The management of pregnant patients with ET remains problematic. The major goal of any therapeutic intervention in pregnant patients with ET should be the prevention of the vasoocclusive events that lead to placental infarction; intrauterine fetal growth retardation; and, in some cases, fetal death. Patients with *JAK2V617F*-positive ET are at a higher risk of developing such complications. In one large series, there was no significant relationship between the fetal outcome and the degree of maternal thrombocytosis or the presence of disease complications. In this series, there were no instances of excessive bleeding or other related complications during delivery. This group did not recommend the use of therapeutic platelet pheresis and, in fact, claimed that specific therapy (aspirin, heparin, or platelet pheresis) did not alter the clinical course. Low-dose aspirin (81 mg/day), because of its profound effect on events involving the microcirculation such as erythromelalgia and transient ischemic events, has been used with increasing frequency in pregnant patients during the first and second trimesters. Low-dose aspirin therapy is safe in pregnant women. It is recommended that aspirin be discontinued at least 1 week before delivery to avoid bleeding complications such as an epidural hematoma during delivery or during the postpartum period. Because of the high risk of bleeding in patients with platelet counts greater than $1000 \times 10^9/L$ with acquired von Willebrand syndrome, aspirin therapy is contraindicated. There is limited experience reported in the literature with aspirin therapy alone, and although the results are promising, the sample size is too small to confirm a beneficial effect. The observed true birth rate, however, was 75% in those receiving aspirin compared with 43% in the group in the literature who received no therapy. Aspirin therapy has, however, recently been found to be ineffective in preventing complications in *JAK2V617F*-positive pregnant ET patients. Chemotherapeutic drugs should be avoided during the period of conception and especially during the first trimester. Both hydroxyurea and busulfan are known teratogens in animal models. In addition, busulfan and hydroxyurea reduce fertility in men. Because the greatest risk of thrombosis is postpartum, thrombosis prophylaxis should be initiated in the form of low-molecular-weight heparin and low-dose aspirin after delivery, unless the patient is hemorrhaging for approximately 8 weeks. These measures should be continued for 6 weeks. Mothers receiving IFN, anagrelide, or hydroxyurea should refrain from breastfeeding.

IFN- α therapy is not known to be leukemogenic or teratogenic, and because it does not cross the placenta, its use may be considered during pregnancy. The manufacturers of IFN- α still advise that IFN- α not be used during pregnancy because adverse effects on the fetus cannot be ruled out. The effect of IFN- α on male fertility remains uncertain. Anagrelide therapy should be avoided in pregnant patients because of its potential to lead to fetal thrombocytopenia.

Hormone-replacement therapy including oral contraceptives and estrogen-replacement hormone therapy remains controversial in patients with ET. Each of these agents in the normal population is associated with an increased incidence of arterial and venous thrombosis. Intuitively, it would seem wise to avoid such agents in patients

with ET who are already at an increased risk of developing thrombosis. Gangat et al retrospectively reviewed the consequences of such hormonal interventions in 305 women. Oral contraceptive therapy was associated with a high incidence of venous thrombosis occurring within the abdominal cavity, but estrogen-replacement hormone therapy in menopausal women did not appear to be associated with an increased incidence of thrombosis. This observation is surprising and might be a consequence of the limited numbers of patients included within this study.

If a patient with ET develops a thrombotic episode, anticoagulation with low-molecular-weight heparin and then transition to an oral anticoagulant is recommended. The thrombotic episode places a patient into a high-risk group in which myelosuppressive therapy is clearly indicated. Whether patients should have life-long anticoagulation or should receive only 6–12 months of anticoagulation after they are in a complete hematologic remission has not been investigated in a systematic fashion. Because the data necessary to make this decision are not available, this decision can only be made at the discretion of the treating physician. Antiplatelet therapy has been shown to reduce the risks of deep venous thrombosis and pulmonary embolism in a variety of high-risk groups. In patients who have a new thrombosis while they are in complete hematologic remission and are optimally anticoagulated, some consideration should be given to adding low-dose aspirin if the risk of hemorrhage is not excessive.

Lastly, consensus response criteria have been updated recently to allow for more uniform reporting of therapeutic response within clinical trials (Table 69.9). Standardized response categories were created by a working group formed by the ELN and IWG-MRT in 2013 in an attempt to incorporate symptom response with clinical, hematologic, and histologic response criteria in order to ultimately enhance the evaluation of novel therapies tested in clinical trials.³ It is important to note that these response criteria have not been validated in a prospective fashion and their utility in the management of an individual patient with ET in the clinic is uncertain.

FUTURE DIRECTIONS

ET is a hematologic malignancy with its own distinct clinical manifestations and associated complications. Better means of identifying patients at risk for developing fatal thrombotic or hemorrhagic complications are necessary to provide the basis with which to develop the optimal care of such patients. The ability to reduce the incidence of thrombohemorrhagic episodes with cytoreductive therapy in high-risk patients is well established.

Multiinstitutional studies comparing the efficacy of such promising agents as IFN- α or pegylated IFN for the treatment of high-risk patients compared with hydroxyurea are currently being pursued and initial results are anticipated in 2017. The use of low-dose aspirin therapy to reduce the number of episodes of erythromelalgia and transient ischemic attacks is widely practiced, but whether aspirin therapy should be indiscriminately used remains a subject of dispute that will only be resolved with the completion of appropriately powered clinical trials. Another pressing question that requires resolution is the degree of reduction of platelet or leukocyte numbers required for optimal management of ET patients.

The report of 18 patients with high-risk, treatment-refractory ET treated with imetelstat, a 13-mer oligonucleotide competitive inhibitor of telomerase, was recently published indicating a novel MPN therapeutic approach. The rationale for this prospective clinical trial was based on laboratory findings of selective inhibition of malignant megakaryopoiesis compared with megakaryocytes isolated from normal controls after *in vitro* exposure to imetelstat. In this open label, phase II study, the complete hematologic remission was 89% and reductions in driver mutation allele burden (*JAK2*, *MPL*, *CALR*) were observed (median reduction of *JAK2V617F* of 59% at 12 months and reductions in *CALR* and *MPL* allele burden of 15–60%. Grade 3 neutropenia was seen in 22% of treated patients, and low-grade reversible transaminitis was seen in the majority of patients. The role of this infusional agent administered every 3 weeks in the

**TABLE
69.9**

Response Criteria for Essential Thrombocythemia

Criteria	
Complete Remission	
A	Durable ^a resolution of disease-related signs including palpable hepatosplenomegaly, large symptoms improvement, ^b AND
B	Durable ^a peripheral blood count remission, defined as: platelet count $\leq 400 \times 10^9/L$, WBC count $< 10 \times 10^9/L$, absence of leukoerythroblastosis, AND
C	Without signs of progressive disease, and absence of any hemorrhagic or thrombotic events, AND
D	Bone marrow histological remission defined as disappearance of megakaryocyte hyperplasia and absence of $> \text{grade } 1$ reticulin fibrosis.
Partial Remission	
A	Durable ^a resolution of disease-related signs including palpable hepatosplenomegaly, and large symptoms improvement, AND
B	Durable ^a peripheral blood count remission, defined as: platelet count $\leq 400 \times 10^9/L$, WBC count $< 10 \times 10^9/L$, absence of leukoerythroblastosis, AND
C	Without signs of progressive disease, and absence of any hemorrhagic or thrombotic events, AND
D	Without bone marrow histological remission, defined as the persistence of megakaryocyte hyperplasia
No response	Any response that does not satisfy partial remission
Progressive disease	Transformation into PV, post-ET myelofibrosis, myelodysplastic syndrome or acute leukemia ^c

Molecular response is not required for assignment as complete response or partial response. Molecular response evaluation requires analysis in peripheral blood granulocytes. Complete response is defined as eradication of a preexisting abnormality. Partial response applies only to patients with at least 20% mutant allele burden at baseline. Partial response is defined as $\geq 50\%$ decrease in allele burden.

^aLasting at least 12 weeks.

^bLarge symptom improvement (≥ 10 -point decrease) in MPN-SAF TSS.¹⁰

^cFor the diagnosis of PV see World Health Organization criteria (WHO)¹³; for the diagnosis of post-ET myelofibrosis, see the IWG-MRT criteria¹²; for the diagnosis of myelodysplastic syndrome and acute leukemia, see WHO criteria.¹³

ET, Essential thrombocythemia; PV, polycythemia vera; WBC, white blood cell. From Barosi G, Mesa R, Finazzi G, et al: Response criteria for polycythemia vera and essential thrombocythemia: an ELN and IWG-MRT consensus project. *Blood* 121:4778, 2013.

treatment of ET is yet to be determined and currently MF is the focus of ongoing clinical investigation.

Finally, the discovery of the *JAK2V617F*, *MPL*, and *CALR* mutations have already had a major impact on disease classification during routine clinical practice. Diagnostic strategies have now incorporated screening for these driver mutations. This new understanding of the molecular pathogenesis of MPN has led to the development of novel targeted therapies. The use of specific *JAK2* inhibitors for ET patients should be carefully studied in well-controlled clinical trials in which significant endpoints such as incidence of thrombosis, hemorrhage, and transformation to MF and acute leukemia are incorporated. This is critical because the degree of reduction of platelet numbers has not served as a suitable biomarker for the development of these complications (see box on Personal Approach to Therapy of Essential Thrombocythemia).

Personal Approach to Therapy of Essential Thrombocythemia

The optimal therapy for all patients with essential thrombocythemia (ET) remains uncertain. Therapy is geared toward interventions to reduce the potential for developing thrombotic episodes. Patients with the greatest risk of developing a thrombus have a number of characteristics, including age 60 years or older, history of a thrombotic event, leukocytosis (platelet count $\geq 11,000 \times 10^9/L$), and cardiovascular risk factors (hypertension, hypercholesterolemia, diabetes mellitus, obesity). Patients with ET or a prefibrotic form of MF can frequently present with elevated platelet counts and are treated in a similar fashion by us. No known therapy is commercially available that is capable of reversing the bone marrow (BM) fibrosis in such patients or delaying or eliminating evolution to myelofibrosis (MF). Certain concepts, however, apply to all patients. All patients with ET should stop smoking to minimize the risk factors associated with atherosclerotic disease. Indiscriminant use of high doses of nonsteroidal antiinflammatory drugs should be avoided because this practice can lead to an increased risk of hemorrhage. Use of such agents is particularly frequent in elderly patients in whom ET is common. In patients with a life-threatening thrombotic or hemorrhagic episode, plateletpheresis should be initiated in addition to starting them on hydroxyurea therapy.

In high-risk patients, cytoreductive therapy has been shown to lessen the chance of developing additional thrombotic events with the reduction of extreme thrombocytosis to platelet counts below $600,000 \times 10^9/L$. High-risk patients include patients older than 60 years of age and patients with a history of a previous thrombotic episode, including erythromelalgia, transient ischemic attacks, or large-vessel thrombosis. Even though this treatment philosophy has been considered common practice, the recommendation to treat patients older than the age of 60 years who have not experienced a thrombotic episode with cytoreductive therapy is not based on robust data from multiple randomized trials. Asymptomatic high-risk patients without cardiovascular risk factors may not necessarily benefit from this treatment, and the decision on how to treat them should be based on individual assessment.

At present, no therapy is indicated in asymptomatic patients younger than 60 years of age. If a patient has a platelet count greater than or equal to $1500 \times 10^9/L$ and acquired von Willebrand syndrome with bleeding symptoms, platelet-reduction therapy is indicated to avoid the high risk of hemorrhage. In totally asymptomatic patients with platelet counts greater than $1500 \times 10^9/L$, we frequently observe the patients and do not feel compelled to treat them. Patients with acquired von Willebrand syndrome should clearly avoid the use of aspirin.

In patients requiring platelet reduction therapy, the choice among the use of anagrelide, interferon (IFN)- α , pegylated IFN, or hydroxyurea therapy is based on patient age, ease of administration, and drug-related toxicity. Randomized trials comparing these treatments in high-risk patients are ongoing. Until the results are available, we use the following strategy. In patients older than 50 years, hydroxyurea therapy is the treatment of choice, but in younger patients, we prefer to initiate therapy with IFN- α . IFN therapy should be avoided in patients with a history of depression, autoimmune disorders, or retinitis. If the patient cannot tolerate IFN- α or it is not available, we feel comfortable treating symptomatic patients younger than 50 years of age with anagrelide or hydroxyurea. Although we remain concerned about the leukemogenic potential of hydroxyurea, the risk appears to be low if not associated with the prior use of an alkylating agent. The development of malleolar ulcers is a frequent complication of hydroxyurea treatment and is a signal for the elimination of hydroxyurea as a therapeutic agent for that particular patient.

