss-of-function mutations are seen in patients with LEOPARD syndrome. Both are congenital disorders associated with abnormal hematopoiesis. Somatic activating mutations are seen in approximately 35% of patients with juvenile myelomonocytic leukemia. *PTPN11* mutations are also seen in patients with myelodysplastic syndrome, acute lymphoblastic leukemia, and acute myelogenous leukemia. These gain-of-function mutations induce hyperactivation of the Ras pathway, which results in growth factor and cytokine independent proliferation and survival of hematopoietic progenitor cells (HPCs). Increased SHP-2 expression has also been observed in acute leukemia cells, suggesting a potential role in leukemogenesis.

CD45, PTP1B, TC-PTP, PTPRT, and PTP-BL

CD45 is a receptor-like tyrosine phosphatase highly expressed by hematopoietic cells. CD45 was identified as a JAK family phosphatase. CD45 is able to dephosphorylate all JAKs in murine cells, and dephosphorylate JAK1 and JAK3 in human cells. Targeted disruption of the CD45 gene leads to enhanced cytokine and IFN-receptor-mediated

activation of JAKs and STAT proteins. The removal of CD45 also increases erythroid colony formation and antiviral activity, which is consistent with the fact that CD45 negatively regulates EPO and IFN signaling. Inactivating mutations occur in patients with T-cell acute lymphoblastic leukemia. The Src family kinase members Lck and Lyn are key substrates for CD45 in T and B lymphocytes, respectively. CD45 positively regulates T cell receptor-mediated signaling through the activation of Src-family kinases.

PTP1B (PTP1B or PTPN1) and T-cell PTP (TC-PTP or PTPN2) are closely related PTP, sharing 74% homology in their catalytic domain. PTP1B is expressed in many tissues and TC-PTP is ubiquitously expressed with particularly high expression in hematopoietic tissues. PTP1B is involved in multiple signaling pathways by down-regulating several tyrosine kinases. For example, PTP1B-deficient mice display increased insulin sensitivity. Increased phosphorylation of JAK2, Tyk2, STAT3, and STAT5 has been observed in PTP1B-deficient embryonic fibroblasts. TC-PTP targets multiple STAT and JAK proteins in addition to growth factor receptors for dephosphorylation. TC-PTP-deficient mice develop anemia, lymphadenopathy and splenomegaly and die at early age. These mice display excessive inflammation and demonstrate increased numbers of bone marrow, HSCs and HPCs. Other phosphatases such as PTP-receptor type T (PTPRT) and PTP-Basophil like (PTP-BL) and the adapter protein LNK have also been implicated in cytokine signaling. LNK mutations have been reported in patients with myeloproliferative neoplasms including essential thrombocythemia and primary myelofibrosis (Chapters 69 and 70).

Protein Inhibitors of Activated STAT

PIAS3 was the first family member to be identified as a repressor of STAT3 activity.³³ Three additional family members PIAS1, PIASy (or PIAS4), and PIASx (or PIAS2) were later identified with high sequence homology. Other proteins with weak homology (hZIMP7 and hZIMP10) have been reported. PIAS1 was identified as a STAT1-interacting protein and subsequently found to inhibit STAT1-mediated transcriptional activation. The PIAS family members PIASx and PIASy were identified based on sequence similarity to PIAS1 and have been shown to inhibit STAT1 and STAT4, respectively. PIAS proteins have been shown to affect the function of many different proteins, with particular effects on gene transcription.

PIAS proteins contain a domain known as SP-RING (Fig. 16.9) with structural similarity to ubiquitin E3 ligase RING fingers. PIAS binds the protein modifier SUMO (small ubiquitin-like modifier) and recruits the E2 SUMO ligase UBC9, which transfers SUMO to target proteins, particularly to transcription factors such as STATs. PIAS1, PIAS3, and PIASx sumoylate STAT1 at Lys-703, close to the site at which it is phosphorylated by JAKs (Tyr-701). A mutation of Lys-703 results in an increased response to IFN- γ .

Thus the binding of PIAS to STAT results in the inhibition of STAT-mediated gene activation. PIAS1 and PIAS3 inhibit STAT DNA binding activity, while PIASy and PIASx repress STAT1 and STAT4-mediated gene activation without affecting DNA binding. PIAS proteins also act by recruiting other corepressor molecules. One example is the inhibition of natural regulatory T-cell differentiation by PIAS1 through chromatin-based epigenetic repression. Sumoylation may affect nuclear localization of proteins as is the case for the transcriptional factor LEF1, where LEF1 sumoylation by PIASy results in its sequestration into nuclear bodies hindering its transcriptional activity. Given its impact on STAT1 and IFN signaling, PIAS1 has a tangible role in innate immunity. The antiviral activity of IFNs is significantly increased in PIAS^{-/-} cells. In addition, PIAS^{-/-} mice have increased protection against bacterial and viral infection.

Suppressor of Cytokine Signaling

The SOCS family consists of eight proteins that antagonize the signaling of STAT proteins. STATs activate the transcription of genes

Fig. 16.9 THE GENERAL STRUCTURE OF A SOCS AND A PIAS PROTEIN. (A) SOCS protein has a central SH2 domain, an amino-terminal domain of variable length and divergent sequence that contains a kinase inhibitory region (KIR), and a carboxy-terminal 40-amino-acid SOCS box. (B) PIAS protein contains a SAP (SAFA/B, ACINUS, PIAS) domain that is present in other chromatin associated proteins. PIAS proteins that are SUMO E3 ligases contain a conserved SP-RING domain that shares sequence similarity to RING domains of ubiquitin E3 ligases. This domain recruits the SUMO E2 ligase (UBC9).

encoding the SOCS family as a negative feedback regulation.³⁴ For example, expression of SOCS3 is activated by several transcription factors, including STAT1, STAT3, and mitogen-activated protein kinase p38, while expression of SOCS1 is dependent on the production of IFN regulatory factor-1, a STAT1-inducible transcription factor. Each SOCS has two major domains, an SH2 domain and a SOCS box that mediates a complex formation with elongins B and C, a cullin, and Rbx2, to form an E3 ubiquitin ligase (see Fig. 16.9). SOCS proteins function in a negative feedback loop to inhibit cytokine signaling by binding to either phospho-JAK or phospho-receptor through SH2 domain, and thus competing with the STAT proteins or directly inhibiting JAK activity, and also by targeting the receptor complex for ubiquitylation and subsequent proteasome-mediated degradation. Gene targeting studies have delineated the distinct *in vivo* functions of SOCS proteins. For example, SOCS1^{-/-} mice die as neonates from an inflammatory disease caused by dysregulated IFN signaling, and which presents as lymphopenia, infiltration of macrophages, and T cells into the liver and other organs, and fatty degeneration of the liver.³⁵ SOCS3 deletion results in an embryonic lethality at 10 to 16 days because of a defect in placental formation likely from excess LIF1 signaling associated with marked erythrocytosis.³⁶ In addition, the *in vitro* proliferative capacity of high proliferative progenitor cells is greatly increased.

CYTOKINE-RECEPTOR INTRACELLULAR SIGNALING IN THE CONTEXT OF *IN VIVO*

Physiology/Pathology

Targeted gene deletions of JAKS, STATS, and other intracellular signaling molecules have highlighted the embryonic and hematopoietic requirements of these signaling molecules (Table 16.1). However, most information on intracellular signaling is achieved *ex vivo* using full-length cytokines in either natural or recombinant forms. However, *in vivo* these cells are not isolated, but rather are present in an environment with many other cell types, containing numerous other molecules including enzymes that have the capability of modifying the structure, and potentially also the functional capacity of these cytokines and other growth factors.^{37,38} One example

TABLE 16.1 Consequence of Deficiencies in Genes of Intracellular Signaling Molecules

Signal Transduction Molecule	Phenotype of Deficient Mice
JAK1	Perinatal mortality, defects in IL-6, IL-2, and cytokine receptor type II families
JAK2	Embryonic lethality caused by defective definitive hematopoiesis. Defects in TPO, IL-2 family, IL-3 and IFN- γ signaling
JAK3	Immunodeficiency because of absent common γ chain signaling. JAK3 expression is restricted to the hematopoietic system
Tyk2	Reduced responses to IFN- α/β , IL-12, and unexpectedly IFN- γ
STAT1	Complete lack of responsiveness to either IFN- α/β or IFN- γ and high sensitivity to infections by viruses and other microbial pathogens. Normal response to other cytokines such as growth hormone (GH), IL-10, and epidermal growth factor
STAT2	Lack of responsiveness to IFN- α/β ; susceptibility to viral infections
STAT3	Early embryonic lethality before gastrulation STAT3 $\pm$ mice demonstrate decreased HSC/HPCs
STAT4	Defective Th1 response caused by defective IL-12 signaling
STAT5a	Defective mammary gland development and lactogenesis; GM-CSF and follicular lymphoma signaling is impaired but no gross hematopoietic abnormalities
STAT5B	Disrupted sexual dimorphism of body growth rates. Defective GH signaling
STAT5A/B	Anemic embryos of the double knock-outs with apoptotic erythroid progenitors because of impaired EPO signaling. Adult mouse erythrocyte red blood cell number is normal. Loss of GH and prolactin signaling. Infertile females. Severe impairment of IL-2 induced T-cell responses
STAT6	Defective Th2 response with eliminated IL-4 signaling
SHP-1	Natural mutation in <i>moth-eaten</i> mice results in hair loss, immunodeficiency, autoimmune disorders, enhanced SDF-1 chemotactic activities, enhanced hematopoietic progenitor proliferation in response to cytokines such as GM-CSF
CD45	Enhanced cytokine and IFN-receptor-mediated activation of JAKs and STATS
SOCS1	Neonatal lethality probably because of excessive IFN- γ responses, with hematopoietic infiltration of multiple organs, lymphopenia, and fatty liver degeneration
SOCS2	Gigantism caused by GH and/or IFG-1 excessive signaling
SOCS3	Embryonic lethality with placental defect likely because of LIF1 excess signaling Erythrocytosis in embryos

This table outlines the phenotypes of mice deficient in the major signaling molecules that directly interact with the cytokine receptors. The phenotypes range from significant embryonic lethality because of hematopoietic impairment to less remarkable defects in other organ systems. Please refer to the main text for more details on the functions of these molecules. GM-CSF, Granulocyte-macrophage colony-stimulating factor; HPC, hematopoietic progenitor cell; HSC, hematopoietic stem cell; JAK, Janus-activated kinase; LIF, leukemia inhibitory factor; STAT, signal transducer and activator of transcription.

of such an enzyme modifying effect is that of dipeptidylpeptidase 4 (DPP4). This enzyme has the capability to truncate amongst a plethora of growth factors: GM-CSF, G-CSF, IL-3, EPO, and TPO. The DPP4-truncated GM-CSF manifest less or no activity, yet is able to compete by increased receptor-binding capacity to block the functional activity of the full-length GM-CSF. A similar effect is noted for DPP4-truncated IL-3, and DPP4 truncated-GM-CSF and -IL-3 can reciprocally block the stimulating activity of each other through common receptor-mediated events.³⁹ Moreover, the full-length and DPP4 truncated-GM-CSF and -IL-3 each trigger qualitatively, in addition to quantitatively, different intracellular signaling events in terms of proteins, phosphorylated proteins, and microRNAs produced. There is a large and clearly not yet comprehensive list of biologically active molecules with putative DPP4 truncation sites,^{37,38} and the signaling events elicited by these truncated molecules should be taken into account in terms of the effects of different cytokines on normal and abnormal cell growth.

To add another layer of complexity to the emerging knowledge of cytokine induced receptor-mediated intracellular signaling is the state of the cell itself. It is now becoming clear that once a cell is removed from its in vivo hypoxic environment to that of ambient air, which is defined here as normoxic (~21% O₂), a phenomenon termed extraphysiologic oxygen shock/stress (EPHOSS) is initiated and changes the metabolism of hematopoietic stem and progenitor cells, and likely other cell types through an axis encompassing the mitochondrial permeability transition pore-cyclophilin D-p53, which also involves hypoxia inducing factor-1 α and the hypoxamir microRNA 210.^{40,41} Thus the intracellular signaling that one detects by assessing the effects of a cytokine on a cell collected and processed under ambient-air (normoxia) may not exactly mimic how that cytokine might signal in a cell in its in vivo hypoxic environment. Those differences in cascades in signaling molecules may manifest differently under physiologic and pathologic conditions. Ambient air induced EPHOSS, as compared with the in vivo hypoxic environment, results in differences in hematopoietic stem and progenitor numbers and activity. Cyclophilin D-/- and p53-/- have EPHOSS protective effects, while hypoxia inducing factor 1 α -/- and microRNA 210-/- abrogate the protective effects achieved by the harvesting and processing cells under hypoxic conditions.⁴⁰

How cytokine-receptor signaling is influenced by enzyme truncated cytokines/growth factors, such as seen with DPP4 truncated proteins,³⁷⁻³⁹ and consideration of the in vivo hypoxic condition cells are usually bathed in will have to be assessed for more detailed and potentially greater physiologic and pathologic understanding of intracellular signaling and its modification for clinical advantage.^{40,41} Also, how multiple cytokines signal together under these conditions and with that of synthesized small molecules currently being used for ex vivo expansion of hematopoietic stem cells should be considered.^{42,43} It may be that such evaluations will be critical for the development of more efficacious treatments for cancer and related hematologic disorders.

CONTROL OF CELL DIVISION

Martin Fischer, Chi V. Dang, and James A. DeCaprio

THE CELL DIVISION CYCLE

The mammalian cell cycle is divided into four phases: mitosis (M), DNA synthesis (S), and the gap phases G_1 and G_2 (Fig. 17.1). Mitosis is recognized when cells visibly undergo cell division and chromatin becomes condensed, sequentially progressing through prophase, metaphase, anaphase, and telophase. The G_1 phase occurs immediately after mitosis has been completed and ends when DNA synthesis begins. During S phase, cells duplicate their entire genome by DNA replication. G_2 occurs after DNA synthesis has been completed and before chromosomal condensation in mitosis. Although the duration of the S, G_2 , and M phases is relatively constant for most mammalian cells, there can be a large degree of variability in the duration of G_1 . Among the earliest observations regarding the generation time for cells, it was shown that by varying the growth conditions, the length of a cell division cycle could change, with the length of G_1 responsible for most of this variability. Although cells progress through S, G_2 , and M phases in relatively invariable time periods, the length of the G_1 phase is highly variable, and this variability is dependent at least in part on the presence of growth factors.

Quiescence and Differentiation

Quiescence (G_0) is a nonproliferative state in which viable cells have left the cell cycle and may remain for prolonged periods. Quiescent cells may be difficult to distinguish morphologically from cells in a prolonged G_1 phase, but they can be distinguished by different markers. Terminally differentiated cells, such as neutrophilic granulocytes, muscle cells, and neurons, have irreversibly exited the cell cycle during the process of differentiation and are examples of cells that have irreversibly entered G_0 . Other cells, including stem cells, reversibly enter G_0 and may be induced to reenter the cell cycle with appropriate stimuli, such as growth factors. Differentiation provides the organism with a supply of cells to execute specific and specialized functions. In some cell types, such as muscle and nerve cells, differentiation and proliferation are mutually exclusive fates, and cells undergo “terminal differentiation.” In other cell types, such as those of the hematopoietic lineage, proliferation may continue after cells acquire differentiated characteristics. For example, erythroblasts, myeloblasts, and megakaryoblasts are committed to particular differentiation pathways and possess lineage-specific markers yet continue to proliferate. T and B lymphocytes are fully differentiated and express antigen-specific receptors but can be induced to proliferate when appropriately stimulated.

G_1 Phase

G_1 , which occupies the period or gap between M and S phases, is the interval between the completion of one round of cell division and initiation of the next. Its duration is the most variable, can be prolonged depending on the cell type, and is subject to regulation by environmental factors such as the availability of growth factors and nutrients. It is the period of cell growth, and as a first approximation, the amount of time a cell spends in G_1 is inversely related to its rate of proliferation. A certain increase in mass usually is required before the cell initiates the next S phase. When conditions are unsuitable for proliferation (e.g., because of insufficient nutrients or absence of

mitogens), cells arrest in G_1 , and those that are already in S, G_2 , or M phase usually complete the round to which they have been committed and arrest only when they reach G_1 again. For example, when the 40S ribosomal protein S6 is missing, cells stop proliferation. If cell size or mass were not regulated, S phase entry might cause cells to become progressively smaller or be at risk for DNA replication errors as a result of insufficient substrates. Cell size regulation is intimately linked to ribosome biogenesis and nutrient-sensing systems, central to which are the phosphoinositide 3-kinase (PI3K) and target of rapamycin (TOR) pathways. Notably, when the MYC transcription factor is missing, cells slow their growth and often do not enter S phase. MYC regulates *cyclin* and *cyclin-dependent kinase* (CDK) genes as well as genes involved in ribosome biogenesis and translation.¹ In aggregate, studies of a variety of cell systems indicate that cell size regulation is linked to cell proliferation, except in specialized cells that undergo endoreplication or in embryos shortly after fertilization, when G_1 is virtually undetectable, and there is no cell enlargement. As a result, the original mass of egg cytoplasm is partitioned among thousands of cells within a few hours without a noticeable increase in size.

S Phase

S phase is the period of wholesale DNA synthesis during which the cell replicates its genetic content; a normal diploid somatic cell with a 2N complement of DNA at the beginning of S phase acquires a 4N complement of DNA at its end. (Recall that N = 1 copy of each chromosome per cell [haploid]; 2N = 2 copies [diploid].) The duration of S phase may vary from only a few minutes in rapidly dividing, early embryo cells to a few hours in most somatic cells. Early embryo cells generally “live off” the accumulated stores of maternal RNA and proteins present in the egg and are transcriptionally silent, whereas cells in later development and mature organisms must actively transcribe subsets of their genes to survive and maintain specialized functions. The longer time required for the latter to complete S phase probably allows these cells to coordinate DNA replication with transcription and to preserve higher-order gene and chromatin structural information that influences gene expression for transmission to progeny cells.

G_2 Phase

G_2 is the period or gap between S and M phases when cells have finished replicating their DNA, are preparing to divide, and have a 4N DNA content. For most cells entering S phase, passage through G_2 is “automatic,” and the duration of G_2 is fixed, except under unusual circumstances. For example, G_2 duration can be extremely short and is essentially undetectable in rapidly proliferating, early embryonic cells.

M Phase

Mitosis, or M phase, is the period of actual nuclear and cell division during which the duplicated chromosomes are divided equally between two progeny cells. It is obvious microscopically as the period of chromosome condensation and segregation, nuclear division

Fig. 17.1 THE CELL DIVISION CYCLE. The mammalian cell cycle is divided into four phases that include mitosis (M), DNA synthesis (S), and the gap phases G_1 and G_2 . Mitosis is subdivided into prophase, metaphase, anaphase, and telophase. Quiescence (G_0) is a nonproliferative state in which viable cells have left the cell cycle and may remain for prolonged periods. A particularly important point in G_1 is the restriction point, or R, which occurs near the G_1 -S boundary. After the cell passes the G_1 /S restriction point, it is committed to cell cycle progression.

(karyokinesis), and physical separation of the two daughter cells (cytokinesis). A cell entering M phase has a $4N$ DNA content and finishes as two cells, each with an identical $2N$ complement of DNA. The complex sequence of changes that take place allows mitosis to be subdivided into prophase, prometaphase, metaphase, anaphase, and telophase. *Prophase* is the period of chromatin/chromosome condensation, centrosome separation/migration to opposite poles, and nuclear membrane breakdown. The centrosomes are microtubule organization centers that eventually give rise to the bipole mitotic spindle apparatus that will separate the sister chromatids of each duplicated chromosome. During *prometaphase*, chromosomes attach to microtubules of the mitotic spindle, so that sister chromatids become attached to opposite poles. In *metaphase*, the condensed chromosomes align at the equatorial plate. The cohesive “bond” between sister chromatids of duplicated chromosomes is dissolved, allowing *anaphase*, the period of sister chromatid separation, to proceed. On reaching their poles, nuclear membranes form to envelop each of the two separated sets of chromosomes, which also begin to decondense, marking *telophase* and karyokinesis. This is soon followed by cytokinesis and exit from mitosis. Following mitosis, cells reenter G_1 , and for approximately 3 hours they are capable of leaving the cell cycle into quiescence when growth factors and nutrients are missing. Once past this point, cells are no longer sensitive to mitogen withdrawal and can commit to another round of cell division.

SIGNALING

To decide whether to proliferate, cells scan their environment with the help of cell surface receptors such as receptor tyrosine kinases (RTKs) that bind extracellular ligands and activate signaling pathways. RTKs become activated by ligand-stabilized dimerization that allows autophosphorylation. The intracellular phosphotyrosine residues are recognized by SH2 (Src homology 2) or PTB (phosphotyrosine-binding) protein domains, leading to the recruitment of signaling effectors and formation of signaling complexes. In turn, these complexes permit activation of signaling pathways, such as RAS–mitogen-activated protein kinase (MAPK), PI3K, and phospholipase $C\gamma$

Fig. 17.2 SIGNALING PATHWAYS, SUCH AS THE RAS–MITOGEN-ACTIVATED PROTEIN KINASE (MAPK) PATHWAY, CONTROL CELL CYCLE ENTRY. Cells scan their environment with the help of cell surface receptors such as receptor tyrosine kinases (RTKs). When RTKs become activated by ligand-stabilized dimerization, they can induce signaling pathways. The RAS–MAPK signaling pathway plays a particularly important role in proliferation. RAS GTPases are activated by many receptors, such as T-cell receptors (TCRs), B-cell receptors (BCRs), and colony-stimulating factor 1 receptor (CSF-1R), and recruit MAPK complexes. These complexes are formed by scaffolds, such as kinase suppressor of RAS (KSR), binding to the three-tier MAPK module that comprises RAF, mitogen-activated protein kinase kinase (MEK), and extracellular signal-regulated kinase (ERK). When activated by RAS (H-RAS, K-RAS, N-RAS), the MAPKKK RAF (RAF-1, A-RAF, B-RAF) phosphorylates the MAPKK MEK (MEK1, MEK2), which in turn phosphorylates the MAPK ERK (ERK1, ERK2). Activated ERK kinases phosphorylate the transcription factors MYC and activator protein 1 (JUN/FOS), leading to transcription activation of cyclin D1, CDK4, and CDK6. Monophosphorylation of retinoblastoma protein (RB) by cyclin D-CDK4/6 is required for cells to leave quiescence and enter the cell cycle.

(PLC γ). Together, these signaling pathways stimulate cell proliferation (Fig. 17.2).

T-Cell Receptor

Activation of T cells occurs upon ligation of the T-cell receptor (TCR) by major histocompatibility complex molecules in antigen-presenting cells.² The TCR and its coreceptors CD4 and CD8 have no intrinsic enzymatic activity. Instead, the associated non-RTK LCK binds to cytoplasmic domains of TCR coreceptors CD4 and CD8, and their activation leads to phosphorylation of immunoreceptor tyrosine-based activation motifs (ITAMs) in CD3. Phosphorylated CD3 recruits the tyrosine kinase ZAP70, leading to a cascade of phosphorylation events that in turn activates LAT (linker for activation of T cells) complexes. The LAT signalosome triggers the release of intracellular Ca^{2+} and production of diacylglycerol (DAG). The latter activates RAS–MAPK and protein kinase C (PKC)–nuclear factor κB (NF κB) signaling pathways.

B-Cell Receptor

Every normal B cell has a unique B-cell receptor (BCR) consisting of pairs of immunoglobulin heavy (IgH) and light (IgL) chains. Each IgH and IgL has a unique variable region that allows the BCR to recognize and bind to diverse antigens, both soluble and on the surface of antigen-presenting cells. Antigen-induced aggregation of BCR leads to phosphorylation of ITAMs by the Src family tyrosine kinase LYN. This phosphorylation event initiates the assembly of intracellular signaling molecules, including SYK, PLC γ 2, Bruton tyrosine kinase (BTK), VAV, and the adaptor B-cell linker (BLNK). The BCR coreceptor CD19 is also phosphorylated by LYN, leading to the recruitment of PI3K, BTK, and AKT.⁵ Together, this signaling leads to the release of intracellular Ca²⁺ and production of DAG, and ultimately leads to activation of RAS-MAPK and PKC-NF κ B signaling pathways.

Macrophage Colony-Stimulating Factor Receptor

The known ligands of macrophage colony-stimulating factor 1 receptor (CSF-1R) are CSF-1 and interleukin (IL)-34.⁴ CSF-1 was the first hemopoietic growth factor to be isolated, and it can promote the growth of pure colonies of macrophages from bone marrow progenitors. CSF-1R is an RTK that belongs to the platelet-derived growth factor family. Binding of CSF-1 or IL-34 to CSF-1R leads to dimerization of CSF-1R, which allows autophosphorylation. Numerous proteins, such as GRB2, SOS, SFK, CBL, and p85, are recruited to the intracellular domain phosphotyrosines, leading to the activation of the PI3K-AKT and RAS-MAPK pathways, among others.

RAS Pathway to Cyclin D

The RAS-MAPK pathway is evolutionarily conserved and controls many fundamental processes, including cell proliferation. RAS GTPases are activated by many receptors, such as TCR, BCR, and CSF-1R, and recruit MAPK complexes. These complexes are formed by scaffolds, such as KSR (kinase suppressor of RAS), binding to the three-tier MAPK module that comprises RAF, mitogen-activated protein kinase (MEK), and extracellular signal-regulated kinase (ERK). When activated by RAS (H-RAS, K-RAS, N-RAS), the MAPKKK RAF (RAF-1, A-RAF, B-RAF) phosphorylates the MAPKK MEK (MEK1, MEK2), which in turn phosphorylates the MAPK ERK (ERK1, ERK2). The principal function of RAS in cell cycle induction is to inactivate retinoblastoma protein (RB), relieving cells from its growth-inhibitory actions.⁵ The RAS-MAPK signaling pathway is required to induce complexes of cyclin D1 and CDK4/CDK6. Activated ERK kinases phosphorylate the transcription factors MYC and activator protein 1, leading to transcription activation of cyclin D1, CDK4, and CDK6. Notably, PI3K-AKT and PKC-NF κ B pathways cooperate with RAS-MAPK in activating cyclin D1. Monophosphorylation of RB by cyclin D-CDK4/6 is required for cells to leave quiescence and enter the cell cycle. Given the important functions of RAS-MAPK signaling in cell proliferation, it is not surprising that cancer hijacks this pathway: K-RAS, N-RAS, and B-RAF are frequently mutated in cancer, leading to constant activation of the RAS-MAPK pathway.

CYCLINS AND CDKS

The 2001 Nobel Prize in Physiology or Medicine was awarded for discoveries concerning the control of the cell cycle: Leland Hartwell, Tim Hunt, and Paul Nurse discovered CDKs and cyclins that regulate the cell cycle. Identification and subsequent functional analysis of the factors and cofactors involved in mammalian cell cycle regulation have led to the current view that progression through the cell division cycle is driven by CDKs. CDKs are serine/threonine protein kinases that play an essential role in promoting the cell division cycle.⁶ There

are many cyclins and CDKs, but only a limited number directly contribute to promoting cell cycle entry and progression (Fig. 17.3). Typically, the cyclin component binding to the CDK activates the kinase activity. Additionally, the cyclin component provides specificity to the substrate. During G₁ phase, cyclin D (cyclin D1, D2, or D3) binds to either CDK4 or CDK6. The principal targets of cyclin D-CDK4/6 are RB and the RB-related protein p130, which become monophosphorylated by cyclin D-CDK4/6.⁷ Unphosphorylated and monophosphorylated RB can bind to the activating E2F (E2F1-E2F3) transcription factors and block E2F-dependent gene expression. In accordance with the important functions of cyclin D-CDK4/6 complexes in leaving quiescence and entering the cell cycle, they are frequently found overexpressed or mutated in some cancers. At the G₁-to S-phase transition, E-type cyclins (E1 and E2) bind to and activate CDK2, which promotes multiple phosphorylation (hyperphosphorylation) of RB and dissociation of RB from E2F. Consequently, E2F-dependent gene expression is enabled, leading to the expression of genes that encode for proteins required for DNA replication. Cyclin A binds to CDK2 at the end of S phase and promotes entry into mitosis. CDK2 bound to cyclin E and cyclin A can phosphorylate multiple targets that contribute to DNA replication and cell cycle progression during S and G₂ phases. Finally, cyclin B (B1 and B2) associates with CDK1 (CDC2) and contributes to phosphorylation of many cellular proteins, driving cells through mitosis.

Control of cyclin-CDK activity occurs at many levels. First is the appearance and disappearance of different cyclins at specific phases of the cell cycle, which dictates the cyclin-CDK complexes that can form in each phase. Regulation at this level is a result of highly regulated synthesis and degradation of cyclin messenger RNA (mRNA) and protein at different points in the cell cycle. A second level of regulation is afforded by posttranslational modification of CDK kinases, which is often necessary to activate their function. Cyclin B-CDK1 complexes, for example, are initially inhibited by WEE1 kinase and are activated by CDC25C phosphatase when cells enter mitosis. A third level of regulation is provided by proteins that inhibit the activity of CDK kinases or cyclin-CDK complexes (see later).

Additional kinases and substrates that contribute to cell cycle progression include DDK (Dbf4-dependent kinase), PLK (polo-like kinase), and Aurora kinases. The DDK CDC7, together with cyclin E-CDK2, coordinates the initiation of DNA replication. The polo-like kinase PLK1 activates, among others, CDC25C and deactivates WEE1, leading to active cyclin B-CDK1 complexes that drive mitosis, and PLK4 regulates centriole biogenesis during mitosis. Aurora kinases coordinate mitotic progression through phosphorylation of multiple proteins that function in chromosome segregation and cytokinesis.

CDK INHIBITORS

Sharp control of CDK activity is achieved by two major classes of small polypeptide CDK inhibitors: the INK4 family (inhibitors of CDK4) comprising p16 (INK4A), p15 (INK4B), p18 (INK4C), and p19 (INK4D); and the CIP/KIP (CDK-interacting protein/kinase inhibitor protein) family that comprises p21 (CDKN1A), p27 (CDKN1B), and p57 (CDKN1C).⁸ All members of the INK4 family specifically bind to CDK4 and CDK6, inhibiting their kinase activity by competing with their association with cyclin D. In contrast, CDK inhibitors of the CIP/KIP family bind to cyclin-CDK complexes and disturb their activities.

The first inhibitor to be identified and cloned in mammalian cells was p21 (CIP1, CDKN1A), which binds several different cyclin-CDK complexes. The proteins p27 (Kip1) and p57 (Kip2) were subsequently identified as CDK inhibitors with structural and functional similarities to p21. The regulation of p21 expression sheds light on its function⁹: Expression is transcriptionally induced by p53, the tumor suppressor protein activated by DNA damage, and induction of p21 expression provides a mechanism for halting cell proliferation after DNA damage to allow time for damage assessment and repair.

Fig. 17.3 A MULTILAYERED NETWORK CONTROLS THE CELL CYCLE. Many proteins that carry out important functions during the cell cycle are encoded by genes that display a periodic expression pattern during the cell cycle. In G_0 and early G_1 , dimerization partner, RB-like, E2F, and multivulval class B (DREAM) and retinoblastoma protein (RB) complexes repress the expression of cell cycle genes. In late G_1 and S phases, RB releases the activating E2F transcription factors that upregulate G_1/S cell cycle genes encoding for important proteins in the process of DNA replication. When S phase is completed, E2F7 and E2F8 will replace E2F1–E2F3 and serve to repress the expression of the G_1/S genes. In G_2 and mitosis, B-MYB and FOXM1 transcription factors bind to the MuvB core and promote the expression of G_2/M genes that encode important proteins for cell division. These transcription factors, as well as many other important cell cycle effectors, are controlled through phosphorylation by cyclin–cyclin-dependent kinase (CDK) complexes. Cyclin D–CDK4/6 complexes promote cell cycle entry and progression through G_1 phase. Cyclin E–CDK2 complexes stimulate S-phase entry and progression, and cyclin A–CDK2 complexes facilitate S-phase completion. Cyclin A–CDK1 complexes promote G_2 phase progression and cyclin B–CDK1 complexes regulate mitosis. These proteins are targets of an additional layer of cell cycle control that mediates their proteasomal degradation. anaphase-promoting complex/cyclosome (APC/C)^{CDH1} becomes activated in anaphase and promotes exit from mitosis, and ensures proper G_1 -phase progression. Skp, Cullin, F-box-containing complex SCF^{SKP2} functions in late G_1 and early S phase, whereas SCF^{βTRCP} and SCF^{FBXW7} are active throughout S phase. SCF^{cyclin F} stimulates mitosis entry, and APC/C^{CDC20} promotes progression through mitosis. Importantly, SCE, APC/C, and cyclin-CDK complexes also regulate each other, and all these complexes contain effector proteins that are transcriptionally regulated by RB-E2F and MuvB complexes. This multilayered network ensures precise control of the cell cycle.

The p21 protein also can be expressed in cells lacking functional p53, indicating that p53-independent pathways of expression exist. These other pathways may account for increased p21 expression in other circumstances associated with cell cycle arrest, such as senescence and terminal differentiation. p21 inhibits cell cycle progression primarily through the inhibition of CDK2 activity: RB pocket proteins lose

their hyperphosphorylated state, leading to the formation of RB-E2F and DREAM (dimerization partner, RB-like, E2F, and multivulval class B) complexes and downregulation of cell cycle genes. Interestingly, p21 promotes the formation of cyclin D–CDK4/6 complexes, and the resulting RB monophosphorylation is required for RB function in the DNA damage response program.⁷ Inversely, cyclin

D-CDK4/6 can sequester p21, preventing inactivation of CDK2-containing complexes.

In marked contrast with the transcriptional regulation of p21, regulation of p27 (KIP1, CDKN1B) occurs posttranscriptionally, such that mRNA levels remain largely constant, whereas levels of the protein change. p27 protein levels are maximal during quiescence and early G₁, and p27 protein binds and inhibits cyclin E–CDK2 complexes. The progressive decrease in p27 protein levels during G₁ allows for activation of cyclin E–CDK2 complexes that are required for the transition into S phase. Notably, to the end of G₁ phase, active cyclin E–CDK2 complexes phosphorylate p27, causing its ubiquitin-mediated degradation and leading to a dramatic decline in p27 protein levels. In accordance with the ability of p21 and p27 to inhibit cyclin-CDK activity and cell cycling, *p21* and *p27* are candidate tumor suppressor genes, but silencing or loss of these genes is very uncommon in cancers. Unlike its ubiquitous siblings, p57 has a tissue-specific expression pattern during embryogenesis, and in the adult, and it is the only CDK inhibitor required for embryonic development.

Striking diversity in the pattern of expression of *INK4* genes suggests that this family of CDK inhibitors might have cell type-specific or tissue-specific functions. The two founding members, p16 and p15, were cloned as tumor suppressor genes, and the p18 and p19 proteins were subsequently cloned on the basis of homology to p16 and p15. *INK4* CDK inhibitors block CDK4 and CDK6, and as RB family proteins are prime targets of cyclin D–CDK4/6 kinase; phosphorylation of these proteins is crucial for G₁ progression, and inhibitors of the *INK4* family induce cell cycle arrest in G₁. Evidence that *INK4* proteins inhibit cell proliferation by preventing phosphorylation of RB pocket proteins is provided by the observation that p16 overexpression inhibits proliferation only of cells containing functional RB pocket proteins. p16 and p15 CDK inhibitors are inactivated by mutations in various cancers, providing evidence for their function as tumor suppressors. Importantly, p16 and p15 are neighboring genes on chromosome 9, and *CDKN2A*, the gene encoding for p16, also encodes for ARF using an alternative reading frame that produces a totally different protein. This overlap means that inactivating mutations affect p16 and ARF function. Because ARF is a positive regulator of p53 expression and a tumor suppressor protein in its own right, attribution of a tumor suppressor effect to each of these two genes is difficult. An interesting aspect of p16 expression

is its upregulation in aging tissues and in response to oncogene activation. For example, in response to continuously high RAS or E2F activity, *CDKN2A* is transcriptionally induced, leading to cell cycle arrest and senescence.

TRANSCRIPTIONAL REGULATION: MYC, RB-E2F, DREAM, AND MMB-FOXM1

Cell cycle entry and progression require specific genes to be expressed at certain times. When cell proliferation is triggered by growth conditions and cells leave quiescence, mitogen signaling leads to the activation of the MYC transcription factor.¹⁰ MYC has the capability to drive cell proliferation because it activates cyclin D and CDK4/6, and it also plays an important role in cell growth because it upregulates ribosomal RNA and proteins, leading to increased ribosome biogenesis and translation. Indeed, experiments showed that when MYC is missing, cell growth and proliferation slow down and cells arrest primarily in G₁ phase. MYC activity ensures that cells reach a certain size before entering S phase and progressing through the cell cycle.

The two main cell cycle events—DNA synthesis and mitosis—take place after the cell passes the G₁/S restriction point and is committed to cell cycle progression. Entry into S phase requires the expression of genes required for DNA replication. These genes are distinct from the ones required for entry into mitosis. In general, there are two major waves of gene expression, one occurring just before entry into S phase and a second wave occurring just before entry into mitosis (Fig. 17.3 and 17.4). The periodic expression of mRNA produces the specific protein factors required for DNA replication and cell division. Once S phase is completed and cells have passed through mitosis, many of these protein factors are ubiquitinated and degraded by the proteasome, thereby ensuring one-way progression through S and M phases of the cell cycle.

Proliferating cells require the expression of specialized genes for synthesis of DNA during S phase and for cell division during mitosis. These cell cycle-dependent genes are not typically required for the survival of quiescent cells. The expression of more than 1000 cell cycle-dependent genes is nearly absent during quiescence in G₀ cells. For the most part, expression of these cell cycle-dependent genes is repressed by the DREAM complex. The DREAM complex is a multisubunit protein complex that binds to promoters of cell

Fig. 17.4 TRANSCRIPTION CONTROL OF G₁/S AND G₂/M CELL CYCLE GENES. There are two major waves of gene expression, one occurring just before entry into S phase and a second wave just before entry into mitosis. The dimerization partner, RB-like, E2F, and multivulval class B (DREAM) complex represses both early and late cell cycle gene expression during quiescence (magenta line). Retinoblastoma protein (RB) binds to the activating E2F transcription factors (E2F1–E2F3) and blocks E2F-mediated activation of S-phase genes. In late G₁ phase and S phase, the activating E2Fs dimerize with dimerization partner 1 (DP1) or DP2, bind to the promoters of genes required for DNA synthesis through E2F promoter elements, and promote their expression. During late S phase, E2F7 and E2F8 will replace E2F1–E2F3 and serve to repress the expression of the G₁/S genes when DNA synthesis is completed. The B-MYB transcription factor binds to the MuvB core when p130, E2F4, and DP are released from the DREAM complex. The B-MYB–MuvB (MMB) complex recruits FOXM1 to promote the expression of genes in late G₂ phase and M phase.

cycle-regulated genes and contributes to their repression.¹¹ The DREAM complex is comprised of the RB-like protein p130 (RBL2), E2F4 or E2F5, DP1 or DP2, and the 5-component MuvB complex containing LIN9, LIN37, LIN52, LIN54, and RBBP4. Whereas the DREAM complex contributes to the expression of both S phase- and M phase-specific genes, the RB protein specifically represses S phase-specific genes.¹² RB binds to the activating E2F transcription factors (E2F1–E2F3) and blocks E2F-mediated activation of S-phase genes. S- and M-phase genes possess distinct promoter elements that mediate binding of RB–E2F and DREAM complexes. E2F promoter elements can be found in S-phase genes and specifically mediate binding of E2F transcription factors. In contrast, M-phase genes possess cell cycle genes homology region (CHR) promoter elements that specifically mediate binding of the MuvB complex.

When a quiescent cell is stimulated to enter the cell cycle, it begins to express cyclin D that binds to CDK4 or CDK6 and is capable of monophosphorylating RB. In late G₁ phase, Cyclin E–CDK2 complexes multiphosphorylate the monophosphorylated RB, leading to the release of the activating E2F transcription factors.⁷ The activating E2Fs dimerize with DP1 or DP2, bind to the promoters of genes required for DNA synthesis through E2F promoter elements, and promote their expression during late G₁ phase and S phase. These G₁/S genes encode many of the factors required for DNA replication. During late S phase, E2F7 and E2F8, which are E2F targets themselves, will replace E2F1–E2F3 and serve to repress the expression of the G₁/S phase genes when DNA synthesis is completed.¹³

Cyclin D–CDK4/6 and cyclin E–CDK2 are also capable of phosphorylating p130, thereby enabling the release of p130 from the DREAM complex. The B-MYB (MYBL2) transcription factor is encoded by a G₁/S gene and binds to the MuvB core when p130, E2F4, and DP are released from the DREAM complex.¹¹ The newly formed MMB (B-MYB–MuvB) complex does not contain any E2F transcription factor and thus binds exclusively to genes that possess CHR promoter elements. These genes are highly expressed in late G₂ phase and M phase, and encode for proteins that carry out essential functions in mitosis. The MMB complex recruits FOXM1, a third transcription factor, to promote the expression of these G₂/M genes. Notably, *FOXM1* is a G₂/M gene itself, and together with the important role of FOXM1 in promoting the expression of G₂/M genes, *FOXM1* has emerged as one of the most robust biomarkers for stratifying high-risk and low-risk cancers.¹⁴ The B-MYB and FOXM1 factors are ubiquitinated and destroyed by the proteasome during late mitosis, resulting in decrease in expression of the G₂/M genes when a cell exits mitosis. Therefore the DREAM complex represses all cell cycle genes during quiescence, with the G₁/S cell cycle genes being activated by E2F1–E2F3 and the G₂/M late cell cycle genes being activated by B-MYB–MuvB–FOXM1.

Together, proliferation signals will enable MYC-dependent gene expression that contributes to the growth in size of the cell, whereas the E2F and B-MYB/FOXM1-dependent gene expression induces genes required for DNA replication during S phase and cell division during mitosis.

UBIQUITINATION

Cells employ a variety of mechanisms to control the cell division cycle, ensuring one-way progression through S and M phases of the cell cycle. Cell cycle genes are cell cycle-dependently expressed at certain times, and cyclin-CDK complexes drive the cell cycle through the control of the cell cycle transcription machinery and regulation of critical events in S and M phases. The mRNA of many cyclins and CDKs is also cell cycle-dependently regulated, and in addition, cyclin-CDK activity is regulated by CDK inhibitors. Yet, cells employ an additional layer of cell cycle control through the timed destruction of essential cell cycle proteins, including cyclins, CDKs, and cell cycle transcription factors (Fig. 17.3). Two ubiquitin ligases, the Skp, Cullin, F-box-containing complex (SCF) and the anaphase-promoting complex/cyclosome (APC/C), are responsible for the specific ubiquitination of many of these cell cycle proteins.¹⁵

The SCF complex consists of the three invariable components RBX1, CUL1, and SKP1. RBX1 is a RING finger protein that functions as an E3 ubiquitin ligase, CUL1 is a scaffold protein, and SKP1 is an adaptor protein. In addition to the three invariable components, one variable coactivator, known as an F-box protein, binds through its F-box motif to SKP1 and is responsible for substrate recognition. Approximately 70 putative F-box proteins have been identified in humans, and at least 4 of them are thought to be involved in cell cycle control: SKP2, FBXW7, β -transducin repeats-containing proteins (β -TRCP), and cyclin F. The SCF complex mediates degradation of cell cycle proteins during the progression from late G₁ phase through S phase until the onset of mitosis. Important substrates include cyclin D and cyclin E; the transcriptional regulators MYC, E2F1, and p130; the CDK inhibitors p27 and p21; and WEE1 kinase. WEE1 kinase deactivates cyclin B–CDK1 complexes. Degradation of these important cell cycle regulators allows for proper S-phase entry and completion, and onset of mitosis.

The APC/C complex consists of several invariable components, and the central ones are structurally similar to the SCF complex components. APC11 is a RING-finger protein related to RBX1, and APC2 is a scaffold protein related to CUL1. Similar to the SCF complex, APC/C contains a variable coactivator that confers substrate specificity. Two of such variable coactivators function in the cell cycle: CDC20 and CDH1. APC/C^{CDC20} mediates the degradation of substrates during mitosis, whereas APC/C^{CDH1} functions primarily in G₁ phase. Key substrates of APC/C^{CDC20} are cyclin A and cyclin B. With the onset of anaphase, activation of APC/C^{CDH1} leads to the degradation of CDC20, PLK1, and Aurora kinases.

Similar to the other cell cycle control systems, SCF and APC/C are controlled within the cell cycle, in part by their own substrates. Most important, SCF and APC/C can regulate each other. The cell cycle protein FBXO5 (EMI1) functions as an inhibitor of APC/C^{CDC20} and is sent to proteasomal degradation by SCF ^{β -TRCP} when mitosis starts, and SCF^{Cyclin F} mediates degradation of CDH1. Similarly, ubiquitination of CDC20 and cyclin F by APC/C^{CDH1} leads to their destruction when cells exit mitosis. Further regulation occurs on the transcriptional level because substrate-specific components of SCF and APC/C are encoded by cell cycle-regulated genes, including *SKP2*, *FBXO5*, *Cyclin F*, and *CDC20*.

DNA REPLICATION

The initiation of DNA replication represents a commitment to cell proliferation, and is a central event in the growth and division of all organisms.¹⁶ The assembly of replication machineries is coordinated by multiple proteins, which ensure that DNA synthesis begins at the correct chromosomal locus. Strict regulation of initiation is crucial to viability because inappropriate replication start is linked to genetic instability, including alterations in gene copy number and DNA damage. DNA replication starts with the assembly of prereplication complexes (pre-RCs) at multiple DNA replication origins during the G₁ phase. At the transition from G₁ to S phase, the replicative helicase is activated, leading to a change from pre-RCs to preinitiation complexes, which unwind DNA and initiate DNA synthesis. The recognition of pre-RC sites is known as replication origin licensing, and the activation of DNA synthesis is known as origin firing. Separation of these two steps is critical for preventing rereplication within the same cell cycle.

Replication origin licensing in G₁ phase involves sequential assembly of different proteins. The origin recognition complex (ORC) consists of the subunits ORC1–ORC6 and binds initially to replication origins. Then, CDC6 and CDT1 are recruited to the ORC, leading to the recruitment of the minichromosome maintenance (MCM) complex, which consists of six subunits: MCM2–MCM7. The MCM complex is a helicase that forms a double hexamer and encircles double-stranded DNA. Together, the inactive assembly of ORC, CDC6, CDT1, and MCM are known as the pre-RC. Notably, the Meier-Gorlin syndrome, a form of primordial

dwarfism, is linked to mutation or depletion of ORC1, which impairs cell cycle progression.

During the transition from G_1 to S phase, the MCM complex is phosphorylated by CDC7 and cyclin E–CDK2, leading to the recruitment of CDC45 and the four-protein DNA replication complex GINS. Together, CDC45, MCM, and GINS represent the CMG complex, and dissociation of the two MCM hexamers enables the formation of two preinitiation complexes at a replication origin. Cyclin E–CDK2 phosphorylates Treslin (TICRR) and RECQL4 that, with TOPBP1 and MCM10, facilitate the formation of the preinitiation complex. After replication origins are licensed, ORC1 phosphorylation by cyclin A–CDK1 inhibits rebinding of ORC1 to replication origins, and CDT1 is blocked by Geminin (GMNN) and sent to proteasomal degradation by SCF^{SKP2} to prevent relicensing during S phase.

In S phase, initiation of DNA replication by CDK2 promotes helicase activation, which leads to unwinding of DNA and recruitment of DNA polymerases alpha (POLA), delta (POLD), and epsilon (POLE), together with PCNA (proliferating cell nuclear antigen) and RFC (replication factor C). The MCM complex translocates from replication origins to unwind double-stranded DNA, whereas POLA binds to single-stranded DNA and initiates DNA synthesis on both the leading and lagging strands by providing an RNA primer and synthesizing the first bases of DNA. POLE and POLD elongate these primers with a base substitution error rate of approximately 10^{-5} . When they occasionally incorporate a false nucleotide, it is usually removed by an exonuclease associated with these DNA polymerases. This so-called proofreading, together with DNA mismatch repair mechanisms, leads to mutation rates of as low as 10^{-9} per base and per cell division cycle.

An immediate consequence of DNA replication is the disruption of chromatin in front of the replication fork, which results in release of parental histones. When the replication fork has passed, chromatin is rapidly reassembled onto old as well as newly replicated DNA, and in the reassembled chromatin, half of the histones are recycled from the parental chromatin, whereas the other half are newly synthesized. Then, the multiprotein complex cohesin mediates cohesion between replicated sister chromatids in S phase, which is essential for chromosome segregation in M phase.

In addition to DNA replication, the centrosome also needs to be replicated to allow the formation of two daughter cells.¹⁷ The centrosome is the major microtubule-organizing center and consists of two centrioles. Phosphorylation by cyclin E–CDK2 promotes the formation of one procentriole at each centriole. During S and G_2 phases, procentrioles elongate until they reach the length of the older centrioles. In early M phase, the two centrosomes separate to promote cytokinesis.

MITOSIS

The decision to enter mitosis is mediated by a network of proteins that regulate activation of the cyclin B–CDK1 complex. In principle, a feedback system between CDK1, WEE1/CDC25C, and the CDK1-counteracting phosphatases generates a bistable switch, leading to robust directionality that prevents cells from going back and forth between G_2 and M phases. Cyclin B and CDK1 levels increase in late S phase and G_2 phase, and the activity of newly made cyclin B–CDK1 complexes is blocked through phosphorylation by WEE1. Activation of the cyclin B–CDK1 complex is the key to cell entry into mitosis and occurs just before mitosis through the action of CDC25C, causing dephosphorylation of CDK1. The activities of WEE1 and CDC25C are themselves regulated with phosphorylation, inhibiting WEE1 function and enhancing CDC25C function. Once a small amount of cyclin B–CDK1 is activated, it can phosphorylate CDC25C and create a self-amplifying feedback loop that generates more active cyclin B–CDK1 from the large preexisting stock of inactive complex. What starts this sequence of events by initially phosphorylating and activating CDC25C is unclear, but PLK1 is a candidate kinase that can phosphorylate WEE1, CDC25C, and

cyclin B, leading to nuclear localization of cyclin B and CDC25C. Cyclin B–CDK1 can phosphorylate serine/threonine residues in many cellular proteins that are essential for mitosis. Phosphorylation of lamins by cyclin B–CDK1 promotes nuclear lamina disassembly and envelope breakdown, which occurs during prophase. Phosphorylation of some kinesin motor proteins that function in spindle assembly, such as KIF11 and CENPE, by cyclin B–CDK1 increases their efficiency of microtubule binding and increases processive motility along microtubules. Other kinesins that function in midzone formation, such as KIF23, are blocked in their activity by cyclin B–CDK1–mediated phosphorylation.

After chromosome condensation, centrosome separation, and nuclear envelope breakdown during prophase, chromosomes become attached to microtubules of the mitotic spindle apparatus in prometaphase. Kinetochore were originally called *centromeres* because they are located at the center of chromosomes. They are formed by centromere proteins during G_2 phase and prophase and link chromosomes to the mitotic spindle apparatus, so that sister chromatids become attached to opposite poles. In metaphase, the chromosomes align at the equatorial plate, and cyclin B–CDK1 levels start to decline by APC/C^{CDC20}-mediated degradation of cyclin B. The APC/C^{CDC20} further targets securin (PTTG1) and thereby activates separase (ESPL1), which cleaves the cohesin complexes linking sister chromatids. Once CDK1 activity is low, APC/C^{CDH1} becomes active and removes CDC20, PLK1, and Aurora kinases, as well as the mitotic cyclins and CDKs.

In anaphase, the spindle midzone forms between the separating chromosomes by coordinated actions of the microtubule cross-linker PRC1, the kinesin KIF4, and the multiprotein complexes centralspindlin and CPC (chromosomal passenger complex).¹⁸ Centralspindlin consists of the kinesin KIF23 and the Rho GTPase RACGAP1, and the CPC consists of Aurora kinase B, the scaffold INCENP, survivin (BIRC5), and CDCA8. Phosphorylation by CPC promotes recruitment of centralspindlin to the spindle midzone through KIF23 and allows for multimerization and accumulation of centralspindlin, which in turn promotes localization of the RhoGEF ECT2 (epithelial cell transforming 2) to microtubules. ECT2 then fuels RhoA, which promotes the recruitment of effector contractile ring proteins. As the ring closes, the spindle midzone is remodeled to form the densely packed telophase midbody, which organizes the intracellular bridge. At this time in telophase, nuclear membranes form to envelop each of the two separated sets of chromosomes, which also begin to decondense. This is soon followed by the abscission event near the midbody, which completes mitosis.

CELL CYCLE CHECKPOINTS

Competence

Cells require the presence of nutrients and growth factors to switch from quiescence to a state of proliferation. When cells sense that conditions are suitable for proliferation, they leave quiescence into G_1 phase and become competent to enter the cell cycle. G_1 has been subdivided into segments and regulatory points based largely on the study of the proliferative response of cells to sequential application of different growth factors, nutrients, and metabolic inhibitors. From the standpoint of cell cycle regulation, a particularly important point in G_1 is the restriction point, or R, which occurs near the G_1 –S boundary. The period after mitosis, when cells can enter quiescence, is termed G_{1pm} (postmitosis), and the period between quiescence and S phase is termed G_{1ps} (pre-DNA synthesis)¹⁹ (Fig. 17.5). Notably, nearly all of the variability in the length of G_1 can be accounted for by the G_{1ps} interval. Experiments have shown that, to leave quiescence and to enter the cell cycle, cells require growth signals either continuous for several hours during G_1 or, alternatively, as two discrete pulses of approximately 1 hour in duration and with a pause of several hours in between.²⁰ To become competent for cell cycle entry, initial activation of the MAPK pathway by mitogen signals is required that in turn activates essential metabolic programs.

Fig. 17.5 CHECKPOINTS OF CELL CYCLE ENTRY. (A) Quiescence is a nonproliferative state in which viable cells have left the cell cycle and may remain for prolonged periods. In contrast, terminally differentiated cells have irreversibly exited the cell cycle during the process of differentiation. When cells sense that conditions are suitable for proliferation, they leave quiescence into G₁ phase and become competent to enter the cell cycle. G₁ has been subdivided into segments, and a particularly important point is the restriction point, or R, which occurs near the G₁–S boundary. The period after mitosis, when cells can enter quiescence, is termed G₁pm (postmitosis), and the period between quiescence and S phase is termed G₁ps (pre-DNA synthesis). When DNA damage is recognized in G₁, the G₁/S checkpoint becomes activated, which blocks cells from S-phase entry, although they may have passed the restriction point. If damage is not repaired in a timely manner, cells will enter senescence, where they remain viable but not capable of reentering the cell cycle. (B) During quiescence, the cyclin-dependent kinase (CDK) inhibitor p27 prevents cyclin-CDK activity, and dimerization partner, RB-like, E2F, and multivulval class B (DREAM) and retinoblastoma protein (RB) bind and repress cell cycle genes. When prompted by growth signals, cells enter the competent state. Activation of RAS–mitogen-activate protein kinase and phosphoinositide 3-kinase (PI3K) signaling pathways is followed by activation of cyclin D–CDK4/6, leading to monophosphorylation of RB. The progressive decrease in p27 protein levels during G₁ allows for activation of cyclin E–CDK2, which multiphosphorylates the monophosphorylated RB, leading to the release of the activating E2F transcription factors. When DNA damage is recognized in G₁, p53 becomes activated, and the p53 target gene *p21* promotes cell cycle arrest at the G₁/S transition through inhibition of cyclin E–CDK2 and activation of RB. Also, p16 can become activated by oncogenic stress, which leads to inhibition of cyclin D–CDK4/6 and activation of the G₁/S checkpoint. If stress signaling is not relieved, cells will enter a senescent state. *MTOR*, Mammalian target of rapamycin.

However, this initial increase in MAPK activity does not lead to induction of MYC and cyclin D; it leads only to the presence of growth signals several hours later that activate the PI3K pathway and MYC. Functions of MYC include transcriptional activation of *CDK4* and *Cyclin D*, as well as downregulation of CDK inhibitors. The following increase in cyclin D–CDK4 complex activity leads to phosphorylation of the principal target RB during G₁ phase.

Restriction Point

In 1974, Arthur Pardee published the first report on the restriction point, and defined it as a point at which cells become committed to entering S phase, regardless of subsequent availability of growth factors or essential nutrients.²¹ He also correctly predicted that cancer cells undergo changes that lose the dependency on growth factors and are not dependent on the restriction point. In the four decades that have passed since the initial description of the restriction point, many important insights have been gained that revealed the signaling events that contribute to proliferation and growth. In addition to the key

contributions of signaling by MAPK, PI3K, and MYC to enable cell growth, it also became clear that there are restraining activities that can inhibit cell cycle entry and progression. As mentioned earlier, cyclin D levels increase during the progression phase of G₁, and cyclin D–CDK4/6 complexes monophosphorylate RB, which restricts the activating E2F transcription factors.⁷ Later in G₁, cyclin E levels increase, and cyclin E binds specifically to CDK2. This leads to RB hyperphosphorylation and release of the activating E2Fs, enabling E2F-dependent gene expression. Once past this point, growth factors are no longer required for S-phase entry. Therefore expression and activation of cyclin E–CDK2 resulting in the hyperphosphorylation of RB enables a cell to pass the restriction point and become committed to cell cycle entry.

G₁/S Checkpoint

The G₁/S DNA damage checkpoint can be viewed as a point in the cell cycle when the cell has become fully committed to enter into S phase and past the restriction point, but is unable to enter S phase

because cyclin E–CDK2 and cyclin D–CDK4 are inactivated by p21 and p16, respectively, and RB remains capable of binding to and repressing the activating E2Fs, thereby decreasing levels of factors required for DNA synthesis. In G₁, DNA damage is recognized by ataxia-telangiectasia mutated (ATM) kinase, which in turn phosphorylates histone variant H2AX to recruit repair factors and CHEK2 kinase.²² CHEK2-mediated phosphorylation activates p53 and inactivates CDC25A, which is required for the activation of cyclin E–CDK2 complexes. The p53 target genes *p21* and *BTG2* further promote cell cycle arrest at the G₁/S transition through inhibition of cyclin E–CDK2 and activation of RB. If the DNA damage or stress signals are repaired, cells can exit the G₁/S checkpoint and reenter the cell cycle.

S-Phase Checkpoint

Under conditions that put DNA replication at risk, such as DNA damage or nucleotide depletion, the S-phase checkpoint gets activated. Ataxia telangiectasia and Rad3-related protein (ATR) is the main kinase that senses DNA damage during S phase, and it phosphorylates CHEK1 kinase, which in turn activates p53. Similar to the G₁/S checkpoint, inhibition of cyclin E–CDK2 is central to the S-phase checkpoint. The inhibition of CDK2 activity blocks loading of CDC45 onto replication origins and prevents the initiation of new origin firing. In addition to inhibiting cyclin E–CDK2, p21 directly interacts with PCNA to stop DNA replication. If the damage is repaired, cells continue DNA replication and cell cycle progression.

G₂/M Checkpoint

The G₂/M checkpoint prevents cells from initiating mitosis when DNA damage occurs during G₂, or when cells progress into G₂ with some unrepaired damage inflicted during previous S or G₁ phases. The G₂/M checkpoint also involves DNA damage recognition by ATM and ATR kinases and subsequent p53 activation through CHEK1 and CHEK2 kinases, and it ultimately requires activation of the p21 CDK inhibitor. If p21 is missing, both G₁/S and G₂/M checkpoints are abolished. In addition to p21, p53 induces GADD45A and 14-3-3 (SFN), which contribute to G₂/M cell cycle arrest. 14-3-3 removes essential mitotic regulators from the nucleus and thereby promotes G₂/M arrest. Moreover, inhibition of cyclin-CDK activity through p21 induces DREAM and RB-E2F complexes, which in turn repress the transcription of the cell cycle machinery.¹²

Senescence

If damage is not repaired timely, cells will enter a senescent state in which they remain viable but not capable of reentering the cell cycle. Telomere shortening, which signals cell aging, also is recognized as a type of DNA damage and can trigger senescence.²³ RB is key in establishing the senescent state, which is activated downstream of p53 and the CDK inhibitors p16 and p21. During senescence, cells have committed to proliferation and presumably have passed the restriction point. In contrast to quiescence, senescent cells are unable to reenter the cell cycle in response to external stimuli, such as growth signals.

Spindle Assembly Checkpoint

The spindle assembly checkpoint (SAC) involves the MAD (mitotic arrest deficient) proteins MAD1, MAD2, BUBR1 (MAD3), and BUB1.²⁴ To complete mitosis, the cell strictly requires the activity of cyclin B–CDK1. The main effector of the SAC is the mitotic checkpoint complex (MCC), which consists of MAD2, BUBR1, and BUB3 and binds to CDC20, the substrate-specific cofactor of the

APC/C that mediates degradation of cyclin B and securin. Inhibition of CDC20 prolongs prometaphase until all chromosomes have become correctly orientated on the metaphase plate. Unattached kinetochores recruit MCC through BUB1, leading to active MCCs. Only when kinetochores have become correctly attached to the mitotic spindle is the MCC deactivated, which in turn activates APC/C^{CDC20} and allows for mitosis progression.

SPECIAL HEMATOLOGY CELL CYCLE FEATURES

Hematopoietic Stem Cells

Hematopoietic stem cells (HSCs) are characterized by their ability to execute multiple cell fate choices, including self-renewal, quiescence, and differentiation into the many different mature blood cell types. The stem cell niche forms the essential microenvironment for HSCs, and the primary HSC niche in adult organisms is located in the bone marrow. Stem cells are quiescent until prompted to proliferate by external stimuli. Stem cell quiescence is achieved largely through the CDK inhibitors p21, p27, and p57.²⁵ The pool of HSCs contains subsets that differ in self-renewal potential and cell division frequency. So-called short-term HSCs rapidly enter the cell cycle upon mitogen stimulation, whereas long-term HSCs exit quiescence later. A recent study showed that this difference is achieved at least in part through varying CDK6 levels in the HSC subsets.²⁶ The absence of CDK6 in long-term compared with short-term HSCs results in a delay in quiescence exit, and the cumulative effect of this delay limits proliferation of these cells and ultimately preserves long-term integrity of the HSC pool.

Endoreplication

A special type of cell cycle progression is featured in the differentiation of cells that have high metabolic profiles required for synthesis of specific proteins, such as plasma proteins produced by hepatocytes, or for the production of platelets by megakaryocytes (MKs). Thrombopoietin (TPO) is the major regulator that directs the growth and development of MKs from HSCs.²⁷ TPO binds to the MK-specific receptor MPL, leading to MPL dimerization and activation of JAK2 (Janus kinase 2). Initially, this signaling leads to endoreplication and accumulation of DNA content of up to well over 128N before proceeding to final maturation and proplatelet formation. Endoreplication requires impaired cyclin B–CDK1 kinase activity, which is achieved through upregulation of the CDK inhibitor p21 and induction of the APC/C subunit CDH1 after S-phase completion.²⁸ MK endoreplication also requires the prevention of active RhoA through downregulation of ECT2. During S phase, cyclin E–CDK2 inactivates CDH1 to allow for proper DNA replication. As a result of the following CDK1 inhibition, mitosis is completely bypassed after DNA replication. Inhibition of CDK1 and RhoA and activation of APC/C^{CDH1} promote bypass of mitosis and entry into the next G₁ phase.

CELL DEATH

Nika N. Danial and David M. Hockenbery

Cell death is a highly organized fundamental activity that is equally complex in regulation as cell division and differentiation. In the physiologic contexts of embryonic development and tissue renewal, or as a pathologic response to cell injury and infectious pathogens, cell deaths are orchestrated for multiple purposes that benefit the organism. These include maintenance of epithelial barrier function, destruction of microbes, adaptive immune responses, recycling of biologic macromolecules, intracellular signaling, and preservation of genomic integrity. The majority of mammalian cell deaths have morphologic and biochemical features of apoptosis (Fig. 18.1), a self-inflicted death program encoded in the genetic material of all cells (Fig. 18.2). Necrosis, an alternative mechanism of cell death, occurs in the aftermath of extreme cellular insults and could be viewed as a failure of cellular homeostasis. Recently, a programmed pathway of necrosis, referred to as necroptosis, has been identified. Although cells contain their own death apparatus, cell death in multicellular organisms is exquisitely sensitive to the consent of neighboring cells. As might be expected, the internal cell death machinery is tightly interwoven with other essential cell pathways. Investigations of cell death have also informed our understanding of living cells; for example, the recognition that cellular remodeling shares some pathways with apoptotic cell death.

PHYSIOLOGIC CELL TURNOVER

An adult human loses approximately 10^{11} cells/day, with skin, intestine, and hematopoietic tissues accounting for the majority. Apoptotic cell death in the adult occurs most clearly in the context of cyclically renewing (endometrium, breast, hair follicle) tissues. Homeostatic mechanisms in skin and intestine balance generation of new cells with loss of terminally differentiated cells, principally by nonapoptotic mechanisms. In the intestinal epithelium, terminally differentiated enterocytes migrate onto the epithelium surface and are extruded as viable cells, triggered by cellular crowding. Keratinocytes in the external layer of skin undergo a process of cornification to form an epithelial barrier before being shed.

Neutrophils recruited to sites of inflammation undergo apoptosis upon removal of the inflammatory stimulus. Apoptotic neutrophils are unable to degranulate, and reprogram macrophages to an anti-inflammatory phenotype when phagocytosed (termed *efferocytosis*). This clearance mechanism is specialized to apoptotic neutrophils, as necrotic neutrophils and opsonized cells trigger macrophages to secrete inflammatory cytokines. Apoptotic cell death of anucleate platelets controls platelet lifespan, and in the absence of the anti-apoptotic protein BCL- X_L , platelets survive 24 h compared with 5 days in wild-type mice.

Reversible physiologic cell deaths also provide a reserve production capacity for functionally mature cells. The glycoprotein hormone erythropoietin (EPO) is produced by kidney mesangial cells and stimulates excess red blood cell production in proportion to the demand for blood oxygen-carrying capacity. The EPO receptor is expressed on committed erythrocyte precursors (erythroid colony-forming units and proerythroblasts). Growth factors, in general, also generate survival signals. The primary *in vivo* effect of EPO is to rescue erythroid precursors from physiologic death. The EPO-responsive erythroid compartment in the bone marrow and spleen is maintained at a constant size and rate of cell proliferation under

various demands (hypoxia, hypertransfusion), despite widely differing production rates of mature erythroid cells. The *raison d'être* appears to be to overproduce erythroid colony-forming units and proerythroblasts at low altitudes, with excess cells removed prior to the erythroblast stage. This scheme provides a rapidly accessible reserve under conditions of higher demand.