Patients who initially receive hydroxyurea and no longer respond to this agent or experience toxicity and require another agent should not receive an alkylating agent. This sequence of administration is associated with an extremely high risk of leukemic transformation. Patients who have had a trial of hydroxyurea and require further treatment should receive either anagrelide, IFN- α , or pegylated IFN. Doses of each of these agents required for disease control will, of course, be dependent on the target platelet level that one hopes to achieve. Strict control to a platelet count of lower than $600 \times 10^9/L$ does not appear to be necessary. In these patients, the addition of low-dose aspirin (81 mg/day) should be

considered; it is less clear to us if patients who achieve better platelet control with cytoreductive therapy should also be so treated. However, in studies from Europe addressing this question in polycythemia vera, the approach of combining aspirin with cytoreduction therapy appears to minimize thrombotic complications. The use of anagrelide and aspirin in combination should be avoided because of the high risk of a hemorrhage. In patients with thrombotic episodes, especially episodes involving the microcirculation or large vessels, we administer low-dose aspirin (81 mg/day). This dose of aspirin does increase the number of bleeding episodes to a modest degree but is effective in the treatment of thrombotic events. This low-dose aspirin therapy is given in addition to an agent, which reduces platelet numbers.

Hydroxyurea can be started at a dose of 1 g/day and then adjusted to achieve the target platelet count ($\leq 600 \times 10^9/L$) without developing leukopenia. Anagrelide is initiated at 0.5 mg twice daily and increased by 0.5 mg/day every 5–7 days if platelet counts do not begin to drop. The usual dose to achieve platelet number control is 2.0–2.5 mg/day. Alternatively, combination therapy with anagrelide and hydroxyurea may be considered. Some patients do not tolerate either hydroxyurea or anagrelide. In this patient group, IFN- α therapy is initiated at 3 million units three times per week subcutaneously, or consideration to therapy with a pegylated form of interferon (peg-IFN α -2a) should be given. Busulfan at 4 mg/day for 2-week courses every time the platelet count rises above the normal range is another therapeutic option. Busulfan therapy is typically reserved for patients older than 70 years.

Complications even in young, otherwise healthy patients with platelet counts greater than $2000 \times 10^9/L$ are unusual. However, these marked elevations of platelet numbers can be anxiety-provoking situations for the patient and the clinician.

In certain situations, in young, low-risk patients, treatment should be instituted. Surgery can increase the risk of thrombosis, and the use of antiinflammatory agents can increase the risk of bleeding postoperatively. Under these circumstances, the platelet count should be lowered to the normal range. In pregnant patients with ET, low-dose aspirin therapy is the first treatment option. If the patient develops symptoms as a result of thrombosis, platelet reduction therapy is necessary, and IFN- α therapy is the treatment of choice.

In a patient with ET and a serious acute hemorrhagic event, the site of bleeding should be determined immediately, and any antiplatelet-aggregating agents should be stopped. Although the platelet count may be high, these platelets should be considered to be qualitatively abnormal, leading to defective hemostasis. The patient may have acquired von Willebrand syndrome. In patients with acquired von Willebrand syndrome, desmopressin (DDAVP) or factor VIII concentrates containing von Willebrand factor can be used immediately at the same time chemotherapy is being administered. If acquired von Willebrand syndrome is not present, the transfusion of normal platelets is suggested. In patients with persistent hemorrhage, immediate reduction of the platelet count can be achieved by platelet pheresis. If this approach fails, some consideration to the use of activated factor VIIa should be given. Hydroxyurea at 2–4 g/day for 3–5 days should be administered immediately and then reduced to 1 g/day. All patients receiving hydroxyurea should be monitored for the onset of granulocytopenia or thrombocytopenia. Reduction of platelet counts is usually observed within 3–5 days of hydroxyurea treatment.

In contrast, patients with acute arterial thrombosis require immediate institution of platelet antiaggregating agents. Aspirin at a dose of 81 mg/day is suggested. Patients with erythromelalgia or transient ischemic attacks will have a rapid cessation of symptoms after the use of low-dose aspirin. In a patient with a life-threatening arterial thrombosis, the platelet count should be lowered with either a combination of apheresis and hydroxyurea or with hydroxyurea alone, depending on the severity of the event. If the arterial thrombosis involves the microcirculation and is not life threatening (transient ischemic attacks or erythromelalgia), immediate low-dose aspirin therapy is indicated, and platelet-reduction therapy (hydroxyurea, anagrelide, or IFN- α) can be initiated using a standard dose and schedule.

PRIMARY MYELOFIBROSIS

John Mascarenhas, Vesna Najfeld, Marina Kremyanskaya, Alla Keyzner, Mohamed E. Salama, and Ronald Hoffman

Primary myelofibrosis (PMF) is a chronic, malignant hematologic disorder characterized by splenomegaly, cytopenias, systemic symptoms, leukoerythroblastosis, teardrop poikilocytosis (i.e., dacryocytes), ineffective hematopoiesis associated with megakaryocytic hyperplasia and dysplastic megakaryocytopoiesis, and the acquisition of a variety of driver mutations (*JAK2V617F*, calreticulin exon 9 [*CALR*], and the thrombopoietin receptor, *MPL515L/K*) along with varying degrees of bone marrow (BM) fibrosis, increased BM microvessel density, and extramedullary hematopoiesis (EMH). The dysplastic megakaryocytes and clonal populations of myeloid cells elaborate cytokines that are responsible for the development of BM fibrosis. Fibrosis of the BM is not unique to PMF and may accompany many other disorders (Table 70.1). The terms *postpolycythemia vera (PV) myelofibrosis (post-PV MF)* and *postessential thrombocythemia (ET) myelofibrosis (post-ET MF)* have been developed to classify MF that is preceded by a history of PV or ET. In PMF, the BM fibrosis occurs in response to the progeny of a clonal proliferation of hematopoietic stem cells (HSCs). In 1951, Dameshek included PMF among a group of related disorders that he termed *myeloproliferative disorders (MPDs)*. This hypothesis was largely based on clinical observations of patients with PV, chronic myeloid leukemia (CML), and ET who developed BM fibrosis and a clinical picture resembling PMF. Dameshek also noticed that each of these MPDs frequently evolve over time, changing their clinical phenotype, and frequently terminate in a leukemic phase. In 2008, the World Health Organization (WHO) modified the terminology of MPDs to myeloproliferative neoplasms (MPNs) to correctly reflect their malignant nature.¹

EPIDEMIOLOGY

Few epidemiologic studies are available to estimate the incidence of PMF. Previously published reports indicate an annual incidence rate in European, Australian, and North American localities ranging from 0.5 to 1.3 cases per 100,000 persons. The annual incidence rate of PMF in Olmstead County (MN, USA) was reported to be 1.33 cases per 100,000 persons, and in southeast England (UK), the annual incidence has been reported to be 0.37 per 100,000 persons. In Japan, PMF is considered a rare disorder. The incidence of MF among survivors who were 10,000 m or less from the hypocenter of the atomic bomb explosion at Hiroshima, however, was 18 times the incidence reported from the remainder of Japan. These patients became symptomatic an average of 6 years after the bomb blast. Such data indicate a strong link between excessive radiation exposure and development of PMF, which is further substantiated by the high incidence of MF in patients who have received the contrast material Thorotrast (which contains ²³²Th, a radioactive element with a half-life of 1.41×10^{10} years). Thorotrast is taken up and retained indefinitely by cells of the reticuloendothelial system, which results in continuous irradiation of the liver, spleen, lymph nodes, and BM. Chronic exposure to several industrial solvents, including benzene and toluene, has also been associated with the development of PMF. Unlike PV, where clusters of patients have been identified in Eastern Pennsylvania, raising the concern for possible environmental effects of waste-coal and Superfund sites, there are no definitive epidemiologic studies supporting environmental exposures in PMF. PMF has been reported as a complication of chronic benzene poisoning since

the chemical was first used in the leather and shoe industries during the 1930s and 1940s. The average age at diagnosis of PMF is approximately 65 years, and most patients are diagnosed between 50 and 69 years of age. In several series, men have been affected more frequently than women, but others have failed to confirm this male predominance. Rarely, PMF has been reported in the pediatric age group. Evidence of genetic transmission exists: a higher incidence has been reported in Ashkenazi Jews than in Arabs, who both live in Northern Israel, and families where multiple members who suffer from a number of the MPNs including PMF have been identified.

PMF is a clonal hematologic malignancy originating in primitive hematopoietic cells capable of producing lymphoid and myeloid cells, while the BM fibrosis represents a secondary reaction of BM stromal cells. The ability of primitive human hematopoietic cells to engraft sublethally irradiated immunodeficient mice is the standard surrogate *in vivo* assay for human HSCs. PMF CD34⁺ cells are capable of engrafting non-obese non-diabetic/severe combined immune deficient (NOD/SCID) mice and generating myeloid and B cells that are clonal, *JAK2V617F* positive, and carry a patient-specific marker chromosomal abnormality.² The differentiation program of PMF CD34⁺ cells after transplant into NOD/SCID mice was also remarkably different from that of normal CD34⁺ cells, producing greater numbers of CD34⁺, CD33⁺, and CD41⁺ cells but fewer CD19⁺ cells. This predisposition to produce greater numbers of megakaryocytes has been further explored by incubating PMF, PV, and CD34⁺ cells *in vitro* in the presence of stem cell factor and thrombopoietin. PMF CD34⁺ cells displayed a far greater proliferative capacity and produced greater numbers of megakaryocytes that were characterized by a resistance to undergo apoptosis *in vitro* caused by overexpression of the antiapoptotic factor B-cell lymphoma-extra large (Bcl-XL). The megakaryocyte hyperplasia in PMF, therefore, could be accounted for by two factors—an increased ability of CD34⁺ cells to generate megakaryocytes and the accumulation of megakaryocytes caused by Bcl-xL overexpression. Although Bcl-xL overexpression has been linked to *JAK2V617F*, PMF megakaryocyte Bcl-xL overexpression also occurred to a similar degree in megakaryocytes generated from CD34⁺ cells isolated from individuals with both *JAK2V617F*-positive and -negative disease. The role of megakaryocytes in the development of fibrosis in PMF is further supported by megakaryocytic hyperplasia with dysplastic or necrotic megakaryocytes that characterizes this disorder; by the increased circulating megakaryocytes and megakaryocyte progenitors that are present in PMF; by the association of BM fibrosis and acute megakaryocytic leukemia; and by the presence of MF in gray platelet syndrome, an inherited disorder of platelet α -granules. Ineffective megakaryocytopoiesis in PMF has been hypothesized to lead to the liberation of excessive amounts of such growth factors, leading to BM fibroblast proliferation and collagen synthesis. PMF platelet-derived growth factor (PDGF) and transforming growth factor- β (TGF- β) levels have been found to be 2.0–3.0-fold and 1.5–3.0-fold higher, respectively, in PMF than in normal control participants, but fibroblast growth factor (FGF) levels in PMF were similar to those of control platelets. The roles of PDGF and TGF- β in the biogenesis of PMF probably are not restricted to promoting fibroblastic proliferation, but are also related to the effect of these two growth factors on synthesis, secretion, and degradation of extracellular matrix components. TGF- β enhances fibronectin and collagens types I, III, and IV, as well as chondroitin or dermatan

sulphate and proteoglycan gene expression. TGF- β decreases the synthesis of various collagenase-like enzymes that degrade extracellular matrices while at the same time stimulating the synthesis of protease inhibitors such as plasminogen activator inhibitor 1. The net effect of these complex interactions is the accumulation of extracellular matrix, which probably contributes to further progression of fibrosis. Additional growth factors including lipocalin 2 (LCN2), which is elaborated by myelocytes and promyelocytes, have been implicated in the development of progressive fibrosis in PMF. Basic FGF (bFGF) is a potent angiogenic factor and is a mitogen for human BM stromal cells. Elevated platelet, megakaryocyte, and serum bFGF levels have been reported in PMF patients with progressive fibrosis. bFGF may be released or leaked from dysplastic and necrotic PMF megakaryocytes or platelets. These findings suggest that bFGF may also contribute to the progressive fibrosis and pronounced angiogenesis frequently observed in PMF. The mechanism by which the pathologic release of growth factors from megakaryocytes occurs in PMF remains unknown. Investigators have suggested that impaired megakaryocyte emperipolesis might lead to this liberation of fibrogenic cytokines. *Emperipolesis* is defined as the random entry of hematopoietic cells into the cytoplasm of megakaryocytes. Impaired emperipolesis of neutrophils and eosinophils in PMF and resultant liberation of myeloperoxidase-positive granules by the engulfed neutrophils has been reported. The degree of emperipolesis in PMF BM biopsies has been shown to be correlated with the degree of BM fibrosis. Abnormal P-selectin distribution in megakaryocytes has been suggested to account for the selective sequestration of granulocytes by PMF megakaryocytes.³

The development of extensive fibrosis of the BM in PMF is frequently preceded by an asymptomatic phase of the disease of variable duration characterized by a hypercellular marrow with megakaryocytic hyperplasia and atypia and minimal fibrosis (prefibrotic phase of MF). Reversal of MF has been observed after allogeneic stem cell transplantation (aSCT) and infrequently seen occasionally after

long-term administration of interferon (IFN). Such findings indicate that the BM fibrosis in PMF is not irreversible and is clearly a secondary consequence of the neoplastic cellular proliferation.

Many of the peripheral blood abnormalities associated with PMF may be attributed to the EMH that is characteristic of this disorder. CD34⁺ cells in PMF are constitutively mobilized and exit from the BM; because of abnormal trafficking patterns, they are filtered out by the spleen, accumulate progressively, and continue to proliferate. Ultimately, there is an unequal distribution of CD34⁺ cells, with a twofold greater number being present in the spleen than the BM. The EMH within the spleen is characterized by disturbances of splenic architecture, including an increased presence of megakaryocytes and their progenitor cells. Intravascular hematopoiesis within the sinusoids of the BM is a conspicuous finding in PMF. The characteristic changes of the BM vascular architecture consist of increased quantities of collagen type IV deposits associated with increased BM microvessel density, resulting in increased blood flow. The excessively dilated BM sinusoids in PMF contain prominent intraluminal foci of hematopoiesis. This increase in BM microvessel density in PMF has been confirmed using immunohistochemical methods and has been shown to correlate with increased spleen size and to be an independent risk factor for overall survival (OS). Vessels from patients with PMF are frequently markedly abnormal and appear as localized vascular nests consisting of numerous short vessels that are highly branched and tortuous. The increased BM microvessel density in PMF is probably mediated by megakaryocyte α -granule constituents. A number of angiogenic growth factors, including bFGF and vascular endothelial growth factor (VEGF), have been implicated as causative factors of the increased BM microvessel density observed in the BMs of PMF patients. Elevated serum VEGF levels have been reported in PMF, and increased expression of bFGF has been reported in PMF megakaryocytes and platelets. Osteosclerosis is a prominent clinical feature of many patients, with PMF frequently manifesting itself as bone pain. The osteosclerosis is a consequence of cytokines produced by the malignant BM cells or stroma conditioned and activated by an interaction with PMF cells. PMF-associated osteosclerosis can be reversed after aSCT with the establishment of normal hematopoiesis. Studies of both PMF patients and animal models of PMF indicate that both TGF- β and stromal cell-derived osteoprotegerin, a member of the TNF receptor family, play pivotal roles in the development of osteosclerosis. Osteoprotegerin is a decoy receptor for the receptor activator of the nuclear factor kappa-B ligand (RANKL). RANKL is a transmembrane protein expressed on the cell surface of osteoblasts that can be cleaved into a soluble form by proteases. Both soluble and membrane-bound RANKL attach to RANK, a cell receptor expressed by osteoclast precursors to stimulate osteoclastogenesis. RANKL and osteoprotegerin are positive and negative regulators of osteoclast differentiation, respectively. Osteoprotegerin can reduce the production of osteoclasts by inhibiting the differentiation of osteoclast progenitor cells into mature osteoclasts, leading to the development of osteosclerosis. In patients with PMF, it remains unknown if the degree of osteosclerosis is corrected with increased levels of osteoprotegerin.

Elevated thrombopoietin levels have been observed in patients with PMF. This unanticipated elevation of plasma thrombopoietin levels is not caused by enhanced production of thrombopoietin messenger RNA (mRNA) by BM fibroblasts or BM cells, but is likely caused by the reduced expression of the thrombopoietin receptor by the platelets and megakaryocytes of PMF patients, leading to decreased clearance of thrombopoietin. In ET and PMF, platelets and megakaryocytes are characterized by lower MPL protein levels and most of the receptors are immature. Endo-H-sensitive activated *JAK2* has been shown to strongly promote cell surface localization and enhance protein levels of MPL. This effect has been shown to be caused by stabilization of the mature endoglycosidase H-resistant form of the receptor. The reduced expression of MPL has also been linked to *JAK2V617F*, leading to receptor ubiquitinylation and degradation by proteasomal and lysosomal pathways. Platelet MPL levels can be restored by treatment with proteasome inhibitors or *JAK2* inhibitors. By contrast, the persistence of MPL expression by

progenitor or stem cells has been linked to the development of myeloproliferation. These observations support a model where a decrease in MPL mass in platelets and megakaryocytes results in increased thrombopoietin levels, which acts on the primitive stem cells contributing to the development of myeloproliferation.

Vannucchi and colleagues studied mutant mice with reduced expression of the transcription factor GATA1 to further define the role of megakaryocytes and the development of BM fibrosis. Mutations in the GATA1 functional pathway in human PMF have not been described. However, at the protein level, a large number of the megakaryocytes in the BM of PMF patients are GATA1 negative, suggesting that whatever the genetic defect leading to PMF is, it involves the pathway that affects the posttranscriptional or post-translational regulation of GATA1 in megakaryocytes.

Megakaryocytes are not the only cells capable of releasing cytokines that promote BM fibrosis. Levels of macrophage colony-stimulating factor, a cytokine that regulates macrophage development and proliferation, are elevated in the serum of PMF patients. Monocytes and macrophages from patients with PMF can produce greater quantities of TGF- β and interleukin-1 (IL-1) than those from normal control participants. IL-1 and TGF- β are fibroblast mitogens that induce extracellular matrix protein production. Monocyte adhesion to extracellular matrix proteins has been shown to lead to the overproduction of IL-1 and TGF- β by PMF monocytes. Monocyte adhesion through the adhesion molecule, CD44, appears to be involved in the induction of fibrogenic cytokines by mediating the interaction between monocytes and accumulated extracellular matrix protein deposits. The proinflammatory transcriptional factor nuclear factor kappa-B (NF κ B) plays a pivotal role in the elaboration of IL-1 and TGF- β in the activation of NF κ B monocytes and that of PMF patients. These investigators suggest that NF κ B stimulates TGF- β production by influencing intracellular IL-1 levels, and may serve as another potential therapeutic target for the treatment of PMF. Abnormal cytokine expression in PMF is thought to represent an inflammatory response to the disease phenotype that contributes not only to the development of BM fibrosis, osteosclerosis, and increased BM microvessel density, but also PMF-associated constitutional symptoms including weight loss, anorexia, pruritus, bone pain, and night sweats. Elevated levels of IL-8 and IL-2R have been closely correlated with the presence of constitutional symptoms, the requirement for red blood cell (RBC) transfusions, and leukocytosis, as well as inferior OS and leukemia-free survival. These observations raise the possibility that mutational events leading to the malignant transformation of hematopoietic cells in PMF may also lead to activation of transcriptional programs that promote hematopoietic cell survival and disease progression. The elevation of a variety of cytokines may therefore not only be responsible for the numerous epiphenomena that occur as a consequence of the presence of these malignant cells, but also act on the malignant clone affecting the proliferation and differentiation in differing microenvironments characteristic of the BM and various extramedullary sites, including the spleen. Ultimately, this may increase the risk of disease progression or leukemic transformation.

When PMF mononuclear cells are cloned in semisolid media, erythroid and megakaryocyte colony formation occurs in the absence of added exogenous cytokines, a finding common to other MPNs. These findings suggest that possible genetic mutations activating several intracellular signaling pathways responsible for normal hematopoiesis might account for this autonomous in vitro hematopoiesis. In addition to a population of autonomous proliferating megakaryocyte progenitor cells, a second and more common population remains dependent on the addition of exogenous growth factors. The search for the genetic mutations that accounted for the autonomous hematopoiesis that characterizes each of the MPNs culminated in the discovery of a gain-of-function mutation of an autoinhibitory domain of the JAK family of protein tyrosine kinases, which is involved in cytokine receptor signalling.⁴ The *JAK2V617F* mutation leads to ongoing phosphorylation activity, which can then bind to a cytokine receptor and promote signal transducer and activator of transcription (STAT) recruitment. This mutation is the likely cause of

the hypersensitivity to cytokines that characterizes hematopoietic progenitors from each of the MPN. In a mouse BM transplant model, BM cells transduced with *JAK2V617F* results in a clinical phenotype that closely resembles PV, including erythrocytosis, EMH, and BM fibrosis. Although >90% of patients with PV are *JAK2V617F* positive, approximately 50% of PMF patients harbor this mutation. The *JAK2V617F* mutation is homozygous in 13% of patients with PMF but in 30% of patients with PV. Homozygosity has been attributed to homologous recombination. Homozygosity of *JAK2V617F* in PMF patients is associated with a more frequent occurrence of unfavorable cytogenetic abnormalities. There are conflicting data as to whether the clinical course of patients with *JAK2V617F*-positive and *JAK2V617F*-negative PMF differ. Additional somatic mutations have been identified in patients with PMF that likely play a role in the biogenesis of PMF. A mutation in the transmembrane domain of the thrombopoietin receptor (*cMPL*) has been documented in 9% of patients with *JAK2V617F*-negative PMF (*MPL W515L* or *MPL W515K*).⁵ *MPL 515L*, *MPL 515K*, and *MPL* wild-type (WT) alleles can coexist in the same patient. Furthermore, 30% of PMF patients with mutations in *cMPL* also have the *JAK2V617F* mutation. By studying archival material, the burden of *MPL 515L*, *MPK 515K*, and *JAK2V617F* in PMF patients has been shown to remain constant throughout the clinical course of patients with PMF. In a murine BM transplant assay, expression of *MPL W515L* but not WT *MPL* resulted in a rapidly progressive, fully penetrable, lethal MPN (18 days) characterized by marked thrombocytosis, leukocytosis, splenomegaly, hepatomegaly, BM megakaryocytic hyperplasia, and BM fibrosis but not erythrocytosis. These data have suggested that the *MPL* mutation favors the development of thrombocytosis but the *JAK2V617F* mutation favors the development of erythrocytosis. PMF patients with *MPL 515L/K* PMF compared with *MPL* WT PMF are older, present with more severe anemia, and are more likely to require transfusional support. The genetic origins of PMF likely represent the culmination of multiple genetic and possibly epigenetic events.

Further insight into the phenotypic heterogeneity of *JAK2V617F*-positive and -negative MPNs has recently been provided. Immunohistochemical analyses of BM have shown that PV is characterized by increased expression of phosphorylated STAT3 and STAT5 protein, but PMF is characterized by reduced expression of STAT3 and STAT5. This expression pattern was independent of *JAK2V617F* status. Such observations suggest that additional or alternative molecular events occur in PMF and PV that might play a role in the development of their distinctive clinical phenotypes.

In 2013, mutations in *CALR* were reported by two separate laboratory groups. *CALR* is located on chromosome 19p13.2 and encodes for a calcium-binding protein with multiple functions including protein folding/chaperoning, cell proliferation and motility, phagocytosis, apoptosis, and calcium homeostasis. *CALR* can be localized to the endoplasmic reticulum, nucleus, extracellular matrix and membrane. *CALR* exon 9 frameshift mutations result in a mutant calreticulin protein with a novel calcium-binding/endoplasmic reticulum retention motif C-terminus. These insertion/deletion mutations (>50 reported) occurring in exon 9 of *CALR* and are found at a frequency of approximately 25% in ET and PMF patients, and appear to be mutually exclusive with *JAK2* and *MPL* mutations (frequency of approximately 75% of *JAK2/MPL* WT). Type 1 (52-bp deletion) and type 2 (5-bp insertion) mutations constitute 80% of the reported mutations in *JAK2*-negative MPN patients. Retrospective studies implicate the presence of *CALR* mutations in PMF patients with higher platelet counts, lower hemoglobin and leukocyte counts, less risk of thrombosis, and better overall prognosis than patients with *JAK2V617F*. Initial studies also appear to implicate a worse prognosis for type 2 *CALR* mutants compared with type 1. Additionally, studies have now shown that *CALR* mutant MF patients also have upregulated JAK-STAT signaling, and are also responsive to the effects of JAK2 inhibitor treatment.

The exact pathobiologic link between *CALR* mutation and the dysregulated JAK-STAT pathway is the subject of intense investigation. Chachoua and colleagues have recently shown that neither

expression of the mutant C-terminus alone nor expression of *CALR* lacking the C-terminus leads to cytokine-independent growth, suggesting that the novel C-terminus is necessary (but not sufficient) for transformation. They found that the oncogenic activity of mutant *CALR* is not encoded within a specific sequence or domain of the mutant C-terminus, but that the positive electrostatic charge of the mutant C-terminus was critical for its transforming capacity. Mutagenizing all 18 lysine/arginine residues (positively charged) within the C-terminus to a neutral glycine residue abrogated *CALR-del52* transformation activity. In contrast, mutagenizing the 18 nonlysine/arginine residues within the C-terminus to glycine did not affect transforming activity, a remarkable finding considering that, in this mutant, 50% of the amino acids have been modified. Using coimmunoprecipitation assays, Elf et al found that mutant *CALR*, but not WT *CALR*, physically interacted with *MPL*, and that neither the mutant C-terminus alone nor mutant *CALR* lacking the C-terminus can bind to *MPL*. This suggests that the tertiary structure of mutant *CALR* is required for binding to *MPL*.