A final physiologic application for apoptosis is as a mechanism for selection of specific cell phenotypes. A well-known example occurs in the adaptive immune system following clonal diversification of T- and B-lymphocyte antigen receptors by gene recombination and error-prone DNA replication. Positive and negative clonal selection to match T-cell receptors to cognate class I and class II histocompatibility antigens on accessory cells and elimination of many receptors reacting with self-antigens takes place in the thymus. Affinity maturation of immunoglobulin-bearing B cells takes place in germinal centers of lymphoid organs. In each case, cells run through a gauntlet of near-death experiences, with death and survival signals directly linked to the binding properties of the antigen receptor on individual cells.

EXECUTIONERS OF APOPTOSIS

Caspases

The central effectors of apoptosis are a family of cysteine proteases known as caspases (cysteiny aspartate-specific protease).¹ All caspases are aspartases with a four residue recognition sequence P4–P1 (Fig. 18.3). A serine protease that also recognizes aspartic acid motifs, granzyme B, is similarly involved in cytolytic T-cell killing. Often only one or two caspase cleavage sites are found in a variety of cellular proteins, in many cases members of the same complex or biochemical pathway, leading to limited digestion of substrate proteins. Proteins truncated by caspase cleavage frequently exhibit altered functions, demonstrating that caspases can act as signaling proteases. The number of identified caspase substrates is over 1500.²

While no single caspase substrate has been identified that is obligate for cell death, some progress has been made in attributing biochemical and morphologic features of apoptotic death to proteolysis of specific substrates. Caspase-mediated cleavage and activation of Rho-associated kinase-1 (ROCK1) stimulates actin–myosin contractility, leading to membrane blebbing and fragmentation of the nucleus weakened by cleavage of nuclear lamins. DNA fragmentation is mediated by an endonuclease, DNA fragmentation factor 40 (DFF40), also known as caspase-activated DNase (CAD), which is activated following caspase-mediated degradation of an inhibitory binding partner, ICAD/DFF45. Extracellular release of ATP, a “find-me” signal for macrophages, is triggered by caspase-mediated cleavage of a C-terminal inhibitory domain from Pannexin 1 channels, and outer plasma membrane leaflet exposure of phosphatidylserine, an “eat-me” signal for efferocytosis, follows caspase-mediated inactivation of ATP11C flippase activity.

In the intracellular battle between survival and proapoptotic factors, caspases can also swing the advantage toward death by altering the balance of forces. The mitochondrial survival proteins BCL-2 and BCL- X_L are subject to N-terminal cleavage by caspases. Not only does N-terminal truncation eliminate a survival function, but the cleaved versions also behave as proapoptotic factors. Activation

of a proapoptotic BCL-2 family member, BID, also features caspase-mediated processing to a truncated factor, tBID, which then traffics to its mitochondrial site of action.

ACTIVATION OF PROCASPASES

Caspases are expressed in healthy cells as zymogens with low-to-absent protease activity, with association as homodimers and proteolytic processing into large and small subunits required for strong activation (Fig. 18.4). Downstream or executioner caspases (caspase-3, -6, and -7) exist as preformed dimers.¹ Cleavage of a flexible interchain connector between subunits facilitates the movement of surface loops to form an open active site. Processing of procaspases occurs immediately after aspartate residues within caspase recognition motifs. Subsite specificities are distributed among caspases so that many caspase zymogens must be processed in *trans* by a different caspase, creating a hierarchy of proteolytic activation. Apical (initiator) caspases (caspase-2, -8, -9, -10) have limited proteolytic (including autocatalytic) activity at high concentrations without a requirement

Fig. 18.2 CLASSIFICATION OF CELL DEATH PATHWAYS.

Fig. 18.3 SUBSTRATE SPECIFICITY OF CASPASES. Subject specificity of caspases is determined by the geometry of specificity binding pockets S4–S1, recognizing peptide side chains numbered P1–P4 on the acyl side of a scissile peptide bond. All caspases require Asp in the S1 pocket.

Fig. 18.4 MATURE CASPASES ARE FORMED BY PROTEOLYTIC PROCESSING OF PROCASPASES TO DIVIDE LARGE AND SMALL SUBUNITS AND REMOVE N-TERMINAL PEPTIDES. Caspase substrate motifs at cleavage sites enable sequential caspase activation, or in the case of initiator caspases, autoactivation. Caspase dimers are assembled from two large and two small subunits. *Asp*, Aspartate.

for processing. Interactions at a dimer interface (induced proximity or induced conformation model) reorient and stabilize the binding pocket conformation of these caspases. Normally monomeric, these zymogens are distinguished by the presence of a long prodomain that serves as a docking site for recruitment into a self-activating complex. Protein associations within these complexes are built around homomeric interactions between three binding cassettes, death (DD), death effector (DED), and CARD domains.

DISCS, APOPTOSOMES, INFLAMMASOMES, AND PIDDOSOMES

Four distinct caspase-activating assemblies are known (Fig. 18.5). Caspase-8 and -10 are engaged by a family of cell surface receptors known as death receptors, including tumor necrosis factor receptor 1 (TNFR1), Fas/CD95, TNFRSF10A, and TNFRSF10B.^{3,4} Ligand binding to trimerized death receptors induces conformational changes that promote binding of adaptor proteins, Fas-associated death domain protein (FADD) and TNFR1-associated death domain protein (TRADD), to the cytoplasmic tail of the death receptor by dimerization of homologous death domains (DDs) from each molecule. A second interaction domain in FADD, a DED, binds to a similar DED in the prodomain of caspase-8/10, leading to caspase dimerization and localized autocatalysis. The prodomain of caspase-8/10 is severed during processing, dispersing active caspases to cellular substrates. Analysis of unprocessed caspase-8 dimers demonstrated that active sites can be formed in the absence of processing, stabilized by hydrophobic interactions at the dimer interface. The death receptor, FADD, and caspase complex is known as the death-inducing signaling complex (DISC) (see Fig. 18.5A). In the case of TNFR1, additional complexes are involved in nuclear factor kappa-B (NFκB) signaling and necroptosis.

The second caspase-activating assembly platform, the apoptosome, is specialized for activating caspase-9 and -7, which have CARD-type prodomains. Formation of the cytoplasmic apoptosome is initiated by release of the soluble electron carrier, cytochrome *c*, from mitochondria. Cytochrome *c* binds to an adaptor protein, apoptotic protease activating factor 1 (APAF-1), enabling adenosine triphosphate (ATP)/dATP-dependent oligomerization of APAF-1 in a heptameric wheel and exposure of its own CARD domain (see Fig. 18.5B). Docking of caspase-9 to the apoptosome through CARD–CARD interactions is both necessary and sufficient for

proteolytic activity. Eventual dissociation from the apoptosome due to cleavage of the prodomain results in loss of proteolytic activity. Both pathways converge with proteolytic activation of caspase-3 by caspase-8, -9, or -10.

Inflammasomes are large multiprotein complexes, visible as speck structures in stimulated cells, that are dedicated to activating caspase-1 in response to molecular cues from infectious pathogens (pathogen-associated molecular patterns [PAMPs]) or endogenous signals (danger-associated molecular patterns [DAMPs]).⁵ A family of nucleotide-binding oligomerization domain (Nod)-like receptors (NLRs) detect PAMPs and DAMPs through leucine-rich repeats (LRRs), triggering oligomerization of Nod domains. A third, N-terminal, region contains one of several protein interaction motifs, including CARD and pyrin domains, for direct interaction with caspase-1 or via an adaptor protein, apoptosis-associated speck-like protein containing a CARD (ASC) (see Fig. 18.5C). The three NLR inflammasomes characterized to date are named after the NLR protein involved. NLRP1 and NLRC4 recognize bacterial muramyl dipeptide and flagellins, respectively, while NLRP3 recognizes multiple stimuli, including saturated fatty acids, bacterial RNA, and urate crystals. Non-NLR family inflammasome proteins, AIM2 and PYRIN, recognize cytosolic dsDNA and modified Rho GTPases, respectively. The inflammasome scaffold is postulated to trigger caspase-1 activity according to the induced proximity model. An inflammatory cell death termed *pyroptosis* is initiated by inflammasome activation. Inflammasome activation may also be triggered by viral PAMPs. RNA viruses are recognized by retinoic acid-inducible gene-1 (RIG-I) and RIG-I-like-receptor (RLR) helicases, which oligomerize upon binding viral RNA and translocate to the interface between mitochondrial membranes and mitochondria-associated membranes. Binding to the mitochondrial antiviral signaling protein (MAVS), a tail-anchored membrane adaptor protein, activates IRF3 and NFκB transcription of antiviral responses.⁶

Caspase-2 is activated following genotoxic damage via a p53-inducible protein, p53-induced protein with a death domain (PIDD), in a complex known as the PIDDosome. Similar to death receptors, death domains in PIDD bind to an adaptor protein, RAIDD, which in turn recruits caspase-2 through death effector domain interactions, generating a large (>670 kDa) multiprotein complex (see Fig. 18.5D). PIDD also activates NFκB downstream of DNA damage responses through competing interactions with the receptor-interacting protein 1 (RIP1) serine/threonine kinase and I-kappa-B kinases (IKK) scaffold, NFκB essential modulator (NEMO).

C

Fig. 18.5 CASPASE ACTIVATION PLATFORMS. (A) DISC (death-inducing signaling complex) is assembled after binding of ligand (Fas) to death receptor (CD95) at the cell surface. Protein interaction domains (death domain [DD] and death effector domain [DED]) mediate associations among death receptor, initiator caspase (caspase-8), and adaptor protein (FADD). (B) Apoptosome resembles a seven-spoked disc, with procaspase-9 molecules bound at the hub extending above one surface and APAF-1 adaptors aligned as spokes, presenting CARD interaction domains at the hub and WD40 propellers bound to cytochrome *c* at the rim. (C) Inflammasomes are multiprotein complexes containing either ICE-protease activating factor (IPAF) or NACHT, LRR, and PYD containing proteins (NALPs) as adaptor proteins that recruit caspase-1 and contain oligomerization domains. IPAF binds procaspase-1 through its CARD domain, while NALP-based inflammasomes recruit procaspase-1 indirectly through ASC-1, which possesses a pyrin domain for NALP binding and a CARD domain for caspase-1 recruitment. (D) The PIDDosome is a molecular platform consisting of the DD-containing p53-inducible protein PIDD, which binds another DD-containing protein RIP-associated Ich-1/CED homologous protein with death domain (RAIDD). RAIDD recruits procaspase-2 through DD-based interactions. *ASC-1*, Apoptosis-associated speck-like protein containing a CARD-1; *APAF-1*, apoptosis protease-activating factor-1; *CARD*, caspase activation and recruitment domain; *IPAF*, ICE-protease activating factor; *NALP*, NACHT, LRR, and PYD containing proteins; *PIDD*: p53-induced protein with a death domain.

NONAPOPTOTIC ROLES FOR CASPASES

Although justifiably known for their apoptotic functions, there is accumulating evidence that caspases also function in healthy cells.⁷ Caspase-1 was originally identified as the processing enzyme for interleukin 1 β (IL-1 β), and subsequently shown to process another proinflammatory cytokine IL-18. Caspases can also be involved in negative-feedback control of erythroblast differentiation by mature erythroblasts through degradation of GATA-1. Several dramatic structural alterations associated with cell differentiation also appear to require transient caspase activation. Cleavage of a limited number of caspase substrates precede nuclear and chromatin changes during terminal erythroid differentiation, and caspase inhibitors block proplatelet formation from megakaryocyte and macrophage differentiation. Caspase-8, in some contexts, has a prosurvival function, inhibiting necroptosis or apoptosis. The more limited caspase activation in these instances may involve some degree of compartmentalization in space or time. Since the activity of unprocessed apical caspases requires persistent binding to adaptor proteins, this constraint may allow for localized, limited caspase activity under some circumstances consistent with a nonapoptotic role.

INHIBITORS OF APOPTOSIS PROTEINS

The only known endogenous caspase inhibitor in mammalian cells is a member of the inhibitor of apoptosis proteins (IAPs) family. IAPs were originally described in insect viruses as viral proteins produced during cellular infection to block host cell apoptosis.⁸ In mammalian cells, X-linked inhibitor of apoptosis (XIAP) is the only fully validated caspase inhibitor. XIAP binds to the active sites of specific caspases^{4,8} to block catalytic activity or interferes with dimerization (caspase-9). IAPs contain one to three baculovirus IAP repeat (BIR) domains that coordinate zinc, and one or more additional protein-interaction domains. IAP-binding motifs (IBMs) consist of a short peptide sequence with an N-terminal alanine and bind to a surface groove on certain BIR domains. Initial processing of caspase-3, -7, and -9 generates an IBM at the N-terminal end of the short subunit, providing an anchor point for additional physical interactions with IAP proteins. XIAP uses different BIR domains to bind IBMs of specific caspases.

Two proteins normally localized in the mitochondrial intermembrane space, second mitochondria-derived activator of caspase (SMAC)/Diablo and Omi/HtrA2, can bind IAPs via an NH₂-terminal IBM sequence and competitively displace bound caspases. Whereas the NH₂-terminus of active SMAC/Diablo is generated by removal of a presequence during mitochondrial import, Omi/HtrA2 is a stress-activated serine protease that is cleaved by autoproteolysis. Cytoplasmic translocation of SMAC/Diablo and Omi/HtrA2 during apoptosis provides an additional mechanism for caspase activation.

CORE APOPTOSIS PATHWAYS

In mammals, the execution of apoptosis downstream of death signals is governed by two molecular programs that terminate in caspase activation, which may be linked in certain cell types. The extrinsic pathway operates downstream of death receptors, such as Fas and other members of the TNF receptor family, which recruit DISC upon ligand binding. This complex, in turn, recruits and activates caspase-8 and -10, leading to activation of other downstream caspases. The second program, also known as the *intrinsic pathway*, is marked by the involvement of mitochondria.⁹⁻¹² Besides their role in biosynthesis, calcium buffering, and ATP production, mitochondria participate in apoptosis by releasing factors such as cytochrome *c*, a component of the mitochondrial electron transport chain. The permeabilization of the outer mitochondrial membrane (MOMP) and release of apoptogenic factors marks the “point of no return” in the intrinsic pathway of apoptosis, and is exquisitely regulated by BCL-2 family proteins. Once released, cytochrome *c* is assembled with APAF-1 and caspase-9

to form the “apoptosome,” which in turn triggers downstream effector caspases (see Fig. 18.5B). Other apoptogenic factors released from mitochondria, including apoptosis-inducing factor (AIF), SMAC/Diablo, Omi/HtrA2, and endonuclease G, augment apoptosis.

BCL-2 FAMILY PROTEINS AND THE INTRINSIC PATHWAY OF APOPTOSIS

The BCL-2 family of proteins constitutes a critical control point in apoptosis residing immediately upstream to irreversible cellular damage, where the members control MOMP.⁹⁻¹³ Several BCL-2 proteins reside at subcellular membranes, including the mitochondrial outer membrane, the endoplasmic reticulum (ER), and nuclear membranes. The different anti- and proapoptotic members of this family form a highly selective network of functional interactions that ultimately governs MOMP. The founding member of this family, *BCL-2*, was discovered as the defining oncogene in follicular lymphomas, located at one reciprocal breakpoint of the t(14;18)(q32;q21) chromosomal translocation. Cells transduced with *BCL-2* remained viable for extended periods in the absence of growth factors. Transgenic mice bearing a *BCL-2-Ig* mini-gene recapitulating the t(14;18) chromosomal translocation displayed B-cell follicular hyperplasia and progressed over time to diffuse large B-cell lymphomas. *BCL-2* expression specifically blocked the morphologic features of apoptosis, including plasma membrane blebbing, nuclear condensation, and DNA cleavage. Importantly, unlike other oncogenes known at that time, *BCL-2* did not promote proliferation, defining a new category of oncogenes, namely regulators of cell death.¹⁰ The first proapoptotic BCL-2 homologous protein to be identified, BAX, coimmunoprecipitated in stoichiometric amounts with BCL-2. BAX-transfected cells died rapidly in the absence of growth factor and BAX was subsequently shown to be capable of directly triggering apoptosis. Since the discovery of BCL-2 and BAX, the BCL-2 family in mammals has expanded, with several family members acting principally as prosurvival proteins and others hastening cell death in various experimental systems (Fig. 18.6). Homologs of BCL-2 proteins exist in all metazoans studied to date, as well as several animal DNA viruses.

The ability of BCL-2 family proteins to selectively bind each other is integral to their function in regulating MOMP and apoptosis. These interactions are modulated by conserved homology domains (BH), which correspond to α -helical and connecting segments that dictate structure and function (see Fig. 18.6).⁹⁻¹³ All antiapoptotic members, such as BCL-2 and BCL-X_L, and a subset of proapoptotic family members, such as BAX and BAK, are “multidomain” proteins sharing sequence homology within 3–4 BH domains. The “BH3-only” subset of proapoptotic molecules, including BCL-2 antagonist of cell death (BAD), BID, BCL-2 interacting mediator of cell death (BIM), NOXA, and p53 upregulated modulator of apoptosis (PUMA), show sequence homology only within a single α -helical segment, the BH3 domain, which is also known as the critical death domain required for binding to “multidomain” BCL-2 family members. BCL-2 family interactions ultimately regulate mitochondrial intramembranous oligomerization of BAX/BAK, which is the prime mechanism of MOMP. BAX and BAK are absolutely required to execute death by all apoptotic signals that activate the intrinsic pathway, nominating these molecules as the requisite gateway to the mitochondrial apoptotic machinery.

A combination of genetic, biochemical, and structural studies has begun to unravel the molecular mechanism underlying regulation of MOMP by BCL-2 proteins (Fig. 18.7). BH3-only molecules are upstream sentinels that selectively respond to proximal death and survival signals to regulate BAX/BAK oligomerization.⁹⁻¹² However, their apoptotic activity is suppressed unless activated by transcriptional and posttranslational mechanisms in a tissue- and signal-specific manner.^{10,12} For example, the activation of NOXA and PUMA is under direct transcriptional regulation by p53, a finding that is consistent with their roles as specialized death sentinels during DNA damage. On the other hand, cytosolic BID is activated upon cleavage by caspase-8, and the apoptotic activity of BAD is regulated

Fig. 18.6 CLASSIFICATION OF THE BCL-2 FAMILY ACCORDING TO CONSERVED DOMAINS. BH1–3 domains form a surface hydrophobic groove capable of binding BH3 domains of other family members. C-terminal hydrophobic sequences function to target and/or anchor BCL-2 family proteins to intracellular lipid membranes. *BAD*, BCL-2 antagonist of cell death; *BAK*, BCL-2 antagonist/killer; *BAX*, BCL-2–associated x protein; *BCL*, B-cell lymphoma; *BID*, BH3-interacting domain death agonist; *BIK*, BCL-2–interacting killer; *BIM*, BCL-2–interacting mediator of cell death; *BMF*, BCL-2–modifying factor; *BOK*, BCL-2–related ovarian killer; *HRK*, harakiri; *MCL-1*, myeloid cell leukemia sequence 1; *PUMA*, p53 upregulated modulator of apoptosis; *TM*, transmembrane domain.

by phosphorylation. Thus the large number of “BH3-only” members is indicative of specialization, rather than redundancy. The unique localizations, protein associations, and mechanisms of activation for the individual BH3-only proteins suggest that each acts as a sentinel for distinct damage signals, thereby increasing the range of inputs for endogenous death pathways.

The proapoptotic activity of BH3-only proteins is associated with exposure of the hydrophobic face of their BH3 helix, which binds the hydrophobic groove of multidomain dimerization partners. Certain BH3-only proteins such as *BAD* and *NOXA*, which are known as “sensitizers” or “de-repressors,” bind and inhibit antiapoptotic partners. Other BH3-only proteins such as *BIM*, *BID*, and *PUMA*, known as “activators,” can directly bind and trigger *BAX/BAK* oligomerization (Fig. 18.8). Activator BH3-only proteins can also bind and inhibit antiapoptotic BCL-2 proteins. Antiapoptotic proteins inhibit apoptosis by engaging activator BH3-only proteins and by inhibiting *BAX/BAK* oligomerization¹¹ (see Fig. 18.8). Activation of BH3-only proapoptotic proteins in response to death stimuli can eventually counter the neutralizing function of antiapoptotic BCL-2 proteins. The complex and selective molecular interactions between the multidomain anti- and proapoptotic molecules also involve both cytosolic and membrane conformers of select family members, each of which is under distinct regulatory mechanisms, including binding affinities, on/off rates, and association with membrane lipids and/or other binding proteins.⁹ For example, membrane-inserted conformers of *BCL-2*, which are defective in oligomerization, can in turn bind membrane-embedded *BAX/BAK*, inhibiting their oligomerization.⁹

BCL-2 FAMILY PROTEIN AND THE ENDOPLASMIC RETICULUM GATEWAY TO APOPTOSIS

Apart from cytochrome *c* release, the control of Ca^{2+} dynamics at the ER by BCL-2 family proteins also affects the threshold for apoptosis.^{9,14} This is consistent with the ability of multiple members of this family to localize to the ER. ER Ca^{2+} content is a chief determinant of the amount of Ca^{2+} that can be released in the cytosol and thus constitutes an important regulator of Ca^{2+} signals known to control myriad cellular functions, including survival/death. The ER Ca^{2+} dynamics directly affect the function of mitochondria as these organelles are in close proximity and mitochondria take up Ca^{2+} released by the ER. Ca^{2+} stimulates important enzymes in the tricarboxylic acid (TCA) cycle, and influences oxidative phosphorylation and ATP synthesis by mitochondria. Supraphysiologic levels of Ca^{2+} , however, can prompt the opening of a large mitochondrial inner-membrane conductance channel known as the *permeability transition pore*, which can eventually cause the swelling and rupture of mitochondria.

Cells overexpressing *BCL-2* or deficient for both *BAX* and *BAK* show lower levels of ER Ca^{2+} and consequently lower Ca^{2+} entry into the mitochondrion. Lower ER Ca^{2+} content in these cells is associated with a higher rate of ER Ca^{2+} leak. Consequently, Ca^{2+} -mobilizing death stimuli specifically require the function of *BAX* and *BAK* at the ER. ER Ca^{2+} content and inhibition of inositol 1,4,5-trisphosphate receptor (IP3R)-mediated Ca^{2+} release is an important component of the prosurvival effect of antiapoptotic BCL-2 proteins, which is reversed by the proapoptotic members of the family. Modulation of

Fig. 18.7 SCHEMATIC REPRESENTATION OF THE INTRINSIC APOPTOTIC PATHWAY IN WHICH A BH3-ONLY MOLECULES SERVE AS UPSTREAM SENTINELS THAT SELECTIVELY RESPOND TO SPECIFIC DEATH SIGNALS. BH3-only molecules ultimately regulate BAX and BAK activation directly or indirectly. This process is in turn inhibited by antiapoptotic BCL-2 family members. BAX and BAK serve as gateways to apoptosis, regulating both cytochrome *c* release from the mitochondria and Ca^{2+} release from the endoplasmic reticulum (ER). See Fig. 18.6 for definition of abbreviations.

Fig. 18.8 REGULATION OF BAX AND BAK OLIGOMERIZATION. BAX/BAK activation is directly triggered by activator BH3-only proteins (BCL-2–interacting mediator of cell death, BH3-interacting domain death agonist, and p53 upregulated modulator of apoptosis) and is inhibited by antiapoptotic BCL-2 family members. Sensitizer BH3-only proteins do not activate BAX and BAK directly, but lower the threshold for apoptosis by binding antiapoptotic members and releasing activators to trigger BAX and BAK oligomerization. BAX and BAK are activated when the number of activator molecules exceeds the neutralizing capacity of antiapoptotic proteins. *BAK*, BCL-2 antagonist/killer; *BAX*, BCL-2–associated x protein; *MOMP*, permeabilization of the outer mitochondrial membrane.

ER Ca^{2+} content by BCL-2 proteins is mediated, at least in part, by their direct or indirect modulation of IP3R and sarcoplasmic/ER calcium ATPase (SERCA).

NONAPOPTOTIC ROLES FOR BCL-2 FAMILY PROTEINS

Biochemical evidence indicates that the network of protein–protein interactions for select BCL-2 proteins extends to a number of non-BCL-2 protein partners that endow them with homeostatic roles beyond regulation of apoptosis.^{15–18} These functions include, but are not limited to, mitochondrial energy and nutrient metabolism, calcium signaling, cell cycle checkpoints, and DNA damage response. The BH3-only protein BAD binds and directly activates glucokinase (hexokinase IV), the product of the maturity-onset diabetes of the young (*MODY*) 2 gene, known for its tissue-restricted regulation of glucose homeostasis through the control of glucose-stimulated insulin secretion by islet β -cells as well as hepatic glucose utilization and storage. The GK-dependent effect of BAD on glucose homeostasis is independent of its apoptotic function and is determined by the phosphorylation state of its BH3 domain, which enables it to activate GK while simultaneously inhibiting its apoptotic function.¹⁷ The BH3-only protein BID, on the other hand, is a downstream substrate for DNA damage checkpoint kinases ATM/ATR, and plays a role in intra-S phase checkpoint separate from its role in apoptosis. In addition, several BCL-2 family proteins have been implicated in the regulation of mitochondrial electron transport chain activity in healthy cells that have not been stressed with any apoptotic signals.¹⁷

For example, proteolytic processing of MCL-1 produces an isoform that targets to mitochondria and regulates oxidative phosphorylation, in part by influencing the assembly of mitochondrial respiratory chain complexes in higher order complexes known to regulate the efficiency of carbon substrate oxidation and ATP production. This MCL-1 isoform does not have antiapoptotic activity. The above findings are but three examples of an emerging notion that BCL-2 family members are an integral component of cellular homeostatic pathways and carry functions separate from their capacity to regulate apoptosis. Understanding the precise molecular mechanisms underlying these functions and how they can be independently manipulated is critical for effective targeting of these proteins in disease settings.

DEATH RECEPTOR SIGNALING AND THE EXTRINSIC PATHWAY OF APOPTOSIS

Death receptors are expressed on many cell types, especially in the immune system, where they have apoptotic and nonapoptotic functions, dependent on cell context.¹⁹ The cytoplasmic sequences of members of the death receptor superfamily all contain the death domain (DD 80 aa) protein–interaction motif. Once clustered by receptor–ligand interaction, the DD serves to nucleate the formation of DISC for initiator caspases (caspases-8 and -10) with distinct protein interaction motifs in their long prodomains.

There are six mammalian death receptors (TNFR1, Fas, DR3, DR4 [TRAILR1], DR5 [TRAILR2], and DR6). Signaling through

TNFR1 and DR3 is predominantly proinflammatory, while the remaining death receptors principally activate cell death pathways. The extracellular segments contain several cysteine-rich domains forming an extended structure stabilized by disulfide bonds. Death receptor ligands share a TNF homology domain and bind as trimers to the corresponding receptors. All known ligands are expressed as type II transmembrane proteins and are subject to limited proteolysis generating soluble forms. In most cases, soluble ligands are inferior to membrane-bound forms for receptor activation. Thus cell-cell contacts are necessary for death-receptor signaling, justifying the characterization of subsequent apoptotic deaths as “fratricides.”

In the simplest example, binding of Fas ligand to CD95/Fas receptor triggers clustering and allosteric conformational activation of a trimeric receptor. An adaptor protein, FADD, binds at the Fas cytoplasmic domain using homotypic DD associations. Similarly, procaspase-8 (or procaspase-10) is bound to FADD by homotypic DED interactions. The induced proteolytic activity of procaspase-8 associated with the DISC appears to be sufficient for autoprocessing in *trans* of neighboring procaspase molecules. An NH₂-proximal cleavage separates the caspase-8 prodomain from the catalytic subunits, allowing untethering of active caspase-8 from the DISC and initiation of a cascade of effector caspase processing. Certain cells (e.g., thymocytes) can bypass BCL-2 interdiction at the mitochondria and activate sufficient effector caspases downstream of death receptor signaling to kill cells (type I cells). Others (e.g., hepatocytes) rely on an amplification loop in which BID cleavage triggers mitochondrial apoptosis (type II cells).

Superimposed on this three-component model are additional factors that can substitute for one of the core components. FLICE/caspase-8 inhibitory protein (FLIP) is homologous to caspase-8 but devoid of protease activity (the active site cysteine is replaced). Different splice forms of FLIP retain the DED motif and compete with caspase-8 for binding to FADD. The long splice variant of FLIP, FLIP_L, forms heterodimers with caspase-8. Caspase-8 bound to FLIP_L has catalytic activity, but is processed inefficiently and remains associated with the DISC. Importantly, the caspase-8–FLIP_L heterodimer is unable to cleave caspase-3 or BID. Thus FLIP can either suppress caspase-8 activation or allow local activity. Moreover, FLIP_L is also a substrate for caspase-mediated cleavage in the DISC. The cleaved product may assist with the recruitment of RIP1 kinase to the DISC, promoting activation of NFκB and MAP kinases. Rapid turnover of FLIP explains the sensitization of death receptor-induced apoptosis by protein synthesis inhibition.

Recent evidence indicates that the signaling output of TNFR1 and other death receptors arises from distinct complexes.¹⁹ The TNFR1-bound complex triggers NFκB/MAPK signaling. Alternatively, a cytosolic complex lacking the TNFR1 is established following deubiquitination of RIPK1 kinase by the CYLD deubiquitinase and ubiquitin-editing functions of A20. This complex, designated the ripoptosome, is capable of apoptosis signaling via caspase-8. Notably, NFκB upregulates expression of FFLIP to inhibit ripoptosome-triggered apoptosis. In the absence of caspase-8 (or presence of caspase inhibitors), a third complex known as the necrosome promotes necroptosis, a programmed necrosis pathway characterized by cell swelling and rupture.²⁰ This requires association with another RIP kinase family member, RIPK3. Curiously, deletion of both caspase-8 and RIPK1/RIPK3 are synthetically viable in mice, indicating that the embryonic lethality associated with caspase-8 is due to RIPK1/RIPK3-dependent necroptosis.¹⁹ The downstream target of RIPK1/RIPK3 in necroptosis, the pseudokinase mixed lineage kinase domain-like protein (MLKL), oligomerizes after phosphorylation by RIPK3 and promotes plasma membrane permeabilization. Caspase-8 suppresses necroptosis by cleaving RIPK1 and RIPK3. Necrostatin 1, a small-molecule RIP1 kinase inhibitor, is a potent inhibitor of necroptosis.²⁰

Two arenas where death receptors have physiologic roles involve lymphocytes. Activation-induced cell death upon antigen restimulation involves Fas receptor signaling. Fas ligand (FasL) and Fas are induced during T-cell activation downstream of Lck and NFκB. Engagement of Fas on one cell by Fas ligand on a second cell triggers apoptosis. Autocrine suicide from FasL and Fas on the same cell have

also been reported. Thus the Fas–FasL system provides an upper limit on the density of activated T cells at sites of inflammation. Lymphocyte cell death is also directed by FasL expression on dissimilar cells. Fas expression in germinal center B-lymphocytes appears to play a role in eliminating cells bearing self-reactive surface immunoglobulin, as mice expressing Fas only on T-lymphocytes acquire high levels of auto-antibodies. In this case, FasL expression on T cells may deliver the fatal blow. T-lymphocytes can also be eliminated by FasL expressed on nonlymphoid cell types.

CELL SURVIVAL/DEATH PATHWAYS AND ADAPTIVE RESPONSES TO STRESS

Autophagy

The main function of survival factor signaling is to support growth and proliferation through activation of metabolism, including regulation of glucose uptake, glycolysis, and mitochondrial membrane potential.²¹ Phosphatidylinositol 3-kinase (PI3K) activation downstream of growth factor receptors, including activation of the serine/threonine kinase AKT, is essential for mediating the metabolic effect of growth factors. Consequently, growth factor withdrawal is associated with metabolic decline, including a drop in cellular ATP levels, blunted glycolytic rates, decrease in O₂ consumption, inhibition of protein synthesis, and induction of apoptosis.

In response to such metabolic stress and nutrient starvation, the cell activates a homeostatic pathway known as autophagy (from Greek meaning to eat [“phagy”] oneself [“auto”]). Autophagy is primarily a housekeeping mechanism that normally serves to degrade long-lived proteins and damaged organelles. It involves the formation of a double-membrane vesicle termed the autophagosome, which engulfs cytoplasmic cargo followed by fusion with the lysosome and subsequent degradation of internal contents. Autophagy is best known as a response to starvation, where the recycling of proteins and organelles supplies required nutrients to the cell.^{22,23} This process is regulated by an evolutionarily conserved set of proteins that ultimately orchestrate the recruitment of protein/organelle cargo to vesicles that will deliver their contents to lysosomes. Autophagy serves multiple functions, including tissue remodeling during development in addition to survival in the face of nutrient starvation or other environmental stress.^{22,23}

The survival signaling pathway and autophagy are hard wired to preserve the cellular bioenergetic balance. Survival signaling inhibits autophagy. Downstream of AKT, the mammalian target of rapamycin (mTOR) kinase (a mechanistic target of rapamycin) serves as a nutrient sensor that is activated by high levels of ATP, glucose, or amino acids, and in turn stimulates protein synthesis and inhibits autophagy. In the presence of growth factors and extracellular nutrients, mTOR inhibits autophagy through inactivation of unc-51 like autophagy activating kinase 1 (ULK1), an autophagy-related serine/threonine kinase that is important for autophagy induction. During nutrient starvation, the activity of mTOR is inhibited by adenosine monophosphate-activated protein kinase (AMPK), another nutrient sensor kinase that is activated when the ratio of AMP to ATP increases during metabolic stress. AMPK activates autophagy by inhibiting mTOR and phosphorylating ULK1. Upon cellular metabolic decline and nutrient starvation, breakdown of organelles and proteins in autophagosomes produces amino acids and metabolites that can then feed into the mitochondrial TCA cycle, sustaining the production of FADH₂ and NADH, ensuring that the flow of electrons through the mitochondrial respiratory chain complexes remains uninterrupted. The bioenergetic benefits of autophagy are temporary until the metabolic stress is eliminated (e.g., growth factor or oxygen availability). Inactivation of autophagy during metabolic decline and nutrient stress leads to apoptosis, unless apoptosis is inactivated (e.g., BAX/BAK deficiency), in which case cell death occurs through necrosis. Whether autophagy is primarily a means of cellular survival or, under certain contexts, can promote cell death, is the subject of intense investigation. Current findings

support the notion that autophagy is primarily a self-limiting survival pathway and a temporary adaptive response during metabolic stress, which can promote cell death if not terminated.

The interrelationship among apoptosis, autophagy, and necrosis carries significant relevance in tumor settings where defects in the apoptotic pathway (e.g., overexpression of BCL-2 or BAX, or BAK deficiency) and abnormal upregulation of proliferation (e.g., constitutive activation of the PI3K/AKT pathway) are common. Prior to vascularization, malignant cells in the center of tumors are exposed to hypoxia and metabolic stress. Here, autophagy meets the bioenergetic demands of tumor cells until vascularization supplies oxygen and nutrients. When exposed to hypoxia and nutrient limitation, such apoptosis-resistant tumor cells cannot undergo autophagy due to constitutive activation of AKT. They revert instead to necrosis, which through inflammation and stimulation of cytokine and chemokine production has been proposed to initiate a cellular repair program analogous to wound healing, further promoting proliferation and angiogenesis. Indeed, necrotic tumors are known to have poor prognosis. The above findings also explain, in part, why defects in autophagy are tumorigenic despite the notion that autophagy is primarily a survival pathway during metabolic stress.

Unfolded Protein Response

Protein stress responses also link into apoptotic pathways. These highly conserved mechanisms provide feedback fidelity control of protein folding, glycosylation, and secretory pathways in the ER and other subcellular compartments. Multiple inputs (amino acid deficiency, glucose deprivation, calcium dysregulation, redox poise) trigger this pathway via their effects on ER protein folding.

Three protein sensors, protein kinase-like ER kinase or EIF2AK3 (PERK), activating transcription factor 6 (ATF6), and inositol requiring transmembrane kinase/endonuclease 1 or ERN1 (IRE1), are triggered in response to unfolded proteins within the ER, and activate a homeostatic process that reduces production of new client proteins for the ER folding machinery, helps refold misfolded proteins, and degrades protein aggregates.^{14,24} The activity of these sensors is normally held dormant due to association with the ER chaperone BiP (HSPA5). During the unfolded protein response (UPR), BiP is bound and sequestered by unfolded proteins, leading to derepression of each UPR sensor. PERK is activated by dimerization and autophosphorylation to subsequently phosphorylate the translation initiation factor eIF2 α , leading to inhibition of general protein translation and selective increase in ATF4 translation. The transcription factor ATF4, in turn, increases the expression of select chaperones and antioxidant defense genes. ATF6 is activated upon translocation to the Golgi and undergoes subsequent proteolytic cleavage to a fragment that translocates to the nucleus and binds the UPR response element found in the promoters of target genes. Another UPR sensor, the bifunctional protein kinase IRE1, is activated by dimerization and transphosphorylation, leading to stimulation of its inherent endoribonuclease activity and processing of mRNA encoding the basic leucine zipper transcription factor X-box binding protein 1 (XBP1). XBP1, together with ATF6, regulates transcription of additional genes required for UPR, including chaperones, folding enzymes, protein disulfide isomerase, ER-associated degradation components, and autophagy genes. Increased ER-associated degradation components and autophagy help clear unfolded proteins, protein aggregates, and damaged organelles. Increased ER biogenesis is also part of the UPR transcriptional program ensuring sufficient ER mass matches the protein quality control response. This process is especially important for the differentiation of B-lymphocytes to antibody-secreting plasma cells. If the integrated outcome of these signaling pathways does not salvage the ER load of unfolded and aggregated proteins, these same UPR sensors can engage the intrinsic pathway of apoptosis.^{14,24} TP53 and CHOP/GADD153, a transcription factor induced by ATF4, initiate an ER stress-associated transcription program that is marked by changes in expression levels of several BCL-2 family members, death receptors such as Fas and DR5, and attenuation of the AKT

survival pathway. In addition, recruitment of the adaptor protein TRAF2 to IRE1 may further sensitize cells to ER-stress mediated apoptosis through activation of ER-linked caspases or c-Jun-terminal kinase.

Emerging evidence from multiple experimental systems indicates that select protein modulators of UPR can be both prosurvival or prodeath depending on the extent of ER damage or the duration of UPR. The discovery of BAX and BAK association with IRE1 and modulation of its downstream effectors, such as XBP1, suggest cross-talk between BCL-2 family proteins and UPR.¹⁴ Interestingly, the role of BAX and BAK in UPR is distinct from their function at mitochondria. How BAX and BAK modulate IRE1 activity/signaling and whether they execute a direct role or an accessory function during each of the adaptive/protective or apoptotic phases of UPR and ER stress remain to be determined.

Oncogene-Induced Apoptosis

Hyperactivity of mitogenic oncogenes such as Myc, adenovirus E1A, and Ras triggers a common pathway of p53 accumulation via stabilization of the ARF tumor suppressor protein. p14ARF (or p19ARF in mice) is encoded by an alternative reading frame in the p16INK4a locus. ARF inhibits Mdm2, the p53 E3 ubiquitin ligase, and also exhibits p53-independent functions, including binding to Myc and E2F transcription factors, inhibiting transactivation of target genes. The nature of the oncogenic stress leading to induction of ARF is still poorly understood, but may involve DNA replication or nucleolar stress.

CLINICAL APPLICATIONS

Abnormal regulation of cell death pathways is believed to contribute significantly to several diseases associated with excess cell number or function (e.g., neoplasia, autoimmune disorders) or accelerated cell loss (marrow failure syndromes, neurodegenerative diseases). The clearest supporting evidence is linkage to an altered gene sequence or epigenetic alteration, followed by mechanism testing in cellular/animal models. As previously discussed, BCL-2 gene rearrangement is associated with t(14;18) in follicular B-cell lymphomas, leading to transcriptional activation and high expression levels. Mutations in the Bax coding region are found in approximately 50% of colorectal and gastric cancers associated with mismatch repair defects, representing frame-shift mutations at a poly(G)8 tract in the coding region.

One of the anticipated benefits of basic research on cell death pathways is the ability to selectively manipulate cell survival or cell death through rational drug design. Members of the BCL-2 protein family, p53, and caspases have been targets of intensive efforts at drug discovery and design. Two small-molecule inhibitors of BCL-2 and related antiapoptotic proteins (BCL-X_L and MCL-1) have advanced to phase I–II clinical trials for chronic lymphocytic leukemia, Hodgkin and non-Hodgkin lymphoma, acute myelogenous leukemia, multiple myeloma, and myelofibrosis.^{25,26} These and several other inhibitors in late preclinical development bind to the hydrophobic groove in a similar manner to proapoptotic BH3 peptides, and are understood to act by preventing antiapoptotic proteins from sequestering proapoptotic proteins in the BCL-2 family. In addition, a broad-spectrum oxamyl dipeptide caspase inhibitor has completed phase II trials in treatment-resistant hepatitis C and orthotopic liver transplantation.²⁷

As targeted drugs against individual members of the BCL-2 antiapoptotic protein family enter clinical trials, a rapid and accurate cellular assay known as BH3 profiling has been developed to predict their efficacy in primary cancer cells.²⁸

SUMMARY

Apoptosis is an evolutionarily conserved, highly regulated mechanism for maintaining cell and tissue homeostasis in multicellular organisms.

Numerous signals are capable of modulating cell death. After a death stimulus, the signal is propagated and amplified through the activation of caspases, culminating in the ordered disassembly of the cell. The process may transpire through an intrinsic, mitochondria-dependent pathway, or an extrinsic pathway depending on the death signal and cell type involved. The BCL-2 family of proteins is situated upstream of irreversible cell damage in the apoptotic pathway, providing a pivotal checkpoint in the fate of a cell after a death stimulus. The proapoptotic molecules BAX and BAK undergo allosteric conformational activation to permeabilize mitochondria upon receipt of a death stimulus. BH3-only members connect distinct upstream signal transduction pathways with the common, core apoptotic pathway. The distribution and responsiveness of the BH3-only members suggests that they function as sentinels for recognizing cellular damage. This model would explain how seemingly diverse cellular injuries converge on a final common pathway of cell death.

OVERVIEW AND COMPARTMENTALIZATION OF THE IMMUNE SYSTEM

Dinesh S. Rao

The immune system is critical to the survival of humans and other mammals, keeping at bay a seemingly endless variety of pathogenic organisms that are encountered continuously in the course of life. It is a complex, multilayered system that has evolved over millions of years. From its earliest evolutionary incarnation in invertebrate species as a system of cells that ingests and destroys pathogens, the human immune system has evolved a variety of functions, including the ability to discriminate between highly related biochemical structures that differentiate harmful pathogens from harmless antigens. It also plays an increasingly recognized role in the clearance of dead cells and tissues, promotion of wound healing, and recognition of transformed cells. Disorders that are the consequence of immune under- or overactivity are found in all areas of medicine. Methods of manipulating the immune system in the areas of infectious disease, transplantation biology, autoimmunity, and tumor immunology are active frontiers of medical research and drug development.

Conceptually, the immune response may be divided into innate and adaptive systems (Table 19.1). The innate system is evolutionarily the oldest, with many components found in invertebrate species. Activated early in an immune response, the innate immune system is responsible for a rapid response mediated by cells with invariant pathogen recognition receptors. Pathogen–receptor binding results in the immediate activation of specific protective humoral and cellular responses. In contrast, cells of the adaptive system are responsible for development of long-term immunity against specific pathogens. In general, recurrent infections or infections by pathogens that escape the innate immune system result in the expansion of populations of pathogen-specific lymphocytes and the formation of immunologic memory. Although superficially separate, there is extensive cross-talk between the innate and adaptive immune systems, such that pathogens that activate one lead to the recruitment and activation of the other.

The innate and adaptive immune systems have been characterized in depth at the cellular and molecular levels. The principal goal of these systems is defense against pathogens seeking entry through one of four anatomic sites: the respiratory, gastrointestinal, and genitourinary tracts and the skin. Consequently, immune function has to be understood in terms of the anatomy of these four entry points and their relation to lymphatics, blood vessels, and lymphoid organs. This chapter provides an introduction to the molecular and cellular components of innate and adaptive immunity with an overview of their anatomic relationships.

THE INNATE IMMUNE SYSTEM

Pathogen Recognition Receptors and Pathogen-Associated Molecular Patterns

As the first responders to a pathogenic insult, the cells of the innate immune system use surface receptors, known as pathogen (or pattern) recognition receptors (PRRs), that recognize common molecular motifs, known as pathogen-associated molecular patterns (PAMPs), on various types of pathogens.¹ PAMPs are molecular motifs common to bacteria, fungi, and some viruses but not viable mammalian cells. They frequently are characterized by a repeating

pattern of hydrophobic or charged molecules. Common PAMPs include lipopolysaccharide (LPS, or endotoxin of gram-negative bacteria), peptidoglycans and teichoic acids (gram-positive and negative bacteria), mannans (fungi), single-stranded (ss) or double-stranded (ds) RNA (viruses), dsDNA (viruses or necrotic/apoptotic cells), and as most recently discovered, bacterial pigments.² PAMPs are thus integral structural motifs within various pathogens, and these common motifs are recognized by the PRRs (Table 19.2). PRRs are germline encoded and constitutively expressed, key features that distinguish them from the receptors expressed by cells of the adaptive immune system. PRRs may be transmembrane proteins expressed on the surface of bone marrow (BM)-derived effector cells, while others are soluble receptors found both intra- and extracellularly. They are also produced by epithelial cells in the gut, bronchial airways, renal tubules, uterus, skin, and endothelial cells in the liver.³ As such, they are poised to act at the four major portals of pathogen entry.

Pathogen recognition molecules or receptors encompass several different structural families (see Table 19.2). Two PRR families—peptidoglycan receptor proteins (PGRPs) and the Toll-like receptors (TLRs)—were first identified in *Drosophila* and only later demonstrated in vertebrate organisms.⁴ In humans, four PGRPs have been identified and are secreted by neutrophils, hepatocytes, and epithelial cells on mucous membranes and defend against gram-positive and gram-negative organisms. Ten TLRs have been identified; their ligands include bacterial lipopeptides (TLR1, TLR2, TLR6), peptidoglycans (TLR2), LPS (TLR2, TLR4), fungal saccharides (TLR2, TLR6), ds- and ssRNA (TLR3, TLR7, TLR8), flagellin (TLR5), and dsDNA and CpG DNA fragments (TLR9).^{3,5} The TLRs are type I transmembrane proteins that contain leucine repeats extracellularly that bind to their cognate PAMPs and intracellular domains that mediate signaling. Other PRR families include the C-type lectins (including the mannose-binding lectin [MBL] and pulmonary surfactant proteins), dectin-1, macrophage scavenger receptors, RIGI-like receptors (RLRs), NOD-like receptors (NLRs), and the aryl hydrocarbon receptor (AhR).⁶ These families include extracellular PRRs, transmembrane and intracellular (cytosolic) PRRs. The cytosolic PRRs are thought to be important in recognition of intracellular pathogens such as viruses and bacteria. The RLRs recognize RNA viruses via their RNA helicase enzymatic activity; the twenty different NLRs recognize a variety of PAMPs, non-PAMP particles, and cellular stresses, and the AhR binds to bacterial pigments. Hence the innate immune system has evolved a number of strategies to recognize common structural motifs and thereby initiate the immune response.

Consequences of PRR–PAMP Engagement: Phagocytosis, the Cytokine Response, and Priming the Adaptive Immune Response

PRR–PAMP ligation triggers immune and inflammatory responses in three stages. In the first stage, the “professional” innate immune cells, including monocytes, macrophages, and neutrophils, facilitate clearance of pathogens. This process is initiated by pathogen binding directly to PRRs on the surfaces of these cells followed by internalization, or the opsonization of pathogens bound by a soluble PRR, which are subsequently recognized by receptors on a

TABLE 19.1 Human Innate Versus Adaptive Immune System

Feature	Innate	Adaptive
Response time	Hours to days	>5 days
Expression	Constitutive	Induced by pathogen exposure
Shaped by pathogen exposure	No	Yes
Approximate number of gene products involved in direct pathogen recognition	10^2 – 10^3	10^{10} – 10^{14}
Clonal response	No	Yes
Found in invertebrate species	Yes	No

phagocytic cell. Internalized pathogens are destroyed by a combination of hydrolytic and oxidation reactions within vacuoles inside the phagocytic cells. Phagocytosis also triggers the release of bactericidal or bacteriostatic molecules from intracellular granules into the tissue. These products (e.g., lysozyme, lactoferrin, myeloperoxidase, antimicrobial peptides, nitrous oxide, and superoxide radicals) are toxic to pathogens and induce a local inflammatory response that can lead to tissue injury. Other molecules released, including elastase and collagenase, participate in tissue injury and wound healing.^{7,8}

The second stage is cytokine production, which is responsible for initiating, amplifying, and maintaining the innate and adaptive immune response. The signaling pathways involved within the cell vary by PRR, but activation of NF κ B (nuclear factor κ -light-chain-enhancer of activated B cells) is a central event in almost every aspect of the immune response. Other signaling pathways that are activated include the caspases, IRF3/5/7, MyD88, and other kinase cascade pathways. Also involved in the downstream activation and regulation of the immune response are novel small RNA molecules, known as microRNAs. These small RNA molecules can regulate the expression of critical proteins that can be effectors of the immune response (e.g., microRNA-155), and certain microRNAs seem to be key in reigning in overactivity of the immune system (e.g., microRNA-146a).⁹ Downstream of these signaling pathways, cytokines, which include interleukins, interferons (IFNs), and chemokines, are synthesized and secreted. Interleukins, which are produced by monocytes, macrophages, lymphocytes, or certain epithelial cells, can amplify the innate and initiate the adaptive immune responses. IFNs, produced by virtually every cell type, propagate antiviral and antitumor responses by activating T cells and natural killer (NK) cells. Chemokines are produced primarily by cells of the innate immune system and function dually as chemoattractants (i.e., recruiting cells) and cytokines (i.e., activating cells). Members of the tissue necrosis factor family mediate the sepsis response and cell death and participate in the development of lymphoid organs. A simplified organization of some of the better-characterized cytokines by biologic effects is presented in Table 19.3, and a more detailed discussion of some cytokines can be found in Chapter 16.

Finally, activation of the adaptive immune response occurs. Both by the production of cytokines, which activate lymphocytes, and by the processing, transport, and presentation of antigens directly to T cells (primarily done by dendritic cells [DCs]), PRRs and cells of the innate immune system are essential for the development of adaptive immune responses. The biology of T cells, B cells, and DCs is discussed in detail in Chapters 20 to 23.

IMMUNE DEFICIENCY CONDITIONS CAUSED BY MUTATIONS IN THE INNATE IMMUNE SYSTEM

Mutations of several components within the innate immune system have been identified. These include mutations in PRRs, downstream

signaling components and cytokines. For instance, 10 different MBL haplotypes have been identified with serum levels varying by up to 1000-fold. Low levels can be associated with increased severity of infections with encapsulated organisms in immunocompromised or chronically infected hosts. Mutations in TLR3 have been associated with increased susceptibility to encephalitis caused by DNA viruses.¹⁰ Many different mutations of signaling intermediates and cytokines, such as Myd88 and components of IL-12, have also been identified, and lead to susceptibility to streptococcal infections and mycobacterial infections, respectively. However, it should be noted that the complete lack of certain key components of the innate immune system is incompatible with life, as evidenced by experiments in mice. Hence many of the genetic changes found in patients with mild phenotypic changes are better viewed as phenotypic variants, rather than as disease-causing mutations.

INNATE IMMUNITY AND TISSUE HOMEOSTASIS

Pathogen recognition molecules or receptors and cells of the innate immune system also play roles in normal tissue homeostasis. Specific PRRs are involved in the clearance of serum clotting factors, hormones, lysosomal hydrolases, and senescent cells, and in wound healing.¹¹ The class A scavenger receptor on macrophages is involved in the internalization of oxidized low-density lipoprotein, the development of atherosclerosis, and the clearance of apoptotic T cells in the thymus.¹² The immune system is actively involved in surveillance against transformed or cancerous cells, much of it via interfaces between the innate and adaptive immune systems (IFN- γ , $\gamma\delta$ T cells, NK cells, and cytotoxic T lymphocytes [CTLs]).

ADAPTIVE IMMUNE RESPONSE

In juxtaposition to the innate immune system, which is characterized by rapid, fixed, and broad responses to pathogens, the adaptive immune system has evolved to respond to pathogens in a remarkably specific and long-lasting manner. This is accomplished by the generation of a receptor repertoire far more diverse than that represented by PRRs, and the amplification of populations of pathogen-specific cells as a consequence of pathogen exposure (i.e., generation of specific immunologic memory). The two key receptors, those encoding the T-cell receptor (TCR) and the B-cell receptor/immunoglobulin (BCR/Ig), are generated by somatic rearrangements and mutations in TCR and BCR/Ig genes during T- and B-cell development. This process results in a remarkable diversification and amplification of the repertoire of pathogen-specific recognition molecules (see Table 19.1). Indeed, the number of possible pathogen detection motifs encoded by the TCR and BCR/Ig following genetic rearrangement vastly outnumber the number of known pathogenic organisms by many orders of magnitude.

The activation of the adaptive immune system depends on the initial recognition of a pathogenic insult by the innate immune system. This initial response triggers the production of cytokines that activate resident DCs, which then phagocytize and process the antigens by cleaving them into small peptides. These peptides are then presented on the DCs' surfaces bound to major histocompatibility complex (MHC) molecules. Recognition of the processed antigens by the TCR leads to activation of T cells, which in turn activate B cells, thus initiating the adaptive immune response. This antigen presentation step may occur at the site of pathogen exposure, or it may require the migration of antigen-containing DC from the point of pathogen entry through lymphatic channels to lymphoid tissues. In addition, activation of innate immune cells leads to changes in vascular permeability, and lymphocyte adhesion. These steps result in local inflammation and the recruitment of additional lymphocytes to the site of pathogen entry, hence localizing all the correct cellular players to the site of infection. DCs, B cells, and T cells are discussed in depth in Chapters 20 to 23.

TABLE 19.2 Human Pathogen Recognition Receptors

Receptor	Location	Ligands or PAMPs	Features
TLRs (leucine-rich protein)	Leukocytes and some epithelial cells in bronchial airways, urogenital tract, and gut	Cell wall components of gram-positive and gram-negative bacteria (peptidoglycans and lipopeptides), viral dsDNAs, ds- and ssRNAs, bacterial flagellin, and other pathogen-derived molecules	A family of 10 different proteins (TLR1–TLR10) found as transmembrane proteins on the surface of cells or internal endosomes or as free cytosolic proteins; trigger cell activation and cytokine response
CD14 (leucine-rich protein)	Soluble and membrane-bound forms found on monocytes, macrophages, and endothelial cells	LPS from gram-negative bacteria	Binding of LPS on the cell surface forms a complex, including TLR4, which results in cytokine production and the sepsis response
Serum MBL (C-type lectin)	Soluble protein found in serum and lymphatic fluid	Pathogen-derived carbohydrate structures containing mannose, fucose, or <i>N</i> -acetylglucosamine	Secreted by hepatocytes; binding to pathogen triggers complement activation and assembly of the membrane attack complex
Pulmonary surfactant proteins (C-type lectin)	Soluble proteins found extracellularly on pulmonary mucosal surfaces	Carbohydrate structures or lipid motifs on viral, bacterial, or fungal pathogens and inhaled irritants, including pollens	Secreted by alveolar type II cells and nonciliated bronchiolar epithelial cells; binding to pathogen induces opsonization and leukocyte activation (including alveolar macrophages)
Macrophage mannose receptor (C-type lectin)	Surface of monocytes and macrophages	Pathogen-derived carbohydrate structures similar to MBP	Ligand binding results in phagocytosis and monocyte or macrophage activation
NKG2 (C-type lectin)	Surface of NK cells	Carbohydrates on HLA molecules or other host molecules	Involved in recognition and destruction of virally infected or transformed host cells
Dectin-1 (C-type lectin)	Surface of macrophages, neutrophils, and DCs	β -Glucan structures on fungi and plants	Binding results in cell activation, cytokine production, and internalization of pathogen
Class A scavenger receptors (SR-A I/II/III) (scavenger receptor family)	Monocytes, macrophages, and epithelial cells	Modified, cell wall components of gram-positive and gram-negative organisms	Phagocytosis of nonopsonized particles and macromolecules triggers macrophage activation and cytokine release; plays a role in the generation of atherosclerotic plaques and diabetic nephropathy
MARCO (scavenger receptor family)	More restricted macrophage populations than SR-A, including alveolar, peritoneal, and thymic macrophage populations	Similar to SR-A, including silica particles	Phagocytosis of nonopsonized particles and macromolecules triggers macrophage activation and cytokine release
RIG-I like receptors (RLRs) (RIG-I, Mda-5)	Cell cytoplasm	dsRNA	Bind to dsRNA produced during intracellular replication of certain classes of viruses
CRPs and serum amyloid P (Pentraxins)	Serum proteins	Bind to and affect clearance or activation of host proteins (C1q and DNA fragments) as well as constituents of some pathogenic organisms	Secreted by the liver during early acute-phase response and influence clearance and complement activation of recognized macromolecules
Peptidoglycan recognition proteins	Soluble proteins found intracellularly in leukocyte granules or synthesized by the liver and secreted into the serum	Peptidoglycan structures	Direct bacteriocidal or bacteriostatic activity by interfering with bacterial peptidoglycan wall biosynthesis
NOD-LRR receptor family (NLR) (includes NOD, NALP, CIITA, IPAF, and NAIP proteins)	Soluble intracellular proteins	NOD1 and NOD2 bind bacterial peptidoglycan; PAMPs for other proteins not identified	Survey intracellular compartment for intracellular pathogens, binding to bacterial wall fragments produced either during bacterial proliferation or lysosomal degradation; ligand binding triggers activation of NF κ B inflammation pathway
$\alpha_3\beta_3$ (integrin)	Epithelial cells	<i>Trypanosome cruzi</i>	Binding induces opsonization and cell activation
CD11b/CD18 (also CR3) (integrin)	Monocytes, macrophages, and epithelial cells	LPS, constituents of <i>Mycobacterium tuberculosis</i> , yeast saccharides (including zymosan)	Binding induces opsonization and cell activation
Sialic acid-binding immunoglobulin-like lectins (Siglecs)	Surface receptors on monocytes, macrophages, NK cells, and myeloid cells	Sialylated complex carbohydrates (found on endogenous proteins and some pathogenic organisms)	Role for binding and phagocytosis of pathogenic organisms proposed

CIITA, Class II transcription activator; CRP, C-reactive protein; DC, dendritic cell; HLA, human leukocyte antigen; IPAF, ICE-protease activating factor; LDL, low-density lipoprotein; LPS, lipopolysaccharide; MARCO, macrophage receptor with collagenous domain; MBL, mannose-binding lectin; MBP, mannose-binding protein; NAIP, neuronal apoptosis inhibitory protein; NALP, NACHT-, LRR-, and PYD-containing proteins; NF κ B, nuclear factor κ -light-chain-enhancer of activated B cells; NK, natural killer; NLR, NOD-like receptor; NOD-LRR, nucleotide-binding oligomerization domain leucine-rich repeats; PAMPs, pathogen-associated molecular patterns; SR-A, scavenger receptor type A; TLR, Toll-like receptor.

TABLE 19.3 The Cytokines

Cytokines and Cellular Targets	Examples	Biologic Consequences
Interleukins		
Monocyte and macrophages, endothelial cells	IL-1, IL-2, IL-6, IL-10, IL-13, IL-16, TNF- α	Local inflammation, cell recruitment, hepatic acute phase reaction, sepsis response
B cells	IL-2, IL-4, IL-6, IL-7, IL-9, IL-14	Recruitment, activation, differentiation of B cells
T cells (type 1 cytokines)	IFN- $\alpha/\beta/\gamma$, IL-2, IL-12, IL-15	T helper(T_H)1 response: defense against intracellular pathogens
T cells (type 2 cytokines)	IL-4, IL-5, IL-6, IL-10, IL-13	T_H 2 response: defense against parasitic infections
Neutrophils, epithelial cells	IL-17, IL-22	T_H 17 response: defense against extracellular pathogens; mucosal inflammation and release of antimicrobial peptides, neutrophil recruitment, and autoimmunity
Interferons		
T cells and NK cells	IFN- α , IFN- β , IFN- γ	Upregulate activity of T cells and NK cells against virally infected cells and malignant cells
Tissue Necrosis Factors		
All cells except erythrocytes	TNF- α , TNF- β	Pyrexia, tissue hyperemia, capillary leak, sepsis/shock syndrome, enhancement of target cell effector functions, expansion of lymphoid compartments
Chemokines		
Monocytes and macrophages, granulocytes, dendritic cells, lymphocytes	MCPs, eotaxin, TARC, MDC, MIPs, RANTES, PF4	Recruit and activate cells of innate and adaptive immune system to specific sites of pathogen exposure, inflammation, or tissue damage
Hematopoietic Growth Factors		
Hematopoietic cells in marrow and peripheral compartments	G-CSF, GM-CSF, M-CSF, SCF	Maintenance, growth, and differentiation of hematopoietic cells

G-CSF, Granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; MCP, macrophage/monocyte chemotactic protein; M-CSF, macrophage colony-stimulating factor; MDC, macrophage-derived chemokine; MIP, macrophage inflammatory protein; PF4, platelet factor 4; RANTES, regulated on activation, normally T cell expressed and segregated chemokine; SCF, stem cell factor; TARC, thymus and activation-regulated chemokine; TNF, tumor necrosis factor.

CELLS OF THE INNATE AND ADAPTIVE IMMUNE SYSTEMS

Traditionally, cells of the immune system were designated as being either innate or adaptive immune cells: the cells of the innate immune system included granulocytes, monocytes/macrophages, and dendritic cells, while the major cells of the adaptive immune system were lymphocytes, including B cells, T cells, and NK cells. Through the years, it has been discovered that several subsets of lymphocytes have innate immune cell-like properties, and hence this traditional distinction has been blurred somewhat. Nonetheless, it remains conceptually useful to understand the function of these cells as contributing to innate or adaptive immunity. For the most part, immune cells are generated in the BM and may undergo subsequent maturation steps in the periphery. Innate cells such as monocytes mature in tissues where they may become resident, while lymphocytes undergo maturation at specific sites: thymus, lymph node, and spleen. In general, innate immune cells are short-lived, whereas antigen-specific lymphocytes are long-lived and provide long-term protection. In addition to these BM-derived cells, additional cells, such as epithelial cells with pathogen clearance functions, are also involved in the immune response.

B Cells

B cells were first described approximately 50 years ago as being the cells in the bursa of chickens that were the likely source of antibody production.¹³ Many different subsets of B cells have been described based on their stage of maturation and their presumed function in the immune response. Surface expression of BCR/Ig marks a mature B cell, and these generally express CD19 and CD20. The majority

of B cells are B2 B cells, which undergo activation by T cells via an antigen-specific mechanism, and are the cornerstone of the adaptive immune response. A second subset, known as B1 B cells, are best described in mice and have distinctive properties. These cells can secrete antibodies in the absence of T cell-mediated stimulation, and are sometimes considered a portion of the innate immune system. Other subsets of B cells include plasma cells, which are specialized secretory cells that produce, on a per-cell basis, incredibly high levels of secreted immunoglobulins, and long-lived memory B cells, which carry a memory of a prior pathogen in the highly specific BCR/Ig that they express.

T Cells

After emerging from the BM compartment, T cells develop further into $\alpha\beta$ T-cell or $\gamma\delta$ T-cell populations (further discussed in [Chapter 21](#)). The $\alpha\beta$ T cells are the most abundant subset and include CD3⁺CD8⁺ and CD3⁺CD4⁺ T-cell populations. CD3⁺CD8⁺ T cells, which develop into CTLs, are involved in defense against virally infected or transformed cells. CD3⁺CD4⁺ T cells can be further subdivided into T helper (TH)1 cells (stimulate development of CTLs), TH2 cells (stimulate isotype switching and antibody production in B cells), TH17 cells (induce or enhance tissue damage secondary to autoimmune or infectious processes), and T-regulatory (Treg) cells (control or limit autoimmune responses). A recently recognized anatomic subset of CD4⁺ T cells, T-follicular helper cells (TFH), are found in germinal centers of activated LNs and constitute the most common cell of origin for T-cell lymphoma.¹⁴ $\gamma\delta$ T cells are CD3⁺ T cells that can develop in the thymus and the gut. Thought to function in innate immunity, $\gamma\delta$ T cells represent only 1% to 5% of circulating T cells but up to 50% of the T cells in certain epithelial sites (e.g., skin and intestinal tract). Carrying a TCR of poorly defined

specificity, $\gamma\delta$ T cells respond to bacterial and viral infections and possibly malignant transformation.

NK Cells

Natural killer cells are a distinct lymphocyte subset and comprise approximately 10% of the circulating lymphocyte population. NK cells are identifiable by their $CD3^-CD56^+$ phenotype. They function in defense against virally infected cells and transformed cells through the generation of cytotoxic cytokines, direct cytolytic activity, and antibody-dependent cellular cytotoxicity. Although traditionally included as a subset of lymphocytes, like B1 B cells and $\gamma\delta$ T cells, NK cells seem to bridge the adaptive and innate immune systems. These cells carry invariant receptors, including both activating and inhibitory receptors. The activating receptors such as $CD94/NKG2s$, and natural cytotoxicity receptors (NCRs), lead to the generation of cytotoxic cytokines and direct cytolytic activity. NK cells also have inhibitory receptors, including the killer cell Ig-like receptors (KIRs), which allow for suppression of NK cell activity, generally through ligation of a self-molecule (classical major histocompatibility class I molecules). Hence the balance between activating and inhibitory signals allows NK cells to function in clearance of infected, damaged, or cancerous cells, and to function in immune system surveillance.

Monocytes, Macrophages, and Dendritic Cells

Monocytes develop in the BM and then circulate through the blood and lymphatics with an average half-life of 1 to 3 days before migrating into tissues and maturing into macrophages.¹⁵ Macrophages can be found in all tissues, particularly at points of entry for pathogens such as the skin, respiratory tract, gastrointestinal tract, and genitourinary tract. Tissue-specific macrophage populations include Kupffer cells (liver), alveolar macrophages (lung), osteoclasts (bone), microglia (central nervous system), and type A lining cells (synovia), which can be identified morphologically and by surface immunophenotype. Macrophages function at many levels in the immune response, with their traditional role being in phagocytosis, cytolytic granule release, and antigen presentation. More recently, their role as cytokine secreting cells and in coordinating the immune response has been appreciated.