Approximately 10% of PMF patients lack any of the three driver mutations. However, recently Milosevic-Feenstra and coworkers identified noncanonical *MPL* mutations by whole-exon sequencing in eight out of 70 (11.4%) and *JAK2* mutations in five out of 57 (8.8%) patients with triple-negative ET and PMF. All mutations were heterozygous. The mutations in *MPL* and *JAK2* were mutually exclusive. Evidence for clonal disease was lacking in 50% of these triple-negative cases and the presence of germ-line mutations indicated that some of these individuals likely had a hereditary rather than an acquired MPN-like disorder. Based upon these findings, sequencing of all coding exons of *MPL* and *JAK2* during the diagnostic work-up of ET and PMF patients who are triple negative is recommended.

A growing list of additional mutations have been identified in PMF patients over the past several years, providing further insight into the complex molecular pathology of this disease.⁶ Many of these mutations impact the epigenome and can coexist in PMF CD34⁺ cells. None of the genetic or epigenetic lesions identified thus far are specific to PMF, clearly aid in prognostication, or appear to be disease-initiating events. Table 70.2 lists the molecular lesions that have been characterized in patients with PMF.

Translocation ten-eleven oncogene family member 2 (*TET2*), located on chromosome 4q24, has been identified in many myeloid malignancies at a frequency of approximately 15%. Acquired somatic

mutations throughout the 11 exons of this gene result in compromised catalytic activity of an α -ketoglutarate-dependent enzyme responsible for oxidation of 5-methylcytosine (5mC) to 5-hydroxymethylcytosine (5hmC) in DNA. Low levels of 5hmC result in a hypermethylation phenotype at CpG sites in various DNA promoter regions. *TET2* mRNA has been found to be highly expressed in Lin⁻, Sca-1⁺, c-Kit^{hi} murine multipotent progenitor cells isolated from the BM and thymus. This expression pattern was maintained in myeloid progenitor cells but low in mature granulocytes. Moreover, in patient samples, when compared with normal samples, low 5hmC levels correlated with a significant decrease in DNA hypermethylation, supporting a role of *TET2* loss of function leading to DNA hypermethylation. It is currently believed that *TET2* mutations result in loss of function and lead to the accumulation of 5mC in DNA, promoting DNA hypermethylation that may inhibit cells from differentiating beyond a HSC-like state. In vitro studies reveal that *TET2* deficiency restrains hematopoietic cells from normal differentiation patterns and skews differentiation in favor of the monocyte/macrophage lineage with transgenic animals, with knockout of *TET2* having a phenotype resembling chronic myelomonocytic leukemia. Somatic, recurrent *TET2* mutations have been reported in normal elderly individuals with acquired clonal hematopoiesis. Alterations in *TET2* that include base substitutions, out-of-frame insertions or deletions, and splice site mutations have been shown to occur in 15–20% of PMF patients. Such mutations are more common in older patients. In families with multiple family members having an MPN, all *TET2* mutations were almost universally acquired, and their incidence was similar to that of patients with sporadic PMF. Clonal analysis studies in MPN patient samples failed to define a consistent temporal sequence of acquisition of *TET2* mutations with respect to *JAK2* mutations and can occur late in the progression of MPNs. These two genetic events appear to occur independently. *TET2* mutational status in PMF patients does not appear to provide a new prognostic marker. *TET2* mutations can be found in PMF patients with and without the *JAK2V617F* mutation, and do not influence rate of thrombosis, leukemic transformation, or OS.

Isocitrate dehydrogenase 1 and 2 (*IDH1/2*), located on chromosome 2q33.3 and 15q26.1, respectively, encode NADP⁺-dependent enzymes that catalyze the oxidative decarboxylation of isocitrate to α -ketoglutarate. Mutant *IDH* forms preferentially transform α -ketoglutarate to 2-hydroxyglutarate and appear to promote tumorigenesis by inducing hypoxia-inducible factor 1 α (HIF-1 α).

TABLE 70.2 Acquired Genetic Lesions Identified in Patients With Primary Myelofibrosis

Gene	Location	Mutation	Frequency
Janus kinase 2 (<i>JAK2</i>)	9p24 exon 14 9p24 exon 12	<i>JAK2V617F</i>	65% Infrequent
Calreticulin (<i>CALR</i>)	19p13.2 exon 9	Type 1 (52 bp del) and Type 2 (5 bp in)	25%
Ten-eleven translocation 2 (<i>TET2</i>)	4q24		17%
Serine/arginine-rich splicing factor 2 (<i>SRSF2</i>)	17q25.1		17%
U2 small nuclear RNA auxiliary factor 1 (<i>U2AF1</i>)	21q22.3		16%
DNA methyltransferase 3 alpha (<i>DNMT3a</i>)	2p23		15%
Enhancer of zeste homolog 2 (<i>EZH2</i>)	7q36.1		13%
Myeloproliferative leukemia virus (<i>MPL</i>)	1p34 exon 10	<i>MPL W515L/K</i>	5%-10%
Casitas B-lineage lymphoma (<i>CBL</i>)	11q23.3	Exons 8 and 9	6%
Splicing factor 3B unit 1 (<i>SF3B1</i>)	2q33.1		6%
Isocitrate dehydrogenase (<i>IDH1</i> and 2)	2q33.3/15q26.1		4%
Lymphocyte specific adapter protein (<i>LNK</i>)	12q24		Infrequent
Ikaros family zinc finger 1 (<i>IKZF1</i>)	7p12		Infrequent
Additional sex Combs-like 1 (<i>ASXL1</i>)	20q11.1		Infrequent

IDH1/2 mutations are found at a frequency of approximately 4% in PMF and can coexist with mutations in *JAK2*, *MPL*, and *TET2*. The specific *IDH* mutant variants seen in MPNs (*IDH1 R132C*, *IDH1 R132S*, *IDH2 R140Q*) all affect arginine residues. *IDH1/2* mutations are not predictive of survival in PMF but do have prognostic significance in multivariate analysis in blast-phase disease. It is not yet clear if different *IDH* mutation variants carry different biologic or prognostic consequences in PMF. A significant association between *IDH1/2* mutation and absence of the 46/1 *JAK2* haplotype has been observed, and supports a theory that PMF patients that are nullizygous for the 46/1 haplotype are more susceptible to acquiring additional molecular lesions that contribute to a poor prognosis.

The additional sex combs-like 1 (*ASXL1*) gene is located on chromosome 20q11.1 and is responsible for encoding an enhancer of the trithorax group (trxG) and polycomb repressive complex (PcG). The PcG proteins (repress) and trxG proteins (activate) regulate gene expression of homeotic genes, such as *Hox* genes via histone methylation. *ASXL1* mutations result in loss of PRC2-mediated H3 lysine (H3K27me3) trimethylation. *ASXL* mutations have been identified in various myeloid malignancies and are in highest frequency in myelodysplastic syndrome (MDS) and CMML patients. In a study of 64 MPN cases, *ASXL1* mutations were found in five MPN patients (three with PMF), all of whom were negative for the *JAK2* mutation. *ASXL1* mutations can be found in the MPN HSC, suggesting acquisition early in the pathogenesis of MPNs. *ASXL1* mutations are associated with an adverse outcome and leukemic transformation in PMF patients.

The Casitas B-lineage lymphoma (*CBL*) proto-oncogene is located on chromosome 11q23.3 and is believed to play a role in the maintenance of the hematopoietic pluripotent stem cell pool. *CBL* has the capacity to downregulate and upregulate tyrosine kinase activity by either serving as an adaptor protein or recruiting downstream targets of the pathway or by activation of E3 ubiquitin protein ligase activity and the subsequent recycling of the receptor through internalization of the receptor/ligand complex or lysosomal-directed destruction. *CBL* mutations were first appreciated in MPNs in the setting of mutational screening of acquired uniparental disomy of chromosome 11q, with a total of 27 *CBL* variants identified in MPNs. Within a cohort of 579 MPN patients screened, three patients with PMF were identified with *CBL* mutations at an overall frequency of 6%. The majority of the *CBL* mutations identified were located in the RING or linker domains, resulting in impaired ubiquitin ligase activity. Additionally, the oncogenic activity of selected *CBL* mutant variants was tested in vitro by monitoring its ability to confer growth factor independence to the IL-3-dependent cell line 32D and by its ability to enhance the proliferation of transformed cells overexpressing WT *FLT3*.

Ikaros is a Kruppel-like zinc finger transcription factor that has pleiotropic functions important in the development of normal hematopoiesis and is encoded by the Ikaros family zinc finger 1 (*IKZF1*) gene located at 7p.12. Mutations involving *IKZF1* have been identified as a molecular event leading to transformation of chronic-phase MPNs to blast-phase disease, and appears to occur after the acquisition of *JAK2V617F*. The mutational frequency in chronic-phase MPN is very low at 0.2%, in contrast to 21% of blast-phase MPN patients, and is highly associated with del7p. The potential effects of an *IKZF1* mutation was studied in mouse primary progenitor cells by creating *IKZF1* deficiency with small hairpin RNA technology, which was associated with cytokine hypersensitivity and increased p-STAT5 expression.

The enhancer of zeste homolog 2 (*EZH2*) gene located on chromosome 7q36.1 encodes the catalytic subunit of the histone methyltransferase polycomb repressor complex 2 (PRC2), and mutations in this gene have also been described in MPN patients. PRC2 is a multiprotein enzyme complex (*EZH2*, *SUZ12*, *EED*, and *YY1*) responsible for the trimethylation of lysine 27 on histone H3 (H3K27me3). Additionally, PRC2 can recruit other polycomb complexes, DNA methyltransferases (DNMTs), and histone deacetylases to the gene site, resulting in chromatin compaction and additional repressive activity. Upregulation of *EZH2* gene expression has

been documented in MPNs, most frequently in PMF patients, suggesting a potential role of tumor suppressor gene silencing as a mechanism in disease progression. In a study of 614 patients with myeloid malignancies, 42 cases were found to have a total of 49 *EZH2* mutations. Thirty PMF patients were analyzed in this cohort, and 13% were found to have an *EZH2* mutation. Microarray and single-nucleotide polymorphism (SNP) analysis did not show an association with copy number alterations or uniparental disomy. Because of small patient numbers and short follow-up, it has not been possible to gauge the true prognostic significance of mutated *EZH2* in PMF. Retrospective studies using archived MPN BM samples to assess for *EZH2* mutations have also not been shown to have prognostic significance in PMF.

The use of next-generation sequencing of 104 genes from a cohort of 197 MPN patients by Skoda et al has provided insight into the impact of clonal evolution on clinical phenotype. Somatic mutations were observed in 90% of patient samples in which approximately 40% harbored mutations other than *JAK2V617F* and *CALR*. *JAK2V617F* was the most common mutation (69%), followed by *CALR* (15%), *TET2* (12%), *ASXL1* (5%) and *DNMT3A* (5%). The presence of two or more acquired somatic mutations portended a poor outcome and increased risk of leukemic transformation. By contrast, none of the patients with a sole mutation in *JAK2*, *MPL*, or *CALR* evolved to AML. However, the rate of acquisition of new mutations was very low when assayed from serial samples (two mutations detected during a total follow-up of 133 patient-years). The majority of mutations were present at low allelic levels from the time of diagnosis, and in the case of *p53*, rapid evolution to blast phase occurred with loss of the WT allele. Mutations in *p53* were frequently present in a heterozygous state for a prolonged period of time, but the loss of the WT allele either by chromosomal deletion or uniparental disomy was associated with leukemic transformation. These data argue against the concepts of hypermutability and genomic instability in MF. These data also support a complex clonal architecture in MPNs, where some individuals may develop biclonal disease and others develop a linear acquisition pattern. In general, mutations in *TET2* and *DNMT3A* appeared earlier in the disease course, whereas mutations in *ASXL1*, *EZH2*, and *IDH1* were often acquired after *JAK2V617F*. The authors provide a model for clonal evolution of MPNs and influence on disease course and risk of transformation to leukemia (Fig. 70.1).

The number of hematopoietic progenitor cells constitutively mobilized into the blood of PMF patients is dramatically increased. The number of CD34⁺ cells present in the peripheral blood in PMF is 360 times greater than in normal control participants and 18–30 times higher than in patients with PV or ET. These findings are so striking that some investigators have suggested that the quantitation of CD34⁺ cells in the peripheral blood might serve as a means of discriminating PMF from other MPNs. A level of 15×10^6 CD34⁺ cells/L in peripheral blood allows differentiation of PMF from PV and ET. The numbers of circulating CD34⁺ cells tend to increase as the disease progresses, and there is a close correlation between patients presenting with more than 300×10^6 CD34⁺ cells/L of peripheral blood and imminent evolution to leukemia. These findings suggest that PMF CD34⁺ cell trafficking abnormality is caused by the inability of these cells to be retained within the BM or their premature release into the peripheral blood.

PMF is characterized not only by the constitutive mobilization of CD34⁺ hematopoietic cells, but also endothelial progenitor cells into the peripheral blood. Endothelial progenitor cell mobilization predominates during the prefibrotic phase of PMF, while hematopoietic stem/progenitor cell mobilization occurs characteristically in more clinically advanced phases of the disease. This dysregulation of stem cell trafficking likely ultimately leads to the seeding of extramedullary sites with primitive hematopoietic and endothelial cells, which results in the production of EMH within the liver and spleen, as well as a variety of other organs. Several proteolytic pathways have been documented to play a role in cytokine-mediated stem cell mobilization. Proteases released by activated neutrophils cleave vascular adhesion molecule-1 (VCAM-1) expressed by stromal cells, leading

Fig. 70.1 MODEL OF MYELOPROLIFERATIVE DISEASE EVOLUTION AND RISK STRATIFICATION IN CORRELATION TO MUTATIONAL EVENTS. In 10% of myeloproliferative (MPN) patients a driver mutation (*JAK2*, *MPL*, *CALR*) is not detected. In approximately 50–60% of MPN patients, either *JAK2V617F* or *CALR* are found, and this group collectively has a favorable prognosis with a low risk of evolution to acute myeloid leukemia (AML). In patients with mutated *CALR*, additional molecular events appear to occur after this initiating event, whereas in the majority of patients with mutated *JAK2*, similar somatic mutations appear to occur prior to the acquisition of *JAK2V617F*. The presence of additional somatic mutations correlates with increased risk of disease evolution and acquisition of *TP53* mutation is associated with development of *JAK2*-mutated or wild-type AML. In model 1 (A), the two phases of disease are phylogenetically related, having arisen from a shared (pre-*JAK2*) founder clone, but in model 2 (B), the two phases of disease are clonally unrelated, reflecting transformation of independent stem cells. AML, Acute myeloid leukemia; HSC, hematopoietic stem cell. (From Lundberg et al: Clonal evolution and clinical correlates of somatic mutations in myeloproliferative neoplasms. *Blood* 123:2220, 2014.)

to the disruption of a key adhesive interaction between VCAM-1 and very late antigen-4 (VLA-4) expressed by HSCs and progenitor cells. The interaction between stromal cell–, endothelial cell–, and osteoblast-derived stromal cell–derived factor-1 (SDF-1 or CXCL12) and the CXC chemokine receptor-4 (CXCR-4) expressed by HSCs

and progenitor cells is also believed to determine patterns of stem cell trafficking. Proteases, including neutrophil elastase, soluble matrix metalloproteinase-9 (MMP-9), and cell-bound MMP-9, have been shown to play a role in the constitutive mobilization of CD34⁺ cells that occurs in PMF patients. The concentrations of soluble VCAM-1,

a degradation product of VCAM-1, is elevated in the plasma of PMF patients, and these levels correlate with the absolute numbers of CD34⁺ cells in the peripheral blood. In addition, these elevated levels of proteases have been shown to be responsible for degradation of the chemokine CXCL12, which plays a role in retention of CD34⁺ cells within the BM because the degradation products lack the ability to attract CD34⁺ cells, thereby favoring their mobilization. By contrast, the amount of intact CXCL12 present within the spleen is increased, likely favoring the homing and localization of HPC/HSC to extramedullary sites such as the spleen. Furthermore, CXCR-4 expression by PMF CD34⁺ cells is epigenetically downregulated, which may account for altered CXCL12–CXCR-4 interactions, participating in CD34⁺ cell mobilization. This downregulation of CXCR4 expression can be reversed in vitro by treatment with chromatin-modifying agents. Furthermore, the expression levels of CXCR4 were significantly lower in patients with a high burden of *JAK2V617F* (allele frequency: 75%) compared with patients with low-burden *JAK2V617F*, suggesting the dependence of gene expression on the frequency of the mutated allele. Similar degrees of CD34⁺ cell mobilization are observed in post-ET and post-PV MF, as occurs in PMF. In PV patients, Passamonti and coworkers have demonstrated a relationship between *JAK2V617F* allele burden and the degree of constitutive mobilization of CD34⁺ cells, suggesting that such mobilization may be a consequence of the transition from *JAK2V617F* heterozygosity to homozygosity that is accompanied by granulocyte activation. Drugs that target the proteases responsible for constitutive CD34⁺ cell mobilization may present a possible strategy to prevent the establishment of extramedullary sites of hematopoiesis in patients with PMF.

The kinetics of engraftment of normal stem cells after aSCT in PMF patients and the slow regression of fibrosis after transplant lead one to question if the distorted BM architecture associated with fibrosis in PMF actually disrupts the functions of the BM microenvironment. In PMF patients, normal stem cells engraft after transplant and hematopoietic cell recovery occurs before the BM fibrosis has resolved. These observations raise some questions concerning the prospects for success with strategies for the treatment of patients with PMF that are directed solely toward reversing the BM fibrosis rather than eliminating the malignant clone and its progeny. Furthermore, in mouse models of MF, inhibition of TGF- β 1 was capable of preventing the development of BM fibrosis but did not rescue animals from a fatal MPN.

CLINICAL MANIFESTATIONS

Table 70.3 lists the symptoms and physical findings of patients with PMF at presentation.

Approximately 25% of patients are entirely asymptomatic and come to medical attention because of an enlarged spleen detected during routine physical examination or because of an abnormal blood cell count or peripheral blood smear. The most common symptom in PMF is fatigue, which in the majority of patients affects the quality of daily life and social activities. Fatigue may be the result of anemia, which leads to the associated complaints of weakness, dyspnea on exertion, and palpitations. But when patients were questioned with the aid of specific questionnaires, fatigue was found to be a significant burden even in patients who were not anemic. The presence of anemia, splenomegaly, and other features associated with advanced disease favors the development of higher levels of fatigue. Other nonspecific constitutional symptoms, including fever, night sweats, pruritus, bone pain, and weight loss, are present at diagnosis in 20–50% of patients with PMF and are more frequent in older patients.

With enlargement of the spleen, various syndromes characterized by abdominal discomfort emerge. Pressure of the spleen on the stomach may lead to delayed gastric emptying and early satiety. Patients may merely complain of a dull, heavy sensation in the left upper quadrant. Pain of extreme severity, simulating an acute abdominal emergency, is produced by splenic infarction. Pressure of the spleen on the colon or small bowel may be responsible of severe, disabling diarrhea.

TABLE 70.3

Summary of Symptoms and Physical Findings of Patients With Primary Myelofibrosis Detected at Diagnosis

Symptom or Finding	Incidence (%)
Asymptomatic	16–30
Fatigue	47–71
Fever	5–15
Weight loss	7–39
Night sweats	6–21
Symptoms due to enlarged spleen	11–48
Bleeding	5–20
Gout or renal stones	6–13
Pallor	60
Petechiae or ecchymoses	15–20
Splenomegaly	89–99
Hepatomegaly	39–70
Peripheral edema	13
Evidence of portal hypertension	2–6
Lymphadenopathy	1–10
Jaundice	0–4

Thrombotic episodes are rarely a presenting feature of the disease but may occur during its course, with a probability of 9.6% at 5 years, a rate higher than in the control general population. Thromboses may be venous (cerebral venous sinus thrombosis, splanchnic vein thrombosis, deep venous thrombosis, pulmonary thromboembolism) or arterial (stroke, transient ischemic attacks, retinal artery occlusion, myocardial infarction, angina pectoris, and peripheral arterial disease). The cellular phase of PMF with thrombocytosis and presence of cardiovascular risk factors such as hypertension, smoking, hypercholesterolemia, and diabetes are independent predictors of thrombosis.⁷ The prefibrotic phase of MF as defined by WHO criteria is associated with a higher thrombotic risk than that observed in ET patients. After splenectomy, the rate of thrombosis increases and is associated with the development of thrombocytosis after the procedure. A systematic review of *JAK2V617F*-positive PMF patients failed to clearly define a statistically significant increased risk of thrombosis in this population.

Bleeding problems may complicate the clinical course of PMF patients and range from petechiae and ecchymoses, to life-threatening issues such as uncontrollable esophageal variceal bleeding. Bleeding can be a direct result of thrombocytopenia or impaired platelet function. Bleeding may be only initially encountered during a surgical procedure such as splenectomy; in this case, the bleeding diathesis may result from inapparent disseminated intravascular coagulopathy and has the potential for catastrophic consequences.

Occurrence of isolated sites of ectopic sites of EMH occur particularly in the pulmonary, gastrointestinal, central nervous, and genitourinary systems. EMH can rarely occur in the skin, manifesting as nontender, occasionally pruritic red, pink, or violaceous plaques, papules, or hemangioma-like nodules. These dermal infiltrates, when biopsied, are composed of combinations of myeloid, erythroid, and megakaryocytic cells. Patients with nonsplenic EMH, depending on the location, can present with cough, headache, or paralysis resulting from “brain tumors or spinal cord tumors,” small-bowel obstruction, or intractable ascites from ectopic implants of hematopoietic tissue in the gut or peritoneum. Ascites occurring in a patient with PMF may result from peritoneal or mesenteric implants of EMH or from portal hypertension. If the ascites result from peritoneal implants, the fluid is always exudative and sterile, and frequently contains myeloid, erythroid, and megakaryocytic elements. Such cytologic studies

should routinely be performed on ascitic or pleural fluid obtained from patients with PMF. Table 70.3 lists the prominent physical findings in patients with PMF.⁸ Splenomegaly serves as the hallmark of the disease. Its extent may vary, but massive splenomegaly, with the organ occupying the entire left side of the abdomen and extending into the pelvis, may occur in 35% of patients. Hepatomegaly occurs in almost 70% of cases, and lymphadenopathy is observed in 10–20%, but the degree of nodal enlargement is frequently only moderate. Other important physical findings include pallor, signs of cachexia peripheral edema, jaundice, and bony tenderness. Acute monoarticular inflammation caused by secondary gout is seen in 6% of patients.

Portal hypertension may occur and is a result of massive increases in hepatic blood flow and intrahepatic obstruction. Clinical features of portal hypertension, such as ascites or esophageal varices, occur in 9–18% of patients with PMF. Occasionally, cirrhosis or evidence of thrombosis of the portal or hepatic veins has been reported. In patients with portal hypertension, thrombotic lesions in small- or medium-sized portal veins and in extrahepatic portal veins were observed. Nodular regenerative liver hyperplasia occurred in 14.6% of cases and correlated closely with the presence of portal vein lesions.

Rarely, the development of PMF can be preceded by the appearance of multiple cutaneous edematous plaques and nodules characteristic of Sweet syndrome, a cutaneous process occurring in response to a number of hematologic malignancies. Pyoderma gangrenosum has been reported to be associated with PMF, and atypical pyoderma gangrenosum is reported to be a complication at splenectomy incision.

PMF may be associated with the development of pulmonary hypertension. These patients present with progressive dyspnea, signs of biventricular heart failure, and rapidly increasing hepatosplenomegaly. An elevation in pulmonary artery pressure can be documented by transthoracic Doppler echocardiography and right-heart catheterization. Many of these patients succumb to cardio-pulmonary complications within 18 months of the documentation of pulmonary artery hypertension. The development of pulmonary artery hypertension can be attributed to thromboembolic disease, EMH diffusely involving the lung, or pulmonary fibrosis due to the elaboration of fibrogenic cytokines from dysfunctional circulating megakaryocytes and platelets. BM fibrosis also occurs in patients with primary pulmonary hypertension and can be associated with anemia and thrombocytopenia. These patients can be distinguished from patients with PMF by their lack of high levels of circulating CD34⁺ cells, teardrop RBCs, hematopoietic cell clonality, and absence of molecular markers such as *JAK2V617F*, *CALR*, or *MPL* mutations.

The nephrotic syndrome can occasionally be associated with PMF. Renal EMH is a constant finding in these cases, but renal biopsy may also reveal a picture of mesangioproliferative glomerulopathy or membranous glomerulonephritis. Immunocomplex deposition with subepithelial electron-dense deposits caused by immunodysfunction of PMF has been proposed as the pathogenetic explanation for this association.

PMF may be associated with preexisting or simultaneously appearing autoimmune diseases, such as systemic lupus erythematosus (SLE), scleroderma, primary biliary cirrhosis, ulcerative colitis, polyarteritis nodosa, or juvenile rheumatoid arthritis. These nonmalignant autoimmune forms of MF are most commonly associated with SLE. These patients characteristically are young females who have cytopenias and BM fibrosis, but have a limited degree of splenomegaly and only mild numbers of teardrop RBC and immature myeloid cells in the peripheral blood. Circulating immune complexes and autoantibodies in SLE are thought to act on the megakaryocyte Fc-receptors and release growth factors, which are known to induce collagen production.