Dendritic cells are specialized antigen-presenting cells (APCs). Similar to macrophages, DCs are found at points of pathogen entry, including the skin and mucosal surfaces, and locations of lymphocyte proliferation, such as germinal centers (GCs). Their main role is to present processed antigens to T-helper cells, but they are also known to activate the cytotoxic T-cell response. DC biology is described further in Chapter 23.

Granulocytes

Granulocytes can be further subclassified into neutrophils, basophils, and eosinophils by the types of cytoplasmic granules that they contain. Neutrophils mature in the BM, and large pools of neutrophils are found there, with significant numbers also found in the lung, spleen, and liver. The recruitment of neutrophils from these reservoirs into the circulation and inflamed tissues can occur within hours of exposure to bacterial products such as endotoxin. Neutrophils can be triggered to their effector function via PAMP-PRR ligation. Neutrophils have multiple functions, including the direct killing of foreign organisms via phagocytosis or release of toxic enzymes from granules, release of PRRs, and the formation of neutrophil extracellular nets (webs of degraded nucleic acids and histones), which trap organisms. Neutrophils can also recruit and activate the cells of the adaptive immune system (lymphocytes and DCs).

The basophilic leukocytes—mast cells and basophils—have several structural and functional similarities. They are key mediators of immediate allergic and inflammatory responses, with mast cells

being more predominant in tissues and basophils in circulation. Both cell types express Fc ϵ R, which induces rapid degranulation when triggered by aggregated IgE, and have granules containing histamine, platelet-activating factor, and bioactive proteoglycans. Degranulation can be rapid, producing anaphylaxis, or sustained, inducing a more sustained inflammatory response. Mast cells and diseases related to mast cells are discussed in Chapter 72.

Eosinophils are found predominantly in tissues, with a smaller fraction found in circulation. The eosinophilic granules of this subset contain hydrolytic enzymes that may be damaging to invading pathogens and host tissues. Eosinophil activation also triggers leukotriene production and the release of an array of cytokines. A role in allergic responses and defense against helminth pathogens has long been presumed consequent to the eosinophilia characteristic of these conditions; however, the true physiologic function of eosinophils remains elusive. Although traditionally thought of as part of the innate immune system, eosinophils may be viewed as effector cells of the adaptive immune system because they can be acutely triggered by a B-cell product (IgE) and their development in part depends on T cells. Disorders of eosinophils are discussed in Chapter 71.

Non-Bone Marrow–Derived Cells Involved in Immune Function

Populations of non-BM–derived cells function in innate immunity. Renal tubular cells and epithelial cells in the gut, bronchial airways, reproductive organs, and dermis express PRRs. In these cells, the receptors function in pathogen clearance or by triggering pathogen-dependent inflammatory responses. Bronchial airway cells secrete pulmonary surfactants and antimicrobial peptides, creating a localized antimicrobial barrier. Liver endothelial cells use several PRRs, including the Fc γ , scavenger, and mannose receptors, to clear particular serum proteins and pathogens. The functions of these cells dovetail with those of the leukocytes in pathogen defense and tissue homeostasis.

ANATOMY OF THE IMMUNE SYSTEM

An array of soluble mediators and a repertoire of immune cells mediate the host response to microbial pathogens, to tumors, to self-antigens in autoimmunity, and to foreign antigens in graft rejections. Where do these cells and mediators come from, and where do these interactions take place?

Immune Cell Development: Primary and Secondary Lymphoid Organs

The organs and tissues of the immune system are divided into the primary (or *generative*) *lymphoid organs* and *secondary* (or *peripheral*) *lymphoid organs*. The *primary lymphoid organs* consist of the BM and thymus and are the sites where cells of the innate and adaptive immune system are generated and produced. The *secondary lymphoid organs* include the spleen, LNs, and epithelial- and mucosa-associated lymphoid tissues such as Peyer patches in the small intestine. These secondary lymphoid tissues are the anatomic site for coordination of the adaptive immune response.

Most immune cells arise in the BM (discussed in detail in Chapters 9, 20, 21, and 27). The cellular components of the innate immune response—neutrophils, eosinophils, basophils, and monocytes—leave the BM as mature, functional cells. In contrast, the cellular components of the adaptive immune response require further development and refinement of function in specific anatomic sites. T-cell precursors leave the BM and migrate to the thymus, where they develop their antigen receptor, the TCR. Following acquisition of a functional TCR, the T cells undergo further refinement of function in the periphery, where they can adopt various fates. Although B cells leave the BM with a functional BCR/Ig, they require further maturation

Fig. 19.1 ANATOMY OF THE THYMUS. The human thymus (*left*) is composed of lobules, each separated by a thin capsule. Immediately under the capsule is a narrow zone called the *subcapsular cortex* that surrounds the larger zone of the cortex, the darkly staining region. In the center of each lobule is the medulla, the lighter staining region. In the medulla, nests of epithelial cells called *Hassall corpuscles* (*inset*) are visible. T-cell precursors (*right, morphology shown in inset 2 on left*) arising in the bone marrow migrate through the blood and enter the thymus as immature cells. During maturation in the cortex, most of the immature thymocytes fail to produce functional T-cell receptors (TCRs) and die. Cells that produce functional TCRs are positively selected to survive and migrate to the thymic medulla. Mature, naive T cells exit the medulla to the peripheral circulation.

following interaction with T cells and antigen in secondary lymphoid organs, such as the spleen or LNs.

T-Cell Maturation

T-cell precursors mature into functional T cells in the thymus ([Fig. 19.1](#)).¹⁶ The thymus is composed of developing T lymphocytes, DCs, epithelial cells, and mesenchymal components, collectively referred to as the thymic stroma. The thymic stroma arises primarily from the third and fourth pharyngeal pouches during fetal development, and is then populated by waves of lymphocyte precursors emigrating from the BM. The stromal meshwork is essential for thymic T-cell development, as evidenced by patients with DiGeorge syndrome, otherwise known as 22q11 deletion (del22q11) syndrome. These patients have a failure of involution of the third and fourth pharyngeal pouches and consequent absence of thymic stroma, consequent to the deletion of developmentally critical genes. Although patients with DiGeorge syndrome have T-cell precursors in the BM, they have no recognizable thymus and have markedly reduced numbers of mature T cells in the peripheral circulation and in tissues. As discussed in “Secondary Lymphoid Tissue,” the observation that most patients with DiGeorge syndrome do have small numbers of circulating mature T cells suggests that extrathymic sites in these patients may partially substitute for the thymus in promoting T-cell maturation.

The thymus is divided histologically into two general zones, the cortex and the medulla, although further distinctions in zonal properties of resident thymocytes have been noted.¹⁷ Early T-cell precursors leave the BM, circulate in the blood, and selectively home to the thymus, entering to populate the subcapsular cortex. At this site, TCR rearrangement begins, and maturing thymocytes move into and through the cortex, continuing to proliferate. Interactions among TCRs expressed by developing T cells and self-peptide/MHC-I complexes presented by resident thymic cortical and medullary epithelial cells (cTECs and mTECs) mediate the process known as selection.¹⁷ A large fraction of thymocytes, however, fail to express a functional TCR and are never able to interact with cTECs; as a result, these cells do not receive critical survival signals from cTECs and thus undergo programmed cell death. T cells that do express a functional TCR undergo one of two fates—positive selection or negative selection. In positive selection, thymocytes that have successfully assembled

a TCR with low to intermediate affinity for self-peptide–MHC complexes are selected to survive and mature. In negative selection, thymocytes bearing TCRs with a high affinity undergo apoptosis. Hence the two extremes of TCR signal strength, absence and high affinity, lead to an identical fate, apoptosis, while intermediate levels allow the cell to survive and become part of the T-cell repertoire.¹⁸

T cells that survive the selection process in the cortex proceed to the medulla, where they commit to a particular T-cell lineage (CD4 or CD8) and undergo further negative selection by interactions with mTECs that express tissue-specific antigens promiscuously.¹⁷ Negative selection by the mTECs is partially regulated by the transcription factor termed *autoimmune regulator* (AIRE). AIRE deficiency results in inadequate deletion of self-reactive T cells and manifests clinically as autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy in humans (APECED).¹⁹

Only 1% to 3% of the initial thymic progenitor cells succeed in surviving the selection process and thus emigrate from the thymus as non-self-reactive, functional CD4 or CD8 cells. This remarkably complex process hinges on the special anatomic organization of the thymus and leads to the establishment of a T-cell repertoire capable of directing the adaptive immune response against a broad range of antigens. The development of T cells is further elaborated in [Chapter 21](#).

B-Cell Maturation

Although there are parallels between T- and B-cell development, important differences exist. For example, B cells have a functional BCR/Ig by the time they leave the BM, which is discussed in [Chapter 20](#). Nonetheless, they have not yet encountered antigen, and these naive B cells traffic to *secondary lymphoid tissues*, where cells of the adaptive immune system encounter non-self-antigens and become activated. Briefly, naive cells enter primary follicles in the cortex of the secondary lymphoid tissue.²⁰ When B cells in primary follicles encounter antigens that are recognized by their surface BCR/Ig, this is presented to T cells bearing receptors for non-self-antigens. The T cells become activated and in turn provide signals to the B cells, leading them to proliferate and to activate the DNA-editing enzyme, activation-induced deaminase (AID).²¹ This enzyme causes double-stranded breaks in the DNA, which allows for two

concurrent processes: class switch recombination (CSR) and somatic hypermutation (SHM) of immunoglobulin genes. CSR allows the B cell to express a secreted Ig with unique properties, by replacing the constant region of the BCR/Ig with a different constant region via DNA recombination. SHM can sometimes lead to advantageous mutations that can allow a BCR to have higher affinity for a pathogenic antigen. These B cells, bearing a higher-affinity BCR than the B-cell clone that they derived from, are positively selected to proliferate.

When B-cell proliferation begins, the primary follicle becomes a secondary follicle. The secondary follicle has two general regions: (1) a GC filled with proliferating B cells, some T cells, macrophages, and DC; and (2) the surrounding mantle zone of nonproliferating B cells that have not encountered an antigen they recognize. The GC can be further divided into dark and light zones, depending on the stage of proliferation, as discussed later in “Systemwide Surveillance.”

ENCOUNTERS WITH ANTIGEN: THE INFLAMMATORY RESPONSE

A primary function of the immune system is to protect against microbial pathogens. The most common sites for microbes to breach the protective barriers of epithelium are the skin and the respiratory, gastrointestinal, and genitourinary tracts. These tissues directly encounter the outside world and possess complex, multifaceted mechanisms for dealing with antigens. It should be noted, however, that there is a vast array of nonpathogenic microbes that live in close proximity to these epithelial barriers, and an emerging body of scientific work points to the importance of these commensal organisms for maintaining immune homeostasis.^{22,23}

To defend against pathogenic organisms, these barriers contain many components of the innate immune system, including macrophages and DCs. Some tissues have specialized or unique populations of macrophages and DCs, although these cells have many common features in different tissues. Macrophages provide a critical first line of defense against pathogens by directly phagocytizing microorganisms. Macrophages also send the first signals that recruit granulocytes from the circulation into the tissues (Fig. 19.2). These signals include cytokines, nitrous oxide, and leukotrienes that cause vasodilation,

endothelial cell activation, leukocyte adhesion to endothelial cells at the inflammatory site, and diapedesis of leukocytes into the tissues (see Chapter 13). The resulting exudate fluid at the site of vasodilation is also rich in plasma proteins that participate in innate immunity, such as complement and PRRs. Hence the soluble and cellular components of the innate immune system provide the first line of defense at the tissues where pathogens invade.

The epithelial barriers also contain resident lymphocytes and plasma cells. The lymphoid cells respond to cytokines secreted by resident macrophages, such as IL-2, which stimulates T-cell proliferation. The ability of macrophages to secrete mediators that cause vasodilation and recruitment of granulocytes, as well as initiate T-cell activation, illustrates the interplay between innate and adaptive immunity and underscores the point that the innate and adaptive immune systems work in concert in host defense. Resident T cells and plasma cells in the tissue can respond to antigen, with local activation of antigen-specific effector T cells and increased antibody secretion, respectively, so that the adaptive immune response is stimulated locally after pathogens are sensed by the innate immune system.

SYSTEMWIDE SURVEILLANCE: THE ROLE OF LYMPHATIC CIRCULATION

Lymphatics are an essential component of the vascular system (Fig. 19.3). Even in the absence of inflammation, a fraction of the fluid component of blood continually leaves the capillary bed during circulation caused by the pressure drop between the arterial and venous sides. This fluid bathes the tissues of the body picking up antigens and cells and then drains into lymphatic channels that interdigitate in every capillary bed.

At sites of inflammation, the amount of fluid and cells draining into the local lymphatics increases because of changes in the vascular tone and permeability mediated by macrophage- and neutrophil-derived chemokines, lipid mediators, and oxygen radicals. This exuded fluid, along with antigen-loaded DCs, T cells, and cytokines, drains from the tissues back through the lymphatic channels.

Lymphatic fluid eventually returns to blood circulation via the thoracic duct, which drains into the vena cava. However, before

Fig. 19.2 ENCOUNTERS WITH ANTIGEN. The immune system evolved primarily to protect against invading microorganisms that penetrate the epithelial coverings of the body. In this schematic, microbes entering through a break in the skin epithelium are phagocytosed by resident macrophages as the first line of defense in innate immunity. The macrophages can secrete products that are directly microbicidal, as well as cytokines and other mediators that cause vasodilation and endothelial cell separation, to allow influx of soluble mediators and inflammatory cells such as neutrophils and lymphocytes into the skin. Neutrophils, as a component of innate immunity, can also directly kill microorganisms, typically by releasing granular contents. Lymphocytes responding to microbial antigens proliferate and contribute to the adaptive immune response against microbes.

Fig. 19.3 LYMPHATIC DRAINAGE IS A CRITICAL PART OF IMMUNE SURVEILLANCE. As shown in Fig. 19.2, fluid and cells leave the vasculature at sites of inflammation. Hydrostatic pressure across the capillary bed continually drives transudation of fluid from the blood into tissues. The extravasated fluid, along with antigen-presenting cells (APCs) such as macrophages and dendritic cells, collects in lymphatics (inset). Lymphatics drain past series of lymph nodes (dark ovals), affording the APCs the opportunity to migrate to lymph nodes and stimulate lymphocytes in the nodes. Fluid in lymphatics passing through chains of lymph nodes eventually collects in the thoracic duct, which returns the fluid to the vascular circulation by draining into the vena cava.

returning to the venous circulation, lymphatic fluid travels through the secondary lymphoid tissues and undergoes sampling for foreign antigens, thus providing a mechanism of systemic immune surveillance. The organization and structure of these secondary lymphoid tissues create a close interface between antigens, APCs, and lymphocytes to optimize cellular interactions and produce an efficient and robust adaptive immune response. Signals from cells within the LNs can also expand the lymphatic vessel network, again resulting in increased drainage of DCs and antigens into the LNs. The movement of lymphatic fluid through secondary lymphoid tissue is an essential component of the adaptive immune system.

Lymph node anatomy is shown schematically (Fig. 19.4); the anatomy of LNs and the spleen is also discussed in Chapter 20. Fluid and cells gain entry to the convex surface of the LN via afferent lymphatic vessels that drain into the subcapsular sinus. Lymphatic fluid in the subcapsular sinus then courses into the trabecular sinus network that runs perpendicular to the capsule through an area called the cortex. The cortex is composed of follicles and interfollicular zones. Follicles consist mainly of B cells, some T cells, and APCs, including macrophages, and follicular DCs; whereas interfollicular zones consist mainly of T cells and additional APCs. These zones are separate but contiguous compartments where B cells and T cells initially encounter antigen. In the follicles, additional processing of antigens may be carried out by local APCs, such as follicular DCs. The net effect of the antigenic exposure is the proliferation of antigen-specific lymphocytes; and this proliferation further increases lymphatic drainage to the LN. In this way, LNs are a primary site for the refinement and amplification of antigen-specific adaptive immune responses.

Follicles are functionally characterized as either primary or secondary follicles. Primary follicles are composed of nonproliferating

naïve B cells that have yet to encounter antigen recognized by their surface BCR/Ig complex. Recognition of an antigen by the BCR/Ig leads to B cell activation. A complex set of interactions between the B cell, T cell, and APCs leads to the activation and proliferation of B cells carrying an antigen-specific BCR. A fraction of these activated proliferating B cells form GCs, which are surrounded by a mantle zone of naïve B cells, which together comprise a secondary follicle (Fig. 19.5).

Germinal centers are classically divided into two compartments, denoted as the dark and light zone based on their appearance under light microscopy (see Fig. 19.5, inset). Dark zones are located adjacent to the T-cell areas, and contain a high density of proliferating B cells termed *centroblasts*, which are large cells with a high nuclear:cytoplasmic ratio, and do not express surface BCR/Ig. The light zone has a lower cellular density secondary to the presence of an extensive loose network of follicular DCs, and this imparts the “light” appearance.²⁴ B cells in the light zone are termed *centrocytes*, which in contrast to the centroblasts, are small B cells expressing surface BCR/Ig. Some of these cell types, such as centrocytes and centroblasts, are discussed in Chapter 73 in the context of lymphoid malignancies.

Within the germinal center, the series of sequential shuttling and reentry of B cells into the dark and light zones is termed the GC reaction, or the B-cell selection process. The cyclic reentry model proposes that centroblasts in the dark zone undergo cell division and SHM of variable light-chain genes mediated by AID. Next, they reexpress BCR/sIg and exit the cell cycle, migrating into the light zone to interact with antigen-presenting follicular DCs and TFH cells. In light zones, B cells with increased affinity for antigen are preferentially selected for survival by receiving vital signals from TFH cells; in contrast, B cells with impaired or absent antigen binding undergo apoptosis and clearance by resident macrophages, known as tingible body macrophages.²⁵ Selected centrocytes in the light zone are thought to return to the dark zone to undergo further rounds of proliferation, affinity maturation, and selection to improve the affinity of B-cell repertoire. Positively selected GC B cells eventually leave the GC, differentiating into memory B cells or plasma cells possessing somatically mutated immunoglobulin genes that encode for a high-affinity BCR/Ig. The modified capability of these selected B cells to generate a fast, highly specific humoral immune response upon a second encounter with the same pathogen forms the mechanistic basis of humoral memory. Memory B cells may circulate through secondary lymphoid organs and colonize the splenic marginal zone. Plasma cells are long-lived cells that take up residence in the BM and spleen, and are responsible for maintaining high levels of Ig seen in the serum.

The lymphatic fluid within the cortical trabecular sinus network continues to drain toward the medullary sinus, which lies deep to the cortex, forming the central part of the LN, known as the *hilum*. The medullary sinus contains additional APCs, some T cells, and numerous plasma cells that have migrated from the cortex to the medulla. There, plasma cells may leave the LN in the lymphatic fluid via the efferent lymphatic vessel at the hilum, to take up residence in other tissues. Lymphatic fluid travels through additional LNs on the way to the thoracic duct; thus antigens and cells draining from sites of inflammation travel through chains of LNs. In the lymphatic system, antigens, activated immune cells, and cytokines are kept in anatomic proximity, providing numerous opportunities for the antigens to encounter antigen-specific lymphocytes and stimulate the adaptive immune response. Moreover, in this low-pressure system, lymphatic fluid moves very slowly, thus providing a temporal as well as spatial opportunity for immune system activation.

In addition to lymphatic fluid, blood must also travel through LNs to provide oxygen and nutrients and to deliver new B and T cells that have not yet encountered antigen. Arterial blood enters the LN at the hilum, where arterioles arborize toward each follicle. Anatomically, the direction of blood flow is opposite to that of the lymphatic fluid, which drains toward the hilum. Naïve T cells leave the blood to enter LNs through specialized vessels called *postcapillary venules*, which arise from follicular capillary beds, and travel through the T cell–rich interfollicular zones. Naïve T cells exit from these

Fig. 19.4 LYMPH NODE ANATOMY. The lymph node is surrounded by a capsule. Afferent lymphatics draining tissues enter the node on the convex side into the capsule. Fluid and cells drain through the node and collect in the medullary sinus, where the fluid leaves the node through efferent lymphatics to rejoin the lymphatic circulation. The outer rim of the node is called the *cortex* and contains primary follicles composed of naive, nonproliferating B cells that have not encountered antigens, and secondary follicles with proliferating B cells in the germinal center. The germinal center can be subdivided into dark and light zones. Each lymph node is supplied with blood by the arterial circulation. Arterioles expand into a meshwork of capillaries within each follicle, and venous blood drains back out of the node. Naive T cells in the peripheral circulation can exit the blood and enter the lymph node through the high endothelial venules.

Fig. 19.5 B-CELL PROLIFERATION IN FOLLICLES AND GERMINAL CENTERS. B cells primarily populate the lymphoid follicles. A section of lymph node (*left*) demonstrates numerous secondary follicles. Adjacent to the follicles are the T cell–rich zones of the paracortex. Secondary follicles contain germinal centers filled with proliferating B cells, scattered T cells, and specialized antigen-presenting cells called follicular dendritic cells. The germinal center is surrounded by a mantle zone populated by naive B cells. Within each germinal center, are dark zones and light zones (*inset*). The schematic of a section of lymph node (*right*) demonstrates a secondary follicle with a germinal center and a mantle zone. Scattered T cells can be found in the germinal center and are typically helper T cells that stimulate B-cell proliferation.

postcapillary venules, and upon antigenic recognition, remain in the node to proliferate and differentiate. If the naive T cells do not encounter antigens they recognize, the cells drain by means of lymphatic fluid back to the blood and repeat their route in a different LN until they become resident lymphocytes or undergo anergy-mediated cell death (refer to [Chapter 21](#) for further information on T-cell immunity).

Egress of lymphocytes from LNs and from the thymus is regulated by a specialized lipid produced in lymphoid tissue and is known as sphingosine-1-phosphate (S1P). Lymphocytes express S1P receptor-1 (S1P₁) receptors that facilitate their egress from tissues into blood. Novel immunosuppressive therapeutics antagonizing S1P are being developed; these S1P antagonists reduce release of lymphocytes from lymphoid tissues into blood.

SECONDARY LYMPHOID TISSUE: COMMON AND UNIQUE ANATOMY AND FUNCTIONS

In addition to LNs, the spleen is an important site for B-cell development and for antigen presentation and stimulation of the adaptive immune system.^{26–28} Lacking afferent lymphatics, the spleen serves to sample blood, rather than lymphatic fluid for foreign antigens. The

spleen is divided into two functionally and morphologically distinct compartments, the white pulp and the red pulp ([Fig. 19.6](#)). The white pulp is composed mainly of lymphoid cells and is the site of antigenic stimulation of B and T cells. The red pulp consists mainly of myeloid cells, including macrophages that ingest opsonized antigens and damaged erythrocytes from the systemic circulation. The red pulp functions also as a site of extramedullary hematopoiesis early in fetal life and is a storage site for iron, erythrocytes, and platelets. Extramedullary hematopoiesis in the spleen may also occur postnatally in patients whose BM is incapable of producing adequate numbers of mature blood cells.

In many mammalian species, including humans, splenic blood flows through a unique vascular circulation that ensures the interposing of blood (and therefore blood-borne antigens) with the lymphoid areas of the white pulp. This has been best characterized in the murine model. In this model, the splenic white pulp consists of three compartments—the periarteriolar lymphoid sheath (PALS), follicles, and the marginal zone—that interact with blood through an open sinusoidal arterial network. The PALS is the spleen's T-cell zone and is found surrounding the central artery. Follicles in the spleen are found adjacent to the PALS and are capable of generating primary and secondary follicles with GCs as in LNs. The marginal zone, composed of subsets of B cells and macrophages, surrounds the

Fig. 19.6 ANATOMY OF THE SPLEEN. The spleen consists broadly of red pulp and white pulp (A). The red pulp is the site of myeloid cells (B) that ingest and remove opsonized antigens and damaged red blood cells from the circulation. The white pulp consists of lymphoid cells, with a periarteriolar T-cell sheath and mixed B- and T-cell follicles (C). In addition to lymph nodes, this is a major site for antigen-dependent B-cell maturation and activation. The schematic of splenic anatomy (D) demonstrates how the microscopic architecture is integrated into spleen to yield a site for the interaction of the innate and adaptive immune systems.

follicles in the spleen and serves as the major route of entry of blood-borne antigens and lymphocytes from the blood into the white pulp. Unlike other organs that have a closed vascular circulation in which blood travels from arterial to venous circulation through capillary beds, branches of the splenic artery penetrate the white pulp, forming an open sinusoidal network termed the *marginal sinuses*. From the marginal sinuses, blood filters through the white pulp regions of the spleen and encounters resident B and T cells. Following this encounter, the blood is drained via branches of the splenic vein, but an efferent lymphatic circulation also collects and drains the spleen. Beyond the white pulp, the splenic artery sends additional branches into the red pulp for further blood antigen surveillance and filtration that is accomplished by macrophages.

In addition to LNs and the spleen, there are numerous other sites of secondary lymphoid tissue.²⁹ A critical part of the secondary lymphoid system is the mucosa-associated lymphatic tissue (MALT). As the name implies, the MALT is in physical proximity with the mucosa (i.e., the epithelium and associated connective tissue that line the surfaces of the body). MALT is found at sites where antigens most commonly breach these epithelial barriers: the gastrointestinal, respiratory, and genitourinary tracts. In some tissues, the MALT forms relatively large structures that can be clearly distinguished histologically, such as the Peyer patches in the ileum and in the lymphoid tissue under the epithelium of the appendix. In these sites, perhaps because of the constant stimulation by microbial pathogens in the intestine, the MALT resembles lymphatic tissue in the spleen and LNs, with well-demarcated primary and secondary follicles that contain primarily B cells and intervening T cell-rich zones.

In other tissues, such as the genitourinary tract and the salivary glands, the microscopic anatomy of the MALT may not be as well defined as seen in Peyer patches; but the stromal tissue underlying the epithelium contains numerous lymphocytes and APCs. These sites provide an additional compartment of secondary lymphoid tissue where antigens can accumulate, be processed, and be presented to lymphocytes to stimulate an adaptive immune response.

Whereas the MALT constitutes a lymphoid population beneath the surface epithelium, a separate population of lymphocytes, primarily T cells, traffics directly through the epithelium in certain tissues, such as the gastrointestinal tract. These intraepithelial lymphocytes (IELs) include $\alpha\beta$ T cells and $\gamma\delta$ T cells, and comprise 1 in every 5 to 10 cells in the intestinal epithelium. Because the lining of the intestine is the largest organ surface area of the body, IELs are one of the largest T-cell populations. These IEL T cells are composed of different subpopulations, some of which are conventional T cells that recognize foreign antigens; others are regulatory T cells that limit the extent of an immune response and maintain immune homeostasis, a critical function in the antigen-rich milieu of the gut.³⁰

B-CELL DEVELOPMENT

Kenneth Dorshkind and David J. Rawlings

B lymphocytes are the subset of white blood cells specialized to synthesize and secrete immunoglobulin (Ig). Their name derives from the finding that the avian *bursa* of Fabricius is a site of B-cell production. However, B-cell production in mammals takes place in the bone marrow (BM). Following their production in that organ, newly generated B lymphocytes migrate into secondary lymphoid organs such as the spleen where they undergo final maturation. At this point, the mature B cells may remain in the spleen or relocate via the circulation to additional tissues such as lymph nodes, where they are poised to respond to antigenic challenge.

This chapter will focus on adult B-cell development and the regulation of that process, although we briefly discuss fetal B lymphopoiesis and its distinguishing features. We then outline B-cell maturation in secondary lymphoid tissues. The information presented provides a basis for understanding abnormalities of B-cell development such as leukemia, lymphoma, and immunodeficiency states, which are discussed in other chapters. Studies in mice have contributed much to what is known about B-cell development and have served as a basis for understanding human B lymphopoiesis. Thus, although we emphasize the human literature as much as possible, frequent reference to findings in mice are made.

STAGES OF B-CELL DEVELOPMENT

As a result of advances in the development of monoclonal antibodies to leukocyte cell surface antigens and in flow cytometry, it is possible to resolve various stages of murine and human B-cell development from the hematopoietic stem cell (HSC) to newly produced, surface IgM-expressing B cells (Fig. 20.1).

Murine B-Cell Development

As the progeny of murine HSCs differentiate, they generate lymphoid-primed multipotent progenitors (LMPPs). LMPPs, defined by their lineage negative (Lin⁻) CD117 (c-kit)⁺ Sca-1⁺ Flt3⁺ phenotype, lack erythroid and megakaryocyte potential but can generate all other lymphoid and myeloid cells. A subset of LMPPs includes early lymphoid progenitors (ELPs), which express the *Rag1* gene (discussed later). ELPs are the precursors of Lin⁻ c-kit^{low} Sca-1^{low} CD127⁺ (interleukin-7 receptor α) common lymphoid progenitors (CLPs). Lin⁻ indicates that the cells lack expression of determinants present on mature myeloid, erythroid, and lymphoid lineage cells. CLPs then mature through pre-pro-B-, pro-B-, pre-B-, and B-cell stages of development that can be phenotypically resolved based on their expression of various cell surface and cytoplasmic determinants, as shown in Fig. 20.1.¹

Human B-Cell Development

Various stages of human B-cell development can also be phenotypically identified.² A population of human Lin⁻ CD10⁻ CD62L^{hi} cells appears to be the human LMPP counterpart, whereas CLPs are CD34⁺ CD45RA⁺ CD10⁺ IL-7R⁺. As in the mouse, CLPs sequentially generate pro-B, pre-B, and B cells.^{3,4} Human pro-B cells can be identified based on their expression of CD10, CD34, and CD19.

μ Heavy chain protein is detected in the cytoplasm of pre-B cells that no longer express CD34. Finally, when Ig light chain expression occurs, the cells become surface IgM-expressing B cells. Developing and mature B lineage cells also express additional cell surface determinants, which include CD20, CD21, CD22, CD24, CD38, and CD40, several of which are linked to critical intracellular signaling pathways. Antibodies against the CD20 determinant (rituximab) are in widespread clinical use for the treatment of lymphoma and, increasingly, autoimmune diseases.

B LINEAGE SPECIFICATION AND COMMITMENT

As differentiation of HSCs and other immature precursors into the B lineage occurs, genetic programs that promote B lymphopoiesis are activated while those used by non-B lineage cells are silenced. This results in gradual “specification” of progenitors towards the B-cell lineage. For example, cells at the CLP stage of development are destined to generate B cells, but they retain limited T and myeloid potential. Because of this, CLPs can be thought of as B lineage “specified.” However, by the time the pro-B-cell stage has been reached, the cells can only generate B lymphocytes and are “committed” to the B-cell lineage. The processes of specification and commitment are dependent on the regulated expression of a network of transcription factors and other regulatory molecules in developing B lineage cells.⁵

Transcriptional Regulation of B-Cell Development

The generation of lymphoid cells from HSCs is critically dependent on expression of the Ets family member PU.1. Mice in which *Sfpi1*, the gene encoding PU.1, is not expressed produce erythroid and megakaryocytic but not monocytic, granulocytic, and lymphoid cells. As a result of this severe defect, PU.1 knock-out mice die during the fetal period or within a few days after birth. PU.1 regulates a number of early events as precursors become B lineage specified. These include the expression of Flt3, which is expressed on LMPPs, the CD45R(B220) cell surface determinant, and IL-7R α . However, deletion of *Sfpi1* at the CLP stage of development has no negative effect on B-cell development, indicating that PU.1 expression is not required once B-cell specification has occurred.

Further specification toward the B-cell lineage is dependent on the expression of additional transcription factors that include early B-cell factor (EBF) and the E2A-encoded splice variants E12 and E47. Each of these DNA-binding proteins regulates the expression of a variety of B-lineage target genes. For example, Ebf1 regulates the expression of Ig α , VpreB, λ 5, and Pax5, and represses genes associated with alternative lineage fates. That EBF and E2A expression play a critical role in B lymphopoiesis has been demonstrated by the fact that mice in which they are not expressed exhibit an almost complete block in B-cell development at the pro-B-cell stage.

Ebf1- and E2A-expressing progenitors can still exhibit some non-B lineage potential, indicating that the expression of these DNA-binding proteins does not result in absolute commitment of cells to the B lineage. Instead, this is dependent on expression of the Pax5 transcription factor.⁶ Phenotypically identifiable B-cell precursors are present in *Pax5* knock-out mice, and when placed under appropriate

Fig. 20.1 HEMATOPOIESIS WITH AN EMPHASIS ON B-CELL DEVELOPMENT. Stages of human and mouse B-cell development and selected cell surface and cytoplasmic determinants that can be used to distinguish various stages of differentiation are shown. Note that there are additional cell surface and molecular determinants that can be used to define the various stages of development. After leaving the bone marrow, newly produced B cells migrate to the spleen and mature through transitional cell stages into marginal zone or follicular B cells. *CLP*, Common lymphoid progenitor; *CMP*, common myeloid progenitor; *ELP*, early lymphoid progenitor; *FO*, follicular B cell; *HSC*, hematopoietic stem cell; *LMPP*, lymphoid-primed multipotential progenitor; *MPP*, multipotential progenitor; *MZ*, marginal zone B cell; *T1*, transitional 1 B cell; *T2*, transitional 2 B cell.

conditions, they can differentiate into myeloid, T, and natural killer (NK) cells. However, if the gene encoding Pax5 is introduced into *Pax5*-deficient precursors, this developmental promiscuity is no longer observed. Thus a critical function of Pax5 is to suppress non-B lineage potential. For example, Pax5 may repress myeloid growth factor receptors, such as those for macrophage colony-stimulating factor, and inhibit the T-cell potential of lymphoid-restricted progenitors by antagonizing expression of Notch1, a cell-surface receptor whose stimulation activates signaling pathways required for commitment to the T-cell lineage. In addition to regulating commitment to the B-cell lineage, continued Pax5 expression is necessary to maintain lineage fidelity even in relatively mature B cells.

Many additional transcription factors, such as Ikaros, Satb1, Foxo1, IRF4, IRF8, c-Myb, Gfi1, Miz-1, Bcl6, and Bach2, function at various times during B-cell development. For example, IRF4 is involved with Ig recombination and the attenuation of the IL-7 signaling pathway, thus promoting the transition from the pre-B to B-cell stages of maturation (discussed later). IRF8, along with PU.1, regulates EBF expression. Ikaros plays a role in regulating expression of key B lineage genes such as IL-7R α and EBF, and promoting B lineage commitment. c-Myb has been shown to synergize with

PU.1 to activate IL-7 receptor gene transcription. Focused reviews should be consulted for a full discussion of these and additional transcriptional regulators of B lymphopoiesis.

MicroRNAs

MicroRNAs (miRNAs) are RNA molecules, 19 to 23 nucleotide long, that are processed from longer RNA precursors. miRNAs are biologically active as RNA molecules and act post-transcriptionally, either by promoting degradation of mRNA targets or by blocking their translation. However, like transcriptional regulators, a single miRNA can potentially regulate many targets to provide coordinated and simultaneous regulation of a network of genes.

Mice with conditional deletion of Dicer, an enzyme necessary for miRNA synthesis, in pro-B cells do not develop B lymphocytes, indicating the importance of miRNA regulatory mechanisms during B-cell differentiation. Work is now ongoing to identify the role of specific miRNAs at specific stages of B-cell development. For example, germ line deletion of miR-17-92 cluster blocks pro-B-cell maturation.⁷

IMMUNOGLOBULIN GENE REARRANGEMENT AND EXPRESSION

The defining feature of a B lymphocyte is its expression of cell surface Ig, which is formed by two heavy chains and two light chains, each of which is encoded by multiple gene segments. The process of Ig gene rearrangement occurs in a step-wise manner as murine and human B cells mature through the cellular stages of development just described.^{8,9}

Heavy Chain Gene Rearrangement

The initial Ig rearrangement events during B-cell development occur at the heavy chain locus. The Ig heavy chain locus includes multiple variable (V), diversity (D), joining (J), and constant (C) region gene segments that are separated from one another by introns. The genes that encode Ig heavy chain protein are located on human chromosome 14 (Fig. 20.2). The V region genes are located at the 5' end of the Ig heavy chain locus, and each consists of approximately 300 base pairs. These genes, which are separated by short intron sequences, are organized into seven families based on sequence homology. There are about 25 human D region genes located 3' to the V region. These also are grouped into families, and at least 10 have been described. Downstream of the D region are six human J region genes. Finally, 10 C region genes representing alternative Ig isotypes are arranged in tandem.

The transcription of the unrearranged heavy chain locus occurs prior to actual Ig gene recombination. This results in the production of developmentally regulated transcripts of unrearranged Ig genes, referred to as germline or sterile transcripts. Multiple species of sterile transcripts have been described, and some could conceivably encode proteins. A mechanistic link between transcription and Ig gene rearrangement has been hypothesized. For example, transcription might make unrearranged Ig genes accessible to both RNA polymerase and V(D)J recombinase, the germline transcripts could function in the rearrangement reaction, or transcription could alter structural characteristics of DNA, making the recombination signal sequences, described later, better targets for recombination.

The initial event during heavy chain gene rearrangement occurs as early as the CLP stage and juxtaposes a D region segment to a J segment. Although in theory any D region gene can join with equal frequency to any J region gene, there may be preferential utilization of selected D and J region genes at various times during fetal and adult B-cell development. The next recombination event involves the rearrangement of a V region gene to the D–J complex, and this occurs at the pro-B-cell stage of development. Evidence suggests that biased usage of J proximal V genes occurs in the newly generated repertoire of neonatal mice and humans. The heavy chain C region remains separated from the rearranged VDJ complex by an intron, and this entire sequence is transcribed. RNA processing subsequently leads to deletion of the intron between the VDJ complex and the most proximal C region genes. After translation, μ heavy chain protein is expressed in the cytoplasm of pre-B cells (Fig. 20.2).

The E2A-encoded transcription factors are particularly important for Ig gene recombination and mediate their effects via binding to specific promoter sequences located 5' of each heavy chain V region and one or more heavy chain enhancer regions located 3' of the J region genes and downstream from the CH region genes (see Fig. 20.2). Before Ig gene rearrangement, E12 and E47 proteins may be in an inactive state owing to their heterodimeric association with another protein known as *Id*. In this configuration, DNA binding by E12 and E47 does not occur. Thus, successful transition from the pro-B- to pre-B-cell stage is dependent on cessation of *Id* expression. This conclusion is consistent with the fact that mice expressing an *Id* transgene have a complete block in B-cell differentiation.

Each pro-B cell has two Ig heavy chain genes, but only one of these encodes heavy chain protein in any given cell. This phenomenon is known as *allelic exclusion*. One theory for how this occurs

is that functional Ig rearrangements are rare, so the chance that two functional rearrangements will occur in an individual cell is extremely low. An increasingly accepted, second model of allelic exclusion is that the expression of heavy chain protein from a successfully rearranged allele inhibits rearrangements at the other heavy chain allele.

Light Chain Gene Rearrangement

Ig light chain protein can be encoded by the kappa (κ) or lambda (λ) genes. Greater than 90% of murine B cells express κ protein. However, the proportions of human κ and λ proteins are more equivalent, with approximately 60% of human B cells expressing κ light chain protein.

The human κ gene is located on chromosome 2 and includes around 40 V κ region genes, clustered in up to seven families, five functional J κ region genes, and one C κ region gene. The human λ locus is located on human chromosome 22. Approximately 30 human V λ genes exist and are grouped into 10 families. There are seven human C λ genes, four of which are functional and three of which are pseudogenes. Each C λ gene is located 3' of a respective J λ gene. Light chain genes do not include D region loci.

The initial event in light chain recombination involves the joining of a V region to a J region. The VJ complex remains separated from the light chain C region by an intron, the entire complex is transcribed, and further splicing of the intron results in formation of a mature V–J–C transcript. Light chain rearrangements in mice occur initially at the kappa locus. If rearrangements at the first κ allele are unsuccessful, attempts are made to rearrange the second κ gene. If this fails, the λ locus is used.

The Ig Recombinatorial Machinery

The process of Ig heavy and light chain gene rearrangement is dependent on enzymes that delete intronic sequences and join coding segments of DNA. The enzymes that mediate these functions act through recognition of recombination signal sequences that are located 3' of each heavy chain V region exon, 5' of each heavy chain J segment, and 5' and 3' of each heavy chain D region gene. Fig. 20.2 shows the association of these recognition sequences with the various heavy chain exons. Each recombination signal sequence consists of conserved heptamer and nonamer sequences separated by nonconserved DNA segments of 12 or 23 base pairs. During Ig gene recombination, these recognition sequences form loops of DNA, which in turn bring the coding exons in apposition to one another. These noncoding loops are subsequently deleted and degraded.

The expression of two highly conserved proteins, referred to as recombinase-activating genes-1 (RAG-1) and RAG-2, is required for heavy and light chain gene recombination.¹⁰ Mice and humans in whom *Rag* genes are not expressed do not generate B or T cells. Results from cell-free systems that measure V(D)J recombination indicate that RAG proteins are involved in cleavage of DNA at recombination signal sequences and the subsequent joining of coding sequences to one another. In addition to the RAG proteins, general DNA repair enzymes, those encoded by the Ku complex of genes in particular, also play a critical role in Ig heavy chain gene recombination.

Generation and Selection of the Primary B-Cell Repertoire

For the organism to mount an effective humoral immune response, an array of Igs with unique antigen-binding specificities, together referred to as the *Ig repertoire*, must be generated. Several mechanisms have evolved to ensure that this occurs.

First, heavy and light chain proteins can be encoded by multiple germline V, J, and, in the case of the heavy chain, D region genes, and the combinatorial diversity among them is enormous. Second, nucleotides not encoded in the germline can be added to D–J and

Fig. 20.2 REARRANGEMENT AND EXPRESSION OF THE HUMAN IMMUNOGLOBULIN HEAVY CHAIN GENE. The figure shows the Ig heavy chain gene and the signal sequences 3' of each V region locus, 5' and 3' of each D region locus, and 5' of each J region locus. These consist of heptamer and nonamer sequences separated by either 12 or 23 base pairs. During immunoglobulin (Ig) recombination, a signal sequence of 12 base pairs can only join to another of 23 base pairs (the so-called 12–23 rule). As shown in the figure, initial heavy chain gene rearrangements form coding joints between D and J regions, as well as signal joints that are ultimately degraded. Subsequently, the joining of the V region gene to the DJ complex occurs. After a successful rearrangement, the VDJ complex, the μ intron, and portions of the constant regions are transcribed. RNA processing and differential splicing results in formation of an mRNA molecule that is then translated. In the example shown, the rearranged VDJ complex and the constant region, with the μ and δ C region genes, is transcribed. After RNA processing and translation, a particular B cell could then express μ protein, δ protein, or both.

VDJ junctions by a nuclear enzyme known as *terminal deoxynucleotidyl transferase* (TdT). Two splice variants of TdT, encoded by a single gene, have been identified. The short (509-amino acid) variant catalyzes the addition of nontemplated nucleotides at coding joints and the long (529-amino acid) form is a 3′–5′ exonuclease that catalyzes the deletion of nucleotides at coding joints. Third, DNA joints that form during recombination are often imprecise and can occur at any of several nucleotides in the germline. Although out-of-frame joints that cannot be transcribed may result, this junctional diversity has the potential to generate different amino acid sequences, resulting in added diversity of the Ig repertoire. Finally, somatic mutation of V region genes can occur, usually in secondary lymphoid tissues. This latter process, which results in an increased affinity of the antibody for antigen, is discussed in more detail in the section on secondary B-cell development.

Because the process of Ig gene recombination is random, some B cells that are self-reactive may be produced. Several mechanisms have been proposed to account for the fate of such self-reactive cells. In some cases, the presence of self-antigen may not activate self-reactive B cells. This scenario may result from weak B-cell affinity for the antigen or the autoantigen may be present at an extremely low concentration. In other instances, interaction of antigen with the autoreactive B cell may result in anergy. The level of membrane Ig on such anergic B cells may be reduced up to 20-fold, the cell's ability to proliferate may be impaired, and differentiation into Ig-secreting cells may be blocked. Finally, self-reactive B cells may be clonally deleted. Clonal deletion may result from cytotoxicity by other cells, such as BM macrophages, or autoreactive B cells may undergo a physiologic change resulting in cell death after receptor engagement.¹¹

The recognition of self-antigen by a B cell may not necessarily result in anergy or deletion but instead may lead to receptor editing. In this process, which represents the most common mechanism for negative selection, rearranged κ light chain alleles can be replaced by secondary rearrangements of upstream V κ genes to downstream, unrearranged J κ segments. These secondary rearrangements, which may delete the primary V κ J κ complex or separate it from C κ by inversion, are possible because of the continual presence of unrearranged V κ regions upstream of the joined V κ J κ coding segments. Finally, unsuccessful rearrangements of the initial κ light chain allele are followed by rearrangements of the second allele, increasing the likelihood of generating a less self-reactive B-cell receptor (BCR).

THE PRO-B- AND PRE-B-CELL CHECKPOINTS

B-cell progenitors progress through two critical checkpoints as they mature into B lymphocytes. The first occurs at the pro-B- to pre-B-cell transition. If successful, pro-B cells mature into pre-B cells that express the pre-BCR. The second transition occurs as pre-B cells mature into B cells that express the BCR.

The Pro-B- to Pre-B-Cell Transition

The key event during the pro-B- to pre-B-cell transition is the rearrangement and expression of the Ig heavy chain genes. It is important to recognize that not all pro-B cells successfully navigate this transition. The principal reason for this is that not all Ig gene recombination events are successful. For example, Ig heavy chain gene rearrangements are productive in only around one-third of pro-B cells. Those cells with nonproductive Ig gene rearrangements undergo apoptosis and are eliminated from the BM by resident macrophages and stromal cells.

However, if Ig heavy chain recombination is productive and μ heavy chain protein is expressed, it appears on the surface of the pre-B cells in association with two additional molecules referred to as the surrogate light chains. The surrogate light chain proteins, Vpre-B and $\lambda 5$, are encoded by genes located on chromosome 16 in mice and on chromosome 22 in humans, and are noncovalently linked to one another. $\lambda 5$ in turn is covalently linked to the CH1 domain of

the μ heavy chain via a carboxyl-terminal (C-terminal) cysteine. One role of the surrogate light chains is to select heavy chains that will ultimately be capable of pairing with conventional light chains.¹² If this does not occur, then these cells will likely be deleted.

The μ heavy chain–surrogate light chain complex is additionally associated with two transmembrane proteins, Ig α (CD79a) and Ig β (CD79b), and the entire complex is referred to as the *pre-BCR* (Fig. 20.3). The intracellular tails of both Ig α and Ig β contain immunoreceptor tyrosine activation motifs (ITAMs) critical to the signaling function of the pre-BCR (Fig. 20.3, upper panel). Lipid rafts that contain mediators of intracellular signaling such as Lyn are constitutively associated with the pre-BCR in human pre-B cells. Cross-linking of the pre-BCR leads to an increase in Lyn kinase activity, phosphorylation of the Ig β chain, and recruitment and activation within the pre-BCR complex of additional signaling intermediates, including spleen tyrosine kinase (Syk), B-cell linker protein (BLNK), phosphatidylinositol 3-kinase (PI3K), Bruton's tyrosine kinase (Btk), VAV, and phospholipase C- γ (PLC γ 2). These events lead to calcium flux and activation of signaling cascades within the pre-B cell.

These signaling pathways are crucial in developing pre-B cells. One of the best examples of this requirement is the prototypical humoral immunodeficiency, X-linked agammaglobulinemia (XLA). XLA results from mutations within the gene segments that encode the nonreceptor tyrosine kinase, Btk. In males who express a defective Btk protein, pre-B-cell clonal expansion is markedly depressed, and there is an almost complete loss of immature B cells in the BM and in secondary lymphoid organs. As a result, affected males develop recurrent bacterial infections early in life because of a profound decrease in circulating Ig. A nearly identical clinical phenotype also has been observed in persons with mutations in additional components of the pre-BCR signaling complex, including the μ heavy chain, $\lambda 5$, Ig α , Ig β , the key B-cell adaptor protein BLNK, and the lipid kinase PLC γ 2.

How signaling through the pre-BCR is initiated is unclear. It has been suggested that this occurs by binding of the extracellular portion of the pre-BCR to an environmental ligand. The identification of such ligands has been difficult, although galectin-1 may function in this capacity. It has also been proposed that constitutive signaling occurs after pre-BCR surface expression. Recent structural studies suggest that the pre-BCR constitutively assembles as an oligomer, providing a potential mechanism for this behavior.^{13,14}

The Pre-B- to B-Cell Transition

Pre-BCR-expressing cells exhibit two distinct functional responses. Initially they undergo several rounds of proliferation, which expands the size of the clone that expresses a particular μ -heavy chain. *Rag* gene expression is also suppressed in these proliferating cells, which contributes to allelic exclusion. However, at some point these pre-BCR-expressing cells exit the cell cycle and reactivate the recombinatorial machinery so that light chain gene recombination can commence.

Recent studies indicate that a highly regulated balance between signaling through the IL-7 receptor (discussed later) and the pre-BCR ensures that proliferation and Ig recombination are mutually exclusive events. IL-7 receptor signaling stimulates cell proliferation and inhibits light chain gene rearrangements.¹⁴ In contrast, pre-BCR signaling represses proliferation, likely through activation of the RAS–extracellular-signal-regulated kinase (ERK) pathway as well as via limiting PI3K activity through BLNK-mediated signals.¹⁴ This in turn leads to the expression of transcription factors, including E2A, IRF4, and PAX5, that induce cell cycle exit, RAG expression, and light chain gene recombination. These events are strongly influenced by the movement of developing B-cell progenitors through various niches wherein they are exposed to different environmental signals including, most notably, transitioning from a setting of high to low IL-7 availability (Fig. 20.4).

Once the recombinatorial machinery is reactivated, light chain gene rearrangement and expression occurs. As with heavy chain

Fig. 20.3 THE PRE-B-CELL RECEPTOR AND B-CELL RECEPTOR AND ASSOCIATED SIGNALING INTERMEDIATES. *Top*, μ -Heavy chain protein in pre-B cells is associated with the surrogate light chains ν -pre-B and $\lambda 5$ (*left*) to form the pre-BCR. In newly produced B lymphocytes, μ -heavy chain is associated with conventional light chains (*right*) to form the BCR. Associated with heavy chain in both pre-B and B cells are two additional transmembrane proteins, Ig- α and Ig- β , that contain ITAMs critical to the signaling function. Expression of the pre-BCR (or possibly its binding to a stromal ligand) or binding of antigen to the mature BCR, respectively, initiates the assembly of a lipid raft, BCR-associated “signalosome” composed of multiple signaling molecules, ultimately leading to transcriptional events that promote cell proliferation, survival, and differentiation (*bottom*). BCR, B-cell receptor; ERK, extracellular signal-regulated kinase; Ig, immunoglobulin; ITAM, immunoreceptor tyrosine activation motif; JNK, Janus kinase; NF κ B, nuclear factor kappa-light-chain enhancer of activated B cells; NFAT, nuclear factor of activated T cells; PKC, protein kinase C; PLC γ , phospholipase C- γ ; SHIP, src homology 2-containing inositol phosphatase; SHP, src homology-containing protein tyrosine phosphatase.

recombination, functional light chain gene rearrangements do not occur in all pre-B cells. However, when they are successful, the heavy and light chains assemble and are expressed on the surface of a newly produced B lymphocyte as the B-cell receptor.

Events that disrupt the pre-B-cell transition including, for example, activating lesions in IL-7 receptor subunits or downstream mediators, significantly enhance the risk for development of pre-B acute lymphoblastic leukemia; an improved understanding of these

changes will likely provide new therapeutic targets to inhibit leukemia cell growth.¹⁵

The B-Cell Receptor

Once light chain expression occurs, a complete Ig molecule is expressed on the surface of the newly produced B cells. All newly

Fig. 20.4 THE HEMATOPOIETIC MICROENVIRONMENT. Cross-section of bone showing elements of the medullary circulation, the marrow sinusoids, and the location of stromal cells (*top*). (Courtesy Dorshkind K: Regulation of hematopoiesis by bone marrow stromal cells and their products. *Annu Rev Immunol* 8:111, 1990. Reproduced with permission from the *Annual Review of Immunology*.) During their maturation, B lineage cells are thought to migrate between niches that deliver different cell surface and soluble signals (*bottom*). CXC-chemokine receptor 4 (CXCR4)-expressing pre-pro-B cells are associated with C-X-C motif chemokine ligand 12 (CXCL12)-secreting stromal cells. As differentiation occurs, expression of CXCR4 is gradually downregulated and pro-B cells migrate into IL-7-rich environments. The IL-7 receptor is downregulated on pre-B cells. Once the BCR is expressed, newly produced B cells exit the bone marrow and migrate to secondary lymphoid tissues such as the spleen. The figure also shows that plasma cells generated in secondary lymphoid organs migrate to the bone marrow and are associated with CXCL12-expressing stromal cells.

produced B lymphocytes express IgM, but others may coexpress cell surface IgD (see Fig. 20.2). This occurs because the primary heavy chain transcript includes the rearranged VDJ heavy chain complex, the μ and δ C regions, and the intron separating these exons. If RNA processing results in association of the $C\mu$ region with the VDJ complex, the B cell expresses IgM. Alternatively, if the $C\mu$ exon is deleted along with the heavy chain intron, the VDJ complex and the C δ exon become contiguous and the B cell expresses IgD.

The complex of cell surface Ig, along with Ig α and Ig β , is referred to as the BCR (Fig. 20.3). The cytoplasmic tail of the Ig heavy chain is relatively short, and, as noted earlier, both Ig α and Ig β contain an ITAM in their intracellular tails that is required for signal transduction following antigen binding to the BCR. Antigen engagement initiates assembly of a lipid raft, BCR-associated “signalosome,” composed of multiple signaling molecules that include tyrosine kinases, serine/threonine kinases, lipid kinases, lipases, phosphatases, and linkers and adaptors. This signalosome mediates a cascade of intracellular signals that includes the initiation of calcium influx. Additional calcium-dependent and -independent downstream signals that include the mitogen-activated protein (MAP) kinase cascade (c-jun N-terminal kinase [JNK], p38, ERK) and activation of key transcription factors that include JUN, c-fos, nuclear factor of activated T cells (NFAT), and nuclear factor kappa-B (NF κ B) in turn

mediate transcriptional events leading to cell proliferation, survival, and differentiation. The level and duration of receptor activation and hence transcriptional output are further modified by a series of cell surface coreceptors or “response modifiers” that bind to complement or to receptors on the surface of stromal cells, activated T cells, or other populations present in secondary lymphoid organs.

THE HEMATOPOIETIC MICROENVIRONMENT

Hematopoiesis takes place in the intersinusoidal spaces of the medullary cavity in association with several types of nonhematopoietic cells that together form the hematopoietic microenvironment (Fig. 20.4). For example, HSCs are associated with niches that include osteoblasts as well as endothelial cells that line the sinusoids present in the intersinusoidal spaces. These nonhematopoietic supporting cells, also referred to collectively as stromal cells, support blood cell development via direct cell-to-cell interactions and through the secretion of various soluble mediators.¹⁶

Several cell surface determinants that mediate adhesion between developing B lineage cells and the stroma have been described. Both murine and human pre-B cells express the very late antigen 4 (VLA-4) integrin that interacts with a stromal cell ligand identified as vascular

cell adhesion molecule-1 (VCAM-1). VLA-4 also promotes binding to fibronectin, an extracellular matrix protein. CD44 on developing B lineage cells has been implicated in mediating stromal cell–lymphocyte interactions in the mouse through binding to stromal cell–derived hyaluronate. These intercellular interactions presumably would allow B cells to receive proliferative or developmental signals (or both) from stromal cells. The stromal cells may not be passive populations that constitutively provide these signals. Instead, the binding of the B-lineage cell may stimulate the stromal cell in turn to produce such differentiation or growth-potentiating activities. Various cytokines that regulate the growth, differentiation, and/or survival of B lineage cells have also been described and include C-X-C motif chemokine ligand 12 (CXCL12; SDF1), Flt3 ligand, stem cell factor, IL-7, Wnt family members, transforming growth factor beta (TGF- β) family members, and thymic stromal lymphopoietin (TSLP).¹⁷

A full discussion of these and additional factors that regulate B-cell development is beyond the scope of this chapter. However, the focus can be narrowed considerably when only those with obligate effects on B-cell development are considered. In this regard, the critical B lymphopoietic cytokine in mice is IL-7, which binds to the IL-7 receptor (IL-7R). The IL-7R is formed by the IL-7 receptor α chain and the common cytokine γ chain. The Janus kinases (JAKs) JAK3 and JAK1 are associated with the γ and IL-7R α , respectively, and are critical for IL-7 receptor-mediated signaling. When IL-7 binds to the IL-7 receptor, these JAKs are phosphorylated, and this in turn recruits signal transducer and activator of transcription 5A (STAT5A) and STAT5B. The STAT molecules can then translocate to the nucleus where they act as transcriptional activators. In addition to stimulating the growth and survival of developing B lineage cells, IL-7 signaling also potentiates the recombination of a VH region gene segment to an already rearranged DJH complex. The requirement for IL-7 in murine B-cell development is demonstrated by studies showing a block in B-cell development at approximately the pro-B-cell stage in IL-7 and IL-7 receptor knock-out mice.¹⁴

Developing B-cell progenitors are exposed to IL-7 and other signals, and this is thought to occur as they traffic through different niches in the BM (Fig. 20.4). The most immature B-cell progenitors express the CXC-chemokine receptor 4 (CXCR4) receptor and associate with stromal cells that express high levels of its ligand, CXCL12. CXCL12 induces focal adhesion kinase (FAK) phosphorylation in pro-B cells, and this in turn is thought to promote VLA-4-mediated adhesion to VCAM-1 expressing stroma. As maturation occurs, pro-B cells migrate towards IL-7-producing stromal cells. Ultimately, pre-B cells dissociate from the IL-7-rich environment. As discussed earlier, this movement away from IL-7-expressing niches may be associated with their reduced proliferation, induction of *Rag* gene expression, and Ig light chain recombination. Finally, newly produced B cells exit the BM.¹⁸

IL-7 in Humans

The precise role of IL-7 during human B-cell development is unclear. Human CD34⁺CD19⁺ pro-B cells proliferate in response to IL-7, but human B lymphopoiesis may not be dependent on IL-7, because B cells are present in patients whose B lineage cells express a mutated IL-7R α chain. In addition, B cells are present in patients with X-linked severe combined immunodeficiency; these individuals have mutations in the gene encoding the cytokine common γ chain, which is part of the receptor for IL-7.¹⁹ Other receptors that could compensate for the loss of IL-7 receptor signaling have not been identified.

Systemic Factors

In addition to regulation by microenvironmental factors, there is a growing appreciation that systemic factors, and those of endocrine origin in particular, also regulate B-cell development. For example, B-cell development in mice is dependent on the integrity of the

pituitary–thyroid axis because mice deficient in the production of thyroid hormone or expression of the thyroid hormone receptor exhibit suppressed BM B lymphopoiesis. Whether or not these events also occur in human B lymphopoiesis has not been established. It also has been demonstrated that hormones can negatively affect B-cell development. In particular, increased levels of estrogens occurring during pregnancy inhibit lymphopoiesis.

FETAL B-CELL DEVELOPMENT

Most knowledge of fetal hematopoiesis is based on studies in mice. It has long been recognized that some blood cells in that species are generated prior to the appearance of HSCs in an early wave of hematopoiesis that occurs in tissues such as the yolk sac. It has traditionally been thought that this pre-HSC wave of development is restricted to the production of erythroid and selected myeloid cells. However, emerging data suggest that B- and T-cell potential is also associated with this early wave of hematopoiesis.^{20,21} The contribution of B cells generated in this pre-HSC phase to the adult immune system remains to be determined. HSCs are generated at embryonic day 10.5 of murine gestation, and their B lineage progeny can be detected several days thereafter in fetal liver, BM, and spleen.

Studies of human fetal B-cell development are limited. Hematopoiesis initiates in the human yolk sac at 3 weeks of gestation, pre-B cells are present in human fetal liver by week 8 of gestation, and surface IgM⁺ cells are detectable at week 9. IgM-expressing cells have also been observed in additional human fetal tissues that include the omentum, the peritoneal cavity, and the spleen.

B-1 B Cells in Mice

The B cells that are produced in adult BM and that constitute the majority of B cells in the spleen and lymph nodes are often referred to as B-2 B cells. This nomenclature serves to contrast them with another functionally distinct population of mature B cells that are referred to as B-1 B cells. B-1 B cells are best characterized in mice, where they constitute around 5% of total B lymphocytes. Murine B-1 B cells preferentially localize in serous cavities and can be distinguished by their unusual phenotype that includes high levels of sIgM, low levels of sIgD, and CD11b, a determinant expressed on myeloid cells. B-1 B cells can be further subdivided into B-1a B cells that are CD5⁺ and B-1b B cells that do not express this determinant. Antibodies from B-1 B cells, at least in mice, are required for protection against pathogens such as *Streptococcus pneumoniae*.

B-1 B cells are generated most efficiently from precursors that arise in the fetus. Thus, although HSCs from fetal liver can efficiently generate both B-1 and B-2 B cells, those from the adult primarily produce B-2 B lymphocytes. These observations support the long-held view that B-1 cells are a distinct B-cell lineage preferentially derived from fetal precursors.²² The description of a phenotypically identifiable B-1 B-cell–specified progenitor that is preferentially generated in the fetus provided strong support for this view.

The regulation of B-1 and B-2 development is distinct, providing further support for the conclusion that these are distinct B-cell populations. For example, although B-2 B-cell development is blocked in IL-7-deficient mice, B-1 development can occur. More recently, the preferential generation of B-1 B cells from fetal progenitors has been linked to the expression of the Lin28b miRNA binding factor by fetal HSCs and B lineage progenitors. Adult HSCs are Lin28b⁺, but ectopic Lin28b expression in adult hematopoietic stem/progenitor cells results in their ability to generate B-1 B cells, and B-1a B cells in particular.²³

B-1 B Cells in Humans

B-1a B cells in mice are CD5⁺, and many studies have claimed to have identified human B-1 cells based on simultaneous expression of

CD5 and sIgM. These reports must be viewed with caution because CD5 is not a B-1-restricted determinant. Thus the identification of B-1 B cells in humans has proven elusive. However, a CD20⁺ CD27⁺ CD43⁺ CD70⁺ population of cord blood B cells that has properties consistent with their being classified as human B-1 cells was recently described.²⁴ The further characterization of human B-1 B cells and studies to define their origin remain areas of active investigation.

SECONDARY LYMPHOID COMPARTMENTS

Newly produced B cells are functionally immature, and they complete their final differentiation steps in peripheral, also referred to as secondary, lymphoid tissues. These events in the mouse occur in the spleen. During this process, the BM-derived surface IgM⁺ B cells transit through transitional stages of development before generating marginal zone (MZ) or follicular (FO) B cells (Fig. 20.1). MZ B cells are rapidly recruited in the immune response and play a critical role in the response to T-independent antigens. FO B cells are poised to respond to T-dependent antigens, which, as their name implies, require help from T cells. The localization of MZ and FO B cells in distinct anatomic sites and their intraorgan migration during the response to antigenic stimulation is governed by a variety of cytokines and chemokines.^{25,26}

Transitional B Cells

Two stages of transitional B-cell development have been defined. The most immature transitional cells, referred to as transitional 1 (T1) B cells, localize at the outer edge of the periarterial lymphoid sheath (PALS; see Figs. 20.1 and 20.5). The PALS in mice is occupied by a considerable number of T cells, but in humans few T cells are present in this region. T1 B cells give rise to a more mature population of splenic B cells, referred to as transitional 2 (T2) cells. Each of these transitional cell stages can be phenotypically distinguished.

The T1 and T2 populations respond differentially to developmental stimuli, and a considerable degree of selection occurs during the T1 to T2 transition. For example, T1 cells with BCR specificities for blood-borne self-antigens are deleted by negative selection. Positive selection via BCR signaling must occur, and if it does not, the T2 cells will die by neglect. The survival of T2 cells, but not T1 cells, is also dependent on the B-cell growth factor BAFF (BLyS, TALL-1, THANK, zTNF4), which is produced by the splenic microenvironment. A fraction of T2 cells are no longer in the G0 phase of the cell cycle, suggesting they are in a more activated state than is the case for T1 cells.

Various signals determine whether T2 cells mature into MZ or FO B cells.²⁶ Weak signaling through the BCR along with engagement of the Notch2 receptor promotes entry into the MZ B-cell compartment. There is a marked depletion of MZ B cells when the Notch2 pathway is blocked. Self-reactive B cells are enriched within the MZ population, suggesting that weak self-antigens may play an important role in their generation. This feature may permit them to respond rapidly to cross-reactive epitopes on pathogens. BCR signals, along with activation of the alternative NFκB pathway, are required for T2 cells to mature into an FO B cell. It is estimated based on murine studies that only 1% to 3% of splenic transitional B cells develop into mature, naive B cells.

MZ B Cells

MZ B cells localize at the outer limit of the splenic white pulp in an area known as the *marginal zone* (see Fig. 20.5). This region also contains macrophages and dendritic cells. MZ B cells play a role in T-independent responses elicited by polymeric antigens, such as polysaccharides, that are composed of repetitive antigenic epitopes. On antigen binding, MZ B cells undergo rapid proliferation and maturation into plasma cells that secrete low-affinity IgM and IgG3

Fig. 20.5 ORGANIZATION OF B CELLS IN SECONDARY LYMPHOID ORGANS WITH EMPHASIS ON THE SPLEEN. MZ, Marginal zone.

antibodies that provide a first line of defense. The rapid response of MZ B cells to antigen has led to the idea that this effector population, similar to B-1 B cells, constitutes a key element of the innate immune response to bacterial and other selected pathogens. In view of this, it is not surprising that many of the properties of MZ B cells overlap with those of B-1 B cells.

Human MZ B cells are heterogeneous and include a large proportion of CD27⁺ IgM⁺ unswitched memory B cells with somatically mutated Ig heavy chains. The origin of this cell population is unclear but is presumed to be antigen driven yet may not require T-cell help. Although MZ B cells in rodents appear to be a static, nonrecirculating population, cells with a CD27⁺ IgM⁺ phenotype are clearly present in human peripheral blood as well as other lymphatic tissues. However, it remains unclear if these circulating memory cells can reenter the splenic MZ.