Patients with autoimmune MF frequently have a positive direct antiglobulin test result and antinuclear antibodies (ANAs) but are negative for MPN-associated genetic markers. They also lack marker cytogenetic abnormalities

LABORATORY MANIFESTATIONS

Careful examination of the peripheral blood smear and BM (Fig. 70.2) permits ready diagnosis of PMF. Leukoerythroblastosis with teardrop RBCs strongly suggests this diagnosis. The leukoerythroblastic condition is characterized by the presence of nucleated RBCs and immature myeloid elements in 96% of cases. Megathrombocytes and megakaryocytic fragments are frequent findings. The number of teardrop erythrocytes (i.e., dacryocytes) decreases after splenectomy or institution of chemotherapy, which has led some to suggest that splenic fibrosis causes the development of these RBC changes. In approximately 60% of patients, hemoglobin levels drop to less than 10 g/dL. The degree of anemia is not infrequently difficult to estimate by hemoglobin or hematocrit determinations because individuals with large spleens often have expanded plasma volumes and apparent anemia, which is largely dilutional in nature. Most patients have normochromic normocytic RBC indices. The anemia may be caused by decreased production due to erythroid hypoplasia or ineffective erythropoiesis and shortened RBC survival. The cause of the hemolytic anemia is usually multifactorial, with contributions from hypersplenism, a defect in RBCs resembling paroxysmal nocturnal hemoglobinuria, and antierythrocyte autoantibodies.

Hypochromic microcytic anemia resulting from iron deficiency secondary to blood loss may develop in 5% of PMF patients. Blood loss may be caused by leaking esophageal varices, duodenal ulceration, or intravascular hemolysis. Occasionally, a patient with PMF may develop an occult malignancy or a site of EMH within the gastrointestinal tract, which may serve as a bleeding source. Unexplained microcytosis (mean corpuscular volume <80 fL) has been reported as a laboratory feature in PMF and in general has not been shown to have prognostic relevance. Macrocytic anemia may complicate PMF. Folic acid absorption is normal in these patients, and folic acid deficiency probably results from increased use.

Leukopenia can occur in 13–25% of patients, and leukocytosis is seen in one third. Occasional blast cells and granulocytes with the pseudo-Pelger-Huët anomaly are frequent findings. The leukocyte alkaline phosphatase score is high in more than half of patients but low in about one third. Platelet counts of less than 100,000/mm³ are observed in 31% of patients, and platelet counts of more than 800,000/mm³ have been observed in 12%. In the prefibrotic phase of the disease, almost 90% of patients had platelet counts greater than 500,000/mm³. Defective platelet function is common, and platelets frequently do not respond to collagen or epinephrine. A variety of qualitative platelet anomalies have been documented as abnormal using automated platelet function analyzers such as the platelet function analyzer PF100 or light transmission platelet aggregometry. In 15% of patients, abnormalities suggestive of ongoing DIC are found, including decreased platelet numbers, decreased levels of factor V and VIII, and increased fibrin-split products. Usually, when DIC occurs in PMF, it produces no symptoms and unfortunately may only become clinically apparent after surgical intervention. Associated liver dysfunction may also be a contributory factor to prolongation of the prothrombin time. In addition, patients with a prefibrotic form of MF with extreme thrombocytosis can develop acquired form of Von Willebrand disease, which is not infrequently associated with bleeding.

Additional laboratory abnormalities are quite common. In one series, lactic acid levels were elevated in 95% of patients, bilirubin levels in 40%, uric acid in 60%, and alkaline phosphate and serum glutamic oxaloacetic transaminase levels in 50%. Patients with PMF have decreased levels of total cholesterol. The ratio of high-density lipoprotein cholesterol to low-density lipoprotein cholesterol is diminished.

A variety of immunologic abnormalities have been reported in PMF, including the presence of ANAs, elevated rheumatoid factor titers, direct Coombs test positivity, lupus-type circulating anticoagulants, hypocomplementemia, BM lymphoid nodules, and increased circulating immune complexes. In one series of 50 patients with PMF, increased quantities of circulating immune complexes were detected in 39% and found to be associated with increased disease activity, as

Fig. 70.2 PRIMARY MYELOFIBROSIS. Peripheral blood and bone marrow (BM) biopsy. The leukocyte count can vary in primary myelofibrosis from leukopenia to marked leukocytosis. In the case illustrated, the count was normal (A). However, the smear showed numerous dacryocytes, or teardrop forms (B), and a leukoerythroblastic picture (C–E), which is the presence leukoblasts or immature granulocytic precursors (C), including myeloblasts (D), and circulating nucleated red blood cells or erythroblasts (E). The BM biopsy is frequently hypercellular (F) and comprised of an atypical megakaryocytic and granulocytic proliferation (G) in which some of the megakaryocytes have atypical and pyknotic nuclei. Other megakaryocytes (H) are considered to have nuclei that are “cloud-like”. The BM biopsy frequently shows sinusoidal hematopoiesis (I) and significant fibrosis, as illustrated by a reticulin stain (J).

manifested by increased transfusion requirements, bone pain, and fever. Some investigators have suggested that abnormalities of the complement system may be important in the disease progression of PMF, and others have hypothesized that low levels of C3 may predispose these patients to develop serious bacterial infections. A remarkably high incidence of monoclonal gammopathies has been reported in PMF, with such benign gammopathies occurring in 8–10% of patients in some series. A number of cases of the simultaneous occurrence of a plasma cell or B-cell dyscrasia and PMF have been reported.

Successful BM aspiration is unusual, accomplished in 5–10% of cases, with the tap completely dry in 50% of cases. A BM biopsy is necessary in all cases for the diagnosis and monitoring of the disease. The amount of residual hematopoietic cellular tissue and the degree of BM fibrosis are the key elements that should be assessed. Most BM biopsies in PMF are hypercellular and are remarkable for increased numbers of megakaryocytes. BM fibrosis and osteosclerosis were seen in 67% and 54% of cases, respectively. The characteristic morphologic features include patchiness of hematopoietic cellularity and reticulin fibrosis, some microscopic fields being cellular and others depleted of hematopoietic cells. The amount of reticulin may vary from field to field. Megakaryocytes are increased in number and are often arranged around and within the sinuses and not always clustered in groups. They are large with irregular, roundish, cloudlike nuclei, and distended BM sinusoids frequently containing intravascular hematopoiesis. BM biopsies reveal a substantial increase in vascularity. BM microvessels are more tortuous and branched than observed in normal control participants. The increased microvessel density is correlated with increased VEGF expression by megakaryocytes (Fig. 70.3A and B). A rare histologic variant of PMF is the so-called *MF with fatty BM*, in which the BM is characterized by myeloid hypoplasia associated with fairly complete fatty substitution,

mimicking the BM of aplastic anemia. These patients frequently have areas of clusters of densely aggregated hematopoietic elements exhibiting the histopathologic characteristics of PMF and large numbers of hematopoietic progenitors circulating in their peripheral blood. This variant of PMF is likely caused by the abnormal trafficking of hematopoietic cells from the BM to extramedullary sites, consistent with the osteosclerosis observed in patients with PMF, increased thickness of some bone units with new lamellae, and focal areas of woven bone. There is a net decrease in osteoclast number and conversion of trabecular pillars into plates.

Progressive fibrosis is frequently observed in patients who did not have maximal MF at the time of the initial biopsy. Thiele and colleagues⁷ have described an early prefibrotic subtype of PMF with no or minimal BM reticulin fibrosis and another phase with conspicuous fibrosis and osteosclerotic changes of the BM. Based on a careful histomorphometric evaluation of the BM, a progressive fibroosteosclerotic process during the evolution of the disease that is paralleled by an increase in numbers of small megakaryocytes with irregular perimeters and megakaryocytes with naked nuclei has been observed. The clinical and morphologic findings of patients with the prefibrotic stage of PMF have been further characterized. Although a steady progression to BM fibrosis has been demonstrated in patients with the prefibrotic phase, fibrosis may remain static or diminish in the more advanced stages of PMF.

Different scoring systems for pathologically grading BM cellularity and fibrosis have been used with the aim of staging and documenting progression of the disease. The European consensus classification, the importance of age-dependent decrease in cellularity, was recognized (Table 70.4). Grading of MF was simplified by using four easily reproducible categories, including differentiation between reticulin and collagen. A consensus was reached that the density of fibers must be assessed in relation to the hematopoietic tissue. This feature is

Fig. 70.3 IMMUNOHISTOCHEMICAL STAIN OF BONE MARROW BIOPSY FROM A PATIENT WITH PRIMARY MYELOFIBROSIS. The left side shows immunohistochemical stain for CD34 antibody, which highlights the increased microvessel density, as noted with the increased number of vascular structures with the lumen. Please note also the increased number of scattered CD34⁺ myeloid blasts that are highlighted with granular staining (A). The right side shows immunohistochemical stain for vascular endothelial growth factor (VEGF)C antibody from a matched area of the bone marrow biopsy from the same patient. Note the increased expression of VEGF, as indicated by the brown staining in the cytoplasm of the dysplastic megakaryocytes (B).

TABLE 70.4	Grading of Myelofibrosis According to the European Consensus Criteria
Grading	Description ^a
MF-0	Scattered linear reticulin with no intersections (cross-overs) corresponding to normal bone marrow
MF-1	Loose network of reticulin with many intersections, especially in perivascular areas
MF-2	Diffuse and dense increase in reticulin with extensive intersections, occasionally with focal bundles of collagen, focal osteosclerosis, or both
MF-3	Diffuse and dense increase in reticulin with extensive intersections and coarse bundles of collagen, often associated with osteosclerosis

^aThe quality of the reticulin stain should be assessed by detection of normal staining in vessel walls as internal control. The degree of myelofibrosis should be assessed by disregarding lymphoid nodules and vessels and disregarding fibers framing adipocytes. Areas of prominent scleredema or scarring should be included in the overall grading of myelofibrosis. Fiber density should be assessed in hematopoietic areas.
MF, Myelofibrosis.
Data from Thiele J, Kvasnicka HM, Facchetti F, et al: European consensus on grading bone marrow fibrosis and assessment of cellularity. *Haematologica* 90:1128, 2005.

especially important to avoid a false impression of reduced fiber content in fatty or edematous BM samples after treatment. The progression of BM fibrosis in PMF is accompanied by the expression of subsets of collagenases that is independent of *JAK2V617F* status. Morphologic examination of the spleen frequently reveals follicular atrophy in the white pulp (Fig. 70.4A) with foci of EMH in the sinusoids of the red pulp (Fig. 70.4B) where megakaryocytes, myeloid elements, and nucleated erythroid elements are seen. The extramedullary hematopoietic cells belonging to each of the myeloid lineages can be distributed in the spleen diffusely or be limited to macronodules. The predominance of immature granulocytic forms is associated with an especially poor prognosis. Pathologic examination of the liver reveals hematopoietic cellular elements within the sinusoids (see E-Slide VM03954). Sinusoidal dilatation is a common finding, as

well as prominent intrahepatocyte and Kupffer cell hemosiderin deposition. A marked increase in the hepatic reticulin network has also been observed.

Approximately 30–50% of patients with PMF have karyotypic abnormalities at diagnosis. It is important to perform appropriate cytogenetic analyses to exclude rare cases of chronic myelogenous leukemia with associated BM fibrosis. Because of BM fibrosis, it is often difficult to obtain optimal numbers of metaphase cells for cytogenetic analysis. In the past, a substantial percentage of patients with PMF had a “dry tap” or were uninformative, thereby making cytogenetic analysis challenging. Although cytogenetic analysis of PMF remains time consuming and laborious, cytogenetic studies are now informative in about 99% of patients from unstimulated peripheral blood specimens. This success is due to the presence of large numbers of immature mitotic hematopoietic cells (including CD34⁺ cells) present in the peripheral blood combined with the use of an MPN interphase FISH panel that allows for essentially all PMF patients to be examined for the most frequent cytogenomic changes (Fig. 70.5). There is a high concordance rate (92%) between conventional cytogenetics and interphase FISH for the 12 most frequent chromosomal abnormalities detected in PMF.

Among the Philadelphia chromosome-negative MPNs, PMF has the highest rate of chromosomal abnormalities at diagnosis. Deletions of the long arms of chromosomes 13 and 20, trisomy 8, and abnormalities of chromosomes 1, 7, and 9 constitute more than 80% of all chromosomal abnormalities detected in PMF (see Fig. 70.5). None of these lesions are specific for PMF because they are also detected in PV, ET, MDS, and other myeloid malignancies. Deletion of the long arm of chromosome 13 is substantially more frequent in PMF than in PV. Fine FISH mapping has defined the commonly deleted region to 13q13.3-q14.3 encompassing *RB1*, *D13S319*, and *D13S25* loci. As mentioned in Chapter 68, del(20q) and +9/+9p are more frequent in PV than in PMF. Multiple copies of 9p result in trisomy/tetrasomy or amplification of *JAK2*, and each of these abnormalities has been reported in PMF. A 2.7-Mb region on chromosome 20 spanning *D20S108* (proximal) and *D20S481* (distal) is deleted in all Philadelphia chromosome-negative MPNs. A different region is deleted in other myeloid malignancies, but a common 1.6-kb region may constitute the major site responsible for loss of heterozygosity.

Fig. 70.4 SPLEEN MORPHOLOGY IN PRIMARY MYELOFIBROSIS. The left side shows low-power magnification of spleen tissue from a patient with PMF with expanded red pulp and reduced-to-absent white pulp (A). The right side shows higher power magnification with extramedullary hematopoiesis with intra-sinusoidal dysplastic megakaryocytes (*blocked arrows*), and erythroid progenitor clusters (*arrowheads*) along with scattered myeloid cells (B).

With disease progression from PV/ET to MF, the frequency of cytogenetic abnormalities increases to 70% to 90%. The types of chromosomal abnormalities observed in these cases are similar to those seen at diagnosis of PV/ET or PMF, but through subclonal evolution they may become very complex. The number of genomic alterations is more than two or three times greater in the blast phase as in the chronic phase. Specific regions on 12p (*ETV6*), 17p (*P53*), and on 21q (*RUNX1*) are frequently altered and associated with disease progression.

The use of comparative genomic hybridization techniques suggest that genomic aberrations are much more common than has been previously indicated by conventional cytogenetic analysis and occur in the majority of cases. Gains of 9p were the most frequent finding, occurring in 50% of patients, suggesting that genes on 9p may play a crucial role in the pathogenesis of PMF.

The performance of mutational studies is a critical step in making a definitive diagnosis of PMF. In PMF, the proportion of patients with the *JAK2V617F* mutation in granulocytes has been reported to range from 35% to 95%. The detection rate for *JAK2V617F* is much higher for patients with post-PV MF (91%) than PMF (45%) or post-ET MF (39%). In PV, a high burden of *JAK2V617F* allele has been associated with an increased rate of evolution to MF. Such wide differences in the mutational frequencies can be attributed to the different sensitivity of the techniques used to detect the mutation and to differences in the case mix of the reported series (i.e., proportion of primary and secondary PMF cases). *JAK2V617F* in PMF is associated with an older patient age at diagnosis and a history of thrombosis or pruritus. A common *JAK2* germ-line haplotype (46/1) that is identified by the rs12343867 SNP was found to influence susceptibility to develop PMF regardless of *JAK2* mutational status.

Gain-of-function mutations of the thrombopoietin receptor, *MPL W515L* and *MPL W515K*, are present in approximately 5% of patients with PMF, 1% of patients with ET, but no patients with PV. *MPL* mutations may occur concurrently with *JAK2V617F*, suggesting that these alleles may have functional complementation in MPN. In all cases, the *MPL W515K/L* allele burden occurs in excess of the *JAK2V617F* allele. In contrast to de novo acute myeloid leukemia (AML), mutations in the receptor tyrosine kinases *KIT*, *FMS*, and *FLT3* have not been documented in PMF, and the spectrum of mutations seen at time of leukemic transformation from PMF also differ in that mutations in *JAK2*, *SRSF2*, *TET2*, *IDH1/2*, and *ASXL1* are more common.

The number of circulating cells expressing the CD34 antigen, a phenotypic marker of hematopoietic stem and progenitor cells as well as endothelial cells, in patients with PMF has been reported to be more than 300-times higher than in normal volunteers and 18–30-times higher than in patients with PV or ET. The clinical utility of the cytofluorimetric measurement of CD34⁺ cells as a diagnostic marker of PMF is hampered by the observation that a small number of subjects with PMF exhibit a normal number of CD34⁺ cells in the peripheral blood. Cases with very mild disease or absent or slight reticulin BM fibrosis account for the majority of such patients. High values of CD34⁺ cells ($>200 \times 10^6/L$) have been proposed as an indicator of an accelerated phase of the disease.

The characteristic radiographic features of PMF include a diffuse increase in bone density and increased prominence of the bony trabeculae. This increased bone density may be patchy and can produce a mottled appearance. Such abnormalities have been reported in 25–66% of patients with PMF.

Noninvasive imaging of BM is a promising means of evaluating the BM cellularity and distribution in PMF. Magnetic resonance imaging (MRI) can portray the conversion or reconversion of fatty to cellular BM. Fibrotic BM is easily distinguished from cellular BM by its strikingly low signal intensity with all pulse signals. The BM patterns in the proximal femurs of PMF patients have been reported to be correlated with the clinical severity of the disease. BM MRI has been used to differentiate PMF from ET, where the BM adipose tissue is preserved, but in PMF, the adiposity of the BM is reduced.

DIFFERENTIAL DIAGNOSIS

A patient with hepatosplenomegaly, peripheral cytopenias, teardrop poikilocytosis, leukoerythroblastosis, and BM fibrosis probably has PMF, but other disorders may also lead to this clinical picture (see Table 70.1 and Fig. 70.6). The WHO diagnostic criteria were revised, incorporating testing for *JAK2V617F* and activating *MPL* mutations, as well as greater emphasis on histomorphologic criteria, which allow one to distinguish early phases of PMF from ET (Table 70.5). The WHO criteria are based on the recognition of a prefibrotic form of PMF without reticulin fibrosis and that the primary diagnostic features of PMF are increased megakaryocyte numbers, megakaryocyte morphology, and abnormalities of granulocyte mutation. Secondary MF frequently occurs in patients with lymphoma or metastatic carcinoma of the stomach, prostate, lung, or breast. The clinician should

Fig. 70.5 CYTOGENETIC FINDINGS IN PRIMARY MYELOFIBROSIS. The *top row* shows chromosomal abnormalities and corresponding interphase fluorescence in situ hybridization (FISH) findings associated with a favorable prognosis. They include unbalanced translocations between chromosomes 1 and 6 (both the short and long arms of chromosome 6) resulting in a gain of 1q, sole abnormality of chromosomes 9, 13, and 20, as well as the normal karyotype. Abnormalities include a gain of chromosome 9 and interstitial deletions of the long arm of chromosome 13 and 20. Note, that gain of 1q and jumping 1q is associated with disease progression to acute myeloid leukemia. The *bottom row* shows chromosomal abnormalities and corresponding interphase nuclei after FISH studies associated with an unfavorable prognosis. They include duplication and trisomy 1q. The most frequent abnormality associated with polycythemia vera-related primary myelofibrosis (PMF) is der (9)t(1;9), resulting in a gain of 1q (*red*) and 9p. Inversion of chromosome 3, -5/del(5q) (*red*), and -7/del(7q) (*red*) are rare in PMF, as are rearrangement of 11q23 and deletion of the short arms of chromosome 12. Sole trisomy 8 is a frequent abnormality associated with PMF, and rearrangements of 12q are almost exclusively identified in PMF. The chromosomal abnormalities associated with the most dismal prognosis are heterozygous 17p loss (*red*) and monosomal or complex karyotype.

Fig. 70.6 DIFFERENTIAL DIAGNOSTIC CONSIDERATIONS IN PRIMARY MYELOFIBROSIS. (A–E) Acute panmyelosis with myelofibrosis (APMF). (F and G) Chronic myelogenous leukemia (CML) in an advance phase with fibrosis. (H and I) Myelodysplastic syndrome (MDS) with fibrosis. The bone marrow (BM) biopsy of APMF, CML in advanced phase with fibrosis, and MDS with fibrosis can all look similar to PMF at low power (A, F, and H). In APMF, the distinction from PMF is made in part by seeing increased immature cells on the biopsy (B) interspersed with other hematopoietic precursors. These are usually CD34⁺ (C), but in contrast to acute megakaryoblastic leukemia are usually CD61[−] (D). In addition, the peripheral blood usually shows pancytopenia with neither teardrop red blood cells nor leukoerythroblastosis (E). Although the biopsy of CML presenting in an advanced phase can resemble PMF (F), the peripheral blood usually shows classic granulocytosis with left shift and basophilia (G). In the case illustrated, the 30-year-old female patient had fibrotic BM (F) but presented with a white blood cell count of 148,000/L showing a full spectrum of granulocytes, increased blasts (22%), and basophilia. P210 *BCR/ABL1* was demonstrated. The bone marrow biopsy in MDS with fibrosis has small megakaryocytes (H), but dysplasia is otherwise difficult to evaluate in the absence of an aspirate, and one must rely on the peripheral blood to identify dysplasia, as in the severely dysplastic neutrophil (I).

be extremely careful in making the diagnosis of PMF in a patient who has a history of a primary neoplasm. Demonstration of carcinoma cells in the BM establishes that metastatic carcinoma is the cause of the BM fibrosis (Fig. 70.7A and B). The finding of blastic or lytic bone lesions in patients with MF suggests the presence of an underlying carcinoma. Disseminated tuberculosis and histoplasmosis have been associated with the development of secondary MF. Caseating or noncaseating granulomas observed on BM biopsy suggest the presence of these infectious disorders. Identification of the causative organisms by culture techniques should be pursued.

A number of other primary hematologic disorders can also be accompanied by BM fibrosis (see Table 70.1). A variety of overlap syndromes that share features of both PMF and MDS have been reported and are seen frequently in clinical practice. These so-called *overlap syndromes* have pathologic and clinical features of both MPN and MDS, and are characterized by BM hypercellularity, dysplasia of various myeloid lineages, and proliferative features, as well as ineffective hematopoiesis, modest hepatosplenomegaly, and some degree of BM fibrosis. These patients are occasionally *JAK2V617F* positive and frequently have *TET2* mutations. Such patients frequently present with cytopenias and are at a high risk of developing acute leukemia. These cases indicate the limitations of adhering to strict disease classifications and underscore that a continuum exists between MPNs and MDS. The peripheral blood and BM findings that allow differentiation of these disorders can be enhanced by *JAK2V617F*, *MPL W515L/K* and *CALR* mutational analyses. Patients with the variant

MDS with MF frequently present with cytopenias and have dysplastic cellular abnormalities indistinguishable from those of other patients with myelodysplasia. Their BMs, however, are characterized by the presence of BM fibrosis and a striking megakaryocytic hyperplasia, with a predominance of small hypolobulated forms, in some cases surrounding fibrosis. Reticulocytopenia is characteristic of these patients, as are teardrop RBCs and a clinical picture of leukoerythroblastosis. Unlike patients with PMF, patients with myelodysplasia and BM fibrosis do not have hepatic or splenic enlargement extending more than 3 cm below the costal margin. The OS time of patients with this variant of MDS has been reported to be 30 months, with death resulting from the effects of cytopenias or transformation to acute leukemia. Additional studies have indicated that the presence of MF in patients with myelodysplasia was associated with a particularly short survival time (9.6 months) compared with patients with myelodysplasia without fibrosis (17.4 months).

Hairy cell leukemia can also be confused with PMF. In one study, five out of 61 patients who had originally been diagnosed as having PMF were shown retrospectively to have had hairy cell leukemia. Hairy cell leukemia can present as pancytopenia with splenomegaly and is associated with a dry BM tap. In one series, BM reticulin content was increased in 26 out of 29 patients with hairy cell leukemia. The presence of hairy mononuclear cells possessing tartrate-resistant acid phosphatase or the appropriate phenotype in the peripheral blood or BM should facilitate differentiation of PMF from hairy cell leukemia (see Chapter 78). This exercise is important

because of the different modalities of treatment that can be successfully used for hairy cell leukemia.

BM fibrosis can occur in patients with other MPNs, especially PV and CML, and less frequently with ET. In CML, progressive BM fibrosis may herald the onset of accelerated disease or blast crisis. MF

TABLE 70.5 World Health Organization Criteria for Primary Myelofibrosis^a

Major Criteria

1. Presence of megakaryocyte proliferation and atypia,^b usually accompanied by either reticulin or collagen fibrosis, or, in the absence of significant reticulin fibrosis, the megakaryocyte changes must be accompanied by an increased bone marrow cellularity characterized by granulocytic proliferation and often decreased erythropoiesis (i.e., prefibrotic cellular-phase disease)
2. Not meeting WHO criteria for PV,^c CML,^d MDS,^e or other myeloid neoplasm
3. Demonstration of *JAK2*617V>F or other clonal marker (e.g., *MPL*515W>L/K), or in the absence of a clonal marker, no evidence of bone marrow fibrosis caused by underlying inflammatory or other neoplastic diseases^f

Minor Criteria

1. Leukoerythroblastosis^g
2. Increase in serum lactate dehydrogenase level^h
3. Anemia^g
4. Palpable splenomegaly^g

^aDiagnosis requires meeting all three major criteria and two minor criteria.