The poor response of infants to some types of T-independent antigens correlates with the fact that the MZ is not fully formed until the age of 1 to 2 years. In addition, splenectomized individuals are more susceptible to infection with some bacteria, owing to the deficient antibody response to capsular polysaccharides.

FO B Cells and Germinal Centers

When mature, naive FO B cells are generated, they recirculate and take up residence in various lymphoid tissues that include lymph nodes, intestinal Peyer patches, and the spleen itself. Within these tissues, mature naive cells localize in clusters of B lymphocytes, and each such cluster is termed a *primary follicle* (see Fig. 20.5). Within these regions, the FO B cells are poised to respond to antigen and undergo the germinal center reaction described later. Although some B cells in the MZ can respond to T-dependent antigens, most B cells that do so are the mature, naive FO B cells located in these sites.

After their binding of a T-dependent antigen (as soluble antigen, indirectly via presentation by a local antigen-presenting cell, or as an immune complex) mature, naive B cells in primary follicles undergo a blastogenic response. Some of these cells will immediately mature into plasma cells that secrete low-affinity IgM to provide a rapid initial response to infection. In response to T-cell help, however, other B cells undergo further proliferation and differentiation. The histologic appearance of the follicle changes as these events evolve. The nonresponsive B cells form an outer mantle zone surrounding the proliferating, antigen-responsive B cells in a central germinal center.

Germinal center B cells are shielded from soluble antigens and are exposed only to a unique set of antigens presented by follicular dendritic cells. Two regions can be distinguished within the germinal center of the secondary follicle. At one pole, the cycling B-cell blasts are referred to as *centroblasts* and form the dark zone. The other pole, referred to as the *light zone*, consists of nonproliferating cells referred to as *centrocytes* (Fig. 20.5). Some of these centrocytes go on to become memory B cells, which constitute about 40% of all B cells and are responsible for the relatively rapid response observed on secondary exposure to the same antigen. Others mature into short- or long-lived plasma cells that secrete high-affinity Ig. Plasma cells migrate to the BM where they associate with stromal cells secreting the chemokine CXCL12 and APRIL, a TNF-receptor cytokine similar to BAFF, that supports plasma cell survival (Fig. 20.4).

Immunoglobulin Class Switching and Affinity Maturation

After the initial low-affinity IgM response that helps to keep a developing infection in check, germinal center B cells can undergo three distinct modifications that can increase the affinity of the Ig for antigen.

Ig class switching involves deletions of germline DNA resulting in religation of the VDJ complex to downstream heavy chain C region genes, such as $\gamma 3$, $\gamma 1$, $\gamma 2b$, $\gamma 2a$, ϵ , and α . These DNA deletions are believed to occur at or near nucleotide sequences called *switch regions* that are located in the intron 5' to each CH exon. These class-switching events are highly regulated, secondary-differentiation events that occur in spleen and lymph nodes and are potentiated by helper T cells and their secreted products. Note that Ig class switching is distinct from the previously discussed differential splicing events that allow the newly produced B cell to express the same VDJ complex associated with either the μ or δ heavy chain C regions.²⁷

B cells may also undergo receptor editing. Receptor editing usually involves modifications of the existing light chain, in which an upstream V region segment joins to a downstream J region gene. As a result, the genetic region encoding the originally expressed light chain is deleted. For this process to occur, RAG-1 and RAG-2 expression is required. It has been proposed that B cells in germinal centers might reactivate *Rag* gene expression to mediate events such as receptor editing. However, that this occurs has been questioned. Instead, receptor editing in splenic B cells may be limited to a small subset of recent immature BM immigrants that enter germinal centers before their *Rag* expression has been extinguished.

Somatic hypermutation provides a third means to increase antibody affinity. During this process, single-nucleotide exchanges,

deletions, and mutations are introduced into the genes encoding the antibody-binding regions of the Ig receptor. A B-cell-specific gene that encodes activation-induced cytidine deaminase (AID), which is expressed in germinal center B cells, has been identified. AID is a putative RNA-editing enzyme that acts as a cytidine deaminase and has been shown to be indispensable for somatic hypermutation and class switch recombination.^{27,28}

These events are dependent on signals delivered to the antigen-responsive B cells by antigen-specific T-follicular helper (T_{fh}) lymphocytes that migrate into the germinal center from the PALS. T_{fh} cells mediate their effects on B cells through the secretion of cytokines as well as through direct intercellular contacts, and these stimuli result in B-cell growth, differentiation, and Ig class switching. For example, CD40 is a T-cell-surface glycoprotein encoded by a member of the tumor necrosis gene family, and its ligand is expressed on B cells. CD40 ligand knock-out mice do not form germinal centers, and humans who do not express CD40 ligand have X-linked hyper IgM immunodeficiency. Another key T-cell costimulatory signal includes the cytokine IL-10, which is secreted by T cells in response to their activation via the “inducible costimulator” (ICOS). Humans lacking expression of ICOS on T cells have adult-onset common variable immune deficiency, leading to a severe deficit in generation of class-switched and memory B cells.

There are two unintended consequences of affinity maturation. One is that autoreactive clones may be inadvertently generated. The other is the development of B-cell lymphoma. Lymphomagenesis results in part from the fact that vigorous B-cell proliferation, combined with the changes at the DNA level that lead to molecular alterations, may promote malignant transformation.²⁸ Numerous studies have assigned B-cell lymphomas to each of the normal B-cell counterparts described earlier. Events that limit differentiation of immature or activated mature B cells can also promote malignant transformation. Importantly, many genetic lesions leading to B-cell lymphoma directly affect the BCR signaling cascade, and improved understanding of these signaling events may lead to new therapies. These include application of Btk-specific small-molecule inhibitors in a broad range of human lymphomas.²⁹

EFFECTS OF AGING ON B-CELL DEVELOPMENT AND FUNCTION

Studies of both rodents and humans have demonstrated that the quality of the immune response is diminished with age. Such declines are not incompatible with life, but they may become a factor when the individual is required to mount an immune response to a novel pathogen, respond to vaccination, or when considering the use of BM derived from older donors.³⁰

The production of B cells from HSCs is severely attenuated with age, and the frequency and number of CLPs, pro-B cells, and pre-B cells is significantly reduced in the BM of old mice. Similar age-related reductions in B lymphopoiesis also occur in humans. B-cell progenitors from young and old mice have been compared, and this has revealed that expression of the *Ink4a* and *Arf* genes increases with age and is a factor that contributes to the diminished proliferation and increased apoptosis of aging B-cell progenitors.

In addition to declines in primary B lymphopoiesis, which reduces the number of newly generated naive B cells that are produced, senescence also affects mature B cells resident in peripheral lymphoid tissues. For example, in addition to an accumulation of memory B cells in the spleen of old mice, the Igs they produce are less protective because of low titer and affinity. Some of these defects may be intrinsic to the B cells but others may be secondary to age-related defects in T cells.

Although the molecular changes that underlie the aging of HSCs and B lineage cells are being delineated, the events that trigger the aging process are incompletely defined. One possibility is that HSCs and lymphoid progenitors are genetically programmed to age. An alternative hypothesis is that these age-related events occur secondary to changes in the local and systemic environments.

T-CELL IMMUNITY

Shannon A. Carty, Matthew J. Riese, and Gary A. Koretzky

INTRODUCTION

Thymus-derived (T) lymphocytes play an essential role in the immune response to pathogens and against host cells that have undergone malignant transformation. T cells are critical regulators of other arms of the immune system via soluble mediators they produce and through direct interactions between ligands on the T-cell surface and receptors on other immune cells. This chapter first reviews T-cell activation after engagement by specific antigens and describes how signals delivered by the antigen receptors shape the repertoire of mature T cells in secondary lymphoid organs. We then discuss how different populations of mature T cells exert their effector functions. Because homeostasis of the immune system requires not only that T cells become activated under appropriate conditions but also that their activity be curtailed once the pathogenic challenge has been met, we describe several means by which T-cell activation is terminated. Finally, we review recent therapeutic advances that make use of our understanding of the molecular basis for T-cell activation.

T-CELL ACTIVATION

T-cell activation begins when the T cell encounters a specific antigen that engages and then initiates signal transduction through the T-cell antigen receptor (TCR). Unlike B cells that respond to soluble antigens, T cells are stimulated by small peptides presented on the surface of other cells. These peptides are incorporated into the binding groove of proteins of the major histocompatibility complex (MHC, known in humans as human leukocyte antigen [HLA] complexes) through a process called *antigen presentation*. Thus the ligand for the TCR is a peptide surface that is generated from both amino acids in the antigenic peptide and residues found in the MHC molecules themselves. Engagement of peptide–MHC complexes by the TCR induces a series of intracellular biochemical events that culminate in T-cell activation. Although T cells make use of many of the same biochemical pathways used by other cells for activation, there are a number of molecules unique to immune cells that are critical for T-cell activation. This section discusses TCR signal transduction, focusing on immune cell-specific molecular events.

Antigen Presentation: Creating the Ligand for the T-Cell Receptor

Invading pathogenic bacteria and viruses use different strategies to survive within infected hosts. Many bacteria, such as the pathogens *Staphylococcus*, *Streptococcus*, and various enteric Gram-negative bacilli, survive in the extracellular milieu, whereas viruses and other bacteria, such as *Listeria*, survive inside host cells. Successful elimination of pathogens in each of these locations requires distinct responses from the host. T cells play a central role in the control of extracellular and intracellular pathogens; however, the subset of T cells differs for each type of pathogen, with T cells expressing the cell surface marker CD4 most important for the response against extracellular pathogens and those expressing the CD8 marker essential for control of intracellular organisms. Stimulated CD4⁺ T cells act on other cells of the immune system by producing cytokines, soluble mediators that elicit a variety of cellular responses important for clearance of extracellular

pathogens, whereas CD8⁺ T cells function largely by directly lysing host cells that have become infected with an intracellular organism. It is therefore critical for antigens derived from extracellular sources to stimulate CD4⁺ T cells and for antigens derived from within the cell to stimulate CD8⁺ T cells. Whether a particular antigenic peptide activates a CD4⁺ versus a CD8⁺ T cell is determined by which MHC proteins present the peptide to the TCR.

Class II MHC proteins are found on cells of the innate immune system known as “professional” antigen-presenting cells (APCs) as well as B cells and the thymic epithelium. Professional APCs include dendritic cells (DCs) and various tissue macrophages, which engulf extracellular organisms (often after these are coated with host antibodies), host cells that have undergone apoptosis (programmed cell death), and cellular debris through an endocytic pathway that brings the ingested material into contact with degradative enzymes. The peptides that are formed in these reactions are bound to the MHC class II proteins for presentation to T cells. The MHC class II complex is a dimer consisting of a single α chain and a single β chain. Both α and β contribute to peptide binding and interaction with the TCR. As they are being synthesized within the cell, MHC class II complexes bind invariant chain (Ii), a protein that directs the newly formed MHC proteins into an acidic vesicle. During this trafficking event, a portion of the Ii occupies the peptide-binding site. Once the MHC class II protein reaches the acidic vesicle, Ii is proteolyzed by cathepsin S, leaving behind a small fragment that remains lodged within the peptide-binding cleft of the MHC class II complex. This fragment is termed *the class II–associated invariant chain peptide (CLIP)*. The MHC class II–containing vesicles then fuse with other vesicles containing the peptide fragments from the endocytosed particles. There, CLIP is replaced with a peptide, thus stabilizing the MHC class II complex and allowing it to be transported to the cell surface, where it interacts with CD4⁺ T cells (Fig. 21.1).

All cells of the body are at risk of being infected with intracellular pathogens or becoming transformed. Because protection against such challenges requires a CD8⁺ T-cell response, all nucleated cells in the body express class I MHC, the protein complex that presents antigen to CD8⁺ T cells. Like class II MHC, class I MHC is a protein dimer. However, in contrast to class II, only the α chain of class I MHC is variable. This α chain is associated with β_2 microglobulin, which stabilizes the complex but plays no direct role in antigen presentation. During its assembly in the endoplasmic reticulum (ER), the MHC class I complex comes into contact with peptides derived from proteins being translated in the cell. During protein synthesis, small amounts of protein are modified by ubiquitinylation. This serves as a targeting sequence, directing the modified protein to the proteasome, where it is degraded into small peptide fragments. These fragments are transported back into the ER by the transporters associated with antigen processing (TAP-1 and TAP-2), where they become available for binding to the newly synthesized MHC class I complexes. Peptide association completes the folding and assembly of MHC class I, which is then transported to the cell surface, where it can be recognized by CD8⁺ T cells.

T cells can respond to antigenic peptides only if these peptides fit into the binding pocket of either MHC class I or MHC class II. Although a large number of peptides are able to bind to a specific MHC complex, the diversity of antigen presentation is enhanced through expression of three different MHC class I alleles (in humans, HLA A, B, and C) and class II alleles (in humans, HLA DR, DP,

Fig. 21.1 ANTIGEN PRESENTATION. Presentation of peptides by major histocompatibility complex (MHC) class I and class II molecules occurs by different mechanisms. (A) Processing and presentation of class II peptides are limited to specialized antigen-presenting cells (APCs). (1) MHC class II molecules are synthesized in the APC endoplasmic reticulum (ER) in conjunction with a stabilizing protein known as *invariant chain* (Ii) (purple). (2) After transport into intracellular vesicles, proteases degrade Ii chain, leaving only the class II-associated invariant chain peptide (CLIP) in the antigen presentation cleft of the class II molecule. (3) Peptides for MHC class II molecules are generated from extracellular proteins that are endocytosed from the surrounding milieu and degraded by proteases in intracellular vesicles after vesicle acidification. (4) Class II peptides are exposed to MHC molecules after fusion of peptide-containing vesicles and vesicles containing CLIP-loaded MHC class II complexes. After exposure to peptide, CLIP is replaced with a peptide derived from the ingested materials, and the vesicle moves to the plasma membrane, depositing the peptide-loaded class II molecule at the cell surface (5). (B) All nucleated cells are capable of processing and presenting MHC class I peptides. Peptides for MHC class I molecules are generated from intracellular proteins that are synthesized in the ER (1) and transported into the cytosol. (2) A fraction of these cytosolic proteins become ubiquitinated by E3 ubiquitin ligases that target their proteolysis by the proteasome. Resultant peptides are subsequently transported back into the ER (3) and loaded onto MHC class I molecules (4). Peptide-loaded MHC class I molecules bud into vesicles (5) that fuse with the plasma membrane (6), resulting in cell surface expression.

and DQ). To increase the spectrum of peptides any particular cell may present even further, MHC alleles are always codominantly expressed. Thus any individual expresses a large number of different class II dimers on its APCs and class I dimers on all nucleated cells, providing excellent protection against potential pathogenic organisms. It is possible, however, that even with this degree of potential for antigen presentation, pathogens may evolve that do not possess unique proteins with sequences to fit into the MHC grooves. To circumvent this problem, the MHC locus evolved to be highly polymorphic, thus providing enormous diversity within the population for antigen presentation, ensuring that some individuals will express MHC dimers that can present antigens from virtually any pathogen. Interestingly, predominant MHC alleles exist in different parts of the world, suggesting that there is local pressure, perhaps based upon prevailing microorganisms, that shapes selection of MHC expression.

Neither MHC class I nor MHC class II distinguishes foreign from host peptides as they fill their peptide binding grooves. Because MHC class II samples all ingested antigens and class I is stabilized by a sampling of all proteins produced by the cell, the majority of the MHC complexes are filled with self-peptides. The T cell must distinguish self from nonself to ensure that a response is directed only

against that which is foreign. Control over what antigens elicit a T-cell response is accomplished through selection of a population of T cells expressing appropriate TCRs (see [T-Cell Development](#) section later).

The T-Cell Receptor Complex

The TCR is a multimolecular complex with separate components able to bind ligand or to transduce an activating signal to the cell. The peptide–MHC binding regions of the TCR consist of an α/β heterodimer in the majority of T cells, and the related γ/δ heterodimer in a smaller subset of T cells. α and β as well as γ and δ consist of variable and constant regions. Similar to antibodies (see [Chapter 20](#)), the variable regions of the TCR antigen-binding proteins arise from rearranging gene segments that are imprecisely joined during T-cell development. This process allows for an extraordinarily diverse repertoire of potential antigen reactivity, although there are in total only several hundred genes that make up the α , β , γ , and δ loci. The germline configurations of the α and β loci are different, such that the α -chain locus comprises about 70 variable (V) segments, 60 joining (J) segments, and 1 constant (C) segment, whereas the β -chain locus

Fig. 21.2 GENERATION OF DIVERSITY OF THE T-CELL ANTIGEN RECEPTOR. To generate the diverse repertoire of antigen receptors needed for protective T-cell immunity, the genetic loci encoding the two proteins of the T-cell antigen receptor (TCR) undergo multiple rearrangements to form the mature α and β chains. For the β chain, DNA recombination occurs between a variable (V) segment, a diversity (D) segment, and a joining (J) segment to create, along with remaining joining segments and a constant region, a messenger RNA (mRNA) transcript. This transcript is spliced to remove intervening joining regions, creating the final mature β chain mRNA. For the α chain, recombination takes place between a V segment and a J segment, with the insertion of additional nucleotides between the recombined segments. As with the β chain, mRNA processing removes intervening J segments to permit translation of the mature α chain. After translation, β chains and α chains pair to form the TCR heterodimer that is transported to the cell surface. Note that peptide-binding regions of the TCR are generated from the recombined V(D)J segments of the TCR gene. ER, Endoplasmic reticulum.

comprises 50 V regions, 2 diversity (D) segments, 13 J segments, and 2 C regions. Greater diversity is generated by the addition of nucleotides between the V and J gene segments on α chains and the V, D, and J segments in β chains during the formation of the mature TCR. In total, it has been calculated that approximately 10^{18} different TCRs can be created from these segments, although the functional population is much smaller because of the requirements for selection during maturation in the thymus (see [T-Cell Development](#) section later). Thus, once it has completed its developmental program, an individual T cell expresses a unique TCR encoded by a combination

of gene segments that have been altered and rearranged (Fig. 21.2). The T cells circulating through the lymphatics, lymph nodes, and spleen possess sufficient diversity for nearly all pathogens encountered to express an antigenic sequence recognized by a circulating T cell, which will then expand in number to combat that pathogen.

Soon after identification of the genes encoding TCR α and β , gene transfer studies in cell lines provided definitive proof that the α/β heterodimer contains all of the information necessary for peptide-MHC binding and that it is this protein complex that confers specific antigen reactivity on a particular T-cell clone. It also

became apparent that although sufficient to bind peptide–MHC, the α/β heterodimer was not capable of transmitting an intracellular signal once ligand was bound. A series of studies, first in cell lines and then in mouse models, demonstrated that the signal transduction function of the TCR complex resides in a protein complex that associates noncovalently with the α/β dimer. This complex, CD3, is required both for stable expression of the ligand-binding components of the TCR and for signal transduction. CD3 is composed of three subunits, δ , ϵ , and γ , expressed as heterodimers (γ/ϵ and δ/ϵ) along with the ζ subunit, which is present as a homodimer. Each subunit contains immunoreceptor tyrosine-based activation motifs (ITAMs), a stretch of amino acids with discretely placed tyrosine residues: one ITAM in δ , ϵ , and γ and three ITAMS in ζ . The ITAM tyrosines are key for the CD3 and ζ chains to transduce signals and are inducibly phosphorylated upon engagement of the α/β TCR chains by peptide–MHC. Upon their phosphorylation, the ITAMs become docking sites for other proteins that initiate the signaling cascade for T-cell activation. Notably, the CD4 or CD8 protein also plays a role in mediating signal transduction. These coreceptors bind both the appropriate MHC complex (MHC I for CD8, MHC II for CD4) and, via their cytoplasmic tails, the signaling molecule Lck, one of the kinases capable of phosphorylating the ITAMs (Fig. 21.3).

T-Cell Receptor Signal Transduction

Once the genes were cloned for each TCR complex component, it became clear that, unlike many other cell surface receptors that transduce activating signals, neither the ligand-binding domains nor the CD3 proteins of the complex have intrinsic enzymatic function. Engagement of the TCR by the peptide–MHC was found to result in the rapid activation of protein tyrosine kinases (PTKs) within

the T cells. Exactly how TCR engagement initiates PTK activation remains unclear; however, clustering of TCRs on the cell surface with resultant conformational changes in the CD3 proteins appears critical in the process. Src family (Lck and Fyn) PTKs are activated first following TCR stimulation, and the tyrosines within the CD3 and ζ ITAMs are substrates of these kinases. Phosphorylation of the ITAM tyrosines makes these residues able to bind to Src homology 2 (SH2) domains of other proteins. The most important SH2 domain-containing protein that is recruited to the ITAMs is ζ -associated protein of 70 kDa (ZAP-70), a PTK itself and a member of the Syk family of proteins. Thus binding of the TCR by ligand converts an enzymatically inactive receptor complex into an active PTK through recruitment and activation of cytosolic proteins.

Activation of ZAP-70 leads to tyrosine phosphorylation of a number of substrates, including enzymes that catalyze reactions generating second messengers important for T-cell activation. Phospholipase $C\gamma 1$ (PLC $\gamma 1$) is activated by its tyrosine phosphorylation to cleave phosphatidylinositol-(4,5)-bispophosphate (PIP $_2$) into the second messengers diacylglycerol (DAG) and inositol-(1,4,5)-triphosphate (IP $_3$). DAG is a lipid second messenger that binds to and activates downstream signaling components, including protein kinase C θ (PKC θ) and the Ras guanine exchange factor RasGRP. PKC θ , a serine/threonine kinase, regulates numerous effectors of gene transcription and T-cell effector function development, including the transcription factors nuclear factor κB (NF κB) and activator protein 1 (AP-1). RasGRP is responsible for activating the small molecular weight guanosine triphosphate (GTP)-binding protein Ras by enhancing Ras release of GDP, allowing it to assume its activated GTP-bound form. Active Ras collaborates with PKC family members to stimulate transcription of new genes by activating mitogen-activated protein kinase (MAPK) family members. IP $_3$ mobilizes calcium stores from the ER. This increase in calcium is important for enzyme function,

Fig. 21.3 PROXIMAL T-CELL RECEPTOR SIGNAL TRANSDUCTION. Binding of major histocompatibility complex (MHC) and peptide to the T-cell antigen receptor (TCR) and corresponding coreceptor (CD4 for MHC class II complexes and CD8 for MHC class I complexes) results in a series of molecular events that culminate in T-cell activation. (A) At rest, the TCR exists in a complex with CD3 that consists of heterodimers between δ , ϵ , or γ (δ/ϵ , δ/ϵ , ζ/ζ) chains (olive, left or right of the TCR) and homodimers of ζ chains (olive, between TCR chains). (B) Initially after ligand binding, the Src family kinases Lck (associated with CD4 and CD8) and Fyn (cytoplasmic) phosphorylate immunoreceptor tyrosine-based activation motifs (ITAMs) of CD3 and ζ (black lines). Note that the transmembrane adapter protein linker of activated T cells (LAT) is and the cytosolic adapter protein SH2 domain-containing leukocyte protein of 76 kDa (SLP-76) are not phosphorylated. (C) ITAMs serve as docking sites for the kinase ζ -associated protein of 70 kDa (Zap-70) that subsequently phosphorylates the adapter proteins LAT and SLP-76, which nucleate the complex containing signaling proteins.

Fig. 21.4 INTEGRATION OF T-CELL RECEPTOR SIGNALS BY ADAPTER PROTEINS. Following engagement of the T-cell antigen receptor (TCR) and activation of protein tyrosine kinases, several hematopoietic-specific adapter proteins are phosphorylated, enabling the formation of a multimolecular signaling complex. The transmembrane adapter protein linker of activated T cells (LAT) recruits SH2 domain-containing leukocyte protein of 76 kDa (SLP-76) through the growth factor receptor-bound protein 2 (Grb2) family member Grb2-related adaptor downstream of Shc (Gads). This SLP-76 nucleated complex associates with phospholipase C γ 1 (PLC γ 1), inducible T-cell kinase (Itk), Vav1, and degranulation-promoting adapter protein (ADAP). After phosphorylation by Itk, PLC γ 1 catalyzes the cleavage of phosphatidylinositol-(4,5)-bisphosphate (PIP $_2$) into inositol 1,4,5-trisphosphate (IP $_3$) and diacylglycerol (DAG). IP $_3$ induces calcium flux from the endoplasmic reticulum, leading to activation of the transcription factor nuclear factor of activated T cells (NFAT). DAG binds and activates proteins important in signaling such as protein kinase C θ (PKC θ), a kinase whose substrates initiate the activation of the transcription factor nuclear factor κ B (NF κ B), and Ras guanine exchange factor (RasGRP), a Ras-activating protein that induces activation of extracellular signal-regulated kinase (Erk) and formation of the transcription factor activator protein 1 (AP-1). Apart from transcriptional changes, T cells also undergo cytoskeletal changes after TCR stimulation mediated in part by Vav1, an activating protein for the actin-modulating protein Rac1, and activation of cell surface integrins, mediated in part by the adapter protein ADAP. PTK, Protein tyrosine kinase.

most notably the phosphatase calcineurin that dephosphorylates nuclear factor of activated T cells (NFAT), allowing it to translocate to the nucleus and transactivate genes necessary for T-cell proliferation, such as the gene encoding interleukin 2 (IL-2).

Although early TCR signal transduction studies demonstrated the importance of TCR-initiated PTK activity for T-cell activation, it took longer to unravel how this PTK activation drove the many critical second-messenger cascades. This mechanism was elucidated with the identification and characterization of adapter proteins, which possess modular domains important for intermolecular interactions. Two central adapters in the TCR signaling pathway are linker of activated T cells (LAT) and SH2 domain-containing leukocyte protein of 76 kDa (SLP-76). LAT is a transmembrane protein with seven cytoplasmic tyrosines that are phosphorylated by the PTKs activated by the TCR. SLP-76 is a cytosolic adapter protein that is also phosphorylated by these PTKs. Because these tyrosine phosphorylation events create docking sites for other proteins with SH2 domains, once the TCR is engaged, SLP-76 and LAT nucleate a large complex of signaling molecules at the membrane, in the vicinity of the activated TCR. This cluster of molecules initiates the signaling cascades that are integrated to result in T-cell activation. Key proteins in this complex are Vav1, a guanine nucleotide exchange factor important for cytoskeletal reorganization; inducible T-cell kinase (ITK), a member of the Tec family of PTKs (a third family of PTKs essential for T-cell activation); adhesion and degranulation-promoting adapter protein (ADAP), an adapter that is a key regulator of integrins to promote T-cell interactions with other cells; PLC γ , the enzyme described earlier that initiates both

the calcium and Ras/MAPK pathways in T cells; and growth factor receptor-bound protein 2 (Grb2) and Son of Sevenless (SOS), two proteins, like RasGRP, capable of activating Ras (Fig. 21.4).

For T-cell immunity to be effective, T cells must possess TCRs that are exquisitely sensitive to specific antigen. Because the TCR is generated through random reassortment and alteration of gene segments, it is impossible to prevent generation of TCRs that have the potential to respond to self-antigens. Although the developmental program of T cells in the thymus provides a mechanism to eliminate most potentially self-reactive T cells (see [T-Cell Development](#) section later), this process is not 100% effective. Hence mechanisms exist to prevent mature T cells from responding against normal host tissues. One such mechanism is the requirement for T cells to receive two signals to become activated, one mediated by the TCR and the second through a costimulatory receptor. Although several different T-cell molecules can provide this costimulatory function, the best studied is the surface protein CD28. This additional requirement for T-cell activation helps to prevent autoimmunity because the ligands for CD28 (CD80 and CD86) are upregulated on APCs only in the presence of “danger signals” generated largely by bacterial and viral components or in the setting of cellular stress. (The mechanism of how bacterial and viral components signal through Toll-like receptors to activate APCs is described in [Chapter 23](#).)

For CD28 engagement to provide the second signal for T-cell activation, it must also initiate signal transduction pathways (Fig. 21.5). CD28 signaling not only augments those signals stimulated by the TCR (described earlier) but also delivers independent signals. The interaction between CD28 and its ligands triggers the activation of

Fig. 21.5 TWO SIGNALS ARE REQUIRED TO ACTIVATE T CELLS. T-cell activation requires two signals, one through the T-cell antigen receptor (TCR) and one mediated by a costimulatory molecule, such as CD28. An antigen-presenting cell (APC) will activate a T cell if it presents appropriate peptide–major histocompatibility complex (MHC) to the T cell and also expresses a ligand to engage CD28. If CD28 is engaged without a concomitant TCR signal, the T cell is neither activated nor inactivated. However, if a T cell is stimulated through the TCR in the absence of costimulation through CD28, then it becomes anergic, unresponsive to the initial as well as subsequent stimulations.

phosphatidylinositol 3-kinase (PI3K), a protein that phosphorylates PIP₂ to form phosphatidylinositol-(3,4,5)-trisphosphate (PIP₃). Although the formation of PIP₃ induces broad changes within cells, the PIP₃ effector pathways that have been studied most intensively include two serine/threonine kinases: Akt, a PIP₃-binding protein responsible for regulating the metabolism of T cells to favor cell division, and PKC θ , a protein required for cytokine production in T cells that is dependent upon PIP₃ generation for full activation. The importance of CD28 costimulation of T cells goes beyond its requirement for T-cell activation because engagement of the TCR in the absence of CD28 signaling induces an impaired functional state within T cells termed *anergy* (see [Anergy](#) section later in this chapter).

Although CD28 is the prototypical and best studied costimulatory receptor, a multitude of other costimulatory molecules are expressed on T cells and regulated in a spatiotemporal manner in response to environmental cues, including CD27, inducible costimulator (ICOS), and 4-1BB. These costimulatory molecules bind an array of ligands on other cells (primarily APCs). Stimulation of individual costimulatory molecules can uniquely influence T-cell activation, effector function, and survival. One of the mechanisms by which distinct costimulatory molecules play unique roles in T-cell responses is likely due to the differential activation of discrete signaling pathways through their intracellular signaling domains. For instance, ICOS contains a binding motif that recruits the more active subunit of PI3K, leading to enhanced AKT signaling compared with CD28 activation.

Spatial Coordination of T-Cell Receptor Signal Transduction: The Immunologic Synapse

As the biochemical signaling events that occur following TCR engagement by peptide–MHC became known, investigators sought to define the topography of the activation events. Sophisticated imaging technologies were applied to visualize the contact site between the APC and the T cell, and this interaction was modeled by visualizing the contact between key receptors on T cells and ligands fixed to a solid support. These studies revealed a stepwise reorganization of the T-cell membrane at the contact site called the *immunologic synapse* (IS). The first step in IS formation is an interaction between integrins on the surface of the T cell and their ligands on the APC that brings the T cell and APC into close proximity. If a productive interaction occurs between the TCR and peptide–MHC, the next event is clustering of TCRs in the central portion of the developing IS (the so-called central supramolecular activation complex [cSMAC])

with the activated integrins forming the peripheral supramolecular activation complex (pSMAC), a ring around the clustered TCRs. Although ligands on the APC initially direct the formation of the IS, changes within the T cell, including reorganization of the actin cytoskeleton, are also critical for stabilization of this structure. As sophistication of imaging in real time has advanced and with the advent of tools to visualize smaller and smaller numbers of molecules, it has become clear that the IS is a dynamic structure that includes not only the TCR and integrins but also many of the signaling molecules essential for T-cell activation.

When first described, it was assumed that the purpose of the IS is to cluster the TCR together with key signaling molecules to initiate and sustain the T-cell activation program. Recent work indicates that this notion is too simplistic, because TCR signaling precedes IS formation. These findings led to the suggestion that the IS may function to internalize activated receptors, thus terminating their ability to respond. Further work indicates that under other conditions, perhaps when the avidity of the TCR for its ligand is lower, the IS does appear to maintain contact and allow signaling to occur. In addition to regulating TCR signaling, more recent studies suggest that another important function of the IS is to focus the release of cytokines from T cells toward other cells of the immune system or materials from the lytic granules of cytotoxic T cells toward their targets, thus enhancing the ability of T cells to exert their appropriate effector functions.

T-Cell Proliferation

The number of naive T cells potentially responsive to any particular peptide antigen (the precursor frequency of the responding population) is quite small, yet a large number of antigen-specific T cells are required to combat pathogens. Accordingly, a consequence of TCR plus costimulatory receptor engagement is the clonal expansion of an activated T cell. One outcome of the second-messenger cascades stimulated by the TCR and CD28 is the production of IL-2, an essential cytokine for T-cell proliferation. Another outcome of TCR signaling is upregulation of the high-affinity receptor for IL-2, thus making the activated T cell able to respond to local concentrations of this cytokine. Signaling through the IL-2 receptor is necessary for the proliferative response. Similarly to the TCR, the IL-2 receptor makes use of cytoplasmic PTKs (in this case members of the Janus kinase [JAK] family) to initiate a cascade of second messengers that lead ultimately to T-cell proliferation. The details of IL-2 and other cytokine receptor signaling are provided in [Chapter 16](#).

T-CELL DEVELOPMENT

Protective T-cell immunity requires populating the secondary lymphoid organs with a large number of mature T cells. Unlike most hematopoietic cells that complete the transition from progenitors to mature cells in the bone marrow, T cells develop primarily in the thymus. This population collectively must possess a diverse TCR repertoire capable of recognizing the enormous number of foreign antigens that will be encountered over life. Because the TCR binds antigenic peptide plus amino acid residues of self-MHC molecules, it is essential that only cells with a TCR able to recognize self-MHC, albeit with limited affinity, be exported from the thymus to the periphery. It is also critical, however, that the population of peripheral T cells be restricted to those that respond to foreign antigens, and cells possessing TCRs recognizing self-peptides plus MHC must not be allowed to complete their developmental program. Ensuring that only those cells with an appropriate TCR mature in the thymus relies heavily on many of the same TCR signal transduction events described earlier.

Of the T-cell lineages, those expressing the $\alpha\beta$ TCR cells are the best studied and most numerous. However, $\gamma\delta$ T cells, another population that possesses an antigen receptor generated through combinatorial rearrangement of gene segments, as well as natural

killer (NK) T cells, a subtype of lymphocytes that has characteristics of both T and NK cells (see [Chapter 22](#)), are also generated in the thymus. It has become clear recently that additional small populations of T cells possessing unique characteristics are also produced in the thymus. This chapter focuses primarily on $\alpha\beta$ T cells and touches briefly on $\gamma\delta$ T-cell development.

Early T-Cell Development

Identifying T-cell progenitors is an area of intense investigation because developing tools to manipulate these cells has great therapeutic potential for increasing the speed at which T-cell repopulation may occur following hematopoietic stem cell transplant. A population of bone marrow–derived thymic settling progenitors (TSPs) that can give rise to mature T-cell populations has been identified. As these cells enter the thymus at the corticomedullary junction, they develop into double-negative (DN) T cells, characterized by lack of expression of the CD4 or CD8 coreceptors ([Fig. 21.6](#)). As these early T cells progress through the DN stage, they are further subdivided into DN1, DN2, DN3, and DN4 stages on the basis of the cell surface receptors they express. During DN1, TSPs lose the ability to differentiate into non-T lineages and begin to proliferate in the deep cortex of the thymus. As these early thymocytes progress to the DN2 phase, they begin to express T cell–specific markers, such as Thy-1 (CD90), CD24, and CD25, and initiate TCR gene rearrangement at the TCR- γ , TCR- δ , and TCR- β loci. Throughout the DN1 to DN3 stages, as the cells migrate from the cortex to the subcapsular zone,

interactions between Notch receptors on the developing T cells and specific Notch ligands collaborate with signaling through the IL-7 cytokine receptor to regulate lineage commitment and developmental progression.

During the DN3 stage, rearrangement of TCR- γ , TCR- δ , and TCR- β loci occurs with maximal efficiency, and initial expression of the TCR proteins these genes encode occurs. From this time onward in T-cell development, the proliferation and survival of the developing thymocytes depend on TCR signals. Two key checkpoints must be passed for full T-cell development to occur. First, upon productive rearrangement of the TCR- β locus, the TCR- β protein forms a “pre-TCR” complex with an invariant cytosolic protein designated *pre-T α* . This complex engages the TCR signaling machinery, including the PTKs Lck, Fyn, and Syk (a ZAP-70-related PTK) and the adapters SLP-76 and LAT, to initiate the TCR signaling cascade. The resultant biochemical second messengers suppress rearrangement of the other β allele resulting in “allelic exclusion,” or silencing of the nonrearranged allele, to ensure each T cell expresses only one TCR specificity. These signals also induce continued T-cell development by promoting rearrangements at the α locus, maintaining cellular survival, initiating a proliferative burst, and inducing expression of CD4 and CD8. For effective signaling to occur, the rearranged β locus must encode a protein that folds correctly and pairs with *pre-T α* . Because the rearrangement of the genes that eventually make up the β chain is a random process, it is often the case that the rearranged allele encodes a dysfunctional protein. In this circumstance, signaling does not occur, and the cell initiates rearrangement at the other β chain allele. Again, if this does not result in a functional protein, no

Fig. 21.6 T-CELL DEVELOPMENT IN THE THYMUS. Thymic settling precursors (TSPs) from the bone marrow enter the thymus at the corticomedullary junction. These hematopoietic precursors develop into double-negative (DN) thymocytes, at which time they lose the ability to differentiate into non-T lineages, express T-cell markers, and begin T-cell antigen receptor (TCR) gene rearrangement. Developing $\alpha\beta$ thymocytes pass through the β -selection checkpoint before progression to the double-positive (DP) stage to ensure that the rearranged TCR proteins are able to transduce signals. DP thymocytes undergo positive selection if their TCR is able to recognize self-MHC molecules; otherwise, they undergo “death by neglect.” Negative selection occurs in the thymic medulla, when cells bearing TCRs that bind with strong avidity to self-MHC with self-peptide undergo apoptosis, thereby promoting central tolerance. Mature CD4 single-positive (SP) and CD8 SP cells then emigrate to the periphery. *APC*, Antigen-presenting cell; *mTEC*, medullary thymic epithelial cell.

signaling occurs, and the cell undergoes apoptosis. In other cells, a similar rearrangement process occurs in the γ and δ loci. Productive rearrangements of these gene families create a functional, mature $\gamma\delta$ TCR that also associates with the TCR signaling complex to propagate signals to trigger further cellular development.

Although the determining factors that result in either $\gamma\delta$ or $\alpha\beta$ T-cell development have not been fully elucidated, several molecular events are thought to contribute. The expression of a TCR gene rearrangement product likely plays a role in lineage determination because there is evidence suggesting that developing thymocytes with a functional $\gamma\delta$ TCR are often excluded from the $\alpha\beta$ cell fate. However, TCR expression is not the only factor in determining lineage fate; cytokine signals and TCR signal strength may also play a role. Experiments have shown that DN2 thymocytes distinguished according to IL-7 receptor expression differentiate into $\alpha\beta$ or $\gamma\delta$ T cells, with DN2 cells expressing high IL-7 receptor levels preferentially developing into $\gamma\delta$ T lymphocytes and those with lower expression more likely to differentiate into the $\alpha\beta$ lineage. Other studies have suggested that the strong signals propagated by the $\gamma\delta$ TCR in comparison to those of the pre-TCR complex may promote $\gamma\delta$ lineage commitment.

Positive Selection

Developing $\alpha\beta$ T cells that have passed the first checkpoint demonstrating functional β -chain rearrangement transition into the double-positive (DP; $CD4^+CD8^+$) stage and complete TCR- α rearrangement to produce a mature $\alpha\beta$ TCR heterodimer. The stochastic nature of TCR gene rearrangements guarantees that a significant proportion of cells expressing TCR- $\alpha\beta$ complexes will not be able to interact with self-MHC proteins and hence would not be stimulated by peptide-MHC complexes in the periphery. DP thymocytes therefore undergo a series of tests, collectively known as *positive* and *negative selection*, to determine TCR fitness. If the TCR is not stimulated via peptide-MHC complexes presented by thymic APCs, the developing cell undergoes “death by neglect” through apoptosis. Approximately 90% of developing $\alpha\beta$ DP thymocytes express a TCR that cannot recognize self-peptide-MHC and thus die by neglect. In contrast, those DP thymocytes that interact with self-peptide-MHC complexes on thymic cortical epithelial cells with sufficient strength pass this “positive selection” test and are protected from apoptosis.

CD4 and CD8 Lineage Commitment

The MHC specificity of the TCR on a positively selected DP thymocyte influences lineage fate. Cells signaled through a MHC class I-restricted TCR develop into CD8 single-positive (SP; $CD4^-CD8^+$) cells, and those that receive signals via MHC class II-restricted TCRs develop into CD4 SP T cells. The underlying molecular mechanisms governing CD4/CD8 lineage choice is much debated. Predicated on the thought that TCR signals during positive selection result in the termination of either *CD4* or *CD8* gene transcription, the two classical models of lineage fate are the stochastic selection and instructive models. In the stochastic selection model, TCR signals in a positively selected DP thymocyte randomly terminate either *CD4* or *CD8* expression. In the instructive model, certain TCR signal qualities, such as strength or duration of signal, direct termination of mismatching coreceptor expression. More recently, a kinetic signaling model has emerged. It proposes that CD4 or CD8 lineage fate is determined by TCR signal duration. Experimental models continue to be tested to fully elucidate the mechanisms underlying lineage fate.

Among the many proteins that are involved in CD4 or CD8 lineage choice are key transcription factors. One such example is T-helper-inducing POZ/Krüppel-like factor (Th-POK), a zinc finger protein that is expressed exclusively in $CD4^+$ T cells and not in $CD8^+$ T cells. In transgenic mice, expression of this protein forces the majority of positively selected thymocytes to adopt $CD4^+$ T cell fate,

even those with MHC class I-restricted TCRs. In addition, mice with a spontaneous mutation in *Th-POK* lack virtually all $CD4^+$ T cells, indicating that its expression is necessary for $CD4^+$ T-cell development. Another important factor is RUNX3, a member of the Runx transcription factor family. As DP thymocytes differentiate, RUNX3 regulates $CD8^+$ T-cell differentiation by silencing *CD4* transcription, promoting the initiation of *CD8* gene transcription and downregulating *Th-POK* expression. Additional studies have identified a network of key transcription factors and signaling proteins important for lineage choice in the thymus, underscoring the complexity of this stage of T-cell development.

Negative Selection

Although positive selection ensures that the random combinatorial rearrangement of gene segments results in a TCR that recognizes antigen presented by self-MHC proteins, until this point in T-cell development, there is no guard against the emergence of T cells that possess TCRs with high reactivity against self-peptides in the MHC binding pockets. Thus, to prevent autoimmunity, there must also be a mechanism to eliminate developing T cells with TCRs expressing these potentially autoreactive specificities. This process is called *negative selection*. Negative selection occurs primarily in the thymic medulla, where thymocytes serially interact with medullary thymic epithelial cells (mTECs) and other thymic APCs including DCs. At this stage, if thymocytes with TCRs engage peptide-MHC complexes with high affinity, a strong TCR signal initiates apoptosis. Whereas it is easy to see how this model allows for deletion of developing thymocytes with reactivity against self-antigens generated within the thymus itself, it was difficult to imagine how cells with reactivity against antigens known to be expressed outside the thymus would also be deleted. An explanation for how this occurs came from the discovery of the autoimmune regulator (AIRE) protein. Initially identified as the gene product mutated in a rare human autoimmune disorder, autoimmune polyendocrinopathy-candidiasis-ectoderm dystrophy syndrome (APECED), AIRE was later found to be essential for the expression of peripheral tissue-specific antigens by mTECs. Although AIRE does not regulate thymic expression of all peripheral antigens, its contribution to the elimination of autoreactive cells is highlighted by the widespread, multiorgan autoimmunity seen in patients with APECED. Identifying additional mechanisms responsible for thymic expression of tissue-specific genes is an area of active investigation.

Negative selection is one mechanism for development of “tolerance” or immune unresponsiveness to self-antigens; however, the process is not perfect in eliminating all self-reactive T cells. Hence, other means exist to promote self-tolerance after T cells leave the thymus. One such mechanism relies on development of regulatory T cells (Tregs), which actively interfere with effector T-cell function. Like conventional $\alpha\beta$ T cells, a subset of Tregs (previously known as *natural* or *nTregs* and more recently designated *thymic* or *tTregs*) also develops in the thymus. Tregs are characterized by the surface expression of CD4 and CD25 (the α chain of the IL-2 receptor) and depend on the transcription factor *forkhead box protein 3* (*FoxP3*) for their lineage commitment. The gene encoding *FoxP3* was originally identified as the causal mutation in a rare, and frequently fatal, human autoimmune disease called *immunodysregulation, polyendocrinopathy, and enteropathy, X-linked* (IPEX) syndrome. A mutation in the mouse gene for *FoxP3* causes a similar disease (*scurfy* mice). These naturally occurring loss-of-function mutations demonstrate the necessity for Tregs in maintaining self-tolerance. In the thymus, development into a tTreg is enhanced in cells that have high-affinity TCR-peptide-MHC interactions, suggesting that these cells develop specifically to counter autoreactive responses. The exact mechanism that drives these cells to adopt a Treg fate and avoid negative selection during development is being investigated.

The path of developing $\gamma\delta$ thymocytes contrasts with that of $\alpha\beta$ T-cell development, which is likely related to the function of mature $\gamma\delta$ T cells. In the periphery, $\gamma\delta$ T cells reside in secondary

Fig. 21.7 DIFFERENTIATION OF CD4⁺ T HELPER SUBSETS. When activated, CD4⁺ T cells differentiate into distinct, functionally mature effector subsets. Various factors, including the cytokine milieu, promote the expression of signature transcription factors and effector molecules. CD4⁺ helper subsets are defined largely by their cytokine production driven by these key transcription factors. Th1 cells are induced by interferon γ (IFN- γ) and interleukin 12 (IL-12), express the transcription factor T-bet, and produce IFN- γ . IL-4 is the primary cytokine that promotes Th2 differentiation. Th2 cells are characterized by expression of GATA3 and production of IL-4, IL-5, and IL-13. Naive CD4⁺ cells that are activated in the presence of IL-6 and IL-21 differentiate into Th17 cells, typified by the expression of retinoic acid receptor-related orphan receptor γ t (ROR- γ t) and production of the IL-17 family of cytokines. T follicular helper (Tfh) cell differentiation is mediated by IL-21. These cells are characterized by the transcription factor B cell lymphoma 6 protein (Bcl-6) and production of IL-21. If CD4⁺ helper differentiation and activity are not adequately controlled, imbalanced responses can lead to pathologic conditions.

lymphoid organs with conventional $\alpha\beta$ T cells but also are enriched in epithelial tissues of various organs, such as the skin, intestinal epithelium, reproductive tract, and lung. In these distinct settings, the TCR diversity of the $\gamma\delta$ T cells is more restricted, suggesting that these subsets may preferentially recognize ligands expressed at these anatomic locations during times of infection or tissue damage.

T-CELL FUNCTION

As T cells leave the thymus, they circulate to secondary lymphoid tissues. Before interaction with their cognate antigen, these cells are designated naive T cells. As naive T cells migrate through peripheral lymphoid organs, composed primarily of the spleen, lymph nodes, and mucosa-associated lymphoid tissue, they sample various peptide-MHC complexes on APCs. These APCs include cells residing in the secondary lymphoid organs as well as those in tissues that sample their local environment and then migrate to the secondary lymphoid organs, hence concentrating antigen in these locations. If a naive T cell does not encounter its specific antigen, it leaves the lymphoid tissue via the lymphatic system to reenter the bloodstream and repeat this process.

When a naive T cell recognizes its cognate antigen on an APC, a program of proliferation and differentiation transforms the naive T cell into an effector T cell, now primed to respond rapidly upon encountering its corresponding antigen in the tissues. One important difference between naive and activated T cells is the cell surface expression of chemokine receptors and integrins. These receptors direct the cell to the appropriate tissue where the effector T cell is needed. Thus, as a part of the T-cell activation process, those receptors that direct the naive T cell in its pathway recirculating between the lymphatic organs and blood vessels are altered for those that direct the activated cell to the tissues, so that the effector T cell reaches the site of pathogen challenge.

CD4⁺ and CD8⁺ T cells undergo analogous differentiation processes to acquire functional maturity but play distinct roles in the adaptive immune response to infection. Naive cells of both lineages are activated through peptide-MHC interaction with their TCRs, and their differentiation is influenced by a combination of signals, including TCR signal strength, costimulation by ligands that interact with other T-cell surface receptors, and the local cytokine environment during antigen encounter. Integration of these signals promotes expression of signature transcription factors and key effector molecules, which allow the mature cell to perform its individualized function. Activated CD8⁺ T cells possess the machinery to induce death in host cells that express the appropriate peptide within the binding groove of MHC class I (see later), whereas CD4⁺ T cells exert their functions through the production of cytokines or by interacting with other immune cells through direct cell-cell contact following restimulation of their TCR by peptide presented by class II MHC. These so-called helper functions marshal and activate other cells of the immune system (Fig. 21.7). Until they encounter peptide-MHC, naive CD4⁺ T cells have the potential to develop into one of several effector subsets, including Th1, Th2, Th17, and T follicular helper (Tfh) cells. Additional subsets have been defined recently, but these remain less well characterized and are not discussed in this chapter.

Th1 Cells

Th1 cells activate macrophages, NK cells, and CD8⁺ T cells to combat intracellular pathogens. Th1 cells also stimulate immunoglobulin class switching in B cells for the production of immunoglobulin G2a (IgG2a) antibodies that optimize clearance of viruses and extracellular bacteria (see Chapter 20). During priming of naive CD4⁺ T cells, several factors combine to promote differentiation along the Th1 pathway, including characteristics of the antigen, costimulatory signals from the presenting APC, and the cytokine microenvironment.

Several cytokines are implicated in Th1 differentiation, but the two most critical are interferon γ (IFN- γ) and IL-12. IFN- γ produced by innate immune cells promotes Th1 differentiation by activating signal transducer and activator of transcription 1 (STAT1), a key signaling molecule that regulates T-bet, one of the signature transcription factors associated with Th1 cells. IL-12, produced by activated APCs and other innate immune cells, acts through a separate STAT4-dependent pathway to promote IFN- γ production. IL-12 also signals to upregulate its own receptor and the IL-18 receptor, thereby allowing IL-18 to act in concert with IL-12 to promote IFN- γ production, thus creating a “feedforward” cycle to amplify the Th1 response.

T-bet, a T-box family member, is the key transcription factor associated with Th1 differentiation and function. T-bet-deficient T cells are defective in their ability to differentiate into Th1 cells either *in vitro* or *in vivo*, and T-bet-deficient mice are unable to control *Leishmania major* infection, a well-characterized intracellular pathogen model that depends on the characteristic Th1 cytokines for pathogen clearance. Whereas T-bet is considered the “essential” factor that directs Th1 lineage determination, other transcription factors, such as Runx3 and Hlx, are important for optimal Th1 function.

Once differentiated, Th1 effector cells are characterized by production of proinflammatory cytokines such as IFN- γ and tumor necrosis factor- α (TNF- α) that stimulate macrophages, NK cells, and CD8⁺ T cells to promote pathogen clearance. It is clear, however, that Th1 function must be balanced. Evidence from both animal models and human patients indicates that overexuberant Th1 responses drive inflammatory conditions and may lead to tissue destruction.

Th2 Cells

Th2 cells are critical for the immune response against extracellular parasites, such as helminths, through production of IL-4, IL-5, and IL-13. At initial sites of parasitic infection, epithelial cells of the target organs, including the skin, lungs, and intestines, and resident cells of the innate immune system sense parasite-derived products and produce Th2-inducing cytokines, including thymic stromal lymphopoietin (TSLP), IL-4, IL-25, and IL-33. These cytokines then act on innate immune cells, including basophils and DCs, as well as directly on naive CD4⁺ cells to promote Th2 differentiation.

Recent work has provided insight into how cytokine signaling, particularly IL-4 signaling, promotes Th2 differentiation. Through interaction with its receptor, IL-4 activates STAT6. STAT6 plays a vital role in Th2 differentiation, as evidenced by the profound reduction in development of this lineage in *Stat6*-deficient mice. STAT6 activation leads to its nuclear translocation and subsequent induction of the transcription factor GATA3, which, like T-bet for Th1 cells, is considered the master regulator of Th2 differentiation. GATA3 regulates Th2 cytokine production by binding and activating the “Th2 locus,” which includes the genes encoding IL-4, IL-5, and IL-13. When GATA3 function is abrogated, Th2 differentiation is virtually absent both *in vitro* and *in vivo*. In mature differentiated Th2 cells, GATA3 deficiency results in loss of IL-5 and IL-13 production. GATA3 is both necessary and sufficient for Th2 differentiation because forced expression either by retroviral constructs or transgenic expression promotes Th2 differentiation and represses Th1 differentiation. Repression of Th1 development occurs at least partially through GATA3-dependent inhibition of STAT4, thus interfering with *Ifng* gene transcription.

TCR signal strength also is involved in determining if a naive T cell will differentiate into a Th1 or Th2 cell. Studies in mice using altered peptide ligands that have decreased affinity for particular TCRs and experiments using limiting doses of antigen have demonstrated that diminished TCR stimulation promotes Th2 cell differentiation. Differences in costimulation also affect Th2 pathway differentiation. Mice deficient in CD28 or its ligand have a more pronounced defect in Th2 responses, suggesting that these molecules may play a greater role in promoting Th2 differentiation than Th1 differentiation.

IL-4 produced by mature Th2 cells acts in a positive feedback loop to promote further Th2 cell differentiation in naive T cells as they encounter antigen. Th2-derived IL-4 also mediates IgE class switching in B cells. Soluble IgE binds to and crosslinks its high-affinity receptor Fc ϵ RI on basophils and mast cells, promoting production of histamine and serotonin as well as several cytokines, including IL-4, IL-13, and TNF- α . IL-5 produced from Th2 cells recruits eosinophils, whereas Th2-derived IL-13 promotes both the expulsion of helminths during parasitic infection and also the induction of airway hypersensitivity.

Th2 responses are critical for immunity against extracellular parasites, but excessive Th2 responses are associated with the pathologic conditions of allergy and airway hypersensitivity. The increase in asthma in the developed world has been linked to an imbalance of Th subsets with skewing toward “Th2-ness” in the population. Additional work is necessary to more firmly establish a molecular immunologic link to the epidemiology of these diseases.

Th17 Cells

The original description of Th1 and Th2 cells, indicating that not all mature CD4⁺ T cells were alike, led to the search for other CD4⁺ subsets. Studies exploring the role of IL-23 in experimental autoimmune disease models found IL-23 to be critical for the generation of an IL-17-producing CD4⁺ T-cell population, designated Th17 cells. Extensive analyses of IL-17 and the cells that produce this cytokine demonstrate that Th17 cells are important for the control of extracellular bacterial and fungal infections. With excessive activity, however, these cells also appear to play an important role in autoimmune diseases through the production of proinflammatory cytokines, including IL-17A, IL-17F, IL-21, and IL-22.

Although IL-23 is a key regulator of Th17 cells, the IL-23 receptor is not expressed on naive CD4⁺ cells and hence could not explain the differentiation of cells into the Th17 subset. Subsequent studies demonstrated that the combination of transforming growth factor- β (TGF- β) with either IL-16 or IL-21 induces Th17 differentiation. The cytokines that are key mediators of Th17 differentiation and survival, including IL-6, IL-21, and IL-23, all activate STAT3. The critical role of this STAT family member was demonstrated in murine studies, when its deletion abrogated the ability of T cells to undergo Th17 differentiation. In humans, the importance of STAT3 was highlighted when it was identified as the genetic mutation present in many patients with hyper-IgE syndrome (HIES, or Job syndrome). HIES is a rare immunodeficiency syndrome characterized by recurrent staphylococcal skin abscesses, elevated serum IgE, and pneumatocele-forming pneumonias. Patients with HIES with STAT3 mutations have an impaired ability to form Th17 cells, which may explain part of their immunodeficiency. STAT3 regulates expression of many cytokine and cytokine receptor genes involved in Th17 generation or function, including IL-17A, IL-17F, IL-21, IL-21R, and IL-23R.

STAT3 is also important for induction of the signature Th17 transcription factor ROR- γ t, which is a member of the retinoic acid-related orphan receptor (ROR) family. In naive CD4⁺ cells, ROR- γ t induces IL-17 gene transcription and promotes expression of the IL-23 receptor. Overexpression of ROR- γ t induces Th17 differentiation, but deficiency of ROR- γ t only partially affects Th17 cells *in vivo* because of expression of the related transcription factor ROR- α , which is also expressed in T cells and is induced by IL-6/TGF- β in a STAT3-dependent manner. Cells deficient in both ROR- γ t and ROR- α lose the ability to undergo Th17 differentiation, both *in vitro* and *in vivo*.

Th17 cells are induced during the response to extracellular bacteria and fungi, including *Klebsiella pneumoniae*, *Bacteroides* species, and *Candida albicans*. Indeed, some patients with chronic mucocutaneous candidiasis have been shown to have mutations in IL-17F and the IL-17 receptor genes. Excessive Th17 cell function also plays a role in autoimmune diseases, such as rheumatoid arthritis, psoriasis, and Crohn disease, and therapies targeting the IL-17/IL-23 axis have

been approved or are under active clinical investigation for treating these disorders.

Tfh Cells

In addition to Th1, Th2, and Th17 subsets, naive CD4⁺ cells develop other functions dependent on the cytokines produced. Examples include recently described Th9, Th22, and Tfh cells. This latter subset enhances the humoral immune response by providing help to B cells during germinal center reactions. Tfh cells express high levels of CXCR5, the receptor for the chemokine CXCL13. The expression of CXCR5 permits differentiating Tfh cells to migrate from the T-cell zone to the CXCL13-rich B cell follicle, thereby allowing Tfh cells to interact with B cells and exert their function. In addition to CXCR5 expression, other signals, such as TCR signal strength and costimulatory molecules, are important for Tfh differentiation. A study using adoptive transfer of naive CD4⁺ cells expressing high- and low-affinity transgenic TCRs demonstrated that high-affinity TCR interactions preferentially developed into the Tfh subset. Tfh cells have higher expression of multiple costimulatory molecules, including CD40L, ICOS, and OX40, than other T helper subsets. Because costimulatory molecules enhance B cell differentiation, the higher expression of these molecules on Tfh cells is hypothesized to positively correlate with the enhanced ability to facilitate B cell antibody production. It appears that the expression of costimulatory molecules on Tfh cells is important not only for their function but also for their development and/or maintenance, because both mice and humans deficient in ICOS have fewer Tfh cells with reduced germinal center formation.

Similarly to other CD4⁺ helper subsets, Tfh programming depends on a signature transcription factor, in this case B-cell lymphoma 6 protein (Bcl-6). In Tfh cells, Bcl-6 acts as a transcriptional repressor. Studies employing complementary methods of T cell–specific Bcl-6 deficiency and overexpression demonstrated that Bcl-6 expression in T cells is both necessary and sufficient for Tfh differentiation *in vivo*.

CD4⁺ Th Plasticity

Although CD4⁺ T helper differentiation was classically thought to be a model of lineage specification and differentiation, it is clear that there is more plasticity in the CD4⁺ Th subsets than was originally appreciated. Traditionally, Th subsets are associated with a signature cytokine(s) and transcription factor. However, recent data demonstrate CD4⁺ Th cells can express more than one cytokine, particularly *in vivo*, and even the “master regulators” can be coexpressed in the same cell. The mechanisms that underlie this plasticity and its functional relevance are areas of active investigation.

CD8⁺ Cytotoxic T Cells

The principal function of CD8⁺ cytotoxic T cells (CTLs) is to kill host cells that have been infected with pathogens or that have undergone deleterious changes, such as malignant transformation. Like CD4⁺ cells, naive CD8⁺ cells initially encounter peptide antigen and MHC on the surface of APCs in the secondary lymphoid organs. However, unlike CD4⁺ cells that are stimulated by class II MHC alleles on the APCs, CD8⁺ cells are engaged by class I MHC plus peptide. For many years it remained unclear how APCs, which acquire peptide antigens largely by engulfing materials generated outside the cell, are able to present MHC class I–restricted peptides, which typically are generated within the cell (see earlier). This mystery was solved with the description of “cross-presentation,” a mechanism by which APCs present engulfed antigens on both class I and class II alleles. Thus, tissue-resident phagocytic cells ingest virally infected or malignantly transformed host cells, degrade the ingested material, and present the peptide antigens in the binding grooves of both class I and class II MHC alleles. These activated phagocytic cells then migrate to the

lymph nodes, where they encounter recirculating naive CD8⁺ cells. TCR engagement of foreign peptide–MHC class I complexes triggers activation of the CD8⁺ T cells and initiates CTL differentiation. As part of its activation program, the CTL changes its expression of integrins and chemokine receptors so that it can leave the circulation and enter the tissues, looking for host cells displaying the same antigen that induced CTL activation by the APC in the lymph node.

Once an appropriate target cell is identified in the tissues, the CTL is again stimulated through its TCR, this time by the peptide–MHC class I combination on the target cells. A structure similar to the IS forms between the CTL and the target cell. The CTL contains specialized granules that are transported to the contact site between the CTL and target. These granules are modified lysosomes that contain effector proteins, including perforin, granzymes, and granzyme B. Perforin facilitates the entry of the granzymes into the cytosol of the target cell. The granzyme family, consisting of granzyme A, granzyme B, granzyme H, granzyme K, and granzyme M, are proteases that degrade host cell proteins. Granzyme B is the best-studied family member and is known to cleave caspase 3, activating a proteolytic cascade leading to DNA degradation and apoptosis of the target cell (Fig. 21.8). Granzyme B also promotes cell death in a caspase-independent manner through cleavage of the proapoptotic protein Bid, promoting its migration to and disruption of the outer mitochondrial membrane, resulting in the release of cytochrome c. CTLs also produce cytokines, including IFN- γ , TNF- α , and IL-2. IFN- γ acts to inhibit viral replication in the affected tissues and also induces increased class I MHC expression, thus improving the ability of cells to stimulate the TCR on CTLs. IFN- γ synergizes with TNF- α for macrophage activation.

The transcription factors important for CD8⁺ T-cell effector differentiation include two members of the T-box family, T-bet and Eomesodermin (Eomes). Initially identified as the master Th1-determining transcription factor in CD4⁺ cells, T-bet also plays an essential role in CD8⁺ effector cell differentiation. Recent work has shown that T-bet expression is highest in short-lived effector cells and lower in CD8⁺ T cells destined to become memory cells (see later), suggesting that a gradient of T-bet expression controls the balance between different CD8⁺ effector fates. Eomes cooperates with T-bet in CTL function, and cells deficient in both factors are unable to generate CTLs in response to viral infection.

MATURATION OF T CELL-MEDIATED IMMUNITY

T-Cell Memory

The activation of naive T cells does not complete their maturation process; instead, it is the starting point for the changes that result in T cell–mediated immunity. At the initiation of an infection, individual antigen-specific T cells become activated and expand robustly to combat the pathogen. As the pathogen is eradicated, the large population of activated T cells must contract dramatically to ensure homeostasis of the immune system. However, a discrete but relatively small population of antigen-specific T cells persists. These long-lived T cells have properties distinct from naive or activated T cells, including self-renewal through homeostatic proliferation and the ability to rapidly proliferate and regain effector function upon reexposure to antigen. These are the cardinal features of cell-mediated immunologic memory.

Immunologic memory refers to the observation that after an initial exposure and mounting of an effective immune response to a pathogen, subsequent interactions with that pathogen elicit rapid and robust T-cell activation, with more efficient clearance of the pathogen. Memory is the foundation of vaccination because immunization with pathogen-specific antigens induces a memory response so that first exposure of the host to the intact pathogen results in a rapid, effective response, thus abrogating signs and symptoms of the infection.

Within days of infection, subsets of activated effector CD8⁺ T cells can be identified with different cell fates: those that are terminally differentiated and those that have the potential to develop

Fig. 21.8 CD8⁺ CYTOLYTIC FUNCTION. Cytotoxic CD8⁺ T cells function primarily to kill host cells that have been infected by intracellular pathogens or that have undergone malignant transformation. After naive CD8⁺ cells encounter peptide–major histocompatibility complex (MHC) class I plus costimulation in secondary lymphoid organs, these activated cytotoxic T lymphocytes (CTLs) leave the circulation and enter the tissues. There, upon interaction with a target expressing that same peptide–MHC class I, a CTL forms a lytic synapse, similar to the immunologic synapse, with the target. Cytoplasmic granules containing perforin and granzymes congregate at the synapse, and granule contents are exocytosed into the cleft between the CTL and its target cell. Perforin molecules facilitate entry of the cytolytic molecules into the target cells, and granzymes act to promote apoptosis of the target cell.

into memory cells. How memory cells develop from naive T cells is a subject of ongoing debate, and several models have been proposed. In one model, memory T cells are thought to develop from a broad pool of activated effector T cells, with most effector cells undergoing apoptosis and others surviving to provide memory. A second model suggests that when activated, naive T cells randomly differentiate into either effectors or memory cells. Recent studies using single-cell adoptive transfer experiments demonstrate that individual naive CD8⁺ T cells have the ability to differentiate into a heterogeneous pool of short-lived effector and long-lived memory cells, likely in response to differences in antigen specificity and duration of stimulation, precursor frequency, and the inflammatory environment.

Different subsets of memory cells are observed after resolution of infection. The two main classes are effector memory and central memory T cells. Effector memory T cells, characterized by loss of expression of lymph node homing molecules CD62L and CCR7, rapidly produce cytokines in response to restimulation with previously encountered antigen, thereby allowing for rapid responses to invading pathogens. These cells preferentially reside in nonlymphoid tissues, such as lung and intestinal mucosa, which are frequently sites of pathogen entry. In contrast, central memory cells express high levels of CD62L and CCR7, are more prevalent in lymphoid tissues, and mount a robust proliferative response after reencountering antigen.

As with differentiation of naive T cells into efficient effectors, cytokines play an important role in memory T-cell development and maintenance. IL-2 is essential for initial memory cell differentiation, whereas IL-7 and IL-15 are crucial for memory cell persistence. Other signals, such as the strength of antigenic and inflammatory signals during T-cell activation, also influence memory cell development and maintenance. An important consideration for memory development is cell–cell interactions because CD4⁺ T cells are required during initial priming of CD8⁺ cells for development of fully functional CD8⁺ memory cells. A number of infectious disease models have demonstrated that in the absence of CD4⁺ T-cell help, fewer CD8⁺ memory T cells are maintained, and those that do persist are of the central memory phenotype.

Although great progress has been made in elucidating the molecular underpinnings of immunologic memory, much remains to be learned. Recent data have emerged on the importance of the cellular metabolic state in the control of memory T-cell differentiation. As CD8⁺ T cells are activated, they transition from using primarily oxidative phosphorylation to generate basal energy in the quiescent state to using glycolysis during the effector phase and then back to using oxidative phosphorylation as memory cells. In experimental models,

manipulations of the cell's metabolic profile can influence effector function and memory differentiation. As additional discoveries are made, it is anticipated that new approaches will develop to improve T-cell responses to vaccines against infectious agents, to promote T-cell recall responses to pathogens that today result in chronic infections, and to harness host T-cell responses to combat tumors.

T-Cell Exhaustion: An Aborted T-Cell Response

Under most circumstances, acute infection results in the expansion of T lymphocytes specific for the inciting pathogen, clearance of the pathogen, and the development of memory T cells able to clear that pathogen more effectively upon reexposure of the host. However, some pathogens cannot be efficiently cleared from infected hosts and persist throughout the lifetime of the organism, despite the formation of pathogen-specific T cells. Examples of such pathogens include human immunodeficiency virus and hepatitis viruses B and C. These persistent infections result in chronic antigen exposure, which, instead of continuing to induce maximal productive T-cell responses, leads to the generation of “exhausted” T cells that have reduced ability to kill and produce cytokines in response to infection. The development of T-cell memory and the exhaustion response are initiated in similar ways, with the formation of cells that are capable of responding to antigen challenge through proliferation and the secretion of cytokines. However, during exhaustion, the persistence of pathogen causes T cells to become increasingly less responsive to stimulation. At early time points in this process, exhausted CD8⁺ T cells lose the ability to secrete IL-2 or TNF- α and cannot induce cytotoxicity of infected host cells. At later time points, CD8⁺ T cells become completely unresponsive and ultimately undergo apoptosis. The induction of exhaustion is thought to represent a functional adaptation that permits some degree of control of chronic infection while limiting immune-induced tissue damage.

Concurrent with the loss of functional responses, exhausted cells upregulate inhibitory cell surface receptors. The best studied of these inhibitory receptors is programmed death 1 (PD-1), which binds its ligands, PD-L1 and PD-L2, expressed on activated macrophages and other APCs. Engagement of PD-1 dampens the T-cell response, likely by recruiting phosphatases that oppose the PTKs necessary for T-cell activation. PD-1 is normally expressed on T cells after initial activation, presumably as a means to prevent excessive responses, and is then downregulated as T cells acquire a memory phenotype after the pathogen clearance. Exhausted T cells, however, continue

to express this inhibitory receptor. Early during exhaustion, PD-1 blockade reversed T-cell exhaustion in experimental models; however, other inhibitory receptors become expressed as exhaustion continues. Blockade of PD-1 with these other receptors has been shown to improve T-cell responsiveness, even at later stages of exhaustion. Therapeutic targeting of the PD-1 axis and other key inhibitory receptors is an exciting new avenue for immunotherapy against malignancies (see later) and chronic infections.

INHIBITION OF T CELL-MEDIATED IMMUNITY

Efficient signaling through the TCR and other cell surface molecules is required for initial T-cell activation. Similarly, appropriate maturation of the T-cell response to generate effector and memory cells is critical for adequate responses to pathogens. However, because of the potential for activated T cells to damage host tissues, an integral aspect of the immune system is also to negatively regulate T-cell activities. The mechanisms for inhibiting T-cell responses are critical for the prevention of inappropriate activation of naïve T cells at the initiation of an immune response, for limiting the robustness of an appropriate T-cell response as effector cell functions are developed, and for terminating the T-cell response once an antigenic challenge has been met. This section discusses examples of how T-cell activation is modulated at each of these three critical steps of T-cell immunity.

Prevention of Inappropriate Initiation of T-Cell Responses

Given the enormous power of immune effector cells to damage tissues, it is essential that the immune system be nonreactive (tolerant) to self. As described earlier, T-cell tolerance is achieved centrally through the requirement to pass selection checkpoints during thymic development. However, negative selection in the thymus is not sufficient to eliminate all cells with potential autoreactivity, and some T cells bearing TCRs that may respond to self-antigens are exported from the thymus to the periphery. Mechanisms are in place to prevent these cells from becoming active effectors as they encounter antigen. Two such mechanisms are anergy, a process by which T cells limit their own responsiveness based upon engagement of particular cell surface receptors (a cell-intrinsic path to inactivation), and the action of Treg cells, which instruct potential effectors to remain quiescent.

Anergy

One means of limiting T-cell responses against host tissues is a process of self-inactivation termed *anergy*. As noted earlier, T cells require signaling through both the TCR and costimulatory receptors such as CD28 to become activated (Fig. 21.5). Stimulation of the TCR alone in the absence of adequate costimulation produces T cells that fail to secrete IL-2 or upregulate high-affinity receptors for this cytokine and hence fail to clonally expand. Cells that have been rendered anergic fail to respond to subsequent stimulation, even if ligands for both the TCR and CD28 or other costimulatory receptors are available. This two-signal requirement ensures that only APCs activated by pathogens or other “danger signals” can initiate an immune response, because ligands for costimulatory receptors, such as CD80 and CD86, for CD28 are upregulated only in activated APCs. Thus, under circumstances of pathogen invasion, APCs present peptide antigens to T cells in addition to CD28 ligands. In the absence of an immune challenge, APCs express only low levels of CD80 or CD86. If a T cell encounters an APC that presents a stimulatory peptide-MHC complex but lacks sufficient expression of CD28 ligands, the T cell does not become activated. In this situation, the absence of ligands for CD28 implies that there is no “danger” and that the antigen being recognized is derived from a self-protein. The result of such an encounter leaves the T cell in an anergic state, refractory to

activation even in the face of subsequent TCR stimulation by an activated APC.

The role of anergy in human immunology remains unclear, as investigators have largely used in vitro model systems and/or animal models. However, several lines of evidence indicate that there are self-antigen-reactive T cells that remain quiescent in normal human hosts. The biochemical basis of anergy also remains incompletely understood, but intriguing models suggest that an imbalance between the strength of Ras versus calcium signaling may be crucial. In this paradigm, it is the activation of calcium-dependent transcription factors, such as NFAT, in the absence of transcription factors activated by Ras signaling, such as AP-1, that confers an anergic state. Although anergy is classically thought to persist indefinitely, under some circumstances there is apparent plasticity, as exposure of T cells to high concentrations of IL-2 can improve functional responses in previously anergic cells. Thus the physiologic importance of anergy in limiting endogenous T-cell activation and preventing autoimmunity and whether there are times when anergy must be reversed for appropriate immune responses are areas of active investigation.

Regulatory T Cells

Tregs are a subset of CD4⁺ T cells that suppress the proliferation and cytokine production of activated T cells whose TCRs have been engaged by peptide-MHC, even in the presence of costimulation. Hence, as opposed to anergy, which operates in a cell-intrinsic fashion, Tregs block responsiveness *in trans*, by modulating responses of other cells. Tregs arise in two ways: “thymic” Tregs (tTregs) that acquire function during development in the thymus (described earlier) and “inducible” Tregs (iTregs) that are generated through the differentiation of naïve CD4⁺ T cells in the periphery. Both tTregs and iTregs are characterized by expression of the key transcription factor FoxP3 and by surface expression of CD25, a subunit of the IL-2 receptor.

As noted, there are multiple steps and checkpoints that occur during development of T cells in the thymus. After reaching the DP stage, T cells test their TCR for reactivity against peptide-MHC complexes presented by thymic APCs and epithelial cells. Cells bearing TCRs with no reactivity undergo apoptosis (failed positive selection) as do cells with very strong TCR reactivity (through negative selection). Only cells whose TCRs have moderate affinity for peptide-MHC continue to mature. Within this continuum of permitted reactivity, those cells with TCRs exhibiting the highest affinity for peptide-MHC are induced to express FoxP3 and develop into Tregs. In the periphery, these cells respond to TCR stimulation by diminishing the response of “conventional” T effector cells, thus downregulating immune responses.

iTregs act similarly to tTregs, but these cells do not leave the thymus poised to have suppressive function. Instead, these cells arise from naïve T cells that encounter antigen in the secondary lymphoid structures. Similarly to other CD4⁺ subsets, iTregs are induced on the basis of prevailing cytokine conditions and which receptor-ligand interactions predominate during this initial antigen encounter. Regardless of whether they arise in the thymus or are induced in the periphery, Tregs exert their immunosuppressive functions on a variety of immune cells, including CD4⁺ and CD8⁺ T cells, DCs, B cells, macrophages, and NK cells, within their microenvironment. Tregs mediate these immunosuppressive effects through the secretion of suppressor cytokines such as IL-10 and TGF- β , the consumption of local concentrations of IL-2, and the induction of apoptosis or cell cycle arrest through direct cell-to-cell contact (Fig. 21.9).

Limiting T-Cell Responses After Stimulation by Foreign Antigen

Even when stimulated appropriately to combat an invading pathogen, it is essential to limit T-cell activation. Unchecked T-cell effector functions present a danger to the host through production of

Fig. 21.9 T-REGULATORY CELL ACTIONS. T-regulatory cells (Tregs) act to suppress other T cells through a multitude of mechanisms, including the secretion of suppressor cytokines interleukin 10 (IL-10) and transforming growth factor β (TGF- β), consumption of local concentrations of IL-2, and induction of cell cycle arrest or apoptosis.

proinflammatory cytokines that recruit other cells of the immune system and through direct damage of self-tissues. T-cell effector functions are limited by modulating the T-cell activation pathways through activation of signaling molecules that counter the second messengers stimulated by TCR engagement, through inducible expression of cell surface receptors that compete with activating receptors on the T cell, or by targeting key activating proteins for destruction, thus limiting their ability to promote T-cell effector function. Additionally, the local environment in which the T cell exists may change, with cell extrinsic factors (e.g., inhibitory cytokines) becoming available to dampen T-cell responses (Fig. 21.10).

Limitation of T-Cell Activity From Cell-Intrinsic Components

Protein Tyrosine Phosphatases

As noted earlier, the most proximal known biochemical event to occur following engagement of the TCR by peptide-MHC results in activation of PTKs, including Lck and Zap-70, enzymes central to the T-cell activation program. Thus one means by which to limit TCR signaling is to oppose the activating PTKs with deactivating protein tyrosine phosphatases, reversing the phosphorylation events that drive T-cell activation. Several such phosphatases have now been identified, including SH2 domain-containing phosphatase 1 (SHP-1) and protein tyrosine phosphatase, nonreceptor type 1 (PTPN1). Although the direct targets of these phosphatases have yet to be demonstrated conclusively, there is increasing evidence in murine systems that they are important for control of T-cell activation as well as for regulating the function of other cells of the immune system. Experiments show that, compared with wild-type cells, SHP-1-deficient T cells demonstrate enhanced proliferation and cytokine production after stimulation. These cells also show prolonged phosphorylation of TCR signaling molecules, consistent with a role for SHP-1 in reversing these events. Overexpression of SHP-1 within T cell lines inhibits TCR-mediated signaling events. Furthermore, SHP-1 is recruited into the IS after engagement of the TCR, thus providing an appropriate physical localization for SHP-1 to directly engage targets of the TCR-stimulated PTKs. SHP-1 inhibitory activity appears to be crucial *in vivo* because mice that lack functional SHP-1 develop fatal autoimmunity, likely secondary to alterations of

Fig. 21.10 INHIBITORY PATHWAYS IN T CELLS. Negative influences on T cells and T-cell antigen receptor (TCR) signaling take place at multiple levels within T cells and are crucial for the prevention of autoimmunity. Examples (indicated in *red*) include the protein tyrosine phosphatase SH2 domain-containing phosphatase-1 (SHP-1) that opposes early phosphorylation events mediated by kinases after TCR activation, E3 ubiquitin ligases such as Casitas b-lineage lymphoma-b (Cbl-b) that ubiquitinate key signaling mediators, such as phosphatidylinositol 3-kinase (PI3K), resulting in proteasome-mediated degradation and diacylglycerol kinases (DGKs), which terminate TCR signaling by metabolizing signaling intermediates such as diacylglycerol (DAG). Cytotoxic T-lymphocyte antigen-4 (CTLA-4), a T-cell surface receptor upregulated after activation, also induces T-cell inhibition, both by sequestering CD80/CD86 away from the activating costimulatory molecule CD28 and by transducing its own inhibitory signals after CD80/CD86 binding. Other well-established inhibitory T-cell surface receptors are programmed death 1 (PD-1), which is expressed under prolonged antigenic stimulation or “exhaustion,” and the transforming growth factor β receptor (TGF- β -R), a receptor for one a cytokine key for regulatory T cell-mediated suppression. *IP₃*, Inositol 1,4,5-trisphosphate; *PA*, phosphatidic acid; *PIP₂*, phosphatidylinositol-(4,5)-bisphosphate; *PLCγ1*, phospholipase γ 1.

function of both innate and adaptive immune cells. There is accumulating evidence that other phosphatases are also critical for interfering with T-cell activation, both in animal models and more recently in studies of patients. Polymorphisms in the genes encoding several protein tyrosine phosphatases, including CD45 and *PTPN22*, align with susceptibility to human immune-mediated disorders. These intriguing findings are being pursued actively by researchers in a number of laboratories to uncover the molecular basis of how these phosphatases exert their control on immune cell function.

CTLA-4

A second strategy to limit T-cell activity is through the induced expression and activation of inhibitory cell surface receptors, such as cytotoxic T lymphocyte antigen-4 (CTLA-4). As discussed earlier, activation of T cells requires two independent signals, one through the TCR and a second through a costimulatory receptor such as CD28. Several days after initial T-cell activation, however, another member of the CD28 superfamily, CTLA-4, becomes upregulated on T cells. CTLA-4 differs from CD28 in that, instead of serving as an essential costimulatory receptor, engaged CTLA-4 actively interferes

with T-cell activation. Moreover, CTLA-4 binds CD80 and CD86 with much higher affinity than CD28, thus sequestering these key ligands away from CD28. The importance of CTLA-4 in controlling immune reactions was highlighted in the study of CTLA-4-deficient mice, which were found to die as a result of autoimmune disease at 3 to 4 weeks of age. Targeting CTLA-4 with blocking antibodies to augment T-cell responses is a new therapeutic strategy for human cancer treatment (see later). Conversely, providing soluble CTLA-4 to patients with autoimmunity has been shown to be effective at blocking T-cell activation, presumably by acting as a competitive antagonist and interfering with the ability of CD28 to bind to its ligands, resulting in an anergizing signal to T cells.

E3 Ubiquitin Ligases

TCR signaling is also limited through the targeted destruction of proteins required for TCR signal transduction. E3 ubiquitin ligases are a class of proteins that target intracellular proteins for degradation by the proteasome, the large multisubunit cytosolic complex essential for protein turnover. In T cells, several E3 ubiquitin ligases target components of TCR signal transduction for degradation after TCR activation. These include Casitas b-lineage lymphoma-b (Cbl-b), c-Cbl, and Itch, among many others. As with other negative modulators of TCR signaling, genetic deletion of E3 ubiquitin ligases, either alone or in combination, results in dysregulation of immune function or the development of frank autoimmune disease in mice. The targeted degradation of crucial signaling modulators after T-cell activation thus serves as an additional physiologic mechanism to limit T-cell responses.

Diacylglycerol Kinases

Intrinsic cellular components limit T-cell activity through degradation of second messengers of T-cell signal transduction, such as metabolism of diacylglycerol (DAG) by diacylglycerol kinases (DGKs). As described earlier, engagement of the TCR results in the activation and recruitment of PLC γ 1 that cleaves PIP₂ into the second messengers DAG and IP₃. DAG levels are regulated in T cells through the activity of DGKs that metabolize DAG to terminate its ability to transduce signals. Two DGK isoforms, DGK- α and DGK- ζ , are important for limiting TCR signaling, as deletion of either in mice results in enhanced proliferation and cytokine production after TCR stimulation. Moreover, deletion of DGK- α leads to impaired induction of T-cell anergy. Mice deficient in either isoform of DGK do not develop overt autoimmune disease, likely because of some biochemical redundancy between the isoforms, and, in the case of DGK- ζ , enhanced numbers of tTregs. However, enhanced functional responses to viral infection and tumors have been reported in DGK-deficient T cells, defining an important role for DGKs in limiting immune responses.

Limitation of T-Cell Activity From Cell-Extrinsic Components

Extrinsic factors also help limit the function and activation state of T cells. The predominant influences of T cells in this respect are inhibitory cytokines that bind cell surface receptors and influence transcriptional changes that favor decreased activation. Two cytokines that serve as a paradigm for understanding cytokine-mediated inhibition of T cells are IL-10 and TGF- β .

IL-10 is a major negative regulator of immune effector function. Its central role is underscored by the fact that pathogenic viruses, such as cytomegalovirus and Epstein-Barr virus, use homologs of IL-10 to subvert immunologic activity and create environments more favorable for viral spread and replication. IL-10 is produced by both innate and adaptive immune cells in response to activation. As with other cytokines, binding of IL-10 to the IL-10 receptor induces

signaling through JAKs, resulting in the nuclear translocation of STAT proteins and the implementation of a transcriptional program that results in decreased expression of inflammatory cytokines and in antagonism of crucial signaling molecules.

IL-10 exerts broad changes within the immune system. In monocytes, IL-10 decreases the production of inflammatory mediators and antigen presentation. In T cells, the effects of IL-10 are generally inhibitory, resulting in decreased capacity for proliferation and a decreased capacity to secrete cytokines. These effects vary by T-cell subtype, however, as IL-17 secretion by Th17 cells is not impaired in the presence of IL-10. As in other proteins important in the negative regulation of T cells, *IL10* germline deletion often results in fatal autoimmunity, in this case a gastrointestinal disease resulting from the inability to control inflammation caused by commensal bacteria.

TGF- β is a pleiotropic inhibitor that acts as a potent immunosuppressor. As noted, TGF- β is important both in its capacity to upregulate the transcription factor FoxP3, required for the generation of Tregs, and in inducing more global changes that favor immunosuppression. TGF- β binds its cell surface receptor complex and subsequently induces the phosphorylation, activation, and nuclear transport of intracellular Smad proteins. Effector Smad proteins exert their effects by directly coordinating transcriptional programs that inhibit immune responsiveness. Like IL-10, TGF- β acts on numerous cell types. It has been shown to inhibit the differentiation of effector Th cells; induce the conversion of naive T cells into Tregs; suppress the proliferation and production of IL-2 by T cells; and inhibit the activity of macrophages, DCs, and APCs. Mice lacking TGF- β 1 develop autoimmune-mediated multiorgan failure and die shortly after birth, underscoring the important role that this molecule plays in attenuating immune reactions.

Terminating Immune Responses After Pathogen Clearance

The simplest way in which T-cell responses end following clearance of a pathogenic challenge is by the removal of antigen, which limits the perpetuation of T-cell activation and abrogates the recruitment of new effector cells. Effector functions of those T cells that were stimulated to respond to the pathogen challenge also diminish as the inhibitory mechanisms described earlier exert their effects. However, homeostasis of the immune system also requires that the majority of those T cells that emerged from the clonal expansion of antigen-stimulated cells (at its peak representing several percent of the hosts' T-cell pool) be eliminated, retaining only a small population of memory T cells responsive to the inciting antigens. Elimination of the expanded population occurs through activation-induced cell death (AICD).

AICD is initiated when CD95 (also called Fas), a T-cell surface receptor present on the activated effector cells, is engaged by its ligand (CD95 ligand), expressed on multiple immune cells, including the activated cells themselves. CD95 is a member of the TNF family of receptors and, when stimulated, recruits the adapter molecule Fas-activating via death domain (FADD). FADD creates a multimolecular complex that triggers the activation of several intracellular caspases that induce DNA damage and apoptosis of the effector T cell. During T-cell activation, both CD95 and CD95 ligand are upregulated on the surface of the cell, and all of the machinery is present to initiate AICD. Hence the default pathway for activated T cells is apoptosis, an event that is blocked when T cells are appropriately stimulated to respond to antigen. Once antigen is cleared and the stimulatory events cease, AICD takes over, reducing the expanded population of cells (Fig. 21.11).

Experiments of nature have taught us much about the biology and importance of both CD95 and CD95 ligand. Loss of these proteins as well as components of their signaling machinery results in the human disease autoimmune lymphoproliferative syndrome (ALPS). ALPS is characterized by massive enlargement of lymphoid organs, autoimmune cytopenias, and an increased risk of hematologic malignancy.

Fig. 21.11 CD95-DEPENDENT ACTIVATION-INDUCED CELL DEATH. After T-cell activation and resultant expansion, T cells begin to upregulate the cell death receptor CD95. The ligand for CD95, CD95L, is expressed on many cell types, including antigen-presenting cells (APCs), B cells, and the activated T cells themselves. Binding of CD95 to CD95L triggers recruitment of the adapter protein Fas-activating via death domain (FADD), resulting in activation of caspases and the induction of cell death through apoptosis. The process of CD95 upregulation and apoptosis leads to contraction of activated T-cell populations.

THERAPEUTIC MANIPULATION OF T CELL-MEDIATED IMMUNITY

A comprehensive description of the myriad ways in which the manipulation of T cells has led to important clinical advances is beyond the scope of this chapter. Thus only a subset of the ways in which an enhanced understanding of the molecular basis for T cell-mediated immunity has resulted in changes in clinical practice is described here. Many human diseases are related to T-cell dysfunction, both in cases of overexuberant immune responses, as in autoimmune diseases and rejection of transplanted organs, and in insufficient immune responses, as in the case of some chronic infections and in uncontrolled malignancy. Here, we briefly address T-cell responses in graft rejection and in malignancy as paradigms for how T-cell immunity can be modulated therapeutically.

Modulating T Cells to Permit Allograft Transplantation

The success of solid organ transplant depends greatly on the ability to control the immune response of the recipient against the donor organ. Donor tissues express foreign MHC alleles and other proteins to which endogenous T cells have not been exposed (and therefore tolerized against) during thymic development, and thus these tissues serve as potential targets for T cell-mediated immunity. Initially, the only medications capable of permitting graft survival were high-dose steroids, medications with potent effects in essentially all organ systems and with severe side effects not limited to the immune system. Subsequently, however, several classes of medications were identified that act more specifically on T cells, first cyclosporine and subsequently tacrolimus and sirolimus. These agents target the IL-2 axis: cyclosporine and tacrolimus inhibit IL-2 transcription, and sirolimus inhibits mammalian target of rapamycin (mTOR), which is critical for facilitating IL-2 signal transduction. Because T cells, depending on the treatment modality, are unable to either produce IL-2 or respond to IL-2, they fail to proliferate, despite conditions favorable for stimulation, leading to impaired T cell-mediated immunity and improved survival of transplanted organs.

Cyclosporine and rapamycin were originally identified in screens of compounds that interfered with immune cell function, and their mechanism of action was discerned only after much of the basic biology of T-cell activation was understood. Other agents currently in use in the clinic were designed precisely because of insights that emerged from studies probing the molecular basis of immune cell function. For example, antibodies directed against CD3 are potent T-cell inhibitors and are now used in the setting of acute solid organ transplant rejection. Similarly, blocking the IL-2 receptor with monoclonal antibodies prevents IL-2 receptor signaling and thus abrogates division of stimulated T cells, thereby quelling T cell-mediated immune destruction.

Given the importance of costimulation for T-cell activation and the success in interfering with CD28 signaling in various autoimmune disorders, recent studies have demonstrated efficacy in transplantation with blockade of the CD28/CD80-CD86 interaction using soluble CTLA-4 as a competitive inhibitor of the interaction between CD28 and CD80/CD86. A soluble CTLA-4 fusion protein has recently been approved in the setting of transplant rejection. Additional studies are in progress to examine ways in which modulation of other costimulatory receptors, alone or in combination with soluble CTLA-4, may be used to preserve allografts. As our understanding of how different T-cell subsets are induced is becoming more precise, new therapeutics are on the horizon that are being designed to redirect immune responses by changing the balance of the various effector subsets that emerge as the recipient responses to the transplanted organ. Additional agents directed against receptors and signaling molecules discovered to be key for T-cell activation are currently being tested for clinical efficacy and safety and likely will soon be available to block T-cell responses in the setting of solid organ transplant.

Manipulating T Cells to Improve Activity Against Malignancy

In contrast to the need to impede immune responses in organ transplant, in the setting of malignancy, the desire is to intervene to enhance T-cell activity. T cells face several hurdles in their response to spontaneous malignancy. First, they must recognize peptides and proteins that are unique to tumor tissue. These include oncogenic mutant proteins, fusion proteins that may have formed during the course of tumor development or aberrantly expressed embryonic proteins that result from altered transcription often found in malignant tissue. Second, T cells must overcome the lack of costimulation provided by tumor cells. Because tumor cells originate from normal host tissue, they fail to generate the bacterial or viral products crucial for activating APCs. Third, T cells must overcome the generally immunosuppressive microenvironment within tumor tissue, which may include an abundance of TGF- β , Tregs, immunosuppressive macrophages, and/or the induction of an anergy-like state.

The first broadly successful approach to enhance T cell-mediated responses to tumors also makes use of the biology of CTLA-4. In this case, however, instead of using soluble CTLA-4 as an agent to inhibit T-cell responses by interfering with costimulation, antibodies against CTLA-4 are being used as a means to block the ability of CTLA-4 expressed on activated T cells to inhibit T-cell function. Preliminary studies have shown that CTLA-4 blocking antibodies may prolong T-cell activation in response to malignancy, and their use has resulted in long-term disease remission in approximately 15% of patients with metastatic melanoma, an otherwise uniformly fatal disease. Some antibodies against CTLA-4 may also function by depleting Tregs from immune organs and the tumor microenvironment. Whether CTLA-4 antibodies mediate their effect by inducing the expansion of newly activated tumor-specific cells or by reversing the immunosuppressive microenvironment on existing cells continues to be studied; however, one major concern of using antibodies against CTLA-4 has been the generation of severe autoimmune colitis in a significant fraction of patients.

The initial success achieved by blocking CTLA-4 on the surface of T cells led to the search for other molecules that might similarly be targeted with blocking antibodies. One obvious candidate molecule is PD-1, the inhibitory receptor present on activated and exhausted T cells. Because many, if not all, patients with cancer have circulating T cells capable of binding tumor antigen, albeit with limited responsiveness, it was speculated that relieving exhaustion of tumor-specific T cells with antibodies that block PD-1 would permit improved T-cell responses against malignancy. In fact, therapies targeting PD-1 and its ligand have demonstrated profound activity in patients with malignancy, with overall survival rates as high as 35% in patients with advanced melanoma, and activity in cancers previously thought to be poor targets for immune-based therapy, such as Hodgkin lymphoma, lung and bladder cancers. Surprisingly, in studies described to date, autoimmune disease occurs much less frequently in patients treated with antibodies targeting PD-1 versus those targeting CTLA-4. The biologic basis of this finding is unclear, but it suggests that PD-1 and other “immune checkpoint” receptors, such as Lag-3 and Tim-3, represent superior targets to boost T cell-mediated activity against tumors. In ongoing research, investigators are evaluating how best to integrate PD-1 blocking strategies into existing cancer treatment regimens.

In addition to targeting inhibitory receptors on T cells to augment antitumor responses, studies are underway to engineer T cells to more effectively activate effector T-cell responses against malignancies. Knowledge gained through fundamental studies of proximal signaling events important for T-cell activation has led investigators to engineer chimeric antigen receptors (CARs), which permit direct activation of T cells by tumor cells. These “designer” molecules have a modular structure: an extracellular binding domain for antigens on tumor cells, transmembrane domains from CD8 α or other cell surface proteins, cytoplasmic signaling components of the ζ chain of the TCR complex, and a costimulatory domain(s).

Fig. 21.12 DESIGN OF A CHIMERIC ANTIGEN RECEPTOR T CELL. The modular design of successful chimeric antigen receptors (CARs) uses the knowledge gained through the study of fundamental properties of antigen recognition and signaling pathways in immune cells. The extracellular antigen recognition domain is typically derived from a single-chain variable fragment of an antibody specific for an antigen expressed by the tumor cells. This domain is coupled to a transmembrane domain, which has been derived from either CD8 or CD28 molecules. The CAR transmits an activation signal through the costimulatory domains and the CD3 ζ chain to intracellular T cell signaling pathways. The costimulatory domain contains one (or more) signaling domains derived from costimulatory molecules, including CD28, CD27, 4-1BB, and ICOS (inducible costimulator). This costimulatory domain significantly augments signaling from the CD3 ζ chain and has been shown to improve CAR T-cell function, proliferation, and persistence.

containing other key activating receptors (Fig. 21.12). T cells are removed from patients, genetically engineered to express CARs, and reintroduced into patients with the anticipation that these T cells will engage the tumor through the CAR, resulting in T-cell activation. These activated T cells, when effective, generate robust antitumor responses, bolstering antitumor immunity sufficiently to eliminate the cancer.

Generation of optimal CAR constructs is currently the subject of intensive investigation. Two important considerations in the generation of CARs are the identification of tumor antigens for CAR binding and the selection of signaling domains to combine with the TCR ζ chain to facilitate T-cell activation. One of the most well-studied tumor antigens selected for CAR-T-cell therapy is CD19, a cell surface costimulatory receptor found exclusively on B cells. In patients with refractory B cell leukemias and lymphomas, treatment with CD19-directed CAR-T cells have demonstrated striking success, with a significant proportion of patients achieving complete and durable remission. As predicted from selection of CD19 as the cellular target, these patients also develop B-cell aplasia and hypogammaglobulinemia resulting from the elimination of healthy B cells by CAR-T cells; however, this long-term side effect can be effectively managed by antibody infusions or coupling CAR-T-cell therapy with subsequent bone marrow transplantation. Identification of appropriate target antigens for CAR-T cells is a key challenge because many tumor antigens may also be expressed on normal tissues and “on-target, off-tumor” effects of CAR-T cells could potentially lead to unacceptable toxicity. These concerns will require careful evaluation of each CAR targeting domain for both efficacy against the tumor and potential deleterious effects on normal tissues.

Apart from identifying the best targets for CARs, much effort has also been placed on optimal construction of the CAR signaling domains. First-generation CARs, which contain only the ζ chain of the TCR complex, led to suboptimal antitumor responses. The

incorporation of an additional intracellular signaling domain derived from costimulatory molecules, such as CD28 or 4-1BB, into second-generation CARs augmented CAR-T-cell activation and antitumor efficacy, and third-generation CARs include signaling domains from two costimulatory receptors. Currently, most CARs adhere to the second-generation model. Which intracellular costimulatory domains will work best in CARs and how many costimulatory domains are required for optimal T-cell activation and antitumor efficacy are under active investigation. Other outstanding questions in the biochemistry of CARs concern the optimal number of functional ITAMs present in ζ chain domains and the length and composition of the transmembrane hinge domain and interdomain junctions. Defining the biochemistry and signal transduction of CARs should permit broadening its use to more common malignancies.

The examples presented here are only a small subset of novel approaches in use or being tested to modulate immune cell function based upon our understanding of the molecular basis of T-cell activation. It is anticipated that as more is learned about the molecules and pathways critical for control of T cell–mediated immunity, additional new agents with greater efficacy and improved safety profiles will become available for clinical use. The advent of these new therapeutics and their potential to improve treatments for serious human diseases underscore the importance of continued efforts to understand the mechanisms of T-cell development and function.

NATURAL KILLER CELL IMMUNITY

Don M. Benson, Jr. and Michael A. Caligiuri

Natural killer (NK) cells are large, granular lymphocytes comprising about 10% to 15% of the peripheral circulation.^{1,2} First characterized by their ability to lyse targets independent of activating or initiating stimuli,³ NK cells are a critical cellular component of the innate immune system. In addition, NK cells secrete cytokines that help to marshal and shape the innate and adaptive immune response to infection and malignant transformation. There has been a recent surge of interest in NK cells as new discoveries in both the laboratory and the clinic have characterized the crucial contributions of NK cells in shaping the early immune response.⁴ NK cells play a key role in maintaining host defense, as exemplified in human NK cell deficiency syndromes (which carry increased susceptibility to overwhelming viral, intracellular, and atypical mycobacterial infections)⁵ and in animal models of NK cell deficiency (e.g., such mice are particularly susceptible to developing cancer).^{6,7} This chapter reviews current understanding of NK cell biology, the role of NK cells in human diseases, and the recent clinical applications of NK cells in cancer therapy.

FUNDAMENTAL BIOLOGY

Natural Killer Cell Subsets

NK cells are phenotypically recognized by surface expression of CD56 (also called *neural cell adhesion molecule*) and the absence of the T cell-specific surface antigen CD3 as well as the T-cell receptor.^{8,9} Based on the intensity of CD56 surface expression, two functional subsets (so-called CD56^{bright} and CD56^{dim}) of NK cells may be discriminated from one another. CD56^{dim} NK cells comprise 85% to 90% of the NK cells in peripheral circulation and are potent mediators of cytotoxicity. About 10% to 15% of NK cells in the circulation are CD56^{bright}, and upon activation, this subset is capable of robust cytokine and chemokine production.² Fig. 22.1 graphically represents the NK subsets described later, and Table 22.1 summarizes major surface antigens associated with each NK cell subset.

CD56^{dim} Natural Killer Cells

CD56^{dim} NK cells have exquisite cytolytic properties and are able to kill infected as well as tumor cell targets without prior sensitization.¹⁰ They constitutively express the interleukin-2/15 (IL-2/IL-15) receptor (R) β - and common γ -receptor chains, which together form a receptor complex through which cells may respond to stimulation by either IL-2 or IL-15.^{11,12} CD56^{dim} NK cells can lyse tumor cell targets through at least three distinct mechanisms. First, they can execute cytotoxicity through granule exocytosis of perforin and granzyme.^{13,14} Second, cytotoxicity can be mediated through Fas ligand and tumor necrosis factor (TNF)-related apoptosis-inducing ligand associated with production of cytokines, including interferon- γ (IFN- γ), TNF- α , and granulocyte macrophage colony-stimulating factor.¹⁵ Third, CD56^{dim} NK cells can mediate antibody-dependent cytotoxicity (ADCC) via the high-density surface expression of CD16 (the Fc γ RIII receptor).^{2,16} Freshly isolated, unstimulated CD56^{dim} NK cells have intrinsically greater cytotoxicity against NK-sensitive targets such as the K562 cell line in vitro compared with the CD56^{bright} NK cells.¹⁷

Other antigens are differentially expressed by CD56^{dim} NK cells and provide insight into their functional role in the immune response. For example, CD56^{dim} NK cells also exhibit relatively high surface density expression of killer immunoglobulin-like receptors (KIRs). NK cell KIR expression appears important in preventing autoimmunity and in surveying against malignant transformation.^{16,18}

Both CD56^{dim} and CD56^{bright} NK cells express modest levels of chemokine (C-X-C motif) receptor 3 (CXCR3). However, in contrast to CD56^{bright} NK cells, CD56^{dim} NK cells display relatively abundant surface expression levels of CXCR1, CXCR4, and CX3CR1.¹⁹ CXCR1 binds IL-8, and CXCR4 binds stromal cell-derived factor 1 (SDF-1). These cytokines are associated with local inflammatory response; for example, IL-8 levels are increased in the setting of acute viral infections,²⁰ and IL-8 and SDF-1 levels are increased with solid^{21,22} and hematopoietic malignancies.^{23,24} Thus expression of these chemokine receptors allows NK cells to traffic to local areas of inflammatory response to mediate antiviral and antitumor activity.

CD56^{bright} Natural Killer Cells

CD56^{bright} NK cells play more of an immunoregulatory role. CD56^{bright} NK produce a multitude of cytokines and chemokines, have a relatively high proliferative capacity, reside primarily in the parafollicular T cell-rich region of secondary lymphoid tissue (SLT), and have modest cytolytic granules, KIR, and Fc γ RIII expression (see Table 22.1).¹⁰ CD56^{bright} NK cells are unique among cytotoxic effector cells in their constitutive expression of the high-affinity IL-2R $\alpha\beta\gamma$ complex, making them responsive to picomolar concentrations of IL-2 released by activated T cells in the parafollicular T cell-rich region of SLT.²⁵ As noted, CD56^{bright} NK cells comprise only about 10% of the circulating NK population but predominate almost to the exclusion of the CD56^{dim} NK subset in SLT.^{2,26} This likely results from their selective expression of a number of receptors that assist in homing cells to and retaining cells in SLT (e.g., CCR7 and CD62L).¹⁰

The ability of CD56^{bright} NK cells to produce an abundant variety of cytokines and chemokines compared with the CD56^{dim} subset likely relates more to the differential expression of both negative and positive regulators of cytokine/chemokine production and less to constitutive expression of cytokine-activating receptors. For example, CD56^{bright} NK cells have little or no expression of two negative regulators of cytokine/chemokine production, namely SHIP-1 (Src homology 2 domain-containing inositol 5-phosphatase 1) and HLX (H2.0-like homeobox 1),^{27,28} but CD56^{dim} NK cells lack constitutive expression of a positive regulator of cytokines called SET.²⁹

NATURAL KILLER CELL DEVELOPMENT

NK cells are prototypic, founding members of a population of cells referred to as *innate lymphoid cells* (ILC).³⁰ Three populations of ILC have been described based on differential expression of specific transcription factors and cytokine production, and NK cells are believed to arise from group 1 ILCs, which are characterized by T-bet and EOMES expression.³¹ Acquisition of the IL-15 receptor (CD122) is likely a first step toward NK cell differentiation from CD34⁺ hematopoietic stem cells and a subsequent common lymphoid precursor cell. Moreover, IL-15 is required for NK cell

development in mice and humans,^{32,33} and the NK cell maturation process appears to occur outside the bone marrow.^{2,34} Freud et al identified a CD34^{dim}CD45RA⁺αβ₇^{bright} cell to be the only CD34⁺ subset in SLT.²⁶ Found within the parafollicular T cell-rich region of SLT in the same region as the CD56^{bright} NK cell, this CD34^{dim}CD45RA⁺αβ₇^{bright} cell can differentiate into a CD56^{bright} NK cell in the presence of IL-15.²² Five novel, discrete stages of NK cell development were characterized in situ within the same parafollicular region of SLT, each by their differential expression of CD34, CD117, and CD94.^{30,35,36} As development proceeds along this continuum, cells acquire the ability to secrete cytokines (e.g., IFN-γ), display natural cytotoxicity, and lose the ability to differentiate into dendritic cells, T cells, or both. This orderly development in SLT from a CD34⁺ subset to CD56^{bright} NK cells suggests that CD56^{dim} NK cells represent a terminally differentiated NK stage that follows CD56^{bright} NK development and exit into the periphery. The acquisition of phenotypic markers occurs in a progressive, orderly manner: (1) CD161; (2) CD56, CD94, NKp46, and NKG2D;

Fig. 22.2 SIMPLIFIED REPRESENTATION OF NATURAL KILLER CELL CYTOTOXICITY MEDIATED THROUGH THE BALANCE OF ACTIVATING AND INHIBITORY SIGNALING IN RESPONSE TO LIGANDS ON POTENTIAL TARGETS. and (3) CD16 and KIR. CD94 expression may mark a functional intermediary step between CD56^{bright} and CD56^{dim} human NK cells.³⁷ The abundance of CD56^{dim} NK cells in blood versus SLT and their loss of both CD117 (c-kit) expression and proliferative capacity, along with their acquisition of KIR, FcγRIII, and cytolytic granules, are all consistent with this notion.² CD57 has been identified as a surface marker of terminally differentiated NK cells.³⁸

NATURAL KILLER CELL RECEPTORS

NK cells, as opposed to B and T lymphocytes, do not undergo clonotypic gene rearrangement in order to express antigen receptors; however, through the expression of a complex repertoire of surface molecules, NK cells may efficiently determine nonself from self and rapidly initiate an appropriate response.³⁹ NK cell receptors may be activating or inhibitory—in other words, binding of the receptor to its ligand expressed on a target cell either activates or suppresses a functional NK response. Such receptors fall into three general categories: those that are members of the immunoglobulin-like superfamily (KIR), one type that belongs to the C-type lectin receptor (CTLR) superfamily,⁴⁰ and finally NK cell-specific receptors. The complex function of these receptor subsets is a matter of ongoing research; however, a model by which NK cell receptors KIR may recognize particular features of major histocompatibility complex (MHC) class I alleles (e.g., human leukocyte antigen A [HLA-A],⁴¹ HLA-B,⁴² HLA-C⁴³) or recognize other surface antigens on target cells has been developed.^{44,45} Fig. 22.2 is a simplified, schematic representation of current understanding of the ability of NK cells and their receptors to survey the immune system.

Killer Immunoglobulin-Like Receptors

KIRs provide one method by which NK cells recognize self from nonself to mediate the appropriate cytotoxic response. There are at least 15 KIRs identified on chromosome 19q13.4.^{18,44,45} Structurally, KIRs contain two or three extracellular immunoglobulin-like domains and recognize MHC class I proteins.^{18,41,42} KIRs may be

either inhibitory or activating, a functional feature associated with the intracellular tyrosine-based motif of the molecule.¹⁸ All of this information may be deduced for a particular receptor through the nomenclature used to identify KIRs. The number of immunoglobulin-like domains (two or three) is expressed (e.g., KIR2D or KIR3D), and the length of the intracytoplasmic tail (i.e., a long [L] inhibitory tail or a short [S] activating tail) is also incorporated (e.g., KIR2DL or KIR2DS). A suffix numeral follows the identification of some KIR to represent polymorphic forms of each receptor (e.g., KIR2DS2 and KIR2DS3, each indicating a polymorphic form of an activating KIR that bears the same extracellular domains). HLA-C is particularly important in KIR-mediated self/nonself recognition because many well-described KIR have ligand specificity for HLA-C associated antigens. For example, the inhibitory receptor KIR2DL1 (CD158a) recognizes group 2 HLA-C Asn77Lys80 (HLA-Cw2, w4, w5, w6, and related alleles), and the inhibitory receptors KIR2DL2 and KIR2DL3 recognize group 1 HLA-C Ser77Asn80 (HLA-Cw1, w3, w7, w8, and related alleles).⁴⁵ Activating receptors KIR2DS1 and KIR2DS2 recognize the same group 2 and group 1 antigens as the inhibitory counterparts; however, generally, inhibitory receptors bind with greater avidity or attraction for a corresponding HLA antigen than activating receptors.⁴⁶ Complementary activating and inhibitory KIRs recognize the same cognate extracellular domains on target cells; thus, if an NK cell expresses both activating and inhibitory KIR for an identical ligand, the cell will generally be inhibited from killing.

The KIR family is likely not all-inclusive for human classical type I HLA allotypes; for instance, only one inhibitory KIR directed against HLA-A (KIR3KL2) and none toward HLA-B alleles have been found.⁴⁵ Additionally, specific KIRs may have particular roles in maintaining host immunity in unique settings. For example, KIR2DL4 recognizes the nonclassical HLA-G molecule that is expressed only on fetal extravillous trophoblasts that invade the maternal decidua during pregnancy.⁴⁷ Controversy surrounds the exact nature of this KIR; however, KIR2DL4 is likely not clonally distributed as are other KIRs but is present on the surfaces of most mature NK cells.⁴⁸ Interestingly, despite having an inhibitory intracellular signaling moiety, KIR2DL4 serves to promote IFN- γ secretion but not cytolytic activity.⁴⁸ It is possible that this KIR functions to facilitate immune tolerance to developing fetuses.⁴⁹

C-Type Lectin Receptors

CTLRs, located on human chromosome 12p.12.3, share a common subunit (CD94) covalently bonded to one of four closely related gene products of the NKG2 family.^{50,51} CTLRs represent a second type of NK cell receptor–mediating killing and include NKG2A (and splice variant B), NKG2C, NKG2E (and splice variant H), and NKG2F.⁵¹ NKG2D, which does not bind CD94 and shares little sequence homology to other NKG2 proteins, is discussed later. All but one of the CTLRs are activating and expressed on NK cells and cytotoxic T lymphocytes. CD94/NKG2A is inhibitory and is expressed on NK cells, as well as on cytotoxic T lymphocytes, where they serve to regulate CD8⁺ T-cell antiviral responses.⁵² CD94/NKG2A specifically recognizes the nonclassical HLA-E class I molecule.⁵³ Interestingly, HLA-E specifically presents leader peptides from other HLA receptor antigens; thus sensitivity to HLA-E provides a mechanism for NK cells to sense functional overexpression of class I MHC molecules on cell surfaces. As with KIR, binding between CD94/NKG2A and HLA-E is more avid than binding of activating CTLRs to other epitopes; however, unlike KIR, the target antigens for activating and inhibitory CTLR are not the same.⁵⁴

NKG2D is a CTLR; however, it has only modest sequence homology with other members of the NKG2 family and does not associate with CD94.⁵³ NKG2D exists as a homodimer and does not have inherent signaling capability, but rather signals via the PI3K pathway as recruited through DAP10Wu or KAP10.⁵⁵ This unique signal transduction arrangement renders NKG2D signaling privileged from inhibitory, intracellular intermediaries that modulate

signal transduction of other CTLR systems. NKG2D is constitutively expressed on all NK cells, $\gamma\delta$ T cells, and CD8⁺ T cells.⁵⁶

NKG2D mediates killing of cellular targets expressing two antigens associated with viral or neoplastic transformation.^{45,57} First, MHC class I chain–related antigens (MICs) are a family of proteins whose expression correlates with heat shock and viral and neoplastic transformation.^{56,58} MICA and MICB expression is under the control of promoter elements similar to those of heat shock proteins and has been shown to be upregulated in the setting of cytomegalovirus (CMV) infection as well as in a number of epithelial and hematologic malignancies.^{58,59} Second, UL16 binding protein (ULBP) serves as a ligand for NKG2D. UL16 is a type I transmembrane protein ubiquitously expressed in the setting of CMV infection.⁶⁰ UL16 binds MICB and two other proteins, ULBP-1 and ULBP-2.⁶¹ (These latter proteins have α_1 and α_2 domains but lack an α_3 domain as MIC and MHC class I molecules have; furthermore, they are expressed via a glycosylphosphatidyl inositol anchor and thus have no requirement for β_2 microglobulin.) In binding MICB, ULBP-1, and ULBP-2, CMV-produced UL16 counteracts cell surface expression of these NKG2D ligands, thus providing a mechanism of immune evasion from NK cell surveillance and cytotoxicity.⁶² In a similar fashion, some human tumors downregulate expression of NKG2D ligands or release soluble forms of such (e.g., MICA or ULBPs) as a mechanism of immune escape from NK cells.^{63–65} Although ULBPs are expressed more ubiquitously than MIC proteins, some tissues with high mRNA levels express no protein, implying important posttranscriptional control of these antigens.⁶¹ IL-15 stimulation enhances the NK cell NKG2D-mediated response to tumors expressing ULBP.⁶⁶

Other Activating Natural Killer Receptors

A third family of NK receptors that mediate cell killing are called *natural cytotoxicity receptors* (NCRs).^{59,67} In addition to NKG2D, NCRs comprise an important family of activating NK cell receptors involved in the process of target recognition and elimination. NCRs include three receptors called *NKp46* and *NKp30*, which are exclusively and constitutively expressed on NK cells, and *NKp44*, which is expressed after IL-2 stimulation on NK and some $\gamma\delta$ T cells.^{59,67,68} Infectious, pathogen-specific ligands for NCR have been identified that recognize and engage various virus-specific hemagglutinin and hemagglutinin-neuraminidase.⁶⁹ B7-H6 has been identified as a ligand for NKp30 and a number of other endogenous ligands, and bacterial and parasite-derived proteins have been described in some settings as NCR ligands as well.^{70–73}

ADAPTIVE IMMUNE PROPERTIES OF NATURAL KILLER CELLS

Recent findings regarding NK cell biology are blurring the functional borders between the innate and adaptive arms of the immune system. Although NK cells have traditionally been dichotomized in the innate immune system, emerging data suggest that NK cells demonstrate sophisticated adaptive properties and do not interact in an invariant manner in the microenvironment.⁷⁴

Natural Killer Cell Education

The potential for NK cell autoreactivity exists because some NK cells may lack inhibitory receptors, but others may express activating receptors for self ligands. This can occur because the receptor array that individual NK cells express occurs largely at random and because ligands to these receptors are inherited independently.⁷⁵ Potentially autoreactive NK cells are not clonally deleted but rather rendered hyporesponsive. For example, NK cells lacking inhibitory receptors for self MHC are unresponsive to self cells.⁷⁶ In a complementary manner, humans who lack MHC class I expression do not experience NK cell–mediated autoimmunity. By comparison, through an

MHC-dependent processing termed *licensing*, NK cells that express receptors for self MHC exhibit greater responsiveness to stimulation; however, their effector function against normal cells is blocked by engagement of inhibitory receptors for self MHC.⁷⁷ Whether responsiveness is determined by interaction with cells expressing ligands for NK cell receptors (so-called arming) or hyporesponsiveness is induced via encounters with normal cells lacking MHC ligands (“disarming” or “anergy”) is unclear; however, experimental data suggest that persistent stimulation results in hyporesponsiveness but persistent stimulation with concomitant inhibition leads to NK cell responsiveness.^{78,79} Studies such as these and others suggest that NK cells may be sensitive to changes in the microenvironment and may modulate responsiveness to stimuli.

Natural Killer Cell Memory

Immunologic memory has long been reserved as a process of the adaptive immune system; however, recent data suggest that NK cells possess a form of memory as well. This idea was first demonstrated in a recombina-activating gene 1 (RAG-1)-deficient mouse lacking T and B cells. Hapten-induced hypersensitivity was mediated by NK cells in this model, and “memory” NK cells were described as residing in the liver and bearing Thy1 and CXCR6 on their surfaces.⁸⁰

This concept has also been demonstrated in the setting of viral infection in mice with vesicular stomatitis virus, HIV-1, influenza, and murine CMV (MCMV).^{80,81} In regard to MCMV, for instance, Ly49H⁺ NK cells recognize MCMV m157 glycoprotein, resulting in NK cell-mediated control of the disease. These Ly49H⁺ NK cells preferentially expand in the setting of infection and contract after infection is controlled. However, “memory” NK cells could be detected months after infection, and, upon restimulation, these NK cells exhibited augmented cytotoxicity and cytokine production against MCMV.⁸¹ Although a unique marker of memory is unclear, these NK cells stably express KLRG1, a cadherin-recognizing inhibitory receptor, and could be detected 2 months after infection control even in adoptive transfer models.⁸¹

A third demonstration of functional NK cell memory has been reported whereby human NK cells preactivated after brief exposure to IL-12, IL-15, and IL-18. These cells showed an enhanced response to restimulation up to 3 weeks later that also was retained in dividing NK cells.⁸² This subset was associated with CD94, NKG2A, NKG2C, and CD69 expression and lacked KIR and CD57.

THE ROLE OF NATURAL KILLER CELLS IN HUMAN DISEASE

NK cell deficiencies are rare; however, such conditions provide insight into the role NK cells play in response to infectious pathogens, autoimmune disorders, and the development of malignancy. Selective NK cell deficiency has not been associated with a particular Mendelian disorder⁸³; however, studies have shed new light on the genetic mechanisms responsible for proper NK development and function. Many syndromes have been linked to increased susceptibility to infection, and others may predispose to autoimmune disease.

Natural Killer Deficiency Syndromes Linked to Increased Infectious Risks

The first gene directly implicated in NK deficiency was *FCGR3A*, which codes for FcγRIIIa (CD16) expressed on NK cells. A “T → A” substitution at position 230 leads to coding of a lysine residue at position 48, normally a histidine. Although the protein expressed appears phenotypically normal, patients present with increased susceptibility to severe and disseminated herpes simplex virus (HSV) infections.⁸⁴ Other patients present with progressive Epstein-Barr virus and varicella infections.⁸⁵ Patients have variable deficits in NK cytotoxicity

and responsiveness to cytokine stimulation. Population studies have subsequently suggested that the H48 allele may be necessary but not sufficient to produce clinical disease.⁸⁶

Clinical examples of patients entirely lacking any CD56⁺ lymphocyte subsets have been reported. The first report was of a young patient who presented with life-threatening varicella infection. She subsequently developed CMV pneumonia and cutaneous HSV infection. Analysis of her lymphocyte subsets demonstrated a striking and selective absolute absence of CD56⁺ or CD16⁺ cells.⁵ The patient went on to develop aplastic anemia and died as a result of complications of stem cell transplant.⁸⁶ A second patient who presented with disseminated *Mycobacterium avium* went on to die as a result of disseminated varicella.⁸⁷ Other patients have been described with an isolated deficiency of CD56⁺/CD3⁺ lymphocytes but with normal or even increased populations of CD56⁺/CD3⁺ cells. One such patient presented with severe, recurrent human papilloma virus–related condylomatous disease.⁸⁸ Although the genetic mechanisms of these diseases remain unknown, they highlight the functional role of NK cells in providing immunity toward infectious pathogens.

NK cell deficiencies have been described as a component of other disease processes affecting multiple hematopoietic and immune lineages. The genetic deficiencies responsible for many of these disorders have been described and can be found in Table 22.2.

The Role of Natural Killer Cells in Autoimmunity

Interestingly, NK cells have been implicated in both the regulation and the pathogenesis of autoimmune disorders. For example, in a murine experimental autoimmune encephalomyelitis model of multiple sclerosis in which disease is induced with myelin oligodendrocyte glycoprotein (MOG), NK depletion leads to enhanced T-cell response to MOG. Similarly, in human multiple sclerosis, NK cells have been implicated in the maintenance of disease remission.⁸⁹ NK cells have also been shown to control inflammation in an experimental model of autoimmune colitis.⁹⁰ NK cells may exert this effect through recognition and elimination of T cells activated against autoantigens.⁹¹

There are also examples of NK cells promoting autoimmune disorders. For instance, experimental evidence supports the idea that NK cells may promote development of type 1 diabetes mellitus through targeted elimination of pancreatic islet β cells after viral infection.⁹² This pathobiology may be mediated via an as yet unidentified Nkp46 ligand located in the insulin granules.^{73,93} Other studies suggest that NK cells can promote humorally mediated autoimmune diseases such as myasthenia gravis through potentiation of autoreactive B cells.⁹⁴ Synovocytes of patients with rheumatoid arthritis (RA) have been shown to express abnormally high levels of MICA, the previously described ligand for NKG2D.^{95,96} In fact, NK cells present in acute RA joint effusions may perpetuate this autoimmune inflammatory response.⁹⁷

Finally, NK cell receptor polymorphisms have been implicated in the pathogenesis and progression of autoimmune disease. For example, a T → G substitution at position 559 in the FcγRIIIa (CD16) gene leads to a phenylalanine-to-valine substitution at residue 176 of the FcγRIIIa protein.⁹⁸ Although the receptors are expressed similarly on the cell membrane, the V/V homozygous state is associated with a higher affinity for immunoglobulin G (IgG) binding than the F/F state. The low binding state (F/F) is associated with lupus nephritis.⁹⁹ Others have confirmed this observation by genetic linkage studies in patients with systemic lupus erythematosus.¹⁰⁰ Another polymorphism in the FcγRIIIa receptor (158V/F) has been associated with RA in certain ethnic groups.¹⁰¹ This mutation may also be associated with the development of subcutaneous rheumatoid nodules in patients with established RA.¹⁰¹ Because CD16 is expressed on a number of immune cells, the specific role of NK cells contributing to pathology is unclear; however, as discussed later, these polymorphisms have also been linked to an enhanced response to monoclonal antibody therapy for cancer.

TABLE
22.2

Human Disorders Characterized in Part by Natural Killer Cell Deficiency

Disease	Gene	Protein	Cell Count	Cytotoxicity	ADCC	Cytokine Response
X-linked SCID	1.1.1.1.1.1.1.1 <i>IL2Rg</i>	Common γ -chain	Low/absent	Low/absent	N/A	Reduced

THE THERAPEUTIC POTENTIAL OF NATURAL KILLER CELLS

On one hand, T lymphocytes depend on recognition of tumor-specific antigens to effect an antitumor immune response, an approach limited by the inability to identify such targets for the vast majority of nonviral neoplasms. NK cells, on the other hand, have long been recognized as being capable of antitumor rejection independent of such tumor antigens. As the understanding of how NK cells identify and eliminate targets has advanced, novel roles for the application of NK in clinical anticancer therapy have been defined. Three general approaches have been developed.

First, with therapeutic intent, direct infusion of NK cells into patients has been performed.¹⁰² This strategy was developed on the basis of observations such as that in the allogeneic peripheral blood stem cell transplant setting, where higher doses of transplanted NK cells have been associated with better outcomes as evidenced by reductions in posttransplant infections as well as reduction in nonrelapse mortality.¹⁰³ Several studies have shown this approach to be safe and associated with at least a modicum of effectiveness in the autologous setting.^{104,105} Trials of direct NK cell infusion have been reported in the allogeneic setting, one correlating successful transfer and expansion of haploidentical NK cells with hematologic remission of leukemia.¹⁰⁶ This field has grown in terms of NK cell sources for expansion and infusion¹⁰⁷ as well as in pairing NK cell therapy with combinatorial strategies to enhance efficacy.¹⁰⁸

Second, NK cells have been successfully expanded in vivo in patients with cancer through the exogenous administration of recombinant human cytokines, such as low-, intermediate-, or high-dose IL-2.^{109–113} The first-in-human trial of IL-15 was associated with a greater than 10-fold expansion of NK cells; however, in contradistinction to studies with IL-2, virtually no change in the regulatory T-cell population was observed in parallel with IL-15.¹¹⁴ A novel superagonist form of IL-15 is also in clinical development.¹¹⁵ The tumor nonspecificity of these strategies is being explored by

concomitantly administering a tumor-specific monoclonal antibody whose Fc portion can bind to CD16 expressed on the cytokine-expanded NK cells, thus initiating a process called *antibody-dependent cellular cytotoxicity*.^{112,116,117}

A third methodology under development to enhance the antitumor response of NK cells is based on the emerging understanding of KIR biology.¹¹⁸ More than 25 years ago, an inverse relationship was reported between expression of MHC class I molecules on target cells and the ability of NK cells to kill such targets successfully.³⁹ As this “missing self” model was further characterized, three principal, common HLA class I allele specificities were identified that serve as ligands for three specific NK cell-inhibitory KIR receptors. These have been termed *group 1* HLA-C alleles expressing Asn80 (e.g., HLA-Cw1, w3, w7, w8, and related alleles), *group 2* HLA-C alleles expressing Lys80 (e.g., HLA-Cw2, w4, w5, w6, and related alleles), and HLA-Bw4 alleles (e.g., HLA-B27). As one’s NK receptor repertoire, including inhibitory KIRs, is dictated during development by the HLA class I genotype, ultimately every NK cell expresses at least one inhibitory KIR specific to self HLA class I molecules.¹⁸ Moreover, allogeneic targets sensitive to NK cytotoxicity are identified by their lack of self MHC class I-inhibitory KIR ligands.

These principles have been applied in a number of therapeutic settings. Perhaps most dramatically, Aversa and colleagues¹¹⁹ demonstrated an impressive improvement in survival after allogeneic stem cell transplant-based therapy for patients with acute myeloid leukemia. Donor-versus-recipient NK cell alloreactivity has been shown to contribute to enhanced survival in this setting, as well as to improve engraftment and protect against graft-versus-host-disease.^{120,121} In a series of patients receiving haploidentical grafts with a median follow-up of 4 years, 68% of patients without NK alloreactivity had relapsed disease, but only 15% of patients with NK alloreactivity relapsed.¹²⁰ Similarly, KIR mismatch has been shown to improve outcome after reduced-intensity chemotherapy followed by allogeneic stem cell transplant in patients with multiple myeloma.^{109,122} Fig. 22.3 shows how mismatching KIR epitopes facilitate NK-mediated tumor cytotoxicity in a haploidentical setting.

Fig. 22.3 SIMPLIFIED REPRESENTATION OF HAPLOTYPE-MISMATCHED ALLOGENEIC STEM CELL TRANSPLANT FOR ACUTE MYELOID LEUKEMIA: PROPER MAJOR HISTOCOMPATIBILITY COMPLEX CLASS I MISMATCH CAN LEAD TO DONOR NATURAL KILLER CELL KILLING HOST LEUKEMIC BLASTS. As the human leukocyte antigen C (HLA-C) ligand binds to the natural killer (NK) cell inhibitory killer immunoglobulin-like receptor (KIR) on the left, the inhibitory signal interrupts the activation signal, and no killing occurs. However, when the HLA-C ligand does not bind the NK inhibitor KIR on the right, no inhibitory signal is sent, and tumor killing occurs. (Modified from Farag SS, Fehniger TA, Ruggeri L, et al: Natural killer cell receptors: new biology and insights into the graft-versus-leukemia effect. *Blood* 100:1935, 2002.)

Others have extended on these transplantation-based findings by manipulating the relationship between NK receptors and MHC class I receptors by means of monoclonal antibodies. For example, a murine model lends support to the notion that tumor expression of MHC class I molecules becomes engaged by inhibitory NK cell receptors and thus mediates NK tolerance.¹²³ When antibody fragments were introduced to disrupt this ligand–receptor interaction, increased NK cytotoxicity and decreased tumor growth were observed. Furthermore, adoptive transfer of murine NK cells pretreated with an antibody to block inhibitory NK receptor expression into leukemia-bearing mice led to enhanced survival as compared with transfer of untreated NK cells. These findings support the notion that blocking inhibitory NK receptors may be beneficial in increasing the efficacy of cancer immunotherapy.^{123,124} Phase I clinical trials of anti-KIR antibodies have been completed in humans, and combinatorial trials are now underway.^{125,126} Fig. 22.4 demonstrates this principle.

In complementary fashion, other approaches have sought to enhance activating NK receptors, such as NKG2D. One group has created a novel bivalent protein (ULBP2-BB4) that recognizes NKG2D and CD138, a protein overexpressed in a number of malignancies, including multiple myeloma. Although such an approach is limited by knowledge of particular tumor antigens, the concept of enhancing NK function was demonstrated in this model through increases in NK cytokine secretion as well as abrogation of tumor cell growth in the presence of the molecule.¹²⁷ Bispecific killer cell engager molecules as well as engineered chimeric antigen receptor–expressing NK cells are now in development for a variety of malignancies.^{128–130} Finally, the use of monoclonal antibodies directed against tumor cell antigens has significantly advanced treatment of some malignancies. For example, treatment with the monoclonal, IgG, chimeric anti-CD20 antibody rituximab (just one of over 300 monoclonal antibodies either in development or already in clinical use) has been shown to improve survival of patients with non-Hodgkin lymphoma. As discussed, genotypic, single-nucleotide polymorphisms in the

Fig. 22.4 SIMPLIFIED REPRESENTATION SHOWING THE GENERAL EQUILIBRIUM BETWEEN ACTIVATING AND INHIBITORY SIGNALING THAT FAVORS NO KILLING. General equilibrium favoring no killing is shown on the left. The introduction of an antibody to the inhibitory receptor tips this balance toward activation and elimination of the target cell, as shown on the right. HLA-C, Human leukocyte antigen C; KIR, killer immunoglobulin-like receptor; NK, natural killer. (Modified from Farag SS, Fehniger TA, Ruggeri L, et al: Natural killer cell receptors: New biology and insights into the graft-versus-leukemia effect. *Blood* 100:1935, 2002.)

FcγRIIIA (CD16) receptor expressed on NK cells and other immune cells may convey functional differences in the receptor that have clinical consequences. Patients with the V/V homozygous state at residue 176 have a higher affinity for the Fc portion of the rituximab, and these patients show enhanced clinical response to the antibody.¹³¹ Such a finding supports the notion that enhanced ADCC function in CD16-bearing cells, including NK cells, is one key mechanism of action of rituximab and suggests that antibody-mediated cancer therapies could be advanced by enhancing NK cell numbers and cytotoxic potential in vivo.

FUTURE DIRECTIONS

NK cells are a critical cellular component of innate immunity. Rapid secretion of powerful immunomodulatory cytokines and chemokines support the role of NK cells as “first responders” to immune insults, facilitating mobilization and tailoring of the innate and adaptive immune response. Potent natural cytotoxicity, unrestricted by classical antigen presentation, and costimulation required for adaptive immune cells suggest that NK cells have an important, complementary role to that of cytotoxic T lymphocytes, which provide antigen-specific cytotoxicity and lasting memory. Further understanding of the functional differences between CD56^{dim} and CD56^{bright} subsets, their cytotoxicity and cytokine receptor expression, and their developmental biology will certainly shed more light on the therapeutic potential for NK cells in the pathogenesis, prevention, and treatment of human disease.

DENDRITIC CELL BIOLOGY

Olivier Manches, Luciana R. Muniz, and Nina Bhardwaj

Dendritic cells (DCs) are a sparsely distributed population of bone marrow (BM)-derived mononuclear cells that exist in an “immature” form in virtually all tissues in the body.¹ DCs serve as professional antigen-presenting cells (APCs) with an extraordinary capacity to stimulate naive T lymphocytes (as well as B, natural killer [NK], and NK T cells) and initiate primary immune responses. In their immature state, DCs detect and capture “danger signals” originating from microorganisms or their macromolecular constituents in their resident tissues. Upon encountering such danger signals, DCs undergo a complex series of events leading to their “maturation.”¹ Maturation of DCs is characterized by migration of DCs to draining lymph nodes and by processing and presentation of antigens in the context of antigen-presenting molecules such as major histocompatibility complex (MHC) and CD1 to naive T, B, and NK cells. This chapter provides a snapshot of the current understanding of DC function as well as the potential clinical applications of DCs as immunotherapeutic agents in diseases such as cancer, HIV, and autoimmunity.²

DENDRITIC CELL SUBSETS AND DEVELOPMENT

Extensive research has demonstrated that DCs exist in many “flavors.”^{3,4} However, understanding of DC differentiation and the different DC subsets is complicated by the heterogeneity of data obtained from in vitro human and mouse studies as well as in vivo animal studies and limited in vivo human studies. In this chapter, we will concentrate on human DCs with little reference to murine models. Readers are encouraged to seek additional information in several comprehensive reviews.^{5–14}

Most studies on the developmental origin of human DC subsets have used in vitro culture systems. The CD34⁺ hematopoietic progenitor cells (HPCs) and blood monocytes are commonly used as precursor cells for generating DCs in culture in vitro for both research and immunotherapeutic purposes. Monocytes, obtained by simple adherence of HPCs to plastic, when exposed to a combination of granulocyte-macrophage colony-stimulating factor (GM-CSF) and interleukin-4 (IL-4), yield immature DCs (imDCs) that are comparable to some degree with tissue interstitial DCs. Maturation of these different DCs can be induced by the addition of various stimuli. Recently it was shown that monocyte-derived DCs (moDCs) constitute a subset of DCs that are not equivalent to blood DCs but resemble more inflammatory DC subsets 15 (Fig. 23.1). Pre-DCs and imDCs, similar to other cell types in the immune system, are continuously produced at a steady rate and in a pathogen-independent manner from CD34⁺ hematopoietic stem cells (HSCs) within the BM. Fms-like tyrosine kinase-3 ligand (Flt3L) and granulocyte colony-stimulating factor (G-CSF) represent the key DC growth and differentiation factors.¹⁵ The development of stromal cell culture systems comprising HSCs cultured with BM mouse stromal cells and stem cell factor, GM-CSF, and Flt3L have led to the identification of a definitive pre-DC that gives rise to DC subsets found in the blood.^{15a,16,17}

Recent studies have shown that DCs originate from human granulocyte monocyte dendritic cell precursors, which sequentially develop into monocyte dendritic cell precursors, which subsequently give rise to a common dendritic cell progenitor (hCDP) that is restricted to produce the three major subsets of DCs: 2 classical DC (cDCs)

subsets, DC1 (CD141⁺) and DC2 (CD1c⁺) and the plasmacytoid DCs (pDCs). Prior studies suggesting that DCs can arise from other multilineage sources may not be inconsistent, because these are generally speaking heterogeneous populations. In addition, hCDP can also give rise to pre-cDC progenitors in human cord blood, BM, blood, and peripheral lymphoid organs. These pre-cDCs sustain the CD1c⁺ and CD141⁺ DC subsets, indicating that pDCs and cDCs arise during hematopoiesis from progenitors with already distinct and restricted lineage potential.^{16–18,18a} Moreover, these pre-cDC precursors in the blood can either be uncommitted or display early commitment towards DC1 and DC2 development (pre-DC1 and pre-DC2 phenotypes). Furthermore, Flt3-L given systemically to humans has been shown to increase the pre-cDC pool.^{17,19} Altogether, these studies confirmed that there is a sequential pathway of DC development that involves progenitors which display increasing restricted commitment to give rise to the 3 major DC subsets.

The 3 DC subsets not only can be distinguished phenotypically, but also through molecular signatures. DC1 DCs, as briefly described above, are phenotypically described by their expression of CD141, XCR1 and CADM1; DC2s express CD1c and SIRP α ; and pDCs express CD123. On the molecular level, DC1s express IRF8, Batf3, Zbtb46 and Flt3; DC2s express ETS2, ID2, ZBTB46 IRF4 and Flt3, while pDCs, as expected, express IRF7, TCF4, Spi-B and IL-3RA.¹⁶ In addition to the committed DC subsets, pre-cDCs are also known to express specific markers such as CD45RA, CD123 (at low/intermediate levels), CD135, CD116, CD117 and CX3CR1 and these can be used in the sorting of these precursors for DC1 and DC2 development.¹⁹

Under different culture systems, the CD34⁺ HSCs have been shown to give rise to CD34⁺CLA⁺ and CD34⁺CLA[−] populations (skin homing receptor cutaneous lymphocyte-associated antigen [CLA]), which differentiate to phenotypically distinguishable CD11c⁺CD1a⁺ and CD11c⁺CD1a[−] imDCs, respectively.²⁰ The former migrate into the skin epidermis and differentiate into Langerhans cells, and the latter localize to the skin dermis and other tissues and become interstitial imDCs.²¹ The human Langerhans cell DC subset has distinct markers, including the presence of Birbeck granules, the expression of CD1a, and langerin, a member of the C-type lectin family of receptors involved in the uptake of pathogens.²²

In contrast to the blood “myeloid DCs” derived from pre-cDCs, the “plasmacytoid DCs” contain “lymphoid” mRNA transcripts for pre-T-cell α -chains, germline IgK, and Spi-B and are also called *interferon (IFN) type I-producing cells*. These latter cells display a distinct plasma cell morphology, contain abundant endoplasmic reticulum (ER), and express high levels of IL-3 α R but lack myeloid antigens, including CD11c and most lineage markers. pDCs are found in the peripheral blood, thymus, and many lymphoid tissues. The production of extraordinarily high levels of IFN type I by pDCs is unique to this cell type, and it may be important for initiating a strong antiviral innate response and may promote maturation of bystander CD11c⁺ cDCs to protect them from the cytopathic effect of viruses.^{22–25} It is hypothesized that human cDCs and pDCs have evolved to recognize and respond to different pathogens in unique ways owing to their complementary expression of receptors for pathogen-associated molecular patterns (PAMPs) (see Antigen Acquisition section), capacity to secrete either IFN type I or IL-12, antigen presentation, and migration into secondary lymphoid organs. As mentioned, pDCs secrete high amounts of IFN- α upon viral infection but no IL-12

Fig. 23.1 EXAMPLES OF MONOCYTE-DERIVED MATURE DENDRITIC CELLS. The mononuclear cells were enriched by adherence; were cultured with interleukin-4 (IL-4) and granulocyte colony-stimulating factor for 6 days; and underwent maturation with IL-1, IL-6, tumor necrosis factor- α , and prostaglandin E_2 for 24 hours.

and display poor antigen capture and presentation capacity. Upon activation, pDCs differentiate into cells bearing characteristics similar to those of activated cDCs (i.e., with a dendritic morphology, high expression of MHC class II molecules, and the capacity to prime naive T cells),^{26,27} but they express low levels of CD11c and lack typical myeloid markers. The functional properties of these latter pDC-derived DCs are still to be investigated thoroughly,²⁸ although they may differ from cDCs, especially in their cross-presentation²⁹ or T-cell skewing capacities. Thus, whereas DCs derived from pDCs upon culture with IL-3 and activation by CD40L preferentially prime naive CD4⁺ T cells toward a type 2 T helper (Th2) cell profile, DCs derived from pDCs by viral and/or Toll-like receptor (TLR) stimulation prime toward a Th1 profile in an IFN- α -dependent and IL-12-independent pathway.²⁴ Upon activation, immature cDCs migrate through afferent lymph from nonlymphoid tissues to the T-cell-rich areas of lymph nodes. pDCs, which also migrate into T-cell areas of secondary lymphoid tissues, do so through high endothelial venules of lymph nodes and marginal zone of the spleen, likely using CCR7 and CD62L.³⁰ Both activated blood cDCs and pDCs can migrate in response to lymph node-homing chemokines (CCL19 and CCL21) through expression of CCR7. Although cDCs can be found in virtually every peripheral tissue as well as in lymphoid organs, pDCs seem to display a more restricted distribution. They can be found mostly in the T-cell area of lymphoid organs (lymph node, tonsils, spleen, thymus, BM, and Peyer patches), blood, and some peripheral tissues (liver, nasal mucosa). While cDCs and pDCs express a similar array of chemotactic receptors (e.g., CCR2, CCR5, CXCR2, CXCR4), pDCs do not respond to a number of inflammatory chemokines. However, they accumulate in inflamed tissues, such as in systemic lupus erythematosus (SLE) and contact dermatitis, probably through their expression of ChemR23 and CXCR4.

This division of DCs into cDC and pDC subsets is likely to be an oversimplified view of DC heterogeneity. For example, splenic DCs are heterogeneous with regard to expression of CD4, CD11b, and CD11c, but most of the thymic DCs are CD11c⁺ but lack other myeloid markers, thereby not fitting into either of the classical categories of cDCs and pDCs in blood.³¹

An important role for CD103⁺ (αE integrin) has recently been uncovered. CD103⁺ DCs reside in the intestinal mucosa and play a crucial role in tolerance to commensal bacteria and food antigens.

These cells originate in the lamina propria and migrate to the mesenteric lymph nodes, where they drive the differentiation of gut-homing FoxP3⁺ regulatory T cells (Tregs) by producing retinoic acid (RA) from dietary vitamin A.

In addition, the BDCA3⁺ (DC1 CD141⁺) DC subset has been found to be the equivalent of murine CD8 α ⁺ DCs, and are involved at cross-presenting antigens to CD8⁺ T cells. They express the chemokine receptor XCR1 and the DC NK lectin group receptor 1 C-type lectin, a sensor for necrotic cells, and specifically β -actin, and they mediate the phagocytosis of dead cells. They also express basic leucine zipper transcriptional factor ATF-like-3 (BATF3) and INF regulatory factor-8 (IRF8), which may be essential for their development. BDCA3⁺ DCs express high levels of TLR3 and TLR8, and, upon stimulation by TLR3 agonists (e.g., polyinosinic-polycytidylic acid [poly(I:C)]), they secrete high amounts of IL-12 and IFN- β , both Th1-skewing cytokines. These combined characteristics make them attractive targets for DC-based vaccines in cancer and chronic immune diseases.

Although Langerhans cells and microglia seem to be capable of self-renewal in ectodermal tissues, epidermis, and brain, other DCs arise from blood-borne precursors from BM as described earlier. Recent studies of human immunodeficiencies have highlighted the transcription factors directing the development of DCs and have emphasized their role in defense against microbial pathogens. Thus in DC, monocyte, B, and NK lymphoid deficiency (DCML), blood and interstitial DCs are absent along with monocytes and pDCs. The DCML is attributable to GATA-binding factor 2 mutations, a transcription factor involved in the homeostasis of HSCs. Patients with DCML deficiency have increased susceptibility to *Mycobacteria* spp., fungi, and viruses. Another DC deficiency syndrome is caused by IRF8 mutations. The autosomal recessive K108E mutation leads to defects in peripheral cDCs, pDCs, and monocytes, with increased susceptibility to *Mycobacteria* spp., other intracellular bacteria, and viruses, and it is accompanied by a myeloproliferative syndrome. The dominant sporadic mutation T80A induces a specific loss of CD1c⁺ DCs, with increased susceptibility to mycobacterial infection but otherwise a normal life expectancy.

It seems that whereas cDC differentiation is dependent on the transcription factor Ikaros, pDC development is dependent on the Ets family transcription factor Spi-B and probably PU.1. A recent study also described an important role for the upregulation of basic helix-loop-helix transcription factor (E-protein) E2-2 in developing pDCs, and E2-2-deficient hematopoietic progenitors do not produce pDCs.³³ Studies in mice described the conversion of BM pDCs into cDCs upon viral infection, again highlighting the complexity and plasticity of DC development.³⁴

The migration of myeloid DCs and plasmacytoid pre-DCs from the BM can be increased by administration of Flt3L up to 50-fold for pre-DCs and 15-fold for pDCs.^{35,36} G-CSF is also known to increase the number of pDCs in the circulation. With the advent of newer technologies, it has also become feasible to generate large numbers of DC subsets in vitro.

THE CONCEPT OF MATURATION

In their resting state, imDCs are primed to acquire antigens in situ through a variety of receptors and mechanisms. Upon encountering pathogens or other "activating stimuli," DCs undergo a complicated series of phenotypic and functional changes referred to here as *activation* and *maturation*, respectively.¹ The process of DC activation is an intricate differentiation process under tight control that is closely associated with antigen acquisition. It is induced by various stimuli (Table 23.1) or danger signals (e.g., signs of pathogenic infection or cell injury), including cytokines (e.g., IFN type I, tumor necrosis factor α [TNF- α], and IL-1), microbial products (e.g., lipopolysaccharide [LPS], flagellin), intracellular products (e.g., heat shock proteins [HSPs]), growth factors (e.g., thymic stromal lymphopoietin [TSLP]), immune complexes, and T-cell molecules (e.g., CD40). The process of activation is characterized by upregulation of adhesion

TABLE 23.1 Agents That Cause Dendritic Cell Maturation^a

Agent Property	Molecules
Stimulatory agents	TNF family members (TNF- α , CD40L, FasL, TRANCE) TLR ligands (dsRNA, LPS, imiquimod, CpG ODNs) Growth factors (TSLP) Interferons (IFN- α) Adhesion molecules (CECAM-1 (CD66a)) Costimulatory molecules (LIGHT, B7-DC) Receptors (FcR via Ag-Igs; TREM-2 via Dap-12) Viruses or microbes (influenza, bacteria, bacterial products) Chemokines (MCP, MIP1 α , RANTES, IP10, IL-8, MDC, TARC) Chemokine receptors (CCR7 and loss of CCR2 and CCR5)
Inhibitory agents	Drugs (rapamycin, FK506, cyclosporine A, dexamethasone, IVIg) Chemokines (IL-10) Viruses (EBV, vaccinia, canarypox, HSV) Others (2 microglobulin)
Survival signals	CD40L, TRANCE, B7-DC, Bcl-2

Ag-Igs, Antigen-immunoglobulin immune complexes; Bcl-2, B-cell lymphoma 2; CCR, chemokine (C-C motif) receptor; CECAM-1, carcinoembryonic antigen-related cell adhesion molecule-1; CpG ODNs, CpG oligodeoxynucleotides; dsRNA, double-stranded RNA; EBV, Epstein-Barr virus; FcR, Fc receptor; HSV, herpes simplex virus; IFN, interferon; IL, interleukin; IP10, interferon- γ -induced protein 10; IVIg, intravenous immunoglobulin; LIGHT, homologous to lymphotoxins, exhibits inducible expression, and competes with HSV glycoprotein D for herpesvirus entry mediator, a receptor expressed by T lymphocytes; LPS, lipopolysaccharide; MCP, macrophage/monocyte chemotactic protein; MDC, macrophage and dendritic cell precursor; MIP1 α , macrophage inflammatory protein 1 α ; NK, natural killer; RANTES, regulated on activation, normal T expressed and secreted; TARC, thymus and activation-regulated chemokine; TNF, tumor necrosis factor; TRANCE, TNF-related activation-induced cytokine; TREM-2, triggering receptor expressed on myeloid cells 2; TSLP, thymic stromal lymphopoietin.

and costimulatory molecules such as CD54, CD80, CD86, MHC class I and II molecules, cytokines (e.g., TNF- α , IL-12, IL-18), and chemokines (e.g., RANTES [regulated on activation, normal T expressed and secreted], MIP-1 α [macrophage inflammatory protein 1 α], IP-10 [interferon- γ -induced protein 10]). The latter enable the recruitment of T cells, monocytes, and other DCs into the local environment. In their mature state, DCs express markers, which distinguish them from imDCs such as CD83 (a molecule involved in thymic T-cell selection and DC-DC interactions) and DC-LAMP, a lysosomal protein. Maturation also changes the migratory properties of DCs. They express CCR7 and acquire responsiveness to the chemokines CCL19 and CCL21 that are expressed in the T-cell areas of lymph nodes where mDCs generate immune responses. Concomitantly, DCs downregulate their receptors for CCL3, CCL4, and CCL5, which are secreted at sites of inflammation; reduce their capacity for phagocytosis, macropinocytosis, antigen uptake, and processing; but acquire potent immunostimulatory ability through enhanced T-cell-DC immune synapse formation, production of immunoproteasomes, and upregulation of unique DC-specific costimulatory molecules such as B7-DC.³⁷ However, although increased expression of costimulatory molecules and migration to secondary lymphoid organs often correlate with their capacity to prime CD4 and CD8 immunity, activated DCs may also induce

tolerization of T cells, such as when CD4⁺ T-cell help is missing^{38,39} or on activation by inflammatory cytokines in the absence of TLR engagement,⁴⁰ and they can potentially induce the generation of Tregs. Some stimuli, such as TSLP, can induce phenotypic maturation of DCs without concomitant secretion of proinflammatory cytokines such as IL-12, IL-6, TNF- α , or IL-1.⁴¹ Therefore DC maturation is more appropriately used in a functional sense, with mDCs being defined as able to prime naive T-cell responses. What makes a phenotypically activated DC capable of priming instead of tolerizing a T cell appears multifactorial and dependent on factors such as the state of the microenvironment and the DC subset in question, although this remains to be clearly defined.

Recent work has shed some light on the intricate transcriptional modifications that DCs undergo upon stimulation and activation. This study was focused on mapping genetic variants that contribute to variation of gene expression in DCs and how these associate with response to stimuli such as LPS, influenza virus, and IFN- β . The researchers in this study identified a gene signature that can be instructive of variation in the response to stimuli in a larger cohort of samples. In genome-wide association studies of inflammatory diseases such as psoriasis, multiple sclerosis, Crohn disease, and leprosy, regions closest to the susceptibility loci were enriched in DC-specific genes and in genes induced by LPS or influenza stimulation of DCs. Thus DC pathogen-sensing mechanisms that lead to their activation are potentially implicated in the pathogenesis of inflammatory diseases. These studies underscore the importance of high-throughput and integrative approaches in the analysis of DC-mediated responses.⁴²

ANTIGEN ACQUISITION AND DENDRITIC CELL ACTIVATION

DCs have a remarkable ability to process and present antigens restricted by MHC and CD1 molecules. The processing is tightly associated with DC activation. imDCs sample their environment through several mechanisms, including micropinocytosis, macropinocytosis, receptor-mediated endocytosis, and phagocytosis. They display an array of surface receptors, which facilitate acquisition of antigens and pathogens and at the same time induce differentiation into activated DCs. An important class of receptors is the pattern recognition receptors (PRRs), which recognize PAMPs expressed by many microorganisms. PRRs serve as an important link between innate and adaptive immunity because they directly mature DCs while also inducing the production of a variety of cytokines and chemokines. PRRs consist of several groups of receptors, including secreted molecules (e.g., MBL, CRP, SAP, LBP), cell surface molecules (e.g., CD14, macrophage mannose receptor [MMR], MSR, MARCO),⁴³ and intracellular molecules (e.g., RIG-I and MDA5, which are RNA helicases involved in the recognition of nucleic acids upon viral infection; stimulator of interferon genes [STING], DAI, and AIM2 [absent in melanoma 2], which recognize intracellular DNA⁴⁴; nucleotide-binding oligomerization domain-like [NOD] receptors, which recognize peptidoglycan subcomponents or other bacterial molecules; inflammatory caspases, such as caspase-1 and caspase-5, which form an intracellular complex with NALP1 or NALP2 and NALP3 called the *inflammasome* that recognizes bacterial RNA and other danger signals and induces the production of the proinflammatory cytokines IL-1 β and IL-18) (Table 23.2). TLRs, which constitute another group of PRRs, are expressed by imDCs and mediate activation by microbial components such as peptidoglycan, LPS, flagellin, and unmethylated CpG DNA motifs. Ligation of the TLRs results in the activation of Rel family members, particularly the transcription factor nuclear factor κ B (NF κ B), c-Jun N-terminal kinase, and p38 mitogen-activated protein kinase, leading to the initiation of the maturation process.^{45,46} TLRs are unevenly distributed among DCs, with myeloid DCs expressing TLRs 2, 3, 4, 5, 7, and 8 and pDCs strongly expressing TLRs 7 and 9 (Table 23.3). Another important feature of some TLRs is their capacity to induce secretion of IFN type I for antiviral defense and immune regulation.

TABLE 23.2 Antigen Recognition and Uptake Receptors Expressed by Dendritic Cells^a

Receptor	Antigenic Ligand
C-type lectins (DC-SIGN, MMR, DEC-205)	Mannosylated molecules, viruses, bacteria, fungi
FcγR (CD32, CD64)	Immune complexes, antibody-coated tumor cells
CD1 a, b, c, d	Bisphosphonate moieties in <i>Mycobacterium tuberculosis</i> , BCG, and <i>Listeria monocytogenes</i> ; lipid and glycolipid foreign and self-antigens
Integrins (α _v β ₅ , CR3, CR4)	Opsonized antigens, apoptotic cells
Scavenger receptors (CD36, LOX-1)	Opsonized antigens, apoptotic cells, heat shock proteins
TLRs and other PRRs	TLRs 2–8 (myeloid DC) peptidoglycans, endotoxin, flagellin TLR 7 (plasmacytoid DC) bacterial DNA; RIG-I, MDA5, STING, DAI, AIM2, PKR, NOD proteins
HSP-R (CD91)	Heat shock proteins
Aquaporins	Fluids

^aThe table lists some of the receptors expressed by DCs that are involved in antigen acquisition. The antigen receptor repertoire dictates that range of antigens captured by the DC. Ligation of some of these receptors induces DC maturation.

AIM2, Absent in melanoma 2; BCG, bacillus Calmette-Guérin; DAI, DNA-dependent activator of IFN-regulatory factors; DC, dendritic cell; DC-SIGN, dendritic cell-specific intercellular adhesion molecule-3-grabbing nonintegrin; HSP-R, heat shock protein receptor; MDA5, melanoma differentiation-associated protein 5; NOD, nucleotide oligomerization domain; PKR, protein kinase R; PRR, pattern recognition receptor; RIG-I, retinoid-inducible gene I; STING, stimulator of interferon genes; TLR, Toll-like receptor.

cDCs express TLRs 3 and 4, mediating recognition of viral double-stranded RNA and LPS, respectively, and on triggering secrete low amounts of IFN-β through a signaling pathway using the adaptor Toll/IL-1 receptor domain-containing adapter-inducing IFN-β and the transcription factor IRF3. Although cDCs can also induce IFN type I through RIG-I and MDA-5 upon viral infection, pDCs seem to rely mostly on a specialized MyD88-dependent signaling pathway, allowing them to secrete very high amounts of IFN-α upon triggering of TLRs 7 and 9. This is because of their constitutive high expression of IRF7, a crucial IFN-α gene transcription factor, and because of a specialized spatiotemporal regulation of TLR7 and TLR9 signaling, allowing IRF7 to interact with MyD88 docked onto TLRs in the endosomal membrane.⁴⁷

The inflammasome consists of a family of PRRs that induce IL-1 and IL-18 secretion. IL-1β secretion can be triggered through the NLRP3, NLRC4, and NLRP1 inflammasomes, as well as by the DNA sensor AIM2.⁴⁸ Activation of the inflammasome occurs through activation of the nucleotide-binding domain, leucine-rich repeat-containing proteins (NLRs). NLRs are composed of three domains: at the N-terminus a pyrin domain, a caspase recruitment domain, or a baculovirus inhibitory repeat domain; the central domain is the nucleotide-binding domain responsible for dNTPase activity and oligomerization; and the leucine-rich repeat domain at the C-terminus.⁴⁹ Activation of the inflammasome leads to caspase-1-mediated processing of pro-IL-1 and pro-IL-18 for IL-1β or IL-18 secretion and inflammatory cell death (pyroptosis and pyronecrosis). The inflammasome can be activated by sterile (non-microbial) activators of both host (adenosine triphosphate [ATP], uric acid crystals, amyloid-β) and microenvironment (alum, silica, asbestos) origin. It can also be activated by pathogen-derived products, including PAMPs. Microbial activators include pore-forming toxins, RNA and DNA, flagellin, β-glucans, and zymosan. The

TABLE 23.3 Toll-Like Receptors Expressed by Dendritic Cells^a

mDC	pDC	Ligand(s)
TLR1	TLR1	?

TLR3		Double-stranded RNA (e.g., poly(I:C))
TLR4		LPS + MD-2, taxol, hsp60 (?), heparan sulfate (?), RSV, fibronectin
TLR5		Flagellin (<i>Salmonella typhimurium</i> , <i>Listeria</i> spp.)
TLR6	TLR6 TLR7	? or undergoes dimerization with TLR2 Imiquimod (Aldara), R-848 (resiquimod), single-stranded RNA
TLR8	TLR8	Imiquimod (Aldara), R-848 (resiquimod), single-stranded RNA
	TLR9	CpG ODNs, DNA from bacteria and viruses, chromatin-IgG complexes
	TLR10	?

^aToll-like receptors (TLRs) can form heterodimeric receptor complexes consisting of two different TLRs or homodimers (as in the case of TLR4). The TLR4 receptor complex requires supportive molecules (MD-2) for optimal response to its ligand lipopolysaccharide (LPS). A common feature of the TLR receptors is the cytoplasmic Toll/IL-1 receptor (TIR) domain that serves as a scaffold for a series of protein-protein interactions that result in the activation of a unique signaling module consisting of MyD88; interleukin-1 receptor associated kinase (IRAK) family members; and Tollip, which is used exclusively by TIR family members. Subsequently, several central signaling pathways are activated in parallel, the activation of nuclear factor κB (NFκB) being the most prominent event of the inflammatory response. Recent developments indicate that, in addition to the common signaling module MyD88/IRAK/Tollip, other molecules can modulate signaling by TLRs, especially of TLR4, resulting in differential biologic responses to distinct pathogenic structures. TLR2 is also involved in cross-presentation.

CpG ODNs, CpG oligodeoxynucleotides; IgG, immunoglobulin G; poly(I:C), polyinosinic-polycytidylic acid; RSV, respiratory syncytial virus.

best-studied inflammasome is the NLRP3 inflammasome, whose activation requires two signals: the first upregulates NLRP3 and pro-IL-1β, and the second induces the assembly of the inflammasome complex.⁴⁸ This can occur via various mechanisms: generation of reactive oxygen species (ROS), possibly by the phagosomal NADH (nicotinamide adenine dinucleotide) oxidase, release of cathepsin B upon phagolysosomal destabilization, and pore formation at the plasma membrane through the P2X7 receptor, allowing K⁺ efflux.⁵⁰ Inflammasome components can be found in human DCs, with some found in both pDC and cDC subsets (e.g., NLRP3, ASC, and pro-caspase-1), whereas other molecules are expressed only in cDCs or moDCs in steady state and upon TLR priming (e.g., IL-1 and IL-18).⁵¹

C-type lectins are calcium-dependent, carbohydrate-binding proteins with a broad range of biologic functions, many of which are involved in immune responses. They are well represented on DCs and include the following: DC-SIGN, responsible for binding of HIV-1, HIV-2, simian immunodeficiency virus, Ebola viruses, dengue virus, *Candida* spp., *Leishmania* spp.; BDCA2, potentially responsible for delivering tolerogenic signals; BDCA4/neuropilin-1, capable of binding vascular endothelial growth factor (VEGF); langerin, responsible for uptake and processing of antigens in Langerhans cells; DEC-205 (CD205), involved in the uptake and processing of antigens in MIV (vesicles enriched for MHC class II molecules and proteases such as the cathepsins that mediate antigen processing and MHC class II peptide complex formation), as well

as the generation of tolerogenic signals; and MMR, involved in the processing of microbial organisms.

Other receptors expressed by DCs include FcR, which is involved in cross-presentation of immune complexes and antibody-opsonized dead cells; integrins such as $\alpha_v\beta_5$, scavenger receptor CD36, and Mer family tyrosine kinases for phagocytosis of apoptotic cells and lipoxigenase-1 or CD91 for uptake of HSPs; complement receptors that play a role in uptake of opsonized microbes and apoptotic cells; receptors for viruses (e.g., CD4, CCR5, and CXCR4 for HIV and CD46 for measles virus); and the CD1 family of receptors that activate CD4, CD8, $\gamma\delta$ T cells, and NK T cells through binding and processing of antigens such as sphingolipids, sulfatides, glycosphingolipids, glycosylphosphatidylinositol (GPI)-anchored mucin-like glycoproteins (GPI mucins), glycoinositolphospholipids, and their phosphatidylinositol moieties. Altogether, these various receptors provide substantial avenues for DCs to efficiently capture multitudes of antigens in their environment.

Antigen capture is tightly coupled to DC activation and antigen presentation, and triggering of TLR or exposure to inflammatory cytokines first induces a transient increase in the macropinocytic uptake followed by a nearly complete downregulation of the uptake process. Furthermore, it has been suggested that TLR engagement also enhances microbe-loaded phagosome maturation, potentially discriminating between nonimmunogenic antigens (apoptotic cells) and microbial antigens at the antigen-processing level.⁵²

ANTIGEN PROCESSING

DCs are highly efficient in processing and presenting antigens via their MHC or CD1 molecules and presenting those to other immune

cells such as CD4 and CD8 T cells. Depending on the antigens the DCs encounter, the presentation pathway will differ, as described in detail later.

Major Histocompatibility Complex Class I Antigen Presentation (Endogenous Route)

The process of antigen processing and presentation to CD8⁺ T cells begins with degradation of proteins synthesized within the cytoplasm, either as mature proteins or as neosynthesized defective proteins (defective ribosomal products), into oligopeptides by the ubiquitin–proteasome pathway. Misfolded proteins are also a source of antigenic peptides after retrotranslocation from the ER to the cytosol through the ER-associated degradation pathway. Subsequently, aminopeptidases cleave N-terminal precursors into peptides of appropriate length for presentation on MHC class I molecules. Antigen processing via this route is regulated through activation of the catalytically active subunits of the proteasome, the PA28 proteasome activator, and leucine aminopeptidase, which are upregulated by IFN.⁵³ mDCs in particular express immunoproteasomes containing the active site subunits latent membrane protein 2 (LMP2), LMP7, and MECL-1, which can enhance antigen processing.⁵⁴ After transport into the ER through the transporter associated with antigen processing (Fig. 23.2), long peptides are further trimmed by ER aminopeptidase-1 to 8-mer or 9-mer peptides for loading onto MHC class I molecules.

DCs also have the capacity to acquire antigens exogenously and process them for presentation on MHC class I molecules. This phenomenon, referred to as *cross-presentation*, allows the immune system to recognize antigens that are not otherwise presented or that may not access DCs directly (e.g., tumor cells, viruses). DCs can acquire

Fig. 23.2 PATHWAYS FOR MAJOR HISTOCOMPATIBILITY COMPLEX (MHC) CLASS I PRESENTATION. The classical pathway for MHC class I presentation (1) involves degradation of endogenous or viral antigens into peptides by the proteasome, followed by transport into the endoplasmic reticulum (ER). After further trimming in the ER, the peptides are loaded onto newly synthesized MHC class I molecules, and the peptide–MHC class I complexes are transported to the plasma membrane. Two main pathways of cross-presentation (2, 3) have been described that allow presentation of exogenous antigens in association with MHC class I molecules. Antigens endocytosed or phagocytosed can be cleaved into peptides by proteases and loaded onto recycling MHC class I molecules within the same phagosome or on the cell surface (vacuolar pathway) (2). Alternatively, antigens may escape from the phagosome and enter the cytosol (phagosome-to-cytosol pathway) (3) to be processed via the classical MHC class I pathway. It has been suggested recently that elements of the ER can be associated with phagosomes, allowing transfer of antigens into the cytosol by the ER-associated degradation pathway and degradation by the phagosome-associated proteasome (3a). The importance of each pathway (2, 3) for cross-presentation in vivo as well as the precise mechanisms and the locations of antigen processing in each model are under investigation. TAP, Transporter associated with antigen processing.

such antigens in the form of apoptotic cells, apoptotic microparticles, necrotic cells, antibody-opsonized cells, immune complexes, and HSPs (intracellular chaperones for antigenic peptides, which are released by necrotic cells).^{55,56} DCs even acquire antigens via phagocytosis of particles released from intracellular vesicles (referred to as *exosomes*).⁵⁷ Finally, DCs may even nibble bits of live cells to acquire antigens.⁵⁸ This phenomenon of cross-presentation is especially efficient in, if not unique to, DCs compared with other APCs. Evaluation of freshly isolated lymphoid organ-resident human DCs has confirmed that these cells also have the capacity to cross-present soluble antigens similarly to their blood counterparts.⁵⁹

Mechanistically, cross-presentation occurs via two major pathways: the cytosolic and the vacuolar pathways.⁶⁰ In the first, antigens are transferred to the cytoplasm, which is followed by processing by the proteasome and loading onto newly formed MHC class I molecules (phagosome-to-cytosol pathway), with a possible recruitment of the ER machinery for antigen processing and MHC class I loading (see Fig. 23.2).^{61–64} This pathway is sensitive to proteasome inhibitors, suggesting that proteins access the cytosol and are degraded by proteasomes, but whether the peptide loading occurs via the classical MHC I pathway or in endocytic compartments remains to be determined.^{64,65} The vacuolar pathway is resistant to proteasome inhibitors and sensitive to inhibitors of lysosomal proteolysis, and it is known to be cathepsin S-dependent, thus indicating that both antigen processing and loading onto MHC class I molecules may occur in endocytic compartments (see Fig. 23.2).^{66,67} The relative contribution of the cytosolic and vacuolar pathways is still unclear, but some evidence suggests the predominant use of the cytosolic pathway.⁶⁵ Currently, it is known that specific DC subsets are more efficient at cross-presentation, with the resident CD8 α^+ and the migratory CD1013 $^+$ DCs being the most efficient.^{68,69} In humans, the proposed CD8 α homologue cells—the CD141 $^+$ (BDCA3 $^+$) DCs—are specialized at cross-presentation.^{70–73} Finally, in recent years, it has been described that TLR signaling can influence the maturation of phagosomes and also can have an effect on the accumulation of MHC class I molecules in the phagosomes for cross-presentation.⁷⁴

Major Histocompatibility Class II Antigen Presentation (Exogenous Route)

Assembly of MHC class II molecules, which present antigen in the form of short peptides to CD4 $^+$ T lymphocytes, occurs in the ER of DCs. After being assembled, these MHC class II molecules are transported to specialized compartments in the lysosomal system involved in the processing of exogenous antigens. These include MIIIVs, which are protease-rich compartments containing newly synthesized MHC class II molecules. Epidermal DCs or Langerhans cells contain cytoplasmic tubules with internal striations called *Birbeck granules*. Birbeck granules are rich in langerin (CD205), a C-type lectin necessary for granule formation and possibly for capture of pathogens.⁷⁵ After being endocytosed by imDCs, antigens are partially retained within lysosomes. Upon receiving a maturation signal, the pH of lysosomes decreases to less than 5 (owing to the activation of a vacuolar H $^+$ -ATPase). Concomitantly, there is antigen degradation caused by activation of proteases such as cathepsins. Cystatin C, a protein that blocks the activity of cathepsin S, is also degraded, thereby allowing the degradation of invariant chain peptide (Ii chain), which normally blocks access of antigenic peptides to MHC class II molecules. These changes occur in late endosomes and lysosomes (the MIIIV compartment). After antigenic peptide is bound to MHC class II molecules, it exits the lysosomes through the formation of long tubular structures, which simultaneously deliver costimulatory molecules such as CD86 to the cell surface.^{76,77}

DCs handle internalized antigens in a specialized way unlike other phagocytic cells such as macrophages, which degrade most of the internalized material, leaving only limited amounts of antigenic peptides for presentation onto MHC molecules. On the contrary, internalized antigens in cDCs are preserved for longer times, thereby allowing their transport by maturing DCs to secondary lymphoid

organs, where actual presentation occurs. mDCs display higher levels of proteolysis than imDCs do, allowing appropriate degradation of the antigens for loading onto MHC molecules. These differences are accounted for by several features unique to DCs, such as low levels of lysosomal proteases in immature stages compared with macrophages, expression of protease inhibitors (cystatin C), regulation of lysosomal pH (and hence activity of proteases) by regulation of the acidifying V-type H $^+$ -ATPase activity, and consumption of H $^+$ upon reaction with superoxide radicals generated by NADPH (nicotinamide adenine dinucleotide phosphate) oxidase NOX2 in maturing DCs.⁷⁸ During maturation, trafficking of MHC class II molecules to the surface is dramatically increased, probably because of degradation of Ii chain (containing endosome-lysosome targeting signal) in acidic compartments, leading to transport of MHC class II molecules via the constitutive secretory pathway to the cell membrane.

In addition to direct presentation of intracellular antigens and cross-presentation of internalized material, DCs can acquire preformed MHC class I molecules in complex with antigens from other cells by the process of trogocytosis (transfer of cell-membrane patches or individual proteins between cells) or through gap junctions, in a process termed *cross-dressing*; this allows rapid presentation without processing of antigens. It has been suggested that memory CD8 T cells are preferentially activated by this mode of presentation in contrast to naive T cells.⁷⁹ It further provides a mechanism for antigen transfer between DC populations, which can be exploited for vaccine design. Thus it has been shown that ex vivo loaded DCs sometimes do not directly activate host CD8 $^+$ T cells, which rather requires transfer of peptide-MHC complexes from vaccine DCs to resident DCs for efficient priming.⁸⁰

T-CELL ACTIVATION

T-cell activation systematically requires three signals. Signal 1 is generated by the T-cell receptor (TCR) after engagement by a peptide-MHC complex on the APC. Signal 2, or costimulatory signal, determines qualitative and quantitative elements of T-cell activation and differentiation and is required for priming of naive T cells. Signal 3 specifies the type of response to be mounted, inducing either Th1 or Th2 differentiation in CD4 T cells or promoting a regulatory phenotype. MHC-peptide complexes, costimulatory molecules, and other signaling and adhesion molecules promote DC contact with T cells via formation of an immunologic synapse that determines the duration and strength of signals transduced to T cells, leading to their subsequent activation. The minimum time for productive interaction between naive T cells and DCs is 6 to 30 hours, with shorter time periods required for memory T-cell activation.^{81,82} Although only a few peptide-MHC complexes (<10) are sufficient to trigger calcium fluxes in T cells,⁸³ only mDCs can prime naive CD4 and CD8 T cells.⁸⁴ Remarkably, relatively few peptide-MHC complexes (<200) are necessary on mDCs to activate T cells. Compared with other APCs, such as B cells and monocytes, DCs are up to 1000-fold more efficient at activating T cells.⁸⁵

Costimulatory molecules include the CD80 and CD86 members of the B7 family, which ligate to CD28 on T cells, and members of the TNF family, such as CD40 (Table 23.4).¹² Notably, one new member of the B7 family, B7-DC, is unique to DCs and stimulates naive T cells highly efficiently.⁸⁶ Other molecules play inhibitory roles upon encountering their receptor on T cells. For example, programmed cell death ligand 1 (PD-L1) on DCs interacts with programmed cell death protein 1 (PD-1) on T cells to downregulate T-cell responses. Inducible costimulator ligand (ICOSL) is present on both DCs and B cells and is critical for germinal center formation and immunoglobulin class switching.

Signal 3 determines the skewing of the T-cell response such that T cells may terminally differentiate either toward IFN- γ -producing CD4 $^+$ T cells (Th1 cells), which eradicate intracellular pathogens (bacteria or viruses), or into Th2 cells producing IL-4, IL-5, and IL-13, which promote elimination of extracellular infections.

TABLE 23.4 Costimulatory Molecules Involved in the Interaction Between Dendritic Cells and T Cells (Signal 2)^a

Dendritic Cell	T Cell	Signal
B7 Family		
B7-1(CD80)/B7-2(CD86)	CD28	Activating
B7-1(CD80)/B7-2(CD86)	CTLA-4	Inhibitory
B7-H1(PDL1)/B7-DC(PDL2)	?	Activating
B7-H1(PDL1)/B7-DC(PDL2)	PD-1	Inhibitory
B7-H2 (B7h; B7PR1; ICOSL)	ICOS	Activating
B7H3	?	Activating
B7H4 (B7S1; B7x)	?	Inhibitory
TNF Receptor Family		
4-1BBL	4-1BB	Activating
CD27L	CD27	Activating
OX40L	OX40	Activating
LIGHT	LIGHT-R	Activating
Cytokines		
IL-2	IL-2R	T-cell proliferation
IL-12	IL-12R	T-cell proliferation
IL-18		

^aT-cell activation requires two signals. The T-cell receptor interaction with a peptide-MHC complex (signal 1) is accompanied by signal 2, delivered by one of the mechanisms listed in this table. Formation of the immunologic synapse between a dendritic cell and a T cell determines the fate of the lymphocyte. The number of identified costimulatory molecules responsible for signal 2 is increasing steadily.

CTLA-4, Cytotoxic T-lymphocyte antigen 4; IL, interleukin; LIGHT, homologous to lymphotoxins, exhibits inducible expression, and competes with HSV glycoprotein D for herpesvirus entry mediator, a receptor expressed by T lymphocytes; PD-1, programmed cell death 1; TNF, tumor necrosis factor.

Additionally, cytokines such as IL-12 for Th1 or IL-4 for Th2 differentiation are crucial determinants of initiation or amplification of Th responses. It has been suggested that DCs express the Notch ligands δ or Jagged under Th1 or Th2 conditions, respectively, and that these ligands promote differentiation of naive T cells toward one or the other Th profile.⁸⁷ Thus, whereas factors and pathogens, which stimulate DC maturation and IL-12 production, promote Th1 responses (e.g., *Escherichia coli*), inducers of IL-4 production prime Th2 responses (e.g., *Porphyromonas gingivalis*).

Furthermore, the Th1-polarizing capacity of DCs depends on a number of variables that include the expression of certain transcription factors, the microenvironment, exposure to various maturation stimuli, the kinetics of maturation, and the antigen dose. For example, expression by DCs of the transcription factor T-bet, which controls IFN- γ expression in CD4⁺ T cells, appears to be required for optimal development of Th1 responses.⁸⁸ Epithelial DCs in the respiratory tract may by default induce Th2 responses upon production of factors such as TSLP by epithelial cells.⁴¹ The duration of DC activation and antigen dose also determines the direction of T-cell skewing. Prolonged activation causes IL-12 depletion and results in “exhausted DCs.”³⁷ DCs presenting low amounts of antigen skew toward Th2, whereas high doses skew toward Th1, which in turn depends on the maturation state of the DCs and consequences of environmental exposure.^{89,90}

Since 2005, new CD4 T-cell lineages have been discovered. These include Th9, Th22, and Th17, which is the best characterized of the three.^{91–94} Named *Th17* because of their characteristic secretion of IL-17, this lineage of cells is implicated in several chronic inflammatory disorders. The IL-12 family member IL-23 and transforming growth factor- β (TGF- β) are involved in the generation of Th17 cells.⁹¹ LPS-stimulated DCs secrete inflammatory cytokines, notably IL-6, and in combination with TGF- β seem to divert differentiation of Tregs into Th17 cells.^{95,96} TGF- β upregulates the expression of the pivotal transcription factor retinoic acid-related orphan receptor- γ t

(ROR γ t) in a concentration-dependent manner, but high TGF- β concentration favors Treg development over Th17 differentiation, partly through Foxp3-inhibitory interaction with ROR γ t.⁹⁷ On one hand, the pathogenic role of Th17 cells may depend on the cytokine milieu in which they are differentiated or expand, and DC-derived IL-23 or IL-1 β could contribute to enhanced pathogenicity of Th17 cells. On the other hand, Th17 cells display heightened levels of the IL-10 receptor and are more susceptible to IL-10-mediated regulation, a cytokine secreted by DCs upon ligation of some TLRs (e.g., TLR2, TLR4). Moreover, the pathogenic role of Th17 is also controlled in the intestine.⁹⁸ Therefore the flexibility of DC activation and cytokine secretion profile may affect the pathogenic potential of developing Th17 cells.

The recently described Th9 cells are defined by their secretion of IL-9. Their development relies on several molecules, including signal transducer and activator of transcription 6 (STAT6) (downstream of the IL-4 receptor), needed to suppress T-bet (Th1 transcription factor) and TGF- β -induced Foxp3 expression, as well as IRF4 and STAT5, which directly activate the *Il9* promoter.⁹² Furthermore, TGF- β was shown to redirect Th2 cells into Th9 cells.⁹⁹ These cells have been associated with both protective and pathogenic roles and have been identified as contributors to human atopic disease and inflammatory bowel disease (IBD); however, they are also known to mediate antihelminth infections and have antitumor activity.¹⁰⁰ Recently, Th9-derived IL-9 was shown to inhibit both mouse and human melanoma cell growth, highlighting an antitumor role.^{101,102}

Th22 cells are characterized by their secretion of IL-22, and they have been associated with autoimmune diseases such as psoriasis, SLE, and allergies.⁹⁴ They are closely related to Th17 cells, but the details of this relationship are not very well described. Th22 can modulate antimicrobial pathways in the intestine and skin, and IL-22 was shown to regulate the expression of genes involved in antimicrobial defense (e.g., the Reg family of antimicrobial proteins) in these two tissues.^{103,104}

It is important to note that T-cell priming depends on mDCs because imDCs may induce immunosuppressive or Tregs.^{105,106} In fact, antigen presentation by imDCs in vivo is an important pathway by which tolerance is maintained at both the CD4 and CD8 T-cell levels, either through the induction of Tregs or through the deletion of autoreactive T cells.¹⁰⁷ Nevertheless, recent data suggest that, in some conditions, mDCs can also induce the generation of CD4+CD25+ Tregs.^{108,109}

CD8+ T cells¹⁰⁵ and generation of effective CD8 memory cells in turn require CD4 T-cell help.^{110–112} This help is provided through activation of DC via CD40L–CD40 interactions and the production of cytokines such as IL-2, although some studies have suggested that when cytotoxic T-lymphocyte precursor frequencies are high, priming of CD8 T-cell responses may be CD4 T-cell-independent. In these cases, though, memory generation is likely to be hampered because of the absence of IL-2 during priming,¹¹³ and primed T cells may commit fratricide through expression of tumor necrosis factor-related apoptosis-inducing ligand (TRAIL),¹¹⁴ or they may become functionally tolerant upon receiving signals through the inhibitory receptor PD-1.¹¹⁵

Evidence is accumulating that pDCs, which were believed to play a role only in the innate immune response because of their ability to produce high levels of IFN type I, can present viral and tumor antigens to initiate both CD4⁺ and CD8⁺ T-cell responses.¹¹⁶ pDCs mature in response to certain viral infections (e.g., influenza and HIV), thereby providing an important link between innate and adaptive arms of the immune response. Similarly to their myeloid counterparts, however, pDCs display plasticity, even inducing immunosuppressive responses depending on their microenvironment or the stimuli to which they are exposed.¹¹⁷ Genetic depletion of pDCs, using transgenic mice expressing diphtheria toxin receptor under the control of BDCA2 promoter, has allowed dissecting precisely the role of pDC in antiviral responses. In the case of vesicular stomatitis virus infection, depletion of pDCs resulted in decreased specific CD8⁺ T-cell responses, but depletion of pDCs during lymphocytic choriomeningitis virus (LCMV) did not affect the magnitude of the

LCMV-specific CD8⁺ T-cell response. This suggests that pDCs may be required to enhance weak cytotoxic T-cell responses.¹¹⁸ A recent study targeting Siglec-H by conditional genetic ablation specifically induced specific pDC depletion and demonstrated a complex role of pDCs. Siglec-H and pDCs depleted pDC-suppressed, antigen-specific CD4⁺ T-cell responses in vivo, but they were required to enhance the CD8⁺ T-cell response to soluble and microbial antigens.¹¹⁹

B-CELL ACTIVATION

In addition to affecting T-cell function, DCs can also influence B-cell proliferation, isotype switching, and plasma cell differentiation.¹²⁰ DCs produce factors that activate and induce B-cell proliferation (B-Lys and APRIL).¹²¹ Furthermore, DCs stimulate antibody responses in a T-cell-independent manner against polysaccharide antigens. The initial interactions between B cells and DCs occur in the T-cell area of lymph nodes and in the germinal centers of lymph nodes or splenic red pulp (or both). Importantly, antigen-exposed cDCs possess a specialized nondegradative pathway that allows them to present internalized antigens in their native state for the engagement of B-cell receptors on B cells. This is mediated by endocytosis of antigenic immune complexes through the inhibitory Fc receptor FcγRIIB and recycling of the endocytic vesicle to the surface without antigen degradation.¹²² The follicular DCs, which are present in germinal centers of lymph nodes and which constitute a different class of DCs, participate in the maintenance of B-cell memory by formation of multiple antigen-antibody complexes and continuous stimulation of B cells. The antigen-antibody complexes may remain in the lymph node for an extended period of time (up to months or years).

NATURAL KILLER CELL ACTIVATION

The interactions between DCs and NK cells are complex and further underscore a role of DCs as a link between innate and adaptive immunity.⁸ Direct interactions between NK cells and mDCs can result in NK-cell activation as well as the potentiation of their cytolytic activity, and, conversely, NK cells can induce further DC maturation. NK cells and DCs can form an immune synapse, probably helping directional and confined secretion of cytokines as well as facilitating receptor-ligand interactions with one another. Activated NK cells induce DCs through both cell contact (involving NKp30) and TNF-α and IFN-γ secretion. In turn, activated DCs secrete IL-12/IL-18, IL-15, and IFN-α/β, which enhance IFN-γ secretion, proliferation, and cytotoxicity of NK cells. In some conditions, NK cells can lyse DCs through NKp30, although mDCs are protected from cytolysis. This might represent a form of “cellular editing” whereby immature and tolerogenic DCs (tDCs) are cleared by NK cells in the course of an ongoing immune response.¹²³

It is thus possible that DC and NK cells play complementary roles in sensing pathogens, such that DCs could be the first to detect microbes through their expression of PRRs (TLRs, NOD proteins), whereas NK may become activated in the absence of overt inflammation but in the presence of ligands for activating NK-cell receptors, such as in the setting of tumors (which frequently lose MHC class I expression or express NKG2D ligands, such as MHC class I polypeptide-related sequences A and B). In both situations, either DCs or NK cells could create an inflammatory environment and induce the integrated activation of other cell types. Thus, in mice, infection by murine cytomegalovirus (CMV) induces pDCs to secrete high levels of IFN-α/β, but CD8α⁺ DCs are the major producers of IL-12, and resistance to the virus is associated with expansion of Ly49H⁺ NK cells, driven by IL-12/IL-18.

The interaction between NK cells and DCs is likely to take place early during the course of an immune response. This allows DCs to exploit the ability of NK cells to kill tumor or virus- or parasite-infected cells and to cross-present this material to T cells.¹²⁴

ACTIVATION OF OTHER ELEMENTS OF THE IMMUNE SYSTEM

DCs have proven to be quite versatile in their ability to interact with many constituents of the immune system. For example, they can activate NK T cells by presentation of the synthetic ligand α-galactosyl ceramide on CD1, inducing the production of cytokines such as IFN-γ and resistance to tumors.¹²⁵ CD1-restricted γδT cells, which respond to microbial antigens from *Mycobacterium tuberculosis* and other organisms, induce maturation of resting DCs and also induce IL-12 production. This pathway and the IFN-γ secretion by activated γδT cells provide the immune system with a source of activated APCs, which can polarize Th1 responses.¹²⁶

In summary, the influence of DCs on other cell types of the immune system is broad and integrative (Fig. 23.3). Future studies will ascertain the interplay between the myriad host cells and the innate and adaptive immune responses.

TOLERANCE AND AUTOIMMUNITY

DCs play a pivotal role in the balance between immunity and tolerance. DCs are important in the induction of both central and peripheral tolerance. In the former, DCs play a role in deletion of autoreactive T cells in the thymus. In the latter, imDCs in their steady state induce T-cell deletion, anergy, or generation of Tregs, which interfere with IL-2 production and proliferation of effector T cells against self.¹²⁷

In the thymus, medullary thymic epithelial cells (mTECs) are the major population responsible for inducing central tolerance. Autoreactive T cells in the thymus are negatively selected upon recognition of self-antigens, which are expressed at low levels by mTECs via their expression of autoimmune regulator (AIRE) transcription factor. AIRE induces the release of stalled RNA polymerase II to promote the ectopic expression of these self-antigens.¹²⁸ Thymic DCs contribute to negative selection in that they can cross-present the self-antigens from mTECs to T cells in the thymus. DCs acquire antigen from apoptotic debris of mTECs, a consequence of normal turnover of the cells,¹²⁹ or they can acquire intact antigens via antigen transfer from mTECs,¹³⁰ a process that may occur by tunneling nanotubes,¹³¹ trogocytosis,⁵⁸ or trafficking of mTEC-derived exosomes.¹³² In this context, AIRE was also reported to control the transfer of antigen from mTECs to DCs.¹³³ Additionally, circulating DCs from the periphery have also been shown to migrate to the thymus and play a role in negative selection by inducing clonal deletion of autoreactive T cells or Treg development.¹³⁴

In the periphery, how DCs induce tolerance is still an area of active investigation, although a number of possible mechanisms have been identified. These processes are critical because they limit harmful immune responses to antigens that may not have been available during thymic selection, or from autoreactive T cells that may have escaped central tolerance.¹³⁵ In the steady state, antigen delivery via the endocytosis receptor DEC-205 in imDCs was shown to induce T-cell tolerance, highlighting a function of DCs as promoters of naive peripheral T-cell deletion.¹³⁶ Using a genetic approach, Probst and colleagues showed that antigen expression in steady-state DCs also induced strong CD8⁺ T-cell tolerance to immunodominant antigens and that this effect was dependent on negative costimulation via inhibitory receptors of the CD28 family, such as PD-1 and cytotoxic T lymphocyte-associated protein 4 (CTLA-4).^{127,137}

Production of indoleamine 2,3-dioxygenase (IDO) has been proposed to account for some of the tolerogenic potential of DCs.¹³⁸ IDO is an enzyme that degrades the indole moiety of tryptophan and other molecules and induces the production of immunoregulatory metabolites known as *kynurenines*. Local depletion of tryptophan and increases in proapoptotic kynurenines affect T-cell proliferation and survival. Induction of IDO in DCs has been postulated as one means by which deletional tolerance occurs.¹³⁸ DC-derived IDO can promote T-cell tolerance by mechanisms that may or may not depend

Fig. 23.3 DENDRITIC CELLS (DCs) LINK INNATE AND ADAPTIVE IMMUNITY. Through the expression of pattern recognition receptors (PRRs), such as Toll-like receptors, DCs act as sensors of pathogen intrusion. Upon signaling by PRRs, DCs secrete cytokines and express receptors, allowing stimulation of the innate immune system. Interferon- α (IFN- α) or interleukin-12 (IL-12) stimulates natural killer (NK) cell activation while also inducing the expression of death receptor ligands (tumor necrosis factor-related apoptosis-inducing ligand, or TRAIL) on DCs, harnessing them for direct killing of infected cells. They take up antigens through direct infection or phagocytosis, undergo a complex program of maturation by upregulating the expression of costimulatory and major histocompatibility complex (MHC) molecules, migrate to the secondary lymphoid organs, and stimulate naive T cells. They secrete cytokines, skewing the type of response induced toward Th1, Th2, regulatory T cell (Treg), or Th17 differentiation; inducing the generation of cytotoxic CD8 T cells; or participating in the generation of antibody responses. *pDC*, Plasmacytoid dendritic cell; *TGF*, transforming growth factor.

on IDO's catalytic activity. Moreover, expression of death-inducing ligands such as FasL or perforin may render DCs capable of killing activated T cells and exerting an immunoregulatory role.^{136,139,140}

In addition to T-cell deletion and anergy, DCs contribute to peripheral tolerance largely via induction of Tregs. tDCs are known to promote Tregs via secretion of particular stimuli, such as TGF- β or RA, and the maintenance of Treg numbers was shown to be dependent on tDC expression of costimulatory molecules CD80 and CD86.¹⁴¹ Tregs are CD4⁺ or CD8⁺ in nature and express CD25, CTLA-4, lymphocyte activation gene 3 (LAG3), Helios, and the transcription factor Foxp3 (a member of the Forkhead transcription factor family). These cells exert their tolerogenic effects either via cell contact or through release of immunosuppressive cytokines such as IL-10¹⁴² or TGF- β , preventing proliferation and cytotoxicity of activated CD4 or CD8 T cells, and can also inhibit TLR-mediated maturation of cDCs but not pDCs.¹⁴³ Tregs are fundamental to the maintenance of the tolerogenic potential of DCs, and Foxp3⁺ Treg depletion studies highlighted the role of these cells in preserving DCs in a nonmature state. Furthermore, this effect was mediated by direct TCR-MHC class II interactions between Tregs and DCs.^{144,145} Also, pDCs activated through TLR7 or TLR9 upregulate the expression of IDO and can induce the generation of Tregs from naive CD4⁺ T cells.¹⁴⁶

There are several mechanisms by which Tregs are thought to exert their suppressive functions on DCs. One example is Treg-induced downregulation of CD70 expression in DCs, which is essential for the tolerogenic role of these cells.¹⁴⁷ Another mechanism of suppression by Tregs is via their coinhibitory molecules, such as CTLA-4 and LAG3. CTLA-4 from Tregs was shown to induce downregulation of CD80 and CD86 on DCs, whereas LAG3 was shown to suppress DC

activation via direct binding to MHC class II molecules.^{148,149} Finally, DCs are also targeted by TGF- β -dependent suppression; however, whether this is a Treg-mediated suppression is still unclear.¹⁵⁰

Altogether, these properties of DCs make them attractive candidates for inducing tolerance in the setting of transplantation or autoimmunity. Indeed, injection of antigen-pulsed imDCs in vivo induces antigen-specific IL-10-producing CD8⁺ Tregs, which supplant their IFN- γ -producing effector cell counterparts.^{105,151}

DCs may also be actively rendered tolerogenic via a number of mechanisms. Resting imDCs acquire self-antigens through phagocytosis of apoptotic bodies formed as a consequence of physiologic cell turnover. In the absence of a maturation signal, these DCs induce tolerance to such self-antigens.¹⁵² Some studies have suggested that ligation of specific receptors on DCs, such as complement receptors CR3 and CR4, by apoptotic cells or apoptotic microparticles inhibit their maturation, thereby ensuring the delivery of a tolerogenic rather than stimulatory signals.¹⁵³ Others include MER, CD91/calreticulin, CD36/ $\alpha_v\beta_3$, and CD44.¹⁵⁴ External factors such as steroids, IL-10, and TGF- β may also compromise DC immunostimulatory function by inhibiting their full maturation.¹⁵⁵ For example, DCs isolated from tumor environments are poorly immunostimulatory because of the presence of immunosuppressive cytokines or the induction of costimulatory molecules, such as PD-L1, which deliver negative signals.¹⁵⁶ Moreover, there may exist distinct tDC subsets. A particular DC subset was identified in normal mice that were CD11c^{low}/CD45RB^{high}, secreted IL-10 after activation, and induced tolerance through induction of Tregs.¹⁵⁷ In mice, pDCs have recently been shown to induce tolerance against a vascularized cardiac allograft upon administration of a tolerizing regimen.¹⁵⁸ After capturing pDC alloantigens from the graft, they migrated to peripheral lymph nodes

and induced specific Tregs.¹⁵⁸ Human DC deficiencies are associated with a loss of Tregs, and it seems that DCs and Tregs reciprocally control each other's expansion, where DCs control Treg expansion and Tregs control DC numbers through an Flt3-dependent feedback loop.

The tolerogenic function of DCs can also be regulated intrinsically by signaling molecules such as NF κ B, a key regulator of DC function; A20, a ubiquitin-editing enzyme that is implicated in the degradation of molecules that activate NF κ B, negative regulators of NF κ B (CD31), and mammalian target of rapamycin (mTOR); and β -catenin, which promotes the tolerogenic activity of DCs.^{159–164}

Although DCs promote tolerance via a variety of mechanisms, they are also known to play a role in autoimmunity through activation and differentiation of self-reactive T cells, a process that can be triggered either by inappropriate activation of DCs or by the collapse of negative regulation. Constitutive depletion of DCs in mice results in a syndrome resembling autoimmunity that was accompanied by increased CD4⁺ T-cell infiltration in peripheral tissues, higher Th1 and Th17 cell numbers, autoantibody formation, and neutrophilia.¹⁶⁵ In the steady state, DCs participate in maintaining tolerance, but this balance can be altered by changes in DC number, phenotype, and function.¹⁶⁶ In proinflammatory settings, or when there is an absence of regulatory molecules to control DCs, they can potentially present self-antigens to naive T cells, thus promoting self-reactive T-cell activation and contributing to autoimmunity.¹⁶⁷ DCs are also believed to be important for the induction of the chronic phase of autoimmune diseases. Some of these conditions are discussed in more detail later.

DCs from patients with SLE exhibit altered CD40, CD86, and Fc γ receptor expression¹⁶⁸ and have altered PD-L1 expression, which can modulate T-cell suppression.¹⁶⁹ Activated cDCs (possibly through immune complexes or cell-derived microparticles) may promote lupus pathogenesis by presenting RNA-associated proteins and chromatin to self-reactive T cells.¹⁷⁰ In mouse models of SLE, activated DCs also enhance B-cell proliferation, IL-6 and IFN- γ secretion, and antinuclear antibody production.^{171,172} IFN- α produced by pDCs is thought to contribute to the autoimmune response in SLE.^{173–176} pDCs can be activated through TLR7 and TLR9 by immune complexes containing RNA and DNA, respectively, from dead cells and induced to secrete high amounts of IFN- α . This can further promote the differentiation of monocytes into activated cDCs, thus enhancing presentation of self-antigens, increasing the cytotoxicity of CD8 and NK cells, and promoting plasma cell differentiation and subsequent generation of pathogenic autoantibodies. Several host factors can convert self-DNA into triggers of pDC activation. For example, the antimicrobial peptide LL-37 forms large aggregates with self-DNA released from dying cells, protecting it from extracellular nuclease digestion, and is taken in pDCs for induction of type I IFN. LL-37 has been found to be overexpressed in psoriatic skin, and the gene encoding LL-37 is the most upregulated in the blood of patients with lupus.¹⁷⁷

A role of cDCs during disease onset is also strongly suggested in arthritis, multiple sclerosis, diabetes, and atherosclerosis.^{178–180} The similarity between outcomes of microbial infection and autoimmunity suggests that TLRs or PRRs triggered by microbial molecules on DCs induce their maturation and secretion of cytokines and chemokines. This may cause DCs to upregulate presentation of self-antigens in instances such as apoptosis or necrosis induced directly by pathogens or antimicrobial immune response. Endogenous ligands such as extracellular matrix breakdown products (heparan sulfate and hyaluronate), molecules released from necrotic cells (high-mobility group box 1 protein [HMGB1], uric acid, or even endogenous nucleic acids), fibronectin, and HSPs, which can activate TLRs on cDCs, may also contribute to the generation of autoimmune responses.¹⁸¹

In rheumatoid arthritis (RA), DCs migrate into the synovium, where they produce proinflammatory molecules that concentrate in the vicinity of T cells, thereby possibly contributing to overall inflammation. DCs are hypothesized to regulate the production of autoantibodies in RA, and a correlation between DC numbers and concentration of anticitrullinated peptide antibodies in RA sera has

been found.¹⁸² Additionally, the transfer of mature, collagen-pulsed DCs is sufficient to induce arthritis in a mouse model through induction of local inflammation and priming of autoreactive T cells.¹⁸³ DCs are currently being used to “tolerize” patients with RA in vivo. DCs suppressed with a NF κ B inhibitor and exposed to four citrullinated peptide antigens were recently shown to reduce effector T cells, increase the ratio of regulatory to effector T cells, and reduce serum cytokines and chemokines and a T-cell response to citrullinated vimentin.¹⁸⁴

An anomalous or persistent activation of DCs in the intestine in response to infectious agents with release of proinflammatory cytokines can activate innate and adaptive immune cells, thus contributing to the establishment of a noxious environment in the gut.^{185,186} The dysregulation of DC function (related to pathogen recognition and antigen presentation) was shown to be critical in driving pathologic inflammation in IBD.¹⁸⁵

DCs residing at the perivascular space of the blood–brain barrier act as gatekeepers, presenting antigens to migrating T cells and thus contributing to inflammation in the central nervous system (CNS).^{187,188} However, experimental autoimmune encephalomyelitis (EAE) can be induced in the absence of DCs, and the conditional depletion of DCs does not affect pathogenic Th priming in this model.^{189,190} Thus DCs contribute to the onset of EAE, but they are not strictly necessary for it, and other APCs might promote harmful T-cell differentiation.

DCs play a tolerogenic role in preventing type 1 diabetes,¹⁹¹ but they can promote it if, in an activated state, they cross-present β -cell antigens to T cells, initiating pathogenic T-cell differentiation.¹⁹² A distinct subset of AIRE⁺ DCs was described to express antigen insulin derived from β -cells, suggesting a role for tDCs in controlling activation of insulin-reactive T cells.¹⁹³

Overall, DCs play an important role in the development of autoimmune disease, either via direct activation of self-reactive T cells or indirectly because of the proinflammatory environment that they can create with secretion of cytokines and reduction of Tregs. When considering treatment approaches for these autoimmune diseases, there is a need to identify and define the balance between regulatory and pathogenic DC roles.

SUBVERSION OF DENDRITIC CELL FUNCTION BY PATHOGENS AND TUMORS

Several pathogens have evolved different mechanisms to inhibit DC functions, allowing them to downregulate specific immune responses and hence persist in the host. Numerous viruses, such as measles, vaccinia, herpes simplex, smallpox, and LCMV, can impair antigen presentation by infected cells through different mechanisms. Thus human CMV induces downmodulation of MHC class I or class II molecules and can inhibit activated T cells through secretion of a virally encoded IL-10 homolog. Directly targeting DCs allows viruses to impair the generation and quality of the antiviral immune responses. In mice, CMV has been shown to trigger paralysis of infected DCs, preventing them from secreting IL-12 or IL-2 upon TLR4 triggering, impairing their capacity to mature, and eventually rendering them unable to prime an effective T-cell response.¹⁹⁴ Some viral products interfere with IFN- α secretion pathways, such as the E6 oncoprotein of human papillomavirus, inhibiting transactivation of IRF3 or IRF7, or NS3/4A inhibiting RIG-I- and MDA5-mediated activation of IRF3.

It is now well documented that in HIV-infected patients not only are the number of pDCs and cDCs in blood reduced, but cDCs are also less efficient at stimulating primary T-cell responses and may generate IL-10-secreting T cells with a potential regulatory role. DCs, such as Langerhans cells, may be the first cells to encounter HIV in mucosal tissues and may mediate the spread of virus to CD4⁺ T cells in lymphoid organs. Formation of virions and release from the cell surface are counteracted by tetherin, an IFN-regulated restriction factor that retains virions at the cell surface. The Vpu accessory protein antagonizes tetherin activity to allow virion

release. cDCs can mediate transinfection of CD4⁺ T cells through the formation of an infectious synapse, carrying the virus with or without infection of the DCs themselves. DCs express the coreceptors CD4, CCR5, CXCR4, and the C-type lectin DC-SIGN necessary for binding or entry of HIV. HIV can infect DCs, but its replication is not as efficient as in CD4⁺ T cells because of expression of the viral restriction factor SAMHD1, a deoxynucleoside triphosphate triphosphohydrolase. SAMHD1 functions to reduce cellular dNTP pools, thus reducing reverse transcription, although its restriction activity may be separate from its trihydrolase activity.¹⁹⁵ Under permissive conditions, however, HIV can induce the production of the cyclic dinucleotide cyclic guanosine monophosphate-adenosine monophosphate (cGAMP) via the cytosolic sensor cGAMP synthase (cGAS), suggesting that cGAMP can bypass the block of innate immune responses against HIV.¹⁹⁶ Under these conditions, HIV induces type I IFN production in monocyte-derived DCs that is dependent upon activation of the STING pathway. Recent studies have shown that polyglutamine binding protein 1 (PQBPI) directly binds to reverse-transcribed HIV-1 DNA and interacts with cGAS to generate cGAMP, which in turn primes an IRF3-dependent innate response.¹⁹⁷ Virions formed in cGAMP-expressing cells have the capacity to trigger a STING-dependent antiviral program in newly infected cells. Indeed, cGAMP-loaded lentiviruses are able to activate DCs, revealing a new way by which innate immunity can be transferred between cells.¹⁹⁸ The cGAS pathway is the only signaling pathway triggered by HIV in monocyte-derived DCs thus far. TLR7 and TLR8 do not appear to play a role in this respect.¹⁹⁹

The viral envelope protein gp120 can bind to CD4 and C-type lectins such as DC-SIGN and mannose receptor, but the contribution of each receptor to binding and internalization may vary, depending on the particular type of DC encountered by HIV. Thus, although DCs are not the main reservoir of HIV, the virus can “highjack” DCs to mediate its spread to CD4⁺ T cells from mucosal tissues to lymphoid organs. Nevertheless, although cDCs are only minimally activated by HIV, pDCs can become infected and strongly activated by HIV, causing them to secrete high amounts of IFN- α and other antiviral molecules. This can inhibit the replication of HIV in CD4⁺ T cells, suggesting that the two subsets play different and opposing roles during HIV infection. However, pDCs may also function to downregulate the response by secreting TRAIL.^{200,201} Furthermore, the continuous secretion of IFN- α by pDCs stimulated by HIV may be detrimental to the host by participating to chronic immune activation and CD4⁺ T-cell depletion.

Tumors also evolve mechanisms to negate the functionality of DCs. For example, the number of cDCs (but not pDCs) is reduced in the blood of patients with cancer, and these numbers of DCs are restored upon surgical removal of the tumor, indicating a systemic defect orchestrated by the tumor cells. Moreover, increased numbers of imDCs are found in blood and tumor tissue, also displaying an impaired response to activation stimuli. A subset of immature myeloid cells, composed of immature macrophages, DCs, granulocytes, and myeloid cells at early stages of differentiation, accumulate in the secondary lymphoid organs and tumors of tumor-bearing mice and presumably humans. These myeloid suppressor cells are endowed with suppressive activity toward antitumor T cells through various mechanisms, such as regulation of arginine metabolism and release of ROS. In some tumors, IDO-expressing pDCs are found in significant numbers, thereby decreasing availability of tryptophan and generating tryptophan catabolites. IDO-expressing pDCs can activate intratumoral (IT) Tregs. It seems that tumors impair early myeloid, and in particular DC, differentiation at a systemic level by secreting soluble factors such as VEGF, macrophage colony-stimulating factor, IL-6, and IL-10. Macrophage-derived IL-10, for example, blocks IL-12 production by DCs and prevents the induction of tumor-specific CD8⁺ T cells.²⁰² Many tumors constitutively express activated STAT3, a transcription factor partially implicated in the production of these cytokines, the constitutive activation of which also impairs the secretion of proinflammatory cytokines. STAT3 is also responsible for abnormal differentiation of hematopoietic precursor cells,

suggesting that inhibition of its activity may be a promising route to restoring DC function in cancer. The tumor microenvironment (TME) thus profoundly affects the function of infiltrating DCs and T cells, and it has recently been shown that overexpression of matrix metalloproteinase-2 (MMP-2) conditions DCs to produce low levels of IL-12 and to express OX40L, which biases antitumor CD4⁺ T cells toward suboptimal Th2 differentiation.²⁰³ This pathway has been shown to involve the interaction of MMP-2 and TLR2 on DCs.²⁰⁴ There can also be a failure of recruitment of DCs into the TME. For example, upregulation of a tumor-intrinsic WNT/ β -catenin signaling pathway is associated with poor T-cell infiltration into the TME of melanoma tumors.²⁰⁵ These tumors are defective in CCL4 production, leading to a failure to locally recruit CD103/CD8 α -lineage DCs, the murine equivalent of human CD141⁺ DCs. CD103⁺ DCs are critical for the induction of T-cell immunity, and increased frequencies of these cells are correlated with improved clinical outcomes.²⁰⁶

Immunotherapeutic Strategies and Clinical Trials

The past decade has seen increasing interest in clinical applications of DCs by harnessing the growing knowledge about DC biology. It is becoming apparent that any effective vaccine must activate and induce antigen presentation by DCs, the most potent cells at stimulating T-cell immunity. A number of clinical trials (mostly phases I and II) have been completed describing the use of DCs in cancer immunotherapy (e.g., non-Hodgkin lymphoma, malignant melanoma, multiple myeloma, prostate cancer, renal cell carcinoma, breast cancer) and in the immunotherapy of human pathogens such as HIV. Most of these studies have relied on monocyte-derived DCs, but a few have used DCs prepared from CD34⁺ HPCs. A critical issue is antigen delivery to the DCs and the type of DC, with the nature of the antigen and the vehicle for delivery probably being decisive. DCs can be pulsed with defined antigens in the form of human leukocyte antigen-binding antigenic peptides or whole proteins or the whole assortment of tumor antigens upon phagocytosis of dying or opsonized autologous tumor cells. Artificial fusion of DCs with tumor cells allows the generation of hybrid cells with characteristics of DCs but expressing the whole set of tumor antigens as well. Because autologous tumor cells are not always available from patients with advanced disease, allogeneic tumor cells of the same histologic origin expressing shared tumor antigens are also used for loading DCs.

DCs themselves can also be genetically modified through transfection. However, DCs are terminally differentiated nondividing cells and often challenging to transfect. Methods using RNA electroporation and infection by recombinant viruses (lentivirus, poxvirus, herpes virus, and adeno-associated virus) lead to foreign transgene expression in DC. Another strategy is to target DCs *in situ* using antibodies recognizing DC-specific molecules, such as DEC-205, as demonstrated in mouse models²⁰⁷ and more recently in patients with cancer.²⁰⁸ A phase II trial that involved priming by a recombinant vaccinia virus encoding prostate-specific antigen and the “tricom” CD80, intercellular adhesion molecule-1, and lymphocyte function-associated antigen 3 and boosting by a fowlpox virus gave promising clinical results in patients with prostate cancer. GM-CSF was injected at the same time to further amplify immune stimulation. This vaccine was designed to mimic antigen presentation by DCs, even in an incomplete way, and induce significant overall survival benefit.²⁰⁹ A phase III study using this approach is currently underway.

Because the activation state of antigen-presenting DCs is a determining factor in shaping the ensuing immune response, genetic engineering of DCs or triggering activating receptors also allows enhancing their secretion, migration, and antigen presentation capacity. Thus DCs can be activated by artificial TLR ligands (e.g., R848, which is a ligand for TLR7; unmethylated CpG oligonucleotides, which are ligands for TLR9; or inflammatory cytokines, such as type I IFNs, IL-1 β , IL-6, or TNF- α) that can be used in a clinical setting to activate DCs before injection or even *in vivo*.²¹⁰ DCs can also be

transfected for immunostimulatory molecules, such as cytokine genes (e.g., IL-2, IL-12), or inhibitory small interfering RNA for molecules dampening DC activation (e.g., suppressor of cytokine signaling 1 [SOCS1]).

The first U.S. Food and Drug Administration–approved, cell-based antitumor vaccine, Sipuleucel-T (Dendreon, Seattle, WA), comprising a partially enriched preparation of blood APCs pulsed with a recombinant fusion protein of human prostatic acid phosphatase and GM-CSF and given intravenously, is approved for the treatment of castration-resistant prostate cancer.²¹¹ The vaccine resulted in modest improvement in overall survival, indicating a need to further improve DC-based vaccines in the clinic. Several trials tested over the past two decades have established that DC vaccines are safe, and evidence of their immunogenicity is not in dispute. However, there remains no standardized protocol for their ex vivo manipulation. The optimal source of DCs (monocyte-derived, circulating differentiated DCs, DCs derived from CD34⁺ progenitors), antigen loading, maturation stimulus, and route of delivery are still in contention, and, until appropriately compared, it is difficult to reconcile studies that have addressed these variables.²¹²

To improve immunogenicity, DC vaccines are being manipulated in novel ways. For example, they are being loaded through electroporation with RNA that encodes tumor-associated antigens²¹³ or costimulatory molecules (CD40L, CD70, and constitutively active TLR4) or delivered directly into lymph nodes to improve access to secondary lymphoid organs or even intratumorally.²¹⁴ Because skin injections of DCs result in just a small percentage of cells migrating to draining nodes, investigators are preconditioning the vaccine site to stimulate local production to enhance their migration to draining lymph nodes.²¹⁵ DC–tumor cell hybrids are also being explored as immunogens. With newer methods to readily expand CD34⁺ HPCs from blood, the concept of using these progenitors to derive large numbers of more immunogenic DC subsets (e.g., CD141⁺ DCs) is a future target. The ability to use the CRISPR (clustered regularly interspaced short palindromic repeats)/Cas9 system for gene editing may further facilitate manipulation of DCs, such as to prevent expression of inhibitory molecules or cytokines to improve their effectiveness in vivo or to preferentially drive CTL differentiation. Flt3L is being used to systemically increase the pre-cDC pool and/or to target DCs in vivo using cancer antigens fused to monoclonal antibodies targeting DC surface receptors (e.g., DEC-205).²⁰⁸ This approach is also being tested in combination with decitabine and the IDO inhibitor INCB024360, which suppresses Treg generation. Other receptor targets under consideration for DC targeting include CD40, mannose receptor, DC-SIGN, DCIR, Clec9A, and XCR1.

Indirect approaches to targeting DCs include the use of vaccines that employ tumor cells expressing GM-CSF (GVAX), which are demonstrating evidence of immunogenicity and clinical activity in vivo, viral or bacterial vectors that can infect and mDCs (vaccinia virus, *Listeria monocytogenes* constructs), implantable scaffolds that recruit DCs through expression of TLR agonists and GM-CSF,²¹⁶ and exosomes derived from DCs (dexosomes).

Altogether, DC interventions have clear immunologic and in some cases small clinical impact. Beyond Sipuleucel-T, however, no other DC-based vaccine has reached approval in the clinic. The outcomes of phase III trials that are testing DCs' immunogenicity in renal cancer and glioblastoma multiforme are pending. Ultimately, DCs may be more effective when given as immune prevention after tumor resection or in the neoadjuvant setting, where early studies suggest they may have impact.²¹⁷

Novel approaches to target DCs in situ include the concept of IT vaccination. IT injection of the CpG oligonucleotide (PF-3512676) in low-grade B-cell lymphoma, thus targeting TLR9 on pDCs and B cells, has led to complete and partial clinical in several patients with induction of tumor-specific CD8 T-cell responses.^{218,219} Tumor regression was observed in injected and distant tumor sites. IT approaches are being tested with other immune modulators, such as poly(I:C), a TLR3 and MDA5 agonist,²²⁰ and in combination with antibodies that target checkpoint molecules, such as CTLA-4 and PD-1. Oncolytic viruses are gaining momentum when they are

delivered either IT or systemically. The rationale is that they destroy cancer cells, making them available to be recognized by the immune system. They can be engineered to prevent replication in normal cells. The herpes simplex virus (HSV)-based product talimogene laherparepvec (T-VEC), which is an HSV-engineered oncolytic virus that also expresses GM-CSF (to attract and differentiate DCs) improved the durable response rate in advanced unresectable melanoma (16.3% in the treated group versus 2.1% in subjects receiving only GM-CSF; $p < 0.001$).²²¹ T-VEC is now being tested in combination with ipilimumab or pembrolizumab (anti-PD-1), and early results of the T-VEC and ipilimumab trial appear to be showing synergistic activity. T-VEC has now been approved for the treatment of unresectable melanoma.

Anticancer vaccination can be used in synergy with chemotherapy and radiotherapy. The rationale is that chemotherapy and radiotherapy trigger tumor cell death, which provides a source of tumor antigens to DCs while inducing exposure of immunogenic molecules on tumor cells²²² (Fig. 23.4). Thus anthracycline-treated tumor cells expose the ER chaperones calreticulin and Erp57 because of induction of an ER stress response and potentiate dying tumor cell phagocytosis. Death of tumor cells as a result of radiotherapy is also accompanied by release of nonhistone chromatin-binding nuclear protein HMGB1, which can trigger TLR4 and, in response to taxanes, ATP, which, upon binding to P2RX7 on APCs, potentiates inflammasome activation and IL-1 β release. Finally, cyclophosphamide can cause, through release of tumor-associated nucleic acids, induction of type I IFN.²²² Increased uptake of tumor antigen in the context of maturation signals strongly enhances cross-presentation and cross-priming of tumor antigens by DCs.

Thus far, DC vaccines have not met the desired endpoints in clinical studies (i.e., tumor regression) in the majority of patients, despite clear evidence that DC vaccination can induce measurable cellular or humoral immune responses in patients with cancer.^{223–226} It is likely that, to achieve significant clinical responses upon vaccination for cancer, combining DC vaccination with other strategies will improve the therapeutic outcome. For example, some strategies are aimed at depleting or inactivating Tregs (using a toxin targeting CD25, a molecule expressed by Tregs, or cyclophosphamide), alleviating T-cell anergy (using antagonistic CTLA-4 or PD-1), and differentiating myeloid suppressor cells into nonimmunosuppressive cells (by injection of RA derivative ATRA [all-*trans* retinoic acid]), injection of common γ -chain cytokines such as IL-7, which have potent effects on T-cell survival and function, or adoptive immunotherapy of in vitro activated T cells.^{227,228} Irradiation of the tumor tissue conditions it for enhanced migration of APCs and T cells, augments MHC class I expression on tumor cells, and induces apoptotic cell death, thus augmenting delivery of tumor antigens to DCs.^{229–231} The identification of specific surface receptors regulating DC–T-cell interaction and T-cell activation and differentiation allowed use of targeting antibodies functioning as immune modulators. Thus agonistic antibodies targeting glucocorticoid-induced TNF receptor (GITR), OX40, CD137, or CD40 or cytokines potentially enhancing cytotoxic T-cell responses, such as IL-15, can be harnessed to enhance vaccine-induced antitumor immune responses. Researchers in ongoing trials are testing DCs in combination with antibodies that inhibit checkpoint molecules (e.g., CTLA-4, PD-1), radiation, cytokines (IL-7), and drugs (e.g., enzulutamide [for prostate cancer] and agents that reduce Tregs [cyclophosphamide, temozolomide]), among other strategies.

In the authors' opinion, DC immunotherapy will be most efficacious when coadministered with one or more additional interventions and when the tumor burden is low. The timing of vaccination is probably also crucial, and frequent immunizations may dramatically improve clinical efficacy.²³² In the setting of HIV infection, a recent study of a small group of chronically infected individuals showed that vaccination with DCs loaded with chemically inactivated virus allows stabilization and even suppression of viral load for an extended period of time without any other treatment.²³³ Vaccination with DCs holds great promise in cancer and infectious diseases, but its potential is likely to be best exploited in combination with other strategies manipulating other arms of the immune system.

A. Compromised immunity in advanced cancer

B. Cancer vaccines

Fig. 23.4 ROLES OF CANCER VACCINES. In advanced tumor settings, tumor immunity is compromised in several ways (A). The dendritic cells (DCs) in the tumor are deregulated, and there is also evidence of T-cell exhaustion mediated by inhibitory signals such as cytotoxic T lymphocyte-associated protein 4 (CTLA-4), programmed cell death protein 1 (PD-1), lymphocyte activation gene 3 (LAG3), and T-cell immunoglobulin and mucin domain containing-3 (TIM3). In the tumor bed, there is an immunosuppressive environment with secretion of interleukin-10 (IL-10) and transforming growth factor-β (TGF-β) as well as the presence of immunosuppressive cells such as regulatory T cells (Tregs) and myeloid-derived suppressor cells (MDSCs). The goal of cancer vaccines is to improve antitumor immunity (B), and this can be achieved with numerous approaches, such as DC activation and recruitment into tumors (with the use of DC-based or targeted vaccines) and T-cell activation or checkpoint inhibitor blockade (anti-CTLA-4, anti-PD-1, or anti-PD-L1). Additionally, to reverse inhibition in the tumor microenvironment (TME), methods to induce immunogenic cell death (x-ray therapy [XRT] and chemotherapy) and to target tumor-specific peptides can be implemented. *dLNs*, Draining lymph nodes; *IDO*, indoleamine 2,3-dioxygenase; *mAbs*, monoclonal antibodies; *MHCI*, major histocompatibility complex class I; *VEGF*, vascular endothelial growth factor.

Although DCs are considered the most potent cells in inducing T-cell responses, they can also function as tolerizing cells, a function that can be harnessed against autoimmune diseases and in a transplant setting. Thus it is possible to differentiate in vitro maturation-resistant imDCs or differentially activated DCs using biologic agents such as IL-10, TGF-β, or the fusion protein CTLA-4-Ig, as well as pharmacologic agents such as corticosteroids, cyclosporine, rapamycin, mycophenolate mofetil, vitamin D₃, or prostaglandin E₂ or inhibitors of NFκB.¹⁸⁴ The clinical relevance of some of these strategies is being evaluated in autoimmune diseases such as RA. Another way

to dampen pathologic immune responses is to use antagonists for TLRs or other innate immune sensors participating in amplifying damaging responses. Thus, because the role of DNA-immune complexes has been established as important in the etiology of SLE, synthetic inhibitory oligodeoxyribonucleotides have been developed that can prevent or inhibit activation through TLR9 on pDCs and B cells and block SLE in animal models. Finally, significant challenges remain with respect to DC-based immunotherapy, including the applicability of preclinical models to humans as well as regulatory and funding hurdles.

FUTURE DIRECTIONS

DCs are a sparsely distributed population of BM-derived mononuclear cells that exist in an immature form in virtually all tissues in the body. DCs serve as professional APCs with extraordinary capacity to stimulate naive T lymphocytes (as well as B cells, NK cells, and NK T cells) and initiate primary immune response. They link innate and adaptive immunity and are responsible for activation and inhibition of effector cells. Their clinical applications in cancer, transplantation, and chronic viral infections are under investigation. Promising approaches to enhance their recruitment and promote their activation to improve adaptive immune responses are being tested in the clinic.

COMPLEMENT AND IMMUNOGLOBULIN BIOLOGY LEADING TO CLINICAL TRANSLATION

David J. Araten, Robert J. Mandle, David E. Isenman, and Michael C. Carroll

This chapter is divided into four parts. The first part details the current understanding of the activation and biology of the complement system and how it links innate and adaptive immunity. The second part focuses on immunoglobulins and their importance in protecting against disease. The third part discusses immunoglobulins as therapeutic agents, and the fourth part discusses therapies, including monoclonal antibodies, that target the complement system.

THE COMPLEMENT SYSTEM: AN OVERVIEW

Complement refers to a family of distinct proteins that play a pivotal role in host defense against infection. In the 1880s, the serum factors involved in host response to pathogens were placed into two categories based on sensitivity to heat. Whereas the heat-stable component, antibody, was recognized as being specific for the invading pathogen and arose after immunization, the heat-labile ($>56^{\circ}\text{C}$ [133°F]) fraction displayed nonspecific killing activity. The heat-labile fraction acted to complement the antibody-mediated lytic killing of targeted organisms.¹⁻³

In addition to its lytic role in the effector arm of the antibody response, the complement system serves several other functions. First, components of the complement system are involved in clearance of targeted microorganisms by the process of opsonization. *Opsonization* is the coating of a particle with proteins that facilitate phagocytosis of the particle by tissue macrophages and activated follicular dendritic cells (FDCs) as well as binding by receptors on peripheral blood cells.^{4,5} Second, complement promotes inflammation by releasing small peptide fragments from complement proteins. These peptides cause mast cell degranulation, smooth muscle contraction, and directed migration (chemotaxis) of motile cells to sites of inflammation.^{6,7}

Complement can be activated via three distinct pathways: classical, lectin, and alternative. Although all depend on different molecules for their initiation, eventually they converge to generate the same set of effector molecules. Each of these pathways is described here (Fig. 24.1).

Classical Pathway

The classical pathway (CP), so called because it was the earliest studied arm of the complement system, directly links the innate and acquired immune systems. There are nine proteins in the CP. As a matter of terminology, each CP component protein is designated with an uppercase C followed by a number. Fragments of these proteins generated by cleavage during the complement cascade are designated with a lower-case letter suffix (e.g., C3a, C3b). In general, the smaller product arising from a proteolytic activation step is given the fragment designation “a,” and the larger product is designated “b.” The sole exception to this rule is for the naming of the C2 proteolytic activation fragments, where, for historical reasons, the larger fragment is C2a and the smaller one is C2b.

C1, the first component of the CP, binds and is activated by the Fc portion of the antibody molecule. C1q is a macromolecule complex composed of three individual protein subunits: C1q, C1r, and C1s.⁸⁻¹² The largest of these subunits, C1q, is an 18-chain molecule with six copies each of three chains: A, B, and C.

Structurally, C1q consists of a central core with six radiating arms. Each arm possesses a triple helical structure similar to collagen that is capped at the end with a head region consisting of a quaternary assembly of the globular domains from each of chains A, B, and C. C1q, largely through ionic interactions, links the C1 complex to the antibody molecule. In addition to its capacity for binding to antibody molecules, C1q possesses the capability to bind directly to the surfaces of some microorganisms and apoptotic cells, not unlike mannan-binding lectin (MBL; see lectin pathway discussion, later).

Associated with C1q are two molecules each of C1r and C1s. In unactivated C1, C1r and C1s are proenzyme serine esterases. Upon binding of C1q with an array of target-associated immunoglobulin G (IgG) Fc regions, or directly to surface molecules of the pathogen, a conformational change occurs that leads to reciprocal autoactivation of the associated C1r molecules. The active form of C1r then cleaves its associated C1s to generate an active serine protease.

Activated C1s is responsible for cleaving C4 and C2, the next two proteins in the complement pathway. Cleavage of C4 yields two fragments: C4a and C4b. C4b possesses a highly reactive thioester group that allows it to bind covalently to molecules in the immediate vicinity of its active site. Only a small proportion of the C4b produced binds to proteins or carbohydrates on the targeted surface; the rest is inactivated by reaction with water in the surrounding milieu. This helps to prevent inadvertent C4b binding to surrounding host cells.

C2, the next substrate in the CP cascade, is susceptible to cleavage by C1s. Upon association with C4b, C2 is cleaved by activated C1s into two fragments: C2a and C2b. C2a, which is now an active serine protease, remains bound to C4b, thereby confining it to the targeted surface. C4b2a is termed the *C3 convertase*, an enzymatic complex that is responsible for binding and cleaving C3, the next component in the cascade. The function of the C3 convertase is to cleave large numbers of C3 molecules to produce C3b and C3a. Nascently activated C3b, similar to C4b, also possesses a highly reactive thioester bond, allowing a portion of the nascent C3b to covalently bind to the targeted surface (opsonization of the target) and thereby mark it for phagocytosis. The activated thioester in the bulk of the nascent C3b becomes water hydrolyzed and can no longer bind to a target. By contrast, all of the C3a fragment remains in solution, where it initiates a local inflammatory response.

An Ig-independent mechanism for activation of C1q has been identified.¹³ The lectin protein Sign R1, which is expressed on a subset of macrophages within the outer marginal zone sinus of the spleen, is capable of capturing to the surface of the marginal zone macrophage both C-polysaccharide-containing bacteria and C1q. The recruited C1 becomes activated and propagates the CP to deposit C3b on the captured bacterium. Recently, Sign R1 was identified on the surface of resident dendritic cells (DC) in draining lymph nodes and shown to be important in capture and transport of inactivated influenza virus.^{13a} This novel pathway provides an alternative innate recognition of pathogens leading to activation of the CP of complement.

Lectin Pathway

Before continuing with the discussion of the complement cascade at the point of C3 cleavage by convertase, we turn our attention to the

The lectin pathway is a relatively recently described pathway for complement activation.^{15,16} MBL, similar to C1q, is a triple helical structure with collagen-like arms (most commonly three or four) coupled to C-type lectin globular domains, which form carbohydrate recognition domains that bind repeating polysaccharides present on the surfaces of many microorganisms. MBL attaches to the terminus of polymeric carbohydrate chains in the following order: mannose > GlcNAc > fucose > glucose. The greatest avidity appears to be for repeating mannose-based structural patterns typical of microbial surfaces. On vertebrate cells, these sugars are not as dense as on microbial surfaces, thus decreasing the avidity of the MBL-binding interaction, and furthermore, they often are covered by sialic acid residues, thus limiting recognition by MBL. The MBL-associated serine proteases MASP-1 and MASP-2, whose domain architecture is similar to C1r and C1s, predominantly bind as homodimeric zymogens to separate MBL oligomers. Upon MBL binding to polysaccharides on a pathogen surface, MASP-1 and MASP-2 become activated. The mechanism of activation has recently been clarified and is distinctly different from the conformational distortion-based intracomplex mechanism described above for the C1 activation. Although it had originally been thought that MASP-2 was capable of autoactivating itself when MBL bound to its target, and that MASP-1 played a non-essential and ill-defined augmentary role,¹⁴ under physiological conditions autoactivated MASP-1 has now been firmly established to be the obligatory activator of MASP 2.^{16a,16b} Although the relationship between MASP-1 and MASP-2 parallels that of C1r to C1s in the C1 activation mechanism, what is decidedly different is that MASP-1 autoactivation is intercomplex, as is MASP-2

Gene-targeted knock-out mouse models deficient in MBL components have been described. In general, in pathogenic microbe infection models, such as *Candida albicans* or *Staphylococcus aureus*, MBL knock-out mice showed increased susceptibility to systemic infection and relatively much higher mortality compared to wild type.^{19,20}

Alternative Pathway

The AP may represent one of the earliest forms of innate immunity. Unlike the CP or LP pathway, the AP can be fully activated in the absence of specific pathogen binding by a “recognition” equivalent to C1q or MBL.²¹ In fact, the AP is always “on” at a low level. In addition, the AP forms and uses the distinct C3 convertase C3bBb.²²

Complement C3 is a two-chain protein with an apparent molecular weight of approximately 200 kDa. The crystal structure of native C3, shown as a domain-colored ribbon model in Fig. 24.2A, identified 13 distinct domains, including the thioester domain (TED), which contained the covalent binding site.²³ In the native molecule, the intramolecular thioester bond, formed between the side chains of cysteine and glutamine residues within the sequence CGEQ, is buried within a hydrophobic interface formed between the TED and

MG8 domains, which is nevertheless close to the protein's surface. The subsequent determination of the atomic structure of the activated form of C3 (i.e., C3b) demonstrated a dramatic shift in the location of the TED.^{24,25} Proteolytic cleavage releases the C3a anaphylatoxin peptide, and the TED becomes fully exposed to engage potential targets (see structure-based depiction of C3b in Fig. 24.2B). Thus the dramatic shift in structure also exposes potential binding sites for factor B of the AP and competing sites for regulators of C3b, such as factor H (FH), membrane cofactor protein (MCP), complement receptor type 1 (CR1), and decay accelerating factor (DAF; all described later in this section). At a low so-called “tickover” level, the thioester bond undergoes spontaneous hydrolysis, forming C3(H₂O). This conformationally altered C3b-like form of C3 (see Fig. 24.2B) allows for binding to factor B, a plasma protein. Factor B is a serine protease that is approximately 30% identical to C2. The binding of

Fig. 24.2 THE STRUCTURE OF NATIVE C3, ITS CONFORMATIONAL INTERMEDIATES, AND ITS CLEAVAGE FRAGMENTS. (A) Ribbon diagram representation of the x-ray crystal structure of native C3 indicating the 13 domains (**bold lettering**, color-coded the same as the domain) of which it is composed. (B) Structure-based cartoon representation of the conformational states of intact C3, as well as its cleavage fragments. Where these cartoons are derived from x-ray structures, those structures are depicted as ribbon diagrams adjacent to the cartoon. The remaining cartoons are based on electron micrograph images,²⁷ as well as established biochemical data. In all cases, the domain colors in the cartoons correspond to those in the ribbon diagrams. Proteolytic activation of C3 to C3b results in an approximate 90-Å downward movement of the thioester domain (TED), a significant repositioning of the CUB (complement C1r/C1s, urchin EGF, bone morphogenic protein 1), and a flipping of the positions macroglobulin 7 (MG7) and MG8 domains. The reorientation of these domains creates binding sites for ligands of C3b that were not present in the native molecule. The reactive thioester produced during this conformational transition is capable of binding a portion of the C3b molecules covalently to a target surface (*gray-shaded boxes*). Subsequent cleavage of C3b by factor I releases a small C3f fragment and results in a reorientation of the C3c portion of the molecule relative to C3d/TED within iC3b, a molecule that remains bound to the target. This reorientation relative to C3b relieves the steric blockage by MG1 of a portion of the binding site for CR2/CD21, as iC3b is an equivalent ligand to C3dg and C3d with respect to CR2 binding. C3dg and C3c are the products of an additional cleavage by factor I within the CUB domain. A noncomplement protease removes an N-terminal segment from C3dg, yielding the still target-associated C3d fragment. The remaining “squiggle” on C3d represents 16 residues at its C-terminus that are sufficiently flexible that they were not visible in the x-ray crystal structure of C3d. Although the thioester in native C3 is protected from the solvent, native C3 is in conformational equilibrium with a stable conformational intermediate, C3(H₂O)*, in which the thioester become susceptible to hydrolysis. Although the equilibrium strongly favors the native state, if hydrolysis of the thioester in C3(H₂O)* occurs, it cannot reform, and the molecule undergoes a unidirectional conformational change to the C3(H₂O) stage, which adopts both a C3b-like conformation and functional profile. This conformational transition of intact C3 is the basis of the “tick-over mechanism” for alternative pathway initiation. (Modified from P. Gros, Utrecht University; contains elements previously published in Gros P, Milder FJ, Janssen BJ: Complement driven by conformational changes. *Nat Rev Immunol* 8:48, 2008.)

factor B by C3(H₂O) allows factor D, another protease, to cleave factor B to form Ba and Bb. Bb remains associated with C3(H₂O) to form the C3(H₂O)Bb complex. Factor D appears to function as a serine protease in its native state but can cleave factor B only when bound to C3. Recently, there has been an interesting connection found between factor D and MASP-1, a component of the LP. It was found that a *MASP-1/MASP-3* knockout mouse (the proteins MASP-1 and MASP-3 are alternative splice products of the same gene) completely lacked AP functionality. Upon further investigation, it was determined that the secreted factor D in this mouse possessed a five-residue propeptide at its amino terminus. Removal of this propeptide from factor D by the addition of MASP-1 resulted in restoration of AP functionality.²⁶

C3(H₂O)Bb is an enzymatic complex capable of cleaving native C3. This complex is a fluid-phase C3 convertase. Although it is formed only in small amounts, it can cleave many molecules of C3. Much of the C3b produced in this process is inactivated by hydrolysis, but some attaches covalently to the surface of host cells or pathogens. C3b bound in this way is able to bind factor B, allowing its cleavage by factor D to yield Ba and Bb. The result is the formation of C3bBb, a C3 convertase akin to C4b2a found in the classical and MBL pathways, with the capability of initiating an amplification cascade.

In light of the nonspecific nature of C3b binding in the AP, it is not surprising that a number of complement regulators exist both in the plasma and on host cell membranes to prevent complement activation on self-tissues. Some of these regulatory components are mentioned now for the sake of clarity; more detailed attention is provided later in this chapter (Table 24.1). CR1 and DAF (CD55) compete with factor B for binding to C3b on the cell surface and can displace Bb from a convertase that has already formed.²⁸ Factor I (FI), a serum protease, in concert with CR1 or MCP (CD46) can prevent convertase formation by converting C3b into its inactive derivative, iC3b.²⁹ CR1 is unique among the FI cofactors in facilitating an additional proteolytic cleavage of iC3b to yield C3c and C3dg (see Fig. 24.2B). Trimming of the latter by noncomplement proteases yields the proteolytic limit fragment C3d, which structurally corresponds to the TED domain (see Fig. 24.2B). Another complement regulatory protein found in the plasma is FH. FH binds C3b and is able to compete with factor B and displace Bb from the convertase. In addition, FH acts as a cofactor for FI to convert C3b to iC3b. In addition to interaction sites for C3b, FH possesses two distinct binding sites for polyanionic molecules, particularly various sulfated glycosaminoglycans (e.g., heparan sulfate) or arrays of sialic acid (e.g.,

from membrane surface glycoproteins) found on host surfaces in contact with blood plasma. Although these polyanion binding sites are not required for FH to regulate fluid phase AP C3 convertase, they are required for its activity on surface-bound C3bBb. In fact, this is the basis for FH being able to discriminate between AP C3 convertase adventitiously deposited on host tissue versus that deposited on a microbial surface because the latter do not possess either the sulfated glycosaminoglycans or the sialic acid arrays.^{30,31}

Pathogen surfaces are normally not afforded the protection offered by these regulators. Persistence of the C3bBb convertase on microbial surfaces may additionally be favored by the positive regulator properdin (factor P). This positive modulation of the AP by properdin has traditionally been thought to be attributable to its ability to prolong the lifetime of the AP C3 convertase by forming a C3bBbP complex. This mechanism is still valid, but recently, evidence has been presented that properdin, which circulates predominantly as a homotrimer, may also be able to recognize AP targets directly. Specifically, it has been shown to bind to microbial surfaces, such as to *Neisseria gonorrhoeae* or yeast cell walls, that are known AP activators, but not to strains of *Escherichia coli* that are known to be nonactivators of the AP of complement. Because it is a homotrimer, even if factor P uses two of its subunits to bind to the microbial surface, one is still left that can recruit C3b, or C3(H₂O), from the fluid phase to the microbial surface. The properdin-bound C3b/C3(H₂O) can then act as a platform for recruiting factors B and D, thereby forming a surface-bound AP C3 convertase.³² Consistent with this target recognition model for properdin functionality, individuals with deficiencies in factor P have a heightened susceptibility to infection with *Neisseria*.³³

After forming, the C3bBb convertase rapidly cleaves more C3 to C3b, which can participate in the formation of more molecules of C3bBb convertase. The AP thereby activates an amplification loop that can proceed on the surface of a pathogen but not on a host cell. An additional point regarding amplification by the AP is that C3b deposited on a target as a result of activation of either the CP or the LP can act as a nidus for the formation of an AP C3 convertase.

Although specific antibody is not required for AP activation, many classes of immunoglobulin can facilitate AP activation.³⁴ The mechanism by which this occurs remains elusive, although some evidence indicates that C3b covalently bound to IgG displays a reduced rate of inactivation to iC3b by factors H and I.³⁵ However, in contrast to CP activation, which requires Fc, AP activation can occur with F(ab)₂ fragments.

An instructive demonstration for the role of antibody in continuing the AP cascade, with possible ramifications for human disease, comes from a murine model of rheumatoid arthritis. Mice do not spontaneously develop rheumatoid arthritis.³⁶ However, a murine model has been developed in which expression of antibodies specific for the ubiquitously expressed cytoplasmic protein glucose-6-phosphate can cause joint destruction reminiscent of human rheumatoid arthritis. Interestingly, the disease state, through complement-mediated joint destruction, can occur even if the specific antibodies are of isotypes incapable of fixing complement through the CP. The response may be localized to the joints because of the absence of complement cascade regulators on cartilage.

C3, C5, and the Membrane Attack Complex

The formation of the C3 convertase, C4b2a (CP and LP) and C3bBb (AP), is the point at which the three pathways converge (see Fig. 24.1). The function of these complexes is to convert C3 to C3a and C3b. C3 is the most abundant complement protein in plasma, occurring at a concentration of 1.2 mg/mL, and up to 1000 molecules of C3b can bind in the vicinity of a single C3 convertase.³⁷

The covalent attachment of C3b to either C4b2a or C3bBb converts this enzyme into a trimeric complex (C5 convertase) capable of binding and cleaving C5 into C5a and C5b. Mechanistically, the “adduct” C3b molecule increases the binding affinity of the

TABLE 24.1 Control Proteins of the Classical and Alternative Pathways

Name	Role in the Regulation of Complement Activation
C1 inhibitor (C1INH)	Binds to activated C1r, C1s, removing it from C1q
C4-binding protein (C4BP)	Binds C4b, displacing C2a; cofactor for C4b cleavage by factor I
Complement receptor 1 (CR1)	Binds C4b, displacing C2a, or C3b displacing Bb; cofactor for FI
Factor H (FH)	Binds C3b, displacing Bb; cofactor for factor I
Factor I (FI)	Serine protease that cleaves C3b and C4b: aided by factor H, MCP, C4BP, or CR1
Decay-accelerating factor	Membrane protein that displaces Bb from C3b and C2a from C4b
Membrane cofactor protein	Membrane protein that promotes C3b and C4b inactivation by factor I
CD59	Prevents formation of membrane attack complex on autologous cells expressed on membranes

C5 convertase for its substrate C5 such that its Michaelis constant (K_M) is now well below the physiologic concentration of C5 in plasma.³⁸ C5b is the initiating component of the membrane attack complex (MAC). The MAC is a multiprotein complex whose components are C5b, C6, C7, C8, and multiple C9s.^{39,40} The constituent components of the MAC associate in the numeric order C5b–C6–C7–C8–C9.

The MAC, when viewed by electron microscopy, resembles a cylinder that possesses a hydrophobic outer face and a hydrophilic central core. If assembled near a lipid bilayer, such as a cell or the bacterial membrane of a gram-negative strain, the MAC can associate with and insert into the lipid bilayer. Such insertion can be thought as “punching holes” into the membrane, allowing for passage of water and small ions into the cell. Osmotic equilibrium is thereby lost, leading to eventual lysis of the targeted cell or bacterium. C5b678 are sufficient to form small pores in the target membrane. The role of C9 appears to be to enlarge the channel through multiple C9 polymerization, thereby causing more rapid loss of membrane function and lysis. Deficiencies in complement components C5 to C9 have only been associated with increased susceptibility to *Neisseria* species-based infections, such as gonorrhea and bacterial meningitis. Also, the extended cell wall peptidoglycan layer of gram-positive strains of bacteria make them resistant to the lytic arm of complement. It can be concluded from these observations that the requirement for MAC is limited in host protection.

Complement Receptors and Their Role in Immune Complex Clearance and Activation

As described in the previous section, complement can act by the direct lysis of targeted cells. Another important function of complement in host protection is facilitating the uptake and destruction of pathogens by phagocytic cells. This occurs by the specific recognition of C3b/C4b-coated (opsonized) particles by complement receptors.^{41,42}

The best characterized complement receptor for the uptake of C4-coated immune complexes is CR1 (CD35). CR1 binds C4b/C3b-bearing immune complexes. CR1, similar to most proteins that bind activation products of C4 and C3 molecules, shares a structural motif known as the short consensus repeat (SCR). Each short consensus repeat consists of approximately 60 amino acids. CR1 in humans is composed of 30 linked short consensus repeats. CR1 possesses three binding sites for C4b and two for C3b.

CR1 is expressed on a wide variety of cell types in humans, including erythrocytes, macrophages, polymorphonuclear leukocytes, B cells, monocytes, and FDCs. The role of CR1 expression on B cells and FDCs in activating and maintaining the adaptive immune response is detailed subsequently. For now, the focus is on the other cell types that express CR1.

Because CR1 is not directly associated on its cytoplasmic side with any intracellular signaling molecules, binding of C3b by CR1 expressed on phagocytic cells is not in itself capable of inducing endocytosis of the C3b-opsonized target. A secondary signal is required to induce phagocytosis. This second signal can be provided by IgG binding to the phagocyte's Fc receptor, by carbohydrates commonly found on bacterial surfaces, or by exposure of the phagocytic cell to the appropriate cytokines. In addition, some phagocytic cells, such as macrophages, are activated by binding of C5a through C5a receptor (C5aR, [CD84]) (see [Biologic Activity of C3a and C5a](#), later). What these secondary ligands have in common is that they all bind to receptor domains that are the ligand recognition units of a cell signaling molecule or complex.

The largest pool of CR1-expressing cells is erythrocytes.⁴³ Erythrocytes bearing opsonized material are removed from the circulation presumably to prevent deposition in tissue sites such as the renal glomerulus. Erythrocytes bearing opsonized material traverse the sinusoids of the liver and spleen, where they come into close contact with fixed phagocytic cells. These phagocytic cells affect the transfer of opsonized material from the erythrocyte onto their own

membranes. The transfer of complexes is enhanced by cleavage of C3b to iC3b by FI, as iC3b is a poor ligand for CR1, but is a good ligand for CR1g, a complement receptor of the Ig superfamily present on tissue-resident phagocytic cells (see later for further discussion of CR1g).

Given its central position in the complement cascade, the presence of C3b is tightly regulated. This regulation is brought about by cleaving C3b into inactive derivatives that cannot participate in forming an active convertase. One of the conformationally altered inactive derivatives of C3b, iC3b (see [Fig. 24.2B](#)), can act as an opsonin in its own right for complement receptors CR2 (CD21), CR3 (CD11b/CD18), and CR4 (CD11c/CD18). CR3 binds iC3b and plays a major role in inducing phagocytosis but probably not activation in the absence of a second signal (e.g., Fc receptor or pattern recognition receptor). CR4 also binds iC3b-opsonized particles, resulting in direct endocytosis. Although its role as a phagocytic receptor is not well characterized, CD11c is the major marker for DCs. It is important to understand the functional importance of this complement receptor on DC and how it participates in uptake of antigen for presentation to T lymphocytes.

CR2 expressed on B cells augments cognate antibody receptor signaling (see later section). This receptor recognizes targets that are coated with iC3b, as well as the subsequent degradation products C3dg and C3d, all of which remain covalently bound to the target (see [Fig. 24.2B](#)). CR2 is the only complement receptor that recognizes C3d/TED on its own as its ligand. However, the CR2 binding site on TED only becomes accessible after degradation of C3 to at least the iC3b stage. Activation of complement plays a contributing role in producing a strong antibody response. An interesting aside is that CR2 is the cell surface receptor on human B cells that is recognized by the Epstein-Barr virus.⁴⁴

CR1g is a recently described complement receptor that plays an important role in the clearance of C3b opsonized complexes by phagocytic cells of the liver.⁴⁵ It is also expressed on subsets of macrophages, but less is known about this role. The recent cocrystallization of C3b and CR1g revealed binding to the C3b β chain, which is in contrast to all other known C3-interacting partners, in which binding to the activated C3 occurs via the α chain.

Biologic Activity of C3a and C5a

The role of the complement fragments C3a and C5a in the immune response is to produce localized inflammation.⁴⁶ C3a and C5a are anaphylatoxins and are structurally similar to chemokines. When produced in large amounts or injected systemically, they induce a generalized circulatory collapse and shock-like syndrome similar to that seen in a systemic allergic reaction involving IgE antibodies.⁴⁷

Of the two fragments, C5a is the most stable and possesses the best characterized and possibly highest specific biologic activity. Both C3a and C5a induce smooth muscle contraction and increased vascular permeability. C5a and C3a also act on endothelial cells lining blood vessels to induce adhesion molecule expression.^{48,49} In addition, C3a and C5a can activate the mast cells that populate submucosal tissues and line vessels throughout the body to release histamine, tumor necrosis factor α (TNF- α), and protease.⁶ The changes induced by C3a and C5a recruit antibody, complement, and phagocytic cells to the site of infection, thereby hastening the adaptive immune response. C5a also induces the upregulation of CR1 and CR3 on the surfaces of these cells. C5a is the only complement chemotactic agent for neutrophils, macrophages, and basophils. By contrast, both C3a and C5a possess chemotactic activity for mast cells.⁵⁰ Although a similar fragment, C4a, is produced in the course of C4 activation, its physiologic relevance as an anaphylatoxin is highly questionable. First, human C4a binds to neither C3aR nor C5aR, the two well-characterized complement anaphylatoxin receptors, and a specific C4a-binding entity has not been identified. Second, anaphylatoxin activity for human C4a has only been reported on guinea pig targets, but even there, it is two to three orders of magnitude less potent than human C3a.⁵⁰

Regulation of Complement Activation

Activation of the complement system must be tightly regulated to prevent autologous tissue damage (see Table 24.1).⁵¹ Some of the proteins involved in regulating complement action have been described (see *Alternative Pathway*, earlier). In addition to these regulators, a number of other checkpoints limit the scope and target of complement activation.

As a result of binding to antibody or pathogen, conformational changes to C1q induce the enzymatic activity of C1r and C1s. Both of these enzymes are regulated by the C1 inhibitor (C1-INH). C1-INH is a member of a family of *serine protease inhibitors* termed *serpins*.⁵² Serpins provide a bait sequence that mimics the active site of the substrate. When C1r or C1s proteolytically attacks this sequence, the net result is that their respective active site serine hydroxyls become permanently covalently bound to the C1-INH bait site, thereby destroying their proteolytic activity. C1-INH works in a similar fashion in regulating the activated MASP proteases of the LP. Finally, C1-INH is also responsible for preventing spontaneous fluid-phase activation of C1 in plasma, but this activity can be overridden by immune complexes.

Although C1 is capable of cleaving multiple C4 molecules, only approximately 10% of the produced C4b clusters about the targeted antigen.⁵³ The rest is released into the fluid phase. C4b in the fluid phase is rapidly bound by C4 binding protein (C4bp), which is a cofactor for FI. Factor I cleaves C4b into two fragments, C4c and C4d, which are quickly cleared from the circulation.

In addition to their FI cofactor activities, the soluble regulators C4bp and FH, respectively, promote the dissociation of the CP (C4b2a) and AP (C3bBb) C3 convertases into their constituent components. This decay-dissociation is unidirectional because neither C2a nor Bb can reassociate on its own with their respective C3 convertase subunits. The membrane-bound regulators CR1 and DAF similarly possess decay-accelerating functionality toward both the CP and AP C3 convertases. The importance of CR1 or CR1-like molecules in curbing the complement response can be witnessed in a rather unexpected condition. Complement receptor 1–related gene (*Crry*) is a murine homologue of the human *CR1* gene, although its near-ubiquitous tissue distribution more closely resembles that of MCP (a somewhat more distant homologue).^{54,55} Mice lacking *Crry* are unable to properly regulate C3. *Crry*-deficient mice spontaneously abort because of C3-dependent injury to the fetus. This presumably is the result of uncontrolled C3 deposition on the placenta. This observation in mice sheds light on the possibility that defective MCP (or perhaps CR1) plays a role in recurrent fetal loss manifest in patients with antiphospholipid syndrome.

Biologic Consequences of Complement Cascade Deficiencies

The important role of the complement system in preventing disease is witnessed in cases in which components of the system are absent either because of random mutation in the human population or by design in gene-targeted “knock-out” mice. Some complement cascade deficiencies have been described. This section focuses on the biologic consequences of deficiencies in complement cascade activation that have profound biologic consequences followed by a discussion on deficiencies in complement regulatory proteins.

Homozygous deficiencies in C1q, the most common form of C1 deficiency in humans, is a powerful susceptibility factor for the development of systemic lupus erythematosus (SLE).^{56,57} Patients lacking C1q nearly always present with SLE. They have increased susceptibility to viral and bacterial infections, but it is not nearly as pronounced as in C3 deficiency (see later discussion). C1q knock-out mice show increased mortality, with up to 25% of mice having histologic evidence of glomerulonephritis.

C4 in humans is encoded by two separate loci giving rise to two distinct protein products, C4A and C4B.⁵⁸ Complete C4 deficiency correlates with a 75% prevalence of SLE in humans. However, at least

in certain human populations, the absence, or even haploinsufficiency, of C4A, but not C4B, is associated with elevated risk for development of autoimmune diseases such as SLE and other lupus-like autoimmune disease. The reason for the protective effect of C4A is not settled, but it is worth noting that the one indisputable functional difference between C4A and C4B is in the nature of the covalent bond formed upon target deposition. Whereas C4A transacylates onto amino group nucleophiles, forming amide bonds, C4B shows a strong preference for forming ester linkages to hydroxyl group nucleophiles. The approximately threefold greater propensity of C4A, relative to C4B, to bind to amino group-rich C1-bearing IgG aggregates,⁵⁹ as would be present in immune complexes in need of complement-dependent clearance, is one possible reason for the association of C4A null states with SLE. Finally, as with C1q, mice deficient in C4 are predisposed to SLE-like disease.

C2 deficiency appears to be relatively benign.⁶⁰ Humans lacking C2 appear to have a normally functioning immune system, although autoimmune disorders and, less commonly, infections are observed with increased frequency.

In light of the central role of C3 in the complement cascade, it is not surprising that C3 deficiency has dire consequences for the host organism. Of all known cases of C3 deficiency among humans, no patients have been reported as disease free. Infectious complications, predominantly pyogenic in nature, occur frequently and recurrently. *Streptococcus pneumoniae* and *Neisseria meningitidis* are the major pathogens reported. In addition, SLE, vasculitic syndromes, and glomerulonephritis have been documented in up to 21% of C3-deficient patients. Mice deficient in C3 show, similar to humans, greatly increased susceptibility to streptococcal infection and death.⁶¹ The 50% lethal dose (LD₅₀) is 50-fold less for C3-deficient mice than for C3-sufficient control subjects. This may be attributable in large part to the inability of mice deficient in C3 to effectively opsonize the bacteria. Moreover, the deficient mice have an impaired humoral response (see later section).

Biologic Consequences of Complement Regulatory Protein Deficiencies

Deficiencies in C1-INH have been observed in the human population.⁶² C1-INH deficiency can be inherited as an autosomal dominant trait or can result from autoantibodies that recognize C1-INH, blocking its function.⁵² The inherited form of this deficiency is the cause of hereditary angioedema. Patients with hereditary angioedema experience chronic spontaneous complement activation leading to the production of excess cleaved fragments of C4 and C2. The biochemical cause of angioedema in these patients is not definitively elucidated. One line of reasoning points to excess production of C2 kinin and bradykinin. The peptide C2 kinin is a breakdown product of C2a after cleavage of C2. This peptide causes extensive swelling; the most dangerous is local swelling in the trachea, which can lead to suffocation. Bradykinin, which has similar actions to C2 kinin, is also produced in an uncontrolled fashion in this disease as a result of the lack of inhibition of another plasma protease, kallikrein, which is activated by tissue damage and is regulated by C1-INH. Although C1 is unregulated in patients with hereditary angioedema, large-scale cleavage of C3 is prevented by C4 and C2 control mechanisms and by regulation of C3 convertase formation on host cells. An increased risk of infection is not associated with C1-INH deficiency. This disease can be fully corrected by infusion of purified C1-INH.

Acquired C1-INH deficiency may be associated with lymphoproliferative disorders and in most cases represents development of an autoantibody that binds to and neutralizes C1-INH. In two examined cases, autoantibodies abrogate C1-INH activity by preventing formation of the C1s–C1-INH complex. However, after the complex formed, the autoreactive antibodies had no effect on C1-INH function. To date, there is no uniform, fully effective therapy for these patients.

The role of FI in complement cascade regulation can be witnessed in patients with FI deficiency.⁶³ In the presence of a cofactor protein,

FI cleaves C3b, producing iC3b, the inactive form of C3b. iC3b is incapable of reacting with factor B to form the AP C3 convertase, thereby preventing uncontrolled AP activation. In the absence of FI, unrestrained C3 consumption occurs secondary to accelerated spontaneous AP turnover. Patients with FI deficiency have recurrent infections caused by pyogenic organisms, including meningococcal meningitis.

Likewise, mice deficient in the central protein FH exhibit unrestrained C3 activation via the AP, leading to near depletion of serum C3. An important outcome of the failure to regulate C3 activation is glomerulonephritis. Strikingly, mice deficient in FH develop a disease resembling the human disorder membrane glomerulonephritis. The phenotype of the mice confirms the general notion that the AP is always “on” and that failure to regulate activated C3 results in consumption of circulating C3 and tissue injury.

Another example of the importance of FH regulation are reports of genetic association between variant alleles of FH and the human diseases age-related macular degeneration (AMD) and atypical hemolytic uremic syndrome (aHUS). Whereas AMD is a fairly common condition—indeed, it is the leading cause of blindness in the Western world—it has been the elucidation of the etiology of the much rarer aHUS condition (two cases per million) that has led to a fuller appreciation of the diverse ways through which dysregulation of the AP of complement can give rise to severe pathology. Classically, HUS is a clinical triad of microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure. The disease is characterized by a precipitating injury of endothelial cells. In contrast to the fairly common classical form of HUS, which is diarrhea-associated and is usually caused by a Shiga toxin-secreting pathogen, the atypical form of HUS is nondiarrheal and is caused by genetic predisposition. Even haploinsufficiency of variants of FH, MCP, and FI resulting from either loss of expression—or more commonly, loss of regulatory

function—results in disease pathology. In addition, gain-of-function variants of factor B have been described that either form the AP C3 convertase more efficiently than wild-type factor B or are more resistant to decay-dissociation by FH or DAF. Finally, several C3 variants have been described in aHUS patients that are gain of function in the sense that as C3b there is decreased binding affinity for MCP and FH and thus AP C3 convertases formed with this C3b as subunit would have a prolonged lifetime relative to wild-type C3b.^{64,65}

Because FH mutations account for at least 30% of reported aHUS cases and approximately 70% of these are caused by missense mutations in SCR domains 19 and 20, the molecular basis of this disease association has been intensively investigated, and the findings of these studies are best understood in the context of a structure-based domain model⁶⁶ of FH bound to C3b on a nonactivator (i.e., host) surface (Fig. 24.3). FH consists of 20 SCR domains, where some domains in the middle of the molecule appear to play mainly a structural role, likely allowing the molecule to bend back on itself, but domain clusters near the ends mediate specific functions. SCRs 1 to 4 bind to C3b and mediate both decay-accelerating and FI-cofactor functionalities. Indeed, FH(SCR1–4) on its own is able to regulate a fluid-phase AP C3 convertase, but it cannot do so for surface-bound AP C3 convertases. For regulation of the latter, there are three additional binding interactions that become relevant. Two of these are located within SCRs 19 to 20, specifically, a site localized mainly to SCR19 binds to the C3d/TED domain of the surface-bound C3b molecule, and a site within SCR20 binds to surface-associated polyanions such as sulfated glycosaminoglycans or sialic acid arrays. The aHUS-associated missense mutations found within SCRs 19 to 20 affect one or other of these two binding functions and lead to dysregulation of the AP C3 convertase at the surface of host tissue. In particular, complement-mediated damage to the kidney basement membrane is often a hallmark of aHUS. As a tissue devoid of the membrane-associated complement regulators MCP, DAF, or CR1, but rich in sulfated glycosaminoglycans, the functionality of the soluble AP regulator FH becomes even more crucial for host protection and likely explains the high incidence of missense mutations within SCRs 19 to 20 in aHUS patients. Interestingly, missense mutations in FH SCRs 19 to 20 do not result in systemic C3 consumption, as would be the case for complete deficiencies of FH. This is because SCRs 1 to 4 of the mutant molecule are still capable of regulating spontaneously formed AP C3 convertases in the fluid phase.

In addition to the polyanion binding site in FH SCR 20, there is also one in SCR 7. This SCR is the site of an amino acid polymorphism in FH (tyrosine to histidine at residue 402, Y402H) that is a significant risk factor for AMD but interestingly does not correlate with disease susceptibility for aHUS. Heterozygotes and homozygotes for H402 are respectively 2.7-fold and 7.4-fold more at risk for AMD than homozygous Y402 individuals, and this single polymorphism can account for up to 50% of the risk of AMD.^{67,68} Two significant functional differences have been observed for the Y402 and H402 variants of FH. First, the affinity and specificity for a spectrum of sulfated glycosaminoglycans is different for the two variants of FH. Secondly, the affinity of the H402 variant of FH for C-reactive protein (CRP), an acute-phase protein that binds to damaged tissue, is substantially lower than that of the Y402 variant. It is notable that the Bruch's membrane of the macula, similar to the kidney basement membrane, is devoid of membrane-associated complement regulators and so is highly dependent on FH for local AP regulation. Indeed, the spectrum of sulfated glycosaminoglycans found on the Bruch's membrane appear to be more dependent on the polyanionic binding site in SCR 7 for the interaction than that in SCRs 19 to 20 because even with non-AMD eye tissue, there is preferential binding of the Y402 variant to the Bruch's membrane.⁶⁹ Thus the lower binding affinity of the H402 FH variant, coupled with a possible age-related change in the biosynthesized spectrum of sulfated glycosaminoglycans on Bruch membrane, could account for the dysregulation of the AP in the macula with the ensuing inflammation of the macula seen in AMD patients. There may also be a contribution from the differential binding of the FH variants to CRP present on the particulate debris

Fig. 24.3 A STRUCTURE-BASED MODEL OF THE FACTOR H (FH)-MEDIATED REGULATION OF THE ALTERNATIVE PATHWAY ON HOST CELLS BEARING ADVENTITIOUSLY DEPOSITED C3b. Whereas the depicted interaction of FH domains SCR(1–4) with C3b is sufficient to prevent C3b in solution from becoming a subunit of an AP C3 convertase, for surface-bound C3b, at least two additional interactions are necessary. The first is the interaction indicated between FH SCR19 and the thioester domain (TED)/C3d domain of the C3b molecule. The second is between FH SCR20 and cell surface-associated sulfated glycosaminoglycans (GAGs) or arrays of sialic acid containing glycans, in both cases denoted by pentagons with an internal minus sign. Mutations affecting either the C3d binding site or the polyanion binding site within FH SCR(19–20) lead to alternative pathway dysregulation and the disease atypical hemolytic uremic syndrome (aHUS). There is an additional polyanion binding site in SCR7, which appears to be important for regulating the alternative pathway on some host surfaces, most particularly Bruch's membrane in the eye because the SCR7 Y402H polymorphism is a risk factor for AMD. (Adapted from Kajander T, Lehtinen MJ, Hyvärinen S, et al: Dual interaction of factor H with C3d and glycosaminoglycans in host-nonhost discrimination by complement. *Proc Natl Acad Sci U S A* 108:2897, 2011; reproduced with permission of the National Academy of Science.)

(drusen) residing in between the retinal pigment epithelium and the Bruch's membrane.

The MAC is one mechanism used by the host to rid itself of certain microorganisms. Host cells are protected from MAC-mediated lysis by CD59 (protectin), a membrane-bound protein. CD59 performs its function by inhibiting the binding of C9 to the C5b–C6–C7–C8–C9 complex. CD59 and DAF are linked to the cell surface by a phosphoinositol glycolipid (PIG) tail. One of the enzymes involved in the synthesis of PIG tails is encoded on chromosome X. Mutation of this gene leads to a failure to synthesize PIG tails and with it an inability to express CD59 or DAF on the cell surface.^{61–72} Lack of CD59 and DAF expression on host cell surfaces is the cause of paroxysmal nocturnal hemoglobinuria. This disease is characterized by episodes of chronic intravascular hemolysis and propensity to thrombosis.

Autoimmunity and Complement Deficiencies

There exists a strong correlative relationship between the lack of certain components of the complement system (i.e., C1 and C4) and autoimmune disease, particularly SLE. Two general nonmutually exclusive hypotheses have been put forward to explain the increased incidence of SLE among complement deficient individuals: the clearance hypothesis and the tolerance hypothesis.^{57,73,74} The clearance hypothesis is based on the known role of the CP of complement in binding to foreign antigens and transporting them to the liver and spleen for degradation and removal from the circulation. Thus defects in clearance of apoptotic cells or debris would lead to inappropriate accumulation of self-antigen and overstimulation of self-reactive lymphocytes.

The tolerance model proposes that innate immunity protects against SLE by delivering lupus autoantigens to sites where immature B lymphocytes are tolerized, thereby eliminating a source of autoreactive antibody molecules. SLE is characterized by high-affinity antibodies specific for autoantigens such as double-stranded DNA (dsDNA), ribonuclear proteins, and histones. Validation of the model comes in part from studies with human B cells demonstrating that self-reactive B cells are eliminated or anergized at two major checkpoints, bone marrow (BM) and spleen. Thus counterselection of potentially pathogenic B cells is an active process and most likely involves components of innate immunity.

Recent studies in a mouse model (strain 564 Igi) in which the B cells express an Ig receptor specific for the lupus antigen SSB/LA suggests a third possible explanation for why C4 is critical for protection against SLE. Accordingly, this hypothesis suggests that C4-dependent defects in clearance of immune complexes leads to a loss of tolerance of certain autoreactive B cells. Thus accumulation of immune complexes composed of lupus antigens that bear DNA or ribonucleoprotein (RNP) ligands that trigger Toll-like receptors (TLRs) TLR 7 and TLR 9 may induce myeloid cells to release excess type I interferon (IFN- α). In a feed-forward loop, IFN- α release induces increased sensitivity of TLR 7 and 9 receptors, in particular on B cells, such that the combined effects of engagement of DNA or RNP self-antigen and increased TLR 7 and 9 leads to escape of B-cell tolerance.^{74a,74b}

The first part of this section familiarized the reader with the general aspects of the complement system. The remainder of this section focuses on the role of the complement system in the initiation and propagation of the adaptive immune response and begins with a description of natural antibody.

Natural Antibody

Natural antibody, in contrast to antibody secreted in response to active immunization, is continuously released, mostly by the B1 subpopulation of lymphocytes. Predominantly IgM but also IgA and IgG3 (in mice), natural antibodies tend to be polyreactive, with low-affinity binding for antigens such as nuclear proteins, DNA, and

phosphatidylcholine, which are common structures among both pathogens and host tissue. These antibodies rarely show evidence of somatic mutation. It has been speculated that the variable region genes that predominate among natural antibodies have been selected evolutionarily for their ability to recognize pathogens and act as a rapid response to infection, thereby acting as a stop gap to provide sufficient time for the adaptive immune response to form. Natural antibody mediates its protective effects via the CP of complement.

IgM natural antibody is important in initiating the CP, leading to enhanced humoral immunity. In addition to its role in protecting against pathogens, natural antibody protects against lupus-like disease based on studies in mice. Thus, similar to C1q and C4, deficiency in IgM predisposes to an SLE-like phenotype.

Complement Links Innate and Adaptive Immune Responses

One of the critical functions of CP complement is providing a bridge between innate and acquired immune systems. The process is achieved through attachment of complement products to the antigen or pathogen, either directly to the surface or via antibody (see earlier section). This complement “tag” consists of breakdown products of C3 (i.e., C3b, C3dg, and C3d) that facilitate recognition of pathogens by the immune system. The recognition phase is mediated principally through complement receptors CD21 (CR2) and CD35 (CR1). This section details complement-dependent mechanisms of immune detection and humoral responses to thymus (T)-dependent antigens.

Soluble Complement Mediators of Antibody Responses

The first clue that complement is important in regulating B-lymphocyte responses came from the observation that B lymphocytes bind activated C3 fragments.⁷⁵ Soon thereafter, it was noted that mice depleted of serum C3 by treatment with cobra venom factor had diminished responses to T-dependent antigens.⁷⁶ The discovery of naturally occurring genetic deficiencies in C3, C4, and C2 in species as diverse as guinea pigs,^{77,78} dogs,⁷⁹ and humans^{80,81} allowed description of impaired antibody responses as well. Because the impaired responsiveness is comparable among animals deficient in CP activators (C4, C2) and C3-deficient or C3-depleted animals, a model emerged suggesting that the effect is mediated through the CP of the complement system. That the impaired responsiveness is comparable among diverse animal species indicated the importance of CP complement in regulating antibody responses to T-dependent antigens.

The advance of gene-targeting technology in the murine system led to development of engineered strains devoid of various components of CP complement. C1q-, C4-, and C3-deficient mouse strains generate reduced antibody responses to T-dependent antigens.^{82–85} Furthermore, these strains fail to switch Ig isotypes normally, suggesting that germinal center responses are impaired.⁸⁴ Germinal centers are microanatomic structures whose purpose is to provide for increasing affinity of serum antibody for antigens (affinity maturation), isotype switching, and development and differentiation of memory B lymphocytes and plasma cells.⁸⁶ Consistent with this theory, immunized complement-deficient mice produce fewer and smaller germinal centers compared with immunized wild-type mice.⁸⁴ Importantly, humoral responses in each of the C1q-, C4-, and C3-deficient strains can be rescued by transplantation of wild-type BM.^{56,87,88} Therefore BM-derived cells can produce sufficient complement to reconstitute antibody responses to T-dependent antigens administered intravenously.

It is suggested that the CP potentiates antibody responses through involvement of immune complex formation. The implication is that natural antibodies or specific IgM released early in the response by B cells responding to antigen recognize and bind pathogens, thereby activating the CP. In support of this model, genetically engineered

mice producing only membrane IgM (i.e., with gene-targeted deletion of secretory signals) produce significantly reduced antibody responses to T-dependent antigens.⁸⁹ A second mechanism for initial CP activation on the antigen, which may be relevant to a subset of antigens bearing a repeating epitope, involves binding of the antigen by B cells through the surface IgM of two or more B-cell receptors (BCRs). The cross-linking and distortion that is imparted to the Fc_μ regions of adjacent BCRs is sufficient to activate the CP at the B-cell surface. Indeed, this mechanism does not work if the BCR μ -chain contains a mutation that abolishes C1q binding.⁹⁰ Finally, a third permutation of these mechanisms may apply to monovalent soluble T-dependent antigens. The antigen is first captured by the BCR, creating an antigen array on the B-cell surface, to which low-affinity natural repertoire IgM can bind by virtue of avidity effects and initiate the CP.⁹¹ As illustrated by these examples, immune complex formation is only important for initiating the CP, leading to the deposition of C3 activation products on the antigen or immune complex. Indeed, antigens directly conjugated to C3b or C3d fragments are more potent immunogens compared to unconjugated antigen.^{92,93} Furthermore, the magnitude of the immune response is directly influenced by the number of C3d fragments conjugated to the antigen.⁹² Therefore activated products of complement component C3 act as a natural adjuvant in driving efficient antibody responses.

Complement Receptors and Antibody Responses

B-Lymphocyte Coreceptors

The effects of complement-coated antigens on antibody responses are mediated primarily through complement receptors CD21 and CD35. CD21 and CD35 are expressed predominantly on B lymphocytes and FDCs.^{94,95} CD35 is also found on polymorphonuclear cells, macrophages, mast cells, and DCs.⁹⁴ CD21 and CD35 are encoded for by separate yet closely linked genes in humans.⁹⁶ In mice, CD21 and CD35 originate from the same locus (*Cr2*) and are generated by alternative splicing events at the RNA level.^{97,98}

Two novel sets of experiments demonstrated that CD21 and CD35 are important in regulating B-lymphocyte responses to T-dependent antigens. In the first set of experiments, antibodies specific for both CD21 and CD35 or CD35 alone were administered to immunized mice.^{99–102} In the second set of experiments, a soluble form of CD21 was administered to immunized mice, thereby competing for C3d-coupled antigen interactions.¹⁰³ In both sets of experiments, treatment impaired antibody responses. In the first approach, the antibody that specifically blocked the interaction of C3d with CD21 was much more effective at blocking antibody responses compared with anti-CD35 antibody treatment, which blocked only the binding of C3b to CD35. This suggested that although both receptors contribute, CD21 is more important in regulating antibody responses.¹⁰⁰

Because CD21 and CD35 are found on B lymphocytes and FDCs, two important cell types for humoral responses, two nonmutually exclusive models are proposed for their function. In the first model, CD21 augments antibody responses through activity as a coreceptor on B lymphocytes¹⁰⁴ (Fig. 24.4A). The second model proposes that CD21/CD35 on FDCs trap and focus antigen such that B lymphocytes can efficiently cross-link their antigen receptor to become activated¹⁰⁵ (Fig. 24.4B).

As is apparent from the schematics in Fig. 24.4A–B and as will be elaborated upon further in the ensuing discussion, the key ligand receptor–receptor interaction mediating the linkage between complement and the adaptive humoral immune system is that between the C3d fragment that is covalently coupled to antigen and CD21 (CR2) present on B cells and FDC. The extracellular region of CD21 is composed of 15 or 16 SCR domains (because of the usage of alternative splice sites for exon 11), but the C3d binding site is confined to the two N-terminal-most SCR domains.¹⁰⁶ In what is an instructive lesson on the need to have concordance between x-ray crystallographic

structures and biochemical data, the nature of this important interface had been hotly debated for a decade because of discrepancies between a structure of the CR2(SCR1-2):C3d complex published¹⁰⁷ in 2001 with both preexisting and subsequent biochemical data in the literature. A 2011 de novo structure of this complex,¹⁰⁸ depicted in Fig. 24.4C, appears to have resolved the issue because the interactions seen in the new structure are fully supported by the biochemical data in the literature. For example, the biochemical data suggesting that there should be multiple ionic bonds mediating the binding is fully rationalized in terms of the five such bonds seen in the structure between a very negatively charged interface on a concave face of C3d that is remote from the covalent attachment site and positively charged lysine and arginine side chains from CR2 sticking down and interacting with oppositely charged residues on the C3d interface, as can be appreciated in Fig. 24.4C.

As a coreceptor, engagement of CD21 by complement-coupled antigen on the surface of a B lymphocyte, in combination with membrane Ig (BCR) cross-linking, would lower the threshold of signal through the BCR required to activate the cell.¹⁰⁴ Accordingly, naive B lymphocytes bear low-affinity receptors for antigen; therefore, especially under conditions of limiting antigen, as would be the case during initial encounter with a microbial pathogen, additional signaling by the CD21 coreceptor is required for efficient activation. This was demonstrated in vitro by culturing B lymphocytes with cognate antigen, either uncoupled or coupled to C3d. By measuring intracellular Ca²⁺ levels as a measure of cell activation, it was estimated that 100- to 1000-fold less C3d-conjugated antigen was required to activate B lymphocytes compared with unconjugated antigen.⁹²

The opportunity to test the importance of CD21 and CD35 as B-lymphocyte coreceptors in vivo came from studies using mice with targeted disruption in the *Cr2* locus. Importantly, *Cr2*-deficient mice have impaired humoral responses similar to C1q-, C4-, and C3-deficient mice (Fig. 24.5).^{109–111} Using embryonic stem cells with a disrupted *Cr2* locus, Croix et al.¹¹² used blastocyst complementation of Rag2^{−/−} mice, such that chimeric mice expressed CD21/CD35 on FDCs but not on B lymphocytes. These chimeric mice displayed impaired antibody responses to the T-dependent antigen NP-KLH compared with control subjects. Therefore CD21/CD35 on B lymphocytes is important for normal antibody responses. Although CD21/CD35 on FDC is on its own, insufficient for normal antibody responses, as discussed in the next section, CD21/CD35 on FDC does have a specific role in the memory response of B cell-mediated immunity.

The covalent attachment of complement to antigen engages CD21 as a complex with CD19/CD81 and BCR on the cell surface (see Fig. 24.4A).^{104,113,114} Dual binding of CD21/CD19/CD81 with BCR generates a stronger signal compared with BCR engagement alone.¹⁰⁴ If the combined signal is sufficient, the B lymphocyte is activated. If insufficient, then the B lymphocyte is likely eliminated by apoptosis.^{87,115–119} The major ligand-binding receptor within the CD21/CD19/CD81 complex is CD21. The major role of CD19 is in initiating a signaling cascade within the cell.¹²⁰ CD81 is a tetra-spanning molecule that stabilizes the complex within the membrane. After coligation of the BCR with the CD21/CD19/CD81 complex, CD81 gets S-palmitoylated on a cysteine side chain, and this in turn mobilizes the coligated complexes to a special compartment of the plasma membrane known as a lipid raft. Localization to this compartment facilitates prolonged intracellular signaling because the compartment is rich in signal-propagating phosphokinases but is relatively devoid of the regulatory phosphatases.¹²¹ Absence of any of the CD21/CD19/CD81 components adversely affects antibody responses to T-dependent antigens, although the degree of impairment varies.^{109,122–124}

Focusing Antigen on Follicular Dendritic Cells

The second role of complement receptors CD21 and CD35 in regulating humoral responses is that they permit FDCs to trap antigen (Fig. 24.6).^{105,125} FDCs concentrate in regions of ongoing immune

Fig. 24.4 COUPLING OF C3D TO ANTIGEN ALTERS ITS FATE IN B-CELL RESPONSE. (A) Coligation of the B-cell receptor (BCR) with the CD19/CD21/CD81 complex by antigen coated with C3d regulates essential functions for naïve B-cell activation. The boxed area indicates the key binding interaction between CD21/CR2(SCR1-2), and the C3d fragment that is covalently bound (yellow triangle) to the antigen recognized by this B cell's BCR. (B) C3d-coated antigens are also captured on the surface of the follicular dendritic cells (FDCs) by CD21, allowing for efficient stimulation of previously antigen-engaged B-cell centrocytes in the germinal centers during the process of affinity maturation and the generation of memory B cells. (C) The structure of the CR2(SCR1-2):C3d complex as a surface representation of C3d colored for electrostatic potential (red, negative; blue, positive) and an overlaid, semitransparent, ribbon diagram of CR2(SCR1-2) showing stick models of the side chains of some of the interacting residues. Note the charge complementarity for many of the interacting amino acids. (C, Reproduced with permission from van den Elsen JM, Isenman DE: A crystal structure of the complex between human complement receptor 2 and its ligand C3d. *Science* 332:608, 2011.)

responses, such as germinal centers, and they appear necessary for antibody responses. Germinal centers (see earlier section) promote somatic hypermutation within Ig heavy- and light-chain genes along with isotype switching and production of memory B lymphocytes and plasma cells. They can be divided into two regions, dark zone and light zone. To gain entry into the dark zone, B lymphocytes are activated by receiving above threshold signals from the CD21/CD19/CD81 and BCR in combination with costimulation from helper T lymphocytes.¹²⁶⁻¹²⁸ Within the dark zone, activated B lymphocytes divide and mutate their Ig receptor genes.¹²⁷⁻¹³⁰ After several rounds

of proliferation in the dark zone, B lymphocytes enter the light zone, where they are subjected to selection on antigen deposited on FDCs (i.e., clonal selection).^{131,132} The selection of high-affinity B lymphocyte clones into memory B-lymphocyte and plasma cell pools ensures future protection against repeat antigen exposure.

How antigen is retained on FDCs, both for primary B-lymphocyte responses and for long-term memory responses, is subject to intense research. However, supporting evidence indicates that complement receptors on FDCs are important in both short- and long-term B-lymphocyte responses. Papamichail et al¹⁰⁵ demonstrated that

Fig. 24.5 Classical pathway complement and complement receptors CD21/CD35 are required for the humoral response to replication-defective HD-2 virus or replication-sufficient KOS1.1 wild-type (WT) virus. Mice were injected at days 0 and 21 with 2×10^6 plaque-forming units of replication-defective (A–C) or replication-sufficient (D) virus, HD-2, and KOS1.1, respectively. Antibody titers were determined by enzyme-linked immunosorbent assay. Mean titer $\pm$ SD represents at least five mice analyzed in two separate experiments. (A) Deficiency in either C3 or C4 results in an impaired secondary humoral response to infectious herpes simplex virus (HSV). (B) $Cr2^{-/-}$ mice have an impaired secondary response similar to mice deficient in C3. (C) Humoral response to recombinant virus-expressed heterologous protein (β -galactosidase) is also impaired in mice deficient in C3 or CD21/CD35. (D) Secondary humoral response to replication-sufficient HSV-1 (strain KOS1.1) depends on complement C3 and C4. (From Da Costa XJ, Brockman MA, Alicot E, et al: Humoral response to herpes simplex virus is complement-dependent. *Proc Natl Acad Sci U S A* 96:12708, 1999; reproduced with permission of the National Academy of Science.)

retention of antigen–IgG immune complexes on FDCs was reduced upon depletion of C3 using cobra venom factor. Therefore it appears that immune complex deposition on FDCs is complement dependent. In addition, antibody production in vitro using FDCs demonstrates that antibody production is dependent on CD21/CD35.¹³³

Availability of $Cr2$ -deficient mice has shed light on the importance of FDC-derived CD21/CD35 on humoral responses. Because FDCs are radioresistant, it was possible to generate chimeric mice that restricted CD21/CD35 expression to B lymphocytes by BM transplantation. Ahearn et al¹⁰⁹ made chimeric mice with $Cr2$ -deficient

FDCs by transplanting wild-type BM (B-lymphocyte $Cr2^{+/+}$) into lethally irradiated $Cr2$ -deficient recipient mice (FDC- $Cr2^{-/-}$). After secondary challenge with antigen, the chimeric mice failed to sustain high-level antibody production, suggesting that CD21/CD35 on FDCs is important for recall or memory responses. Fang et al¹³⁴ came to a similar conclusion regarding the importance of CD21/35 expression on FDC for a strong immune response.

CD21/CD35 do appear important for persistence of antibody titers, normal frequencies of memory B lymphocytes and plasma cells, and affinity maturation. Adoptively transferring memory B

Fig. 24.6 ROLE OF COMPLEMENT-TAGGED ANTIGEN IN DIRECTING B-LYMPHOCYTE ACTIVATION AND FORMATION OF MEMORY B LYMPHOCYTES. Mature B lymphocytes survey secondary lymphoid tissues in search of antigen. Survival of mature B lymphocytes after antigen contact and T-cell help within splenic follicles depends on coreceptor signals through CD21/CD35. Lymphocytes receiving requisite signals expand and continue to differentiate within germinal centers, where CD21/CD35 is again important. B lymphocytes not receiving complement–ligand interactions in germinal centers die. In addition, complement-mediated deposition may localize antigen to follicular dendritic cells (FDCs), thereby providing the substrate for B-lymphocyte selection. Selection and differentiation in germinal centers lead to production of long-lived memory B lymphocytes and effector cells. The lifespan of memory B lymphocytes may also depend on continued interaction of antigen deposited on FDCs with CD21/CD35 in the spleen and in bone marrow. *IgG*, Immunoglobulin G.

lymphocytes into recipient mice lacking FDC-derived CD21/CD35 demonstrated that complement receptors on recipient mice stroma were required for each of these elements of memory.¹¹⁵ Importantly, chimeric mice lacking CD21/CD35-bearing FDCs had severely impaired recall responses several months after transfer of memory B lymphocytes compared with wild-type recipients.¹¹⁵ More recent studies identified a mechanism explaining long term retention of complement-opsonized immune complexes. Heesters et al (2013) found that FDC internalize C3d-opsonized complexes via the CD21 receptor into a non-degradative cycling endosomal compartment that periodically exposes intact immune complexes on the cell surface for recognition by cognate B cells.^{115a,115b} These studies suggest that CD21/CD35 on FDCs have an important role in long-term storage of antigen, thereby facilitating B-lymphocyte memory.

Complement and T-Cell Immunity

The complement system is important not only in humoral immunity; it also enhances responses by both CD4 and CD8 T cells.¹³⁵ Studies with influenza in C3-deficient mice first identified an important role for C3 in both the CD8 and CD4 response to infectious virus.¹³⁶ Although the mechanism is not clear, given the importance of DC in uptake and presentation of antigen, one likely role is C3 opsonization of virus. Moreover, the anaphylatoxins C3a and C5a released during complement activation stimulate cytokine releases by mast cells via their respective complement receptors. Studies of mice deficient in C3a receptor identified reduced responsiveness of a subset on CD4 T cells.¹³⁷ Likewise, C5a receptor appears to play an important role in the lung in T cell–dependent allergic responses.

T-cell responses are also “tuned down” via complement receptor. Interestingly, cross-linking of the CD46 complement receptor via C3b on activated CD4 T cells induces differentiation to a T-regulatory phenotype.¹³⁸ Further investigation on this topic will reveal additional

examples whereby the complement system participates in activation and regulation of T cells.

Conclusion

Over the past 20 years, a new appreciation for the complement system has come to light. Not only is the complement system required for host protection and innate immunity, but it also plays a critical role in “directing” the humoral response to thymus-dependent and thymus-independent antigens. Covalent attachment of split products of C3 (i.e., C3d) alters the fate of antigen and targets it to FDC within the lymphoid compartment. Other studies are uncovering additional roles for complement in the regulation of self-reactive B cells. The next decade will likely witness a similar revolution on our understanding of how complement participates in protection against autoimmune diseases such as SLE.

IMMUNOGLOBULINS

Properties and Structure

The mammalian immune system responds to the almost unlimited array of antigens by producing antibodies that react specifically with the molecules that induced their production. During the immune response, the structure of the inducing antigen is imprinted on the immune system, and subsequent challenges with the same or structurally related molecule(s) causes a more rapid rise in antibody levels to much greater concentrations than were achieved after the primary antigenic challenge. Thus the hallmarks of the humoral immune system include induction, specific protein interaction, and memory.

Antibodies belong to the family of proteins called the *immunoglobulins*. The basic structure of all immunoglobulins consists of a

monomer that contains four polypeptide chains: two identical heavy (H) chains and two identical light (L) chains covalently linked by disulfide bonds (Fig. 24.7).¹³⁹ The x-ray crystallographic structure of a monomeric immunoglobulin, specifically a mouse IgG2a monoclonal antibody (mAb), is shown depicted in both ribbon and space-filling models in Fig. 24.8.¹⁴⁰ Depending on the angle between the constituent Fab (fragment antigen-binding) monomers, an immunoglobulin monomer consists of a Y- or T-like structure. The size of the Fab arms is $80 \times 50 \times 40 \text{ \AA}$, and the size of base, called the Fc (fragment crystallizable) region, is approximately $70 \times 45 \times 40 \text{ \AA}$ according to the x-ray structure models. The Ig molecule exhibits considerable flexibility. In electron microscopic, low-angle x-ray scattering, transient electric birefringence, and resonance energy transfer studies, the angle between the Fab domains has been observed to vary from 0 to 180 degrees. All antibodies have two identical combining sites for each antigen located at the ends of the Fab domains.

Fab and Fc represent functional domains in immunoglobulins. They were discovered by performing limited proteolytic digestion of the molecule. Both the H and L chains contribute amino acids that constitute the antigen-binding site in Fab. The monovalent Fab fragment will bind to, but will not precipitate, multivalent antigens, in contrast to native IgG. A fragment can be prepared, called $F(ab')_2$, that is devoid of Fc but still precipitates antigen. This form of immunoglobulin consists of two Fabs disulfide bonded at a part of the molecule called the *hinge region*. The hinge region is the part of the Ig molecule that is responsible for the molecular flexibility exhibited by all immunoglobulins. The other major function of immunoglobulins, binding to specific receptors on cells and certain effector proteins such as C1q, is associated with binding site(s) also found in Fc. The Fc region of IgG, one of the classes of

immunoglobulin, also interacts with protein A, an immune evasion molecule on the cell walls of *S. aureus*. When bound to protein A, the binding of IgG to host effector molecules such as C1q is sterically interfered with.

The chain structure of immunoglobulins explains neither antibody structural diversity nor antibody binding to antigen. The discovery of variable and constant regions of amino acid sequence formed the basis for understanding both phenomena. Thus in the L chain, the 100 or so amino acids in the amino-terminal half of the protein (variable region $[V_L]$) vary among antibody molecules, but in the second half (constant region $[C_L]$), there is virtual complete

Fig. 24.7 DIAGRAMMATIC REPRESENTATION OF THE STRUCTURAL FEATURES OF AN IMMUNOGLOBULIN G (IgG) MOLECULE. NH_2 indicates the N-terminus and $COOH$ the C-terminus. V_H , C_H1 , V_L , and C_L homology domains are shown as boxes. Only the disulfide linkages that join H and L chains are shown. *Left*, Approximate boundaries of the complementarity-determining region (CDR) regions in the V_L and V_H regions. *Right*, Sequences encoded by V_H , D, J_H , V_L , and J_L segments in the V_H and V_L regions.

Fig. 24.8 X-RAY CRYSTALLOGRAPHIC STRUCTURE OF AN INTACT IgG MOLECULE shown as a ribbon diagram (A), or a space-filling model (B). The structure is that of a mouse immunoglobulin G2a (IgG2a) monoclonal antibody (protein data base [PDB] file 1IGT) and it was the first intact IgG to have its structure determined. (A) The two-layer β -sandwich characteristic of the “immunoglobulin fold” is clearly visible within each of the constituent domains of the γ -heavy chains (blue and red) and κ -light chains (green and yellow), respectively. Black lines indicate the positions of inter-heavy chain disulfide bonds in the hinge region. (B) The constant domains of the heavy chains and light chains are in various shades of blue, and the glycan chain lining a region between apposing CH_2 domains is in white. The variable regions are colored according to the genetic segment encoding them. Dark green denotes the polypeptide region encoded by the V segment of V_H and orange the DJ segment of V_H . Light green denotes the polypeptide encoded by the V segment of V_L and yellow that encoded by the J segment of V_L . (A, Modified from http://proteopedia.org/wiki/index.php/Image:Opening_1igt.png; B from http://www.imgt.org/IMGTeducation/Tutorials/IgandBcells/_UK/3Dstructure/Figure2.html.)

correspondence in amino acids, position for position, to the carboxy-terminus. The H chains exhibit a similar pattern and can be divided likewise into V_H and C_H1 , C_H2 , and C_H3 . Comparison of the amino acid sequence of many V_L s has revealed that whereas certain parts of the variable region exhibit excess variability, others are less variable. The former regions are called *hypervariable* or *complementarity-determining regions* (CDRs). The latter framework regions function as a structural scaffold to support the CDRs. Antigen binding is mediated by six CDRs, three in each of the V_H and V_L domains. The combining site for antigen is a trough, cavity, or even flat surface composed of parts of the hypervariable regions of both the H and L chains. It is a small region, representing only 25% of the antibody V region. The region that interacts directly with the epitope on the antigen is even smaller and is formed by the association of the CDR regions, each of which consists of approximately 20 amino acids. Thus the variation in a few amino acids accounts for the specificity and diversity of antibodies with respect to antigen binding.¹⁴¹

Immunoglobulins exhibit additional physical heterogeneity, which imparts to each immunoglobulin a special effector function that is reflected in unique biologic properties independent of antigen-binding activity. In the pregenome era of immunochemical research, heterologous and autologous antisera raised against immunoglobulins were used to classify three types of physical heterogeneity. The first kind is based on the antigenic heterogeneity exhibited by immunoglobulin when it is used as an immunogen in other species. This is called *class* or *isotypic variation*. In humans, five isotypes can be distinguished based on unique antigenic (isotypic) determinants found on the H chain. These are designated by capital Roman letters as IgG, IgM, IgA, IgD, and IgE. The H chain of each class is designated by the lower-case Greek letter corresponding to the Roman letter of the class. Thus the H chain for IgG is γ , for IgM is μ , for IgA is α , for IgD is δ , and for IgE is ϵ . Some of the immunoglobulin classes are composed of polymers of the basic monomer. In humans, the two antigenic varieties of the L chain are kappa (κ) and lambda (λ). Each Ig has two identical L chains; the κ and λ are shared by all classes. The monomeric form of any immunoglobulin is described by its chain structure. The molecular mass of the immunoglobulins can vary from 150 to 1000 kDa. This variation is attributable to polymerization of the basic monomer form. None of the immunoglobulins are polymeric forms of another class. IgG is the most prevalent, constituting 75% of

the total Ig in blood. It is present in normal adults at concentrations of 600 to 1500 mg/dL. IgG is designated $\gamma 2\kappa 2$ or $\gamma 2\lambda 2$. It is the only class of Ig that crosses the placenta (Table 24.2).¹⁴²

The isotype IgM is predominantly a pentamer consisting of five monomeric units disulfide linked at the C-terminus of the H chain. Each monomer of IgM is 180 kDa because of the presence of an additional C_H domain, specifically the $C_{\mu 2}$ domain, which replaces the hinge segment. The complete protein has a sedimentation coefficient of 19 S, which corresponds to a molecular mass of 850 kDa. IgM is designated $(\mu 2\kappa 2)_5$ or $(\mu 2\lambda 2)_5$. IgM also contains a 15-kDa protein called the *J chain*. In the current structural model of IgM, the J chain forms a disulfide-bonded clasp at the C-terminus of two H chains (Fig. 24.9).¹³⁹

The structure of the other isotypes of immunoglobulins are summarized as follows. The isotype IgA has a variable number of monomeric units and is designated $(\alpha 2\kappa 2)_n$ or $(\alpha 2\lambda 2)_n$, where $n = 1-5$. Serum IgA constitutes 20% of the total serum immunoglobulin, and 80% of this is monomeric. The remainder exists as polymers, where $n = 2-5$. The other form of IgA is found in external secretions such as saliva, tracheobronchial secretions, colostrum, milk, and genitourinary secretions. Secretory IgA consists of four components: a dimer of two monomeric molecules, a 70-kDa secretory component that binds noncovalently to the IgA dimer, and the 15-kDa J chain that is believed to form a disulfide-bonded clasp at the C-terminus of the H chains (see Fig. 24.9). The isotype IgD has a molecular mass of 180 kDa. Its serum concentration is very low, approximately 3 mg/dL. IgD apparently functions as a membrane molecule, being associated on mature but unstimulated B cells in association with IgM. IgE is the homocytotropic or reaginic Ig and mediates immediate hypersensitivity. It has a molecular mass of 180 kDa and, similar to IgM, has four C domains. The Fc portion of IgE binds strongly to a receptor on mast cells, Fc ϵ R, and this is how this immunoglobulin exerts its particular activity. The overall properties of the immunoglobulins are summarized in Table 24.2.

Subclasses of isotypes IgG, IgA, and IgM have been identified. The structural basis for this antigenic heterogeneity is variation in amino acid sequence in the Fc portion of the H chain of a given class. The subclasses of human IgG, called IgG1, IgG2, IgG3, and IgG4, are the best characterized. Each has a slightly different structure, with the most notable differences being in the length of the hinge and in

TABLE 24.2 Human Immunoglobulins: Properties and Functions

	IgG1	IgG2	IgG3	IgG4	IgM	IgA1	IgA2	IgD	IgE

Data from Golub ES: *Immunology: A synthesis*. Sunderland, MA, 1987, Sinaur.

Fig. 24.9 (A) Structure of the four subclasses of human immunoglobulin G (IgG). Constant region domains are indicated by C_nN , where n is the subclass and N is the domain. (B) Structure of human IgM. The J chain is shown in the model as disulfide linked to two μ -chains. Other models have been proposed. Filled circles indicate carbohydrate. (C) Structure of human secretory IgA. This model shows the possible arrangement of the two IgA monomers in relation to the secretory component and J chain. As the IgA molecule passes through the epithelial cells, the secretory components are synthesized and attached covalently to the Fc domain of the α -chains that have previously been joined to the J chain with disulfide links. Light chains are shown in blue, heavy chains in purple, disulfide bonds as gray lines, and carbohydrates as red circles. (From Turner M: Molecules which recognize antigens. In Roitt DK, editor: Immunology, London, 1989, Gower, p 51.)

the number of interchain disulfide bonds (see Fig. 24.9 and Table 24.2). IgG1 constitutes 70% of the total IgG and IgG2 20%. IgG3 and IgG4 constitute 8% and 2%, respectively, of the total IgG. The subclasses of IgG exhibit different catabolic rates and bind differentially to cell-associated Fc receptors (Fc γ R) and to C1q. Specifically, IgG2 does not bind to the Fc γ Rs and IgG4 binds about 10-fold less well than do IgG1 and IgG3. For C1q binding, the rank order of affinities is IgG3 > IgG1 > IgG2 >> IgG4. Despite the most obvious sequence differences among the human IgG isotypes being in their hinge regions, studies using engineered domain-swapped chimeric molecules have demonstrated that it is the more subtle amino acid sequence differences within the respective C γ 2 domains that account for the differences in binding to C1q and to the Fc γ Rs. Transport across the placenta is mediated by the Fc-neonatal receptor (FcRn) and for this functional activity IgG2 crosses the placenta slightly more slowly than the other three subclasses. The other known subclasses of Ig isotypes are associated with IgM (IgM1 and IgM2) and IgA (IgA1 and IgA2). The properties and function of these subclasses are less well known.

The second type of variation is called *allotypic variation*. It is attributable to genetically controlled antigenic determinants found on both the H and L chains. Although each human has all immunoglobulin isotypes, an individual has only one form of each

allotype on his or her immunoglobulin molecules. Allotypes are codominantly expressed, but an individual B lymphocyte secretes only one of the parental forms. This phenomenon is called *allelic exclusion*.

The third type of variation is attributable to antigenic determinants that are unique to each particular antibody molecule produced by an individual. These markers are called *idiotypic determinants*, and they are associated with a single species of antibody. The anti-idiotypic antibodies that recognize a particular idio type will not react with any other immunoglobulins in the donor other than the purified antibody that was used to raise the anti-idiotypic antibody. In most cases, the immune response to an antigen results in a mixture of several antibodies, each of which has identical binding specificity but distinct idiotypic determinants. Thus there can be many idiotypes for a given antigenic specificity, which has been interpreted as being a reflection of physical heterogeneity in or near the antibody combining site, for example, in the variable region domains. In some species (notably certain strains of mice), the response to antigen results in a predominant idio type on all antibodies of a given specificity. Because this quality is inherited, the idiotypes are called major, cross-reactive, or public. Some public idiotypes have been found in certain species (again, most notably mice) to be genetically linked to allotypes. Three kinds of anti-idiotypic antibodies have been described,

those that function as an internal image of the original antigen by mimicking the antigen structure, those that recognize antibody combining site-associated idiotypes, and those that are specific for framework-associated determinants. The internal image antiidiotypic antibodies are of clinical interest.

Every immunoglobulin is a glycoprotein, and the critical glycan is attached to the H chain in the Fc domain at the conserved asparagine at position 297 (Asn297). This single, N-linked glycan is essential for maintaining an open conformation of the two H chains as it lines the opposing faces of the pair of C_H2 subdomains of Fc (see Fig. 24.8B). The core structure of the N-linked glycan is a biantennary heptapolydisaccharide containing *N*-acetylglucosamine plus additional sugars (fucose, galactose), with bisecting *N*-acetylglucosamine and sialic acid variably present. Effector functions depend on the Asn297-linked glycan and are influenced by its structure.¹⁴³ Deglycosylated IgG does not interact effectively with Fcγ receptors (FcγRs) and cannot support in vivo effector responses, including antibody-dependent cell-mediated cytotoxicity or complement-dependent cytotoxicity.¹⁴⁴ Individual glycoforms contribute to modulating inflammatory responses and have disease association. For example, glycosylation differs in patients with rheumatoid arthritis¹⁴⁵ or vasculitis¹⁴⁶ compared with the normal population. Addition of sialic acid to the N-linked glycan reduces binding of IgG to FcγRs and reduces in vivo cytotoxicity. Regulation of sialylation of IgG contributes to the antiinflammatory homeostasis of serum IgG. Upon antigen challenge, reduced sialic acid–IgG can mediate immune clearance and protective immunity through interaction with subclass-specific FcγRs. Kaneko et al¹⁴⁷ have proposed that the protective effect of intramuscular immunoglobulin (IVIg) therapy is attributable to the minor fraction of sialylated IgG species in the total IVIg preparation and that the high doses required (1–3 g/kg body weight) for antiinflammatory activity could be significantly reduced by increasing the percentage of sialylated IgG.

THERAPEUTIC USE OF IMMUNOGLOBULIN

IVIg

IgG was one of the first plasma proteins prepared in a purified state as a therapeutic drug for treatment of clinical disorders. It remains, along with albumin and α-proteinase inhibitor, the most widely used therapeutic plasma derivative and is currently the major plasma product on the global market. Polyvalent human immunoglobulin preparations have been used to reconstitute humoral immunity in agammaglobulinemic patients for more than three decades. Until 30 years ago, intramuscular treatment was the mode of administration. Intramuscular preparations caused severe adverse reactions when injected intravenously.^{148–150} The most serious were anaphylactoid reactions and were probably complement mediated. Efforts to reduce anticomplementary activity and the prekallikrein activator activity were initiated in the early 1980s and safer IVIg preparations became available.

Intravenous immunoglobulin is prepared from pooled human plasma pools of 3000 to 50,000 L. The World Health Organization requires more than 1000 donors per lot. The majority of IVIg is produced by cold ethanol fractionation procedures,^{151,152} with filtration and polishing chromatography steps added to increase yield and decrease pathogen transmission.^{153,154} Gamunex (Talecris Biotherapeutics) is produced from cold ethanol fractionation followed by caprylate precipitation and chromatography.^{153,155} This is the first significant change in commercial IVIg production in 20 years. IVIg contains concentrated IgG with normal plasma ratios of IgG1 and IgG2, lower percentages of IgG3 and IgG4, and only trace amounts of IgA and IgM. It retains the antibody repertoire, reflecting the combined immunologic experience of the donors.^{156,157} Hyperimmune IVIg is purified from donor plasma selected for high titer toward a specific pathogen. Prophylaxis for cytomegalovirus and respiratory syncytial virus are two approved clinical applications.^{157,158}

The availability of safe IVIg preparations and the fortuitous observation that IgG treatment of a patient with thrombocytopenia and IgG deficiency increased the patient's platelet count began an intense period of clinical use of IVIg for indications other than primary immune deficiency. In 1990, the National Institutes of Health sponsored a Consensus Development Conference, which produced the first consensus statement on IVIg clinical indications.¹⁵⁹ As a result, six disease indications—primary immunodeficiency, Kawasaki syndrome, chronic lymphocytic leukemia, human immunodeficiency virus (HIV) infections during childhood to prevent infections, BM transplantation to prevent graft-versus-host disease or bacterial infections in adults, and idiopathic purpura—were approved by the Food and Drug Administration (FDA) for labeling and marketing. The licensed indications remain unchanged, but off-label uses include more than 100 conditions (for further discussion, see Chapter 116).^{160,161}

The experience with IVIg clinical development has been largely empiric and anecdotal. The mechanisms for patient benefit or harm are poorly understood, especially for high-dose immune modulation therapy. Various known and some yet undiscovered functions of immunoglobulins in immune homeostasis may contribute, including modulation of the function and expression of Fc receptors, interaction with complement and cytokine systems, antiidiotypic antibodies, and regulation of T-cell and B-cell function.^{162–164}

Many effects of IVIg are explained by mechanisms beyond antigenic recognition of pathogens. IVIg preparations contain up to 30% dimers composed of idiotype–antiidiotype antibody pairs. These dimers appear to be very effective as a sink for activated complement and can inhibit complement activation.¹⁶⁵ Benefit for treatment of immune thrombocytopenia purpura seems to be mediated by Fc-receptor blockade of the reticuloendothelial cell salvage receptor, also known as FcRn, combined with an antiidiotypic neutralization of antiplatelet antibody that together eliminates antiplatelet antibody from the blood. Other indications of antibody neutralization can be seen in IVIg treatment of myasthenia gravis. The dramatic success of IVIg in treating Kawasaki syndrome may be attributable to several mechanisms, including antiidiotypic neutralization of antiendothelial antibodies, inhibition of cytokine production and function, and elimination of causative superantigens.^{166,167} IVIg inhibits B-cell activation and autoantibody production by enhancing CD8⁺ suppressor T-cell function. Cell-mediated immunity is also affected.¹⁶² As mentioned earlier, Kaneko et al¹⁴⁷ ascribe much of the effect of IVIg to a small fraction of it that is sialylated. A 2011 report from this group suggests a mechanism for the way that sialylated IgG in IVIg downmodulates the inflammatory response of the immune system.¹⁶⁸ They suggest that the sialylated IgG Fc region binds to DC-SIGN, a molecule on the surface of “regulatory” myeloid cells, including DCs. In response to DC-SIGN ligation by sialylated IgG, these cells secrete the cytokine IL-33, which in turn stimulates IL-4 production by basophils. IL-4 upregulates the synthesis of the “inhibitory” class of FcγR on effector macrophages, namely FcγRIIB. Because ligation of this class of FcγR by immune complexes actually results in the recruitment of regulatory phosphatases, which shut down intracellular signaling cascades, the net effect is to increase the activation threshold required to initiate inflammation by these effector cells.

Adverse Events Related to Intravenous Immunoglobulin Infusion

Adverse events associated with IVIg can be characterized as (1) early systemic events, (2) infectious disease transfer, and (3) high-dose treatment-related adverse effects.¹⁴⁹

Early Systemic Events

Common transfusion-related early events are listed in Table 24.3. Most early events are self-limiting and infusion rate dependent.

TABLE 24.3 Early Systemic Adverse Events Associated With Intravenous Immunoglobulin Infusion

Fever	Rash or urticaria
Chills	Chest tightness
Sore throat	Dyspnea
Face flush	Wheezing
Tachycardia	Low or high blood pressure
Palpitations	Shock
Lumbar pain	Anxiety
Abdominal pain	Nervousness
Nausea	Headache
Vomiting	Migraine
Shaking	Anaphylaxis
Fatigue	Malaise
Myalgia	Leukopenia

Premedication with steroids, aspirin, or other nonsteroidal antiinflammatory drugs often decreases symptoms. Prophylaxis with propranolol can be effective for induced migraine. Aseptic meningitis is a rare early event, is observed 1 to 2 days postinfusion, is unrelated to infusion rate, and can be treated with intravenous steroids and analgesics.^{149,169}

The frequency of reported adverse events varies considerably, ranging from 10% to 85%.^{149,159,170–172} There are many reasons for this high variability in reporting, including (1) differences in product,^{154,170,173} (2) infusion rate, (3) dose and frequency of dosing, (4) patient population, and (5) relative experience of patient and physician. Both patients and physicians become steered to the adverse events, and because incidents are not life threatening and often respond to prophylaxis medication, they are ignored as “normal.” Nonetheless, these events are common and affect health and quality of life of patients.^{160,170}

Infectious Disease Transfer

A few early preparations of IVIg transmitted hepatitis C virus. Manufacturers have added viral inactivation and partitioning steps, and current licensed products are safe with respect to HIV, hepatitis C virus, hepatitis B virus, and other blood-borne pathogens (see [Chapter 116](#)).¹⁷⁴ The industry has responded to the threat of prions with process validation,^{171,175} donor screening, donor testing, inventory management (look back), and plasma pool testing.

High-Dose Treatment-Related Adverse Events

Intravenous immunoglobulin treatment for immune modulation of neurologic diseases requires doses of 1 to 2 kg/kg body weight or two to five times the dose recommended for replacement therapy. Adverse events with high-dose administration include those listed in [Table 24.3](#) and occasionally thromboembolic events, renal complications, and anemia.^{149,172,176–179} Thromboembolic events include deep venous thrombosis, pulmonary embolism, myocardial infarction, and stroke. Thromboembolic events and renal failure seem to be independent of infusion rate. The cause of thromboembolic events is not known. Dalakas¹⁸⁰ has suggested that increased serum viscosity plays a role. Factor XIa has also been identified in IVIg preparations.¹⁷³ Factor XIa could directly lead to shortening of coagulation time and risk of thrombosis. Renal complications are rare but result in high morbidity and mortality. Whether IgG, contaminants, or excipients are responsible is not clear. Of the 88 renal adverse events reported to the FDA, 90% were stabilized with sucrose.^{149,169} Whether the adverse events

observed with IVIg treatment of neurologic diseases are related to a preexisting medical condition or the high doses required for treatment is not clear.

Passive Immunization and Monoclonal Antibody Therapy

Passive immunization in the broadest sense represents the transfer of antibodies to a human recipient who is unable to produce the antibody due to the acuity of an infection, immunodeficiency, or immune tolerance to the target antigen. The use of plasma from patients who have recovered from Ebola virus to treat those acutely ill with the infection¹⁸¹ is an example of the simplest form of antibody transfer, where neither the antigenic epitope nor the sequence of the antibodies are known, and there is no purification step. Indeed, the pathogen need not be identified; it is only necessary that antibodies can clear the infection.

With the use of intravenous immunoglobulin (described earlier) to normalize IgG levels in patients with inherited immunodeficiencies (e.g., CVID or X-linked hypogammaglobulinemia) or chronic lymphoproliferative disorders, the goal is to provide a wide range of IgG immunoglobulins specific for antigens encountered by the general population, using a product purified from plasma donated by a large pool of healthy donors. Specialized IVIg products have also been developed that are enriched for antibodies that recognize specific pathogens by prescreening donors. Examples include VariZIG (for varicella), Cytogam (CMV), HBIG (hepatitis B) as well as products for rabies, botulinum toxin, and tetanus.

Immunized animals once served as the major source of therapeutic immunoglobulins; indeed, the modern medical era can be traced to the late 1800s, when serum from horses immunized with diphtheria toxin was first used therapeutically. The antigen used to immunize the animal need not be infectious: antivenom products can be used to treat bites from coral snakes, pit vipers, black widow spiders, and scorpions. Some of these products are treated with proteolytic enzymes to produce Fab fragments, such as crotalidae polyvalent immune FAB (Crofab). Digibind is another such Fab product, derived from sheep immunized with digoxin bound to human albumin, as used to treat digoxin overdoses.

When the intended antigen is of human origin, there is the challenge that human plasma donors are likely to be tolerant to the antigen. A notable exception is the Rh-D antigen, which, being genetically polymorphic, is immunogenic to Rh-negative individuals, and human-derived anti-Rh preparations can be used to prevent sensitization during pregnancy and also as a treatment for immune thrombocytopenic purpura. However, apart from this special case, targeting human antigens generally requires a sensitized animal, a prominent example being antithymocyte globulin (ATG), which induces lymphopenia as a treatment for aplastic anemia or as part of an immunosuppressive regimen in organ transplantation.

Polyclonal antibodies can be advantageous in some cases (especially for ATG and antivenin) but the epitopes recognized and the biologic activity may be variable between different lots of the product. In retrospect, then, it is not surprising how Kohler and Milstein's technique for the generation of monoclonal antibodies¹⁸² quickly revolutionized medical diagnostics and almost all of biomedical research. Monoclonal antibodies as therapies came more slowly, and there were initial concerns about the generation of “HAMA” (human antimouse antibodies). However, now there are modifications to partially or fully replace mouse sequences with human sequences ([Fig. 24.10A](#)). Furthermore, fully human antibodies can be generated using mice that are lacking mouse immunoglobulin genes and are transgenic for the human sequences.¹⁸³ Using mice with a germline knockout for the gene encoding the antigen of interest can enable the generation of antibodies that have been previously difficult to obtain.^{183,184} Four fully human monoclonal antibody products (ranibizumab, adalimumab, belimumab, and ramacirumab) now on the market were developed by an alternative method, phage display ([Fig. 24.10B](#)).^{185–189}

A

Fig. 24.10 GENERATION, STRUCTURE, AND MODIFICATION OF MONOCLONAL ANTIBODIES. To generate monoclonal antibodies, based on the technique of Kohler and Milstein,^{182,190} first, a mouse is immunized repeatedly with the antigen, using an adjuvant. After verification of an antibody response, the spleen is removed. Polyethylene glycol is then used to fuse isolated splenic lymphocytes with a mouse nonsecretory myeloma cell line carrying a mutation in the X-linked *Hgpri* gene, which is essential for the purine salvage pathway. The mutation ensures that the myeloma cell line will not grow in HAT (hypoxanthine, aminopterin, thymidine) media. Normal cells can survive despite the presence of aminopterin, which disrupts the de novo purine synthesis pathway, because they have an intact purine salvage pathway and can use hypoxanthine. (Because aminopterin interferes with folate metabolism, which also affects pyrimidine synthesis, provision of thymidine is required.) Fusions (hybridomas) between the lymphocytes and the myeloma cell line can grow in HAT only if they have incorporated an X chromosome with the normal *Hgpri* gene from the mouse lymphocyte, restoring the purine salvage pathway. Unfused lymphocytes, on the other hand, have no stimulus to grow. Hybridomas growing in HAT are then cloned by limiting dilution (e.g., in 96-well plates); some of these hybridomas will have retained the chromosomes containing the rearranged immunoglobulin light and heavy chain of the original lymphocyte. Because these genes are now present in a plasma cell with the cellular apparatus for immunoglobulin secretion, immunoglobulin expressed by the original mouse lymphocyte will now be secreted into the media. The supernatant of each hybridoma clone must be screened for the presence of the desired antibody. (A) Modifications of immunoglobulins derived from monoclonal antibody technology. Chimeric mAbs contain the mouse variable region and retain the human constant regions. Humanized antibodies retain only the mouse sequences from the CDRs, which recognize antigens. Fabs are also shown, which lack the constant region of the heavy chain. scFVs (single chain variable fragments) contain only the N-terminal sequences of the heavy and the light chain required for antigen recognition. Because they no longer have any disulfide bond to connect the heavy and the light chain, a linker peptide must be introduced. In the example shown, the carboxy terminus of the light chain is linked to the amino terminus of the heavy chain. The structure of a bispecific scFv is also shown, which can engage two separate ligands simultaneously, bringing together two separate cell types (e.g., immune effector cells with malignant target cells).

Monoclonal antibodies can affect target cells by activation-induced cell death, blockage of ligand-receptor interactions, activation of complement, antibody-dependent cell-mediated cytotoxicity, and uptake of antibody-coated cells in the reticuloendothelial system. To increase cytotoxicity, immunoglobulins can be conjugated to toxins (e.g., brentuximab vedotin, targeting CD30; trastuzumab emtansine, targeting human epidermal growth factor receptor 2 [HER2]; and gemtuzumab ozogamicin, targeting CD33) or radionuclides (e.g., ibritumomab tiuxetan or I131-tositumomab). Obinutuzumab (for chronic lymphocytic leukemia [CLL]) has been glycoengineered such that its Fc moiety has increased affinity for Fc receptors. A chimeric molecule consisting of bispecific single chain variable antibody sequences (scFvs) has been developed (blinatumomab), to engage cytotoxic CD3+ T cells with CD19 expressing acute lymphoblastic leukemia (ALL) cells. mAbs targeting blood cells have impacted practically every hematologic condition including lymphoma and

autoimmune diseases (rituximab), CLL (rituximab, obinutuzumab, ofatumumab), Hodgkin disease (brentuximab and pembrolizumab¹⁹¹), acute myeloid leukemia (AML) (gemtuzumab¹⁹²⁻¹⁹⁴), myeloma (daratumumab and elotuzumab), and allogeneic transplantation (alemtuzumab¹⁹⁵). In addition to surface molecules, mAbs can target plasma components—in theory, any protein. Vascular endothelial growth factor (VEGF), TNF- α (and other cytokines) are prominent examples, as well as C5 (described later). Omalizumab is a special case of a humanized IgG immunoglobulin molecule that targets a whole class of immunoglobulin: IgE.¹⁹⁶ Targeting plasma proteins may increase their clearance from the circulation and inhibit protein-protein interactions or ligand-receptor binding.

The side effects of any monoclonal or polyclonal antibody therapy depends on the source of the antibody, the target, and the dose. The administration of human-derived IVIg, which involves a very large dose of immunoglobulin, is typically preceded by acetaminophen and

Fig. 24.10, cont'd (B) Isolation of human scFVs by phage display.^{185,188,189} This is a newer technique that does not require mouse immunization. First, a library of human variable chain sequences is generated by amplification of cDNA from pooled human lymphocytes. These sequences are then cloned into the DNA of a filamentous phage, such that one of the phage coat proteins is linked to the scFv. Each phage displays a different scFv, and a critical step is to ensure the diversity of the scFvs contained in the library (typically 10^9 to 10^{10} unique clones are desirable). The phage expressing an scFv can be captured by an immobilized antigen (on a plate, or on the surface of a cell) and the retained phage can be recovered and amplified in bacteria. The phage obtained from this step can be further purified in one or more additional capture steps, and at the end, a phage expressing an scFv highly specific for antigen can be recovered, allowing the human immunoglobulin sequences that recognize the antigen to be determined.

diphenhydramine to prevent infusional reactions, as described earlier. For products derived from animal serum, anaphylactoid reactions are commonly seen, requiring premedication regimens that include high dose steroids, for example, for equine ATG administration. When the patient later makes an antibody response against horse proteins, this can result in immune complex deposition, leading to serum sickness, characterized by fever, rash, and arthritis. Purified chimeric, humanized, or human monoclonal antibodies will typically not result in these reactions. Rather, side effects are dependent, typically, on “on target” effects. A notable example of this are the febrile infusion reactions that occur with the initial use of rituximab caused by the lysis of CD20-expressing (malignant and nonmalignant) B cells and the immunosuppressive effects of drugs targeting TNF- α , C5, and integrins. However, a true “off target” side effect, could, theoretically, occur if a mAb were to cross-react with unintended epitopes on plasma proteins or extracellular surface proteins.

The overall half-life of IgG is approximately 20 days¹⁹⁷; when targeting an abundant surface protein or rapidly produced plasma protein, the half-life may be shorter. Most monoclonal antibodies are administered less often than weekly; based on their affinity constants, doses required are generally high enough that they must be given by intravenous rather than subcutaneous injection, with some exceptions. As of 2016, 52 monoclonal antibodies have been approved by the FDA (Table 24.4). The naming of monoclonal antibodies follows a convention¹⁹⁸ such that the first syllable is coined by the company

developing the drug, the second syllable indicates the use (e.g., “ci” for “cardiovascular,” “li” for “immune system,” “tu” for “tumor”) and the penultimate syllable indicates whether the antibody is derived from mouse sequences (“-omab”), chimeric mouse-human sequences (“-ximab”), more fully humanized molecules (“-zumab”), or fully human sequences (“-umab”). For example, *cetuximab* is a **chimeric** antibody used to treat *tumors*, whereas *eculizumab* is a **humanized** antibody that targets the *immune* system.

DRUGS TARGETING THE COMPLEMENT SYSTEM

Eculizumab

The humanized anti-C5 mAb, eculizumab (Soliris), represents an interesting link between the previous sections of this chapter. Eculizumab has already dramatically affected the management of patients with both paroxysmal nocturnal hemoglobinuria (PNH) (see Chapter 31) and atypical hemolytic uremic syndrome (see Chapter 134), with more indications likely to come.

C5 is an attractive target because it is essential for all three pathways of complement activation and it is present in a considerably lower circulating concentration than C3 (by a factor of about 10.¹⁹⁹) Furthermore, congenital absence of C5 and other downstream members of the MAC results in a predisposition mainly to

**TABLE
24.4****Monoclonal Antibodies Approved by the FDA as Therapies**

Generic Name	Trade Name	Target	Source	Year Approved	Indication	Route of Administration
Muromonab-CD3	Orthoclone	CD3	Murine	1986	Transplant rejection	Intravenous
Rituximab	Rituxan	CD20	Chimeric	1994	Lymphoma, CLL, microscopic polyarteritis nodosa, Wegener, rheumatoid arthritis	Intravenous
Abciximab	ReoPro	GPIIb/IIIa	Chimeric Fab	1994	Angioplasty	Intravenous
Daclizumab	Zenapax	CD25	Humanized	1997	Transplant rejection (no longer available)	Intravenous
Trastuzumab	Herceptin	HER-2	Humanized	1998	Breast cancer, gastric and GE junction tumors	Intravenous
Palivizumab	Synagis	RSV	Humanized	1998	RSV prophylaxis	Intramuscular
Basiliximab	Simulect	CD25	Chimeric	1998	Transplant rejection	Intravenous
Infliximab	Remicade	TNF- α	Chimeric	1998	Crohn disease, ankylosing spondylitis, plaque psoriasis, psoriatic arthritis, rheumatoid arthritis, ulcerative colitis	Intravenous
Gemtuzumab ozogamicin	Mylotarg	CD33	Humanized	2000	AML (no longer available)	Intravenous
Alemtuzumab	Campath/Lemtrada	CD52	Humanized	2001	CLL, T-cell lymphoma, multiple sclerosis	Intravenous or subcutaneous
Adalimumab	Humira	TNF- α	Human	2002	Rheumatoid arthritis, psoriatic arthritis, Crohn disease	Subcutaneous
Ibritumomab tiuxetan	Zevalin	CD20	Mouse radioconjugate	2002	Lymphoma	Intravenous
Omalizumab	Xolair	IgE	Humanized	2003	Severe (allergic) asthma, idiopathic urticaria	Subcutaneous
Tositumomab-I131	Bexxar	CD20	Mouse radioconjugate	2003	Lymphoma (no longer available)	Intravenous
Cetuximab	Erbitux	EGFR	Chimeric	2004	Colon cancer, head and neck cancer,	Intravenous
Natalizumab	Tysabri	$\alpha 4\beta 1$	Humanized	2004	Multiple sclerosis, Crohn disease	Intravenous
Bevacizumab	Avastin	VEGF	Humanized	2004	Colon, renal, cervical, ovarian, and lung cancer	Intravenous
Ranibizumab	Lucentis	VEGF	Humanized Fab	2006	Wet AMD, diabetic macular edema, macular edema following retinal vein occlusion	Intravitreal
Panitumumab	Vectibix	EGFR	Human	2006	Colorectal cancer	Intravenous
Eculizumab	Soliris	C5	Humanized	2007	PNH, aHUS	Intravenous
Certolizumab pegol	Cimzia	TNF- α	Humanized Fab	2008	Crohn disease, psoriatic arthritis	Subcutaneous
Canakinumab	Ilaris	IL-1b	Human	2009	Cryopyrin-associated periodic syndromes, familial cold urticaria, systemic onset juvenile chronic arthritis, Muckle-Wells syndrome	Subcutaneous
Golimumab	Simponi	TNF	Human	2009	Rheumatoid and psoriatic arthritis, ankylosing spondylitis	Subcutaneous

**TABLE
24.4****Monoclonal Antibodies Approved by the FDA as Therapies—cont'd**

Generic Name	Trade Name	Target	Source	Year Approved	Indication	Route of Administration
Ustekinumab	Stelara	IL-12/23	Human	2009	Psoriatic arthritis, plaque psoriasis	Subcutaneous
Ofatumumab	Arzerra	CD20	Human	2009	CLL	Intravenous
Denosumab	Prolia/Xgeva	RANK-L	Human	2010	Bone metastases, osteoporosis	Subcutaneous
Tocilizumab	Actemra	IL-6 receptor	Humanized	2010	Rheumatoid arthritis, systemic juvenile idiopathic arthritis	Intravenous
Bretuximab vedotin	Adcetris	CD30	Chimeric conjugate	2011	Hodgkin, anaplastic large cell lymphoma	Intravenous
Belimumab	Benlysta	BLyS	Human	2011	Systemic lupus	Intravenous
Ipilimumab	Yervoy	CTLA-4	Human	2011	Melanoma	Intravenous
Raxibacumab	From CDC	Anthrax protective antigen	Human	2012	Inhalational anthrax	Intravenous
Pertuzumab	Perjeta	HER2	Humanized	2012	Breast cancer	Intravenous
Obinutuzumab	Gazyva	CD20	Humanized	2013	CLL	Intravenous
Ado trastuzumab emtansine	Kadcyla	HER2	Humanized, conjugated	2013	Breast cancer	Intravenous
Nivolumab	Opdivo	PD1	Human	2014	Melanoma, lung cancer	Intravenous
Blinatumomab	Blincyto	CD19; CD3	Mouse	2014	ALL	Intravenous continuous infusion
Pembrolizumab	Keytruda	PD1	Humanized	2014	Melanoma	Intravenous
Ramucirumab	Cyramza	VEGFR2	Human	2014	Gastric, GE junction, and lung cancer	Intravenous
Vedolizumab	Entyvio	$\alpha 4\beta 7$ integrin	Humanized	2014	Crohn disease, ulcerative colitis	Intravenous
Siltuximab	Sylvant	IL-6	Chimeric	2014	Multicentric Castleman disease	Intravenous
Dinutuximab	Unituxin	Ganglioside GD2	Chimeric	2015	Neuroblastoma	Intravenous
Evolocumab	Repatha	PCSK9	Human	2015	Hypercholesterolemia	Subcutaneous
Idarucizumab	Praxbind	Dabigatran	Humanized Fab	2015	Reversal of anticoagulation effect of dabigatran	Intravenous
Alirocumab	Praluent	PCSK9	Human	2015	Hypercholesterolemia	Subcutaneous
Necitumumab	Portrazza	EGFR	Human	2015	Squamous non-small cell lung cancer	Intravenous
Mepolizumab	Nucala	IL-5	Humanized	2015	Asthma	Subcutaneous
Daratumumab	Darzalex	CD38	Human	2015	Myeloma	Intravenous
Secukinumab	Cosentyx	IL-17a	Human	2015	Plaque psoriasis, psoriatic arthritis, ankylosing spondylitis	Subcutaneous
Elotuzumab	Empliciti	SLAMF7	Humanized	2015	Myeloma	Intravenous
Ixekizumab	Taltz	IL-17	Humanized	2016	Psoriasis	Subcutaneous
Reslizumab	Cinqair	IL-5	Humanized	2016	Asthma with eosinophilic phenotype	Intravenous
Obiltoxaximab	Anthim	Anthrax protective antigen	Humanized	2016	Inhalational anthrax	Intravenous

aHUS, Atypical hemolytic uremic syndrome; AMD, age-related macular degeneration; AML, acute myeloid leukemia; ALL, acute lymphoblastic leukemia; CLL, chronic lymphocytic leukemia; EGFR, epidermal growth factor receptor; GE, gastroesophageal; IL, interleukin; PNH, paroxysmal nocturnal hemoglobinuria; RSV, respiratory syncytial virus; TNF, tumor necrosis factor.

N. meningitidis infections^{200,201} but not to other infections. In contrast, inherited mutations in C3 result in a broader spectrum of infections as well as autoimmunity. Eculizumab is derived from the sequence of an immunoglobulin from a mouse hybridoma, generated by immunizing mice with purified human C5, followed by screening of thousands of clones. The antibody secreted by the selected clone, m5G1.1mAb, could inhibit complement activation at a 0.5:1 ratio (as expected given the bivalency of IgG) in a standard hemolytic assay.^{202–204} The CDRs were cloned and grafted onto the respective human light and heavy chain sequences. An IgG2/IgG4 hybrid was chosen for the constant regions, because IgG2 binds Fc receptors minimally, and IgG4 activates complement minimally, given that these were two functions not desired for this particular drug.²⁰⁵ The humanized antibody retains the affinity of the mouse antibody, with a dissociation constant (K_d) of 120 pM. It has a half-life in humans of approximately 11 days, and it has been suggested that a minimum trough level of 35 µg/mL is required for sustained inhibition of terminal complement in humans.²⁰⁶ Although there is currently only one laboratory that offers serum drug level testing, testing for CH50, which is inhibited by eculizumab, is widely available and predicts clinical responses.²⁰⁷

Early development of eculizumab focused on testing the drug (and in some cases a related single chain variant) in patients with rheumatoid arthritis, lupus, coronary bypass, myocardial infarction, and membranous nephritis.^{208–211} The strategy of therapeutically inhibiting terminal complement in PNH was validated by a pilot study, a randomized study, and an open label study of eculizumab, where dramatic reductions in the serum hemolytic activity, lactate dehydrogenase, visible hemoglobinuria, and transfusion requirements—as well as improvements in male erectile dysfunction and esophageal spasms—were shown after a series of loading doses of 600 mg weekly for 4 weeks followed then by 900 mg, repeated every 2 weeks.^{212–214} While these studies were dramatic enough for drug approval in 2007, the question could have arisen as to whether correction of anemia and amelioration of transfusion requirements was an outcome important enough to justify the risk of meningococcal infection, a potentially fatal outcome, whose incidence was not known at the time. However, that same year, it was reported that the use of eculizumab dramatically decreased the rate of thromboses,²¹⁵ which are often recurrent,²¹⁶ and which represent the most important predictor of mortality. Survival curves in treated patients are now similar to age-matched controls.²¹⁷ Whereas pregnancies had been fraught with thrombotic complications, there is now evidence that not only is eculizumab safe for the fetus, but it also may be instrumental in reducing maternal mortality.²¹⁸ The effect of eculizumab on thrombosis points to a role for complement (e.g., activation of CD59-deficient platelets derived from the PNH clone) among the proposed mechanisms to explain hypercoagulability in PNH.

Neisseria infections, as seen in patients with inherited deficiencies of terminal complement, have indeed been seen in patients treated with eculizumab, sometimes despite immunization²¹⁹; the risk may be ~1% per year. All patients on eculizumab can now be vaccinated with a new quadrivalent meningococcal B vaccine (Trumenba or Bexsero) in addition to one of the quadrivalent a,c,w,y vaccines (e.g., Menactra, Menomune, Menveo). All patients must be instructed to report to an emergency room for blood cultures and immediate empiric treatment with antibiotics (e.g., ceftriaxone) in the event of any fever over 100.0°F or 37.7°C. Patients should also carry with them a letter from their physician explaining their condition (or wear an alert bracelet) and should carry on their persons at all times an antibiotic that covers meningococcal infection, such as azithromycin or ciprofloxacin. Interestingly, meningococcal infections in hypocomplementemic patients are a bit less fulminant than in normal hosts, and generally do not result in central nervous system (CNS) infections but rather septicemia, such that lumbar punctures are rarely required for patients on eculizumab—and should never delay empiric treatment with antibiotics. As for adults who have been splenectomized, practices vary such that in the United Kingdom, all patients on eculizumab are treated prophylactically with penicillin, whereas in the United States, there is more of a concern for the

emergence of resistant strains. It is possible to monitor antibody titers and the CDC is now recommending a booster of the a, c, w, y conjugate vaccine at 2 months for those with complement deficiency.

Patients with PNH may fail to respond to eculizumab because of (1) underlying aplastic anemia; (2) rapid drug clearance, as manifested by a nonsuppressed CH50 level, or a low eculizumab level on day 14 of the treatment cycle; (3) the Arg885His polymorphism in the C5 gene, as seen in about 3% of the Japanese population, such that the drug does not recognize the C5 protein at all²²⁰; or (4) extravascular hemolysis, caused by opsonization of C3d-coated red cells in the reticuloendothelial system.

The latter as described by Risitano et al²³⁶ is most interesting, reflecting a mechanism that has been “unmasked” by eculizumab. Despite blockade at the C5 level, the PNH red cell is still lacking CD55, which normally functions to inhibit the classical and alternative C3 and C5 convertases.²²¹ The PNH red cell is also lacking CD59, which may inhibit not only the MAC formation, but also the deposition of C3d on the red cell in the setting of loss of CD55.²²² Indeed, in some patients on eculizumab, C3d deposition on the red cell can be demonstrated by the direct antiglobulin test or by flow cytometry; such cells would have been lysed by the MAC in untreated patients. Opsonization by C3d can account for persistently elevated reticulocyte counts, the requirement for occasional transfusions, and progressive iron overload in some patients on eculizumab. Polymorphisms in the *CRI* gene, which affect levels of expression of this complement-regulating gene, may predict which patients have a partial versus complete response to eculizumab.²²³

Atypical hemolytic uremic syndrome (aHUS) (see Chapter 134), a different complement-mediated disorder, is the other FDA-approved indication for eculizumab. aHUS is characterized by thrombocytopenia, hemolysis, an elevated lactate dehydrogenase (LDH), microangiopathy, and dysfunction of many organs, but particularly the kidneys. Other entities with similar presentations that need to be distinguished include thrombotic thrombocytopenia purpura (TTP), malignant hypertension, Shiga toxin-producing *E. coli* (STEC), calcineurin inhibitors (and other medications), lupus, and the antiphospholipid antibody syndrome, the latter two being potential triggers for aHUS itself. The disease is recognized by schistocytes on the peripheral smear, an elevated LDH, and a disintegrin and metalloproteinase with thrombospondin motifs 13 (ADAMTS 13) level (drawn before empiric pheresis) that is not significantly decreased, and a variable and often subadequate response to plasmapheresis. Compared with TTP, the degree of thrombocytopenia is not as severe, there are fewer schistocytes, but the degree of renal insufficiency is often much more severe. aHUS is genetically complex, in that it can result from inherited mutations in the genes encoding the inhibitory complement factors H, I, membrane cofactor protein (CD46) or thrombomodulin—or gain of function mutations in the effector complement factors B or C3. Autoantibodies against factor H can produce a similar syndrome, and in a substantial proportion, no mutation is ever found. The inheritance is typically dominant with incomplete penetrance.²²⁴

The FDA granted approval to eculizumab for the treatment of aHUS based on two single arm studies reporting rapid improvement in thrombocytopenia, typically by day 7, and a more gradual improvement in the renal function, in many cases, allowing for discontinuation of dialysis.^{225,226} As in PNH, where eculizumab only masks an underlying defect, relapses have been seen upon drug discontinuation.²²⁷ Since recurrences after renal transplantation are common in aHUS, initiation and maintenance of eculizumab before and after transplant may be critical for maintaining graft function. Since undertreatment would be more serious here than in PNH, the recommended dose in aHUS is higher.

There is a growing literature on successful “off label” use of eculizumab, for example, for catastrophic antiphospholipid antibody syndrome,²²⁸ cold agglutinin disease,²²⁹ HUS due to Shiga toxin-associated *E. coli*,²³⁰ antibody-mediated renal graft rejection and dense deposit disease,²³¹ calcineurin inhibitor-induced thrombotic microangiopathy,²³² Devic neuromyelitis optica,²³³ myasthenia

TABLE 24.5**FDA-Approved Complement Inhibitors and Some New Drugs Under Development**

Company/Reference	Drug/Class	Target	Structure/Derivation	Route	Biochemical Data	Stage
Alexion	Eculizumab	C5	Humanized monoclonal antibody	Intravenous	$K_d = 120$ pM	FDA approved for PNH and aHUS
ViroPharma, CSC Behring	C1 esterase inhibitor: plasma derived	C1 esterase	Human protein	Intravenous		FDA approved for hereditary angioedema
Pharming-Salix	C1 esterase inhibitor: recombinant	C1 esterase	Protein analogue, produced in rabbits	Intravenous		FDA approved for hereditary angioedema
Alexion (Taligen)	TT30	C3 convertase	Factor H-CR2 fusion	Intravenous/subcutaneous	$IC_{50} = 0.5$ μ M	Human studies
Norvartis	LFG 316	C5	mAb	Intravenous/intravitreal		Human studies
Amyndas, Apellis, Potentia	Compstatin analogues	C3/C3b	Cyclic peptide/phage display	Intravitreal, subcutaneous, inhaled	$IC_{50} = 62$ nM, K_d for C3b = 2.3 nM	Human studies
Volusion Akari	Coversin	C5	Peptide/tick saliva	Subcutaneous	Maximal inhibition at 10 μ g/mL	Human studies
Achillion	Small molecule	Complement factor D	X-ray crystallography	Oral	$K_d < 1$ nm, $IC_{50} = 17$ nm (protease inhibition)	Preclinical studies
Amyndas	Mini Factor H	C3 convertase	Derived from factor H		$IC_{50} = 0.22$ μ M (for C3 deposition)	Preclinical studies
Alnylam	ALN-CC5	C5 RNA	RNAi conjugate	Subcutaneous		Preclinical studies
Lindofor et al	3E7/H17	C3b	mAb		100% blockage of lysis at 1 μ M	Preclinical studies
Ra Pharmaceuticals	several	C5	Cyclic peptide	Subcutaneous	K_d 2.6 nM, IC_{50} 8.1 nm (% RBC lysis)	Preclinical studies

aHUS, Atypical hemolytic uremic syndrome; IC_{50} , half maximal inhibitory concentration; K_d , dissociation constant; PNH, paroxysmal nocturnal hemoglobinuria; RBC, red blood cell.

gravis,²³⁴ and lupus nephritis.²³⁵ Other possible uses under investigation include Guillain-Barré syndrome and thrombocytopenia refractory to platelet transfusion.

New Directions and New Anticomplement Therapies

While eculizumab is likely to find additional indications, there is also a plethora of additional agents and targets under investigation—but there will be challenges. Particularly, in targeting complement proteins upstream from C5, there may be a predisposition to a broader range of infections, and possibly also to autoimmune diseases, as seen in patients with genetic deficiencies of C3. Furthermore, C3 may be harder to inhibit because it circulates at considerably higher concentrations than C5. While PNH provides the most convenient clinical endpoint for the efficacy of any new complement inhibitor, it is no longer ethical to randomize patients with a large PNH clone to an arm that contains neither eculizumab nor anticoagulation, at least for long term. Possible approaches could be to investigate new drugs in patients with PNH with inadequate responses to eculizumab (or in those who have the Arg885His polymorphism in the C5 gene), or to conduct a noninferiority study.

Potential targets of new anticomplement drugs include C5, C3, factor B, and factor D. In addition to monoclonal antibodies, fusion proteins, cyclic peptides, small molecules, RNAi conjugates, and soluble complement receptors are examples of approaches under investigation²³⁶ (Table 24.5). Among those already introduced to human subjects include TT30, a fusion of a fragment of complement

inhibitor factor H and the iC3b/C3d binding domain of complement receptor 2 (CR2); this is intended to direct the factor I cofactor activity and decay-accelerating activity of factor H to the site of complement activation on the surface of the red cell.²³⁷ Compstatin analogues are cyclic peptides that are specific for C3 and C3b, originally identified by phage display. There is now a phase I study of the compstatin analogues APL-2 in patients with PNH²³⁸ and POT-4 in age-related macular degeneration.²³⁹ A new anti-C5 mAb has been investigated in humans with macular degeneration in several studies (see Table 24.5), and recently, coversin,²⁴⁰ a peptide derived from ticks, has been examined for its effect on C5 complement activity in healthy volunteers.²⁴¹ It is possible that these new complement inhibitors will need to be used in combination with other drugs for maximal efficacy.