^bSmall-to-large megakaryocytes with an aberrant nuclear-to-cytoplasmic ratio and hyperchromatic, bulbous, or irregularly folded nuclei and dense clustering.

^cRequires the failure of iron-replacement therapy to increase hemoglobin level to the polycythemia vera range in the presence of decreased serum ferritin. Exclusion of polycythemia vera is based on hemoglobin and hematocrit levels. Red blood cell mass measurement is not required.

^dRequires the absence of *BCR-ABL*.

^eRequires the absence of dyserythropoiesis and dysgranulopoiesis.

^fSecondary to infection, autoimmune disorder or other chronic inflammatory condition, hairy cell leukemia or other lymphoid neoplasm, metastatic malignancy, or toxic (chronic) myelopathies. It should be noted that patients with conditions associated with reactive myelofibrosis are not immune to primary myelofibrosis, and the diagnosis should be considered in such cases if other criteria are met.

^gDegree of abnormality could be borderline or marked.

CML, Chronic myeloid leukemia; MDS, myelodysplastic syndrome; PV, polycythemia vera; WHO, World Health Organization.

Data from Tefferi A, Thiele J, Orazi A, et al: Proposals and rationale for revision of the World Health Organization diagnostic criteria for polycythemia vera, essential thrombocythemia, and primary myelofibrosis: Recommendations from an ad hoc international expert panel. *Blood* 110:1092, 2007.

in CML occurs in two distinct patterns, one in which patients present with CML and significant associated BM fibrosis, and a second in which the MF develops late in the course of the CML. The MF in the latter group appears at a mean of 36 months after the diagnosis of CML, is associated with a mean survival time of 4.9 months from the detection of MF, and therefore represents an ominous prognostic sign.

Post-PV MF occurs in 5–15% of patients with PV. This transition occurs, on average, 10 years after the initial diagnosis of PV is made, but in individual cases it may appear after shorter or longer intervals. PMF is clinically indistinguishable from post-PV MF except for the previous history of erythrocytosis in the latter group. Of patients with post-PV MF, 25–50% develop leukemia, and 70% are dead within 3 years of this transition. Post-PV MF represents a transitional myeloproliferative syndrome with relatively grave prognostic implications. MF has also been reported after ET. These investigators claimed that these patients did not represent individuals with prefibrotic stages of PMF but rather evolution of patients with true ET. They estimated the probability of developing such a complication to be 3% 5 years after diagnosis, 8% at 10 years, and 15% at 15 years, and considered this evolution to BM fibrosis a major long-term complication of ET.

Acute panmyelosis with myelofibrosis (APMF) represents a clinical entity distinct from PMF (see Fig. 70.6). This disorder has also been termed *acute MF*, *acute myelosclerosis*, *acute megakaryocytic MF*, and *acute myelodysplasia with MF*. APMF is exceedingly rare and corresponds to less than 1% of the cases of AML. Patients characteristically present with pancytopenia, fever, absence of clinically significant splenomegaly, minimal or absent teardrop poikilocytosis, and fibrotic BM. The BM is characterized by the appearance of immature myeloid cells and blast cells, which frequently express megakaryocytic phenotypic properties. Survival ranges from 1 to 9 months after diagnosis. Its distinction from PMF is important because aggressive chemotherapy and possibly SCT are the treatments of choice. Up to 12% of patients who present with MF have been reported to have an underlying autoimmune disorder such as SLE, although in the authors' clinical practice, this is an extraordinary rare event. Primary autoimmune MF (primary AIMF) likely represents a distinct clinicopathologic syndrome unrelated to other well-defined autoimmune disorders. Eight diagnostic criteria for AIMF, including grade 3 or 4 reticulin fibrosis in the BM, lack of clustered or atypical megakaryocytes, lack of dysplasia or eosinophilia or basophilia, lymphoid infiltration of the BM, lack of osteosclerosis, absent or mild splenomegaly, presence of autoantibodies, and absence of disorders associated with MF, have been outlined. Autoimmune MF occurs predominantly in females with a broad clinical spectrum. Patients

Fig. 70.7 Metastatic carcinoma to the bone marrow often is associated with bone marrow fibrosis as noted in this hematoxylin and eosin-stained section with clusters of carcinoma cells (A) that are highlighted by cytokeratin immunostain (B).

may present with MF in the setting of established SLE or in patients with minimal manifestations of an autoimmune disorder, as in primary AIMF. The presence of teardrop erythrocytes or leukoerythroblastosis in a patient with lupus suggests autoimmune MF. Such patients universally have a positive ANA test result or an elevated anti-DNA titer. Because the physical manifestations of an autoimmune disease may not be evident, all patients with MF should have an ANA test to exclude an autoimmune etiology. Primary AIMF patients lack MPN mutations such as *JAK2V617F*, *MPL W515L/K*, and *CALR*, or marker cytogenetic abnormalities consistent with polyclonal rather than clonal hematopoiesis

PROGNOSIS

The median OS period from the time of diagnosis of PMF varies from series to series but is approximately 6–7 years (Fig. 70.8). The primary causes of death include infection, leukemic transformation, heart failure, bleeding, hepatic failure caused by EMH of the liver, portal hypertension, renal failure, pulmonary embolism, and complications occurring following aSCT. The incidence of acute leukemia as a terminal event ranges from 5% to 22%, (Fig. 70.9). Approximately half of the patients who develop acute leukemia have not received previous treatment with alkylating agents or radiotherapy, indicating that the evolution into acute leukemia is part of the natural history of PMF. The actuarial cumulative risk of death from leukemic

Fig. 70.8 OVERALL SURVIVAL FROM THE TIME OF DIAGNOSIS OF 141 PATIENTS WITH PRIMARY MYELOFIBROSIS. (Data from Silverstein MN: Agnogenic myeloid metaplasia, Acton, MA, 1975, Publishing Sciences Group, p 197.)

transformation at 1 and 5 years after diagnosis has been reported to be 2% and 16%, respectively. Immunologic and morphologic characterization of the blast cell phenotypes comprising these leukemias reveals that a typical myeloid phenotype is most commonly detected; other cell lineages, such as megakaryocytic, erythroid, lymphoid, and even stem cell phenotype, may also be involved, leading to the existence of mixed myeloid and hybrid transformations. Megakaryoblastic transformations have been detected in one-third of cases in one series, an incidence higher than that found in de novo AML. In 50% of cases of *JAK2V617F* MPNs, the blast cells that represent the progeny of the leukemia initiating clone are *JAK2V617F* negative, suggesting that the leukemia originates from a clone distinct from the *JAK2V617F*-positive clone. This coexistent *JAK2V617F*-negative clone appears to have a higher propensity to undergo leukemic transformation. *JAK2V617F* therefore does not appear to be a prerequisite for leukemic transformation of MPNs, suggesting that additional genetic and epigenetic events are required for full transformation to occur. SNP array analysis has shown that genomic alterations occur at an increased frequency during the period of blastic transformation and that no single gene or molecular pathway is sufficient to cause transformation. Acquisition of somatic mutations in *TET2*, *IDH*, *TP53*, and *ASXL1* have all been implicated as genetic events leading to leukemic transformation in MF patients.

A surprising correlation has been observed between the phenotype of the preceding MPN and the *JAK2* mutational status of the leukemic blasts after transformation. In contrast to *JAK2* WT AML in this setting, evolution to leukemias with *JAK2V617F*-positive blast cells is invariably preceded by the evolution of ET or PV to MF. Because of these observations, myelofibrotic transformation of ET or PV likely represents an accelerated phase of the initial MPN preceded by genetic changes that result in evolution to MF and eventually leukemia. *JAK2* WT leukemia, by contrast, usually arises in patients with chronic-phase PV or ET who have not evolved to MF. Some have suggested that these leukemias are therapy related and are the consequence of the administration of myelosuppressive agents administered during the chronic phase. The reversion from *JAK2V617F* to WT *JAK2* in these leukemias is not due to homologous recombination. Two models have previously been proposed to account for the clonal relationship between *JAK2* WT AML and its preceding MPN: (1) Both the chronic MPN and the AML arise from a shared pre-*JAK2V617F* founder clone, and (2) the chronic MPN and AML arise from two independent stem cells. A more recent model proposed by Lundberg and colleagues also reflects similar models incorporating new understanding of phylogenetic ordering of mutated *JAK2* and *CALR* with respect to additional acquired somatic mutations (see Fig. 70.1).⁸ It remains possible that each model is viable and operates in different individual patients. Survival after blast transformation is limited, a phenomenon that is probably a result of patient age and

Fig. 70.9 DISEASE PROGRESSION IN PRIMARY MYELOFIBROSIS. Marked osteosclerosis (A and B) and acute leukemia (C and D). In some patients, primary myelofibrosis progresses to severe osteosclerosis, in which there is markedly thickened and irregular bone formation (A) and a bone marrow space that is fibrotic and nearly depleted of hematopoietic elements (B). A terminal transformation to acute leukemia (C and D) occurs in 5–22% of cases.

TABLE 70.6 Prognostic Scoring Systems for Primary Myelofibrosis

Risk Factor	Lille	IPSS	DIPSS	DIPSS Plus
Anemia (hemoglobin)	X (<10 g/dL)	X (<10 g/dL)	X (<10 g/dL)	X (<10 g/dL)
Leukocytosis (white blood cell count)	X (<4 or >30 × 10 ⁹ /L)	X (>25 × 10 ⁹ /L)	X (>25 × 10 ⁹ /L)	X (>25 × 10 ⁹ /L)
Peripheral blood blasts		X (≥1%)	X (≥1%)	X (≥1%)
Constitutional symptoms		X	X	X
Age (years)		X (>65)	X (adjusted for age)	X
Karyotype				X (unfavorable ^a)
Platelet				X (<100 × 10 ⁹ /L)
Transfusion status				X

^aUnfavorable karyotype includes complex or sole or two abnormalities that include +8, -7/7q-, i7/7q-, i(17q), -5/5q-, 12p-, inv(3), or 11q23 rearrangements. DIPSS, Dynamic international prognostic scoring system; IPSS, international prognostic scoring system.

the aggressive biology of these leukemias. Leukemic transformation of PMF has been reported to be fatal in 98% of patients after a median of 2.6 months. Successful leukemia remission induction therapy in these patients is an extremely rare event. Patients should optimally be sent for aSCT before leukemic transformation. Leukemia-free survival in PMF has been shown to be significantly worse in the presence of a triple-negative mutational status, compared with patients with *CALR*, *JAK2*-, or *MPL*-mutated status. Conversely, *CALR*-mutated patients were at lower risk of leukemic transformation compared with triple-negative and *JAK2*-mutated cases, but not when compared with *MPL*-mutated cases.

The clinical and biologic parameters that are characteristic of patients at diagnosis have been used to identify subgroups of patients with different prognoses. Some investigators have suggested that there are two subpopulations of patients with PMF; short-lived and long-lived subpopulations of patients. These efforts are of importance in identifying which patients have a limited survival and should proceed with aSCT in a timely fashion or in selecting groups of MF patients with a similar prognosis for participation in clinical trials. Each of these efforts have uniformly shown that patients with anemia at presentation have a shorter survival. Dupriez and associates developed an extremely simple scoring system, the Lille scoring system, based on two adverse prognostic factors—hemoglobin level less than 10 g/dL and WBC count less than 4000/mm³ or more than 30,000/mm³, and were able to stratify patients into three groups. The low-risk (zero factors), intermediate-risk (one factor), and high-risk (two factors) groups were associated with median survival times of 93, 26, and 13 months, respectively. Other scoring systems that use simple clinical hematologic parameters have been subsequently proposed.

The International Working Group for Myelofibrosis Research and Treatment (IWG-MRT) have developed an international prognostic scoring systems (IPSS) based on the clinical characteristics of 1054 patients diagnosed with PMF.⁹ Tables 70.6 and 70.7 compare four validated prognostic scoring systems for patients with PMF. The overall median survival for this group was 69 months, and multivariate analysis identified an age greater than 65 years, the presence of constitutional symptoms, hemoglobin below 10 g/dL, leukocyte count above 25 × 10⁹/L, and 1% or greater peripheral blood blasts as significant risk factors. The sum of the risk factors allows for allocation into discrete risk groups. Four risk groups can be discerned with nonoverlapping survival curves based on this model with median survivals of 135, 95, 48, and 27 months for low (0), intermediate-1 (1), intermediate-2 (2), and high-risk (3–5) groups, respectively. Although the presence of *JAK2V617F* was associated with age greater than 65 years, it did not influence survival in this study. The presence of cytogenetic abnormalities influenced the survival of the intermediate-risk groups only. Subsequently, a cohort of 525 PMF patients was followed over time to assess the prognostic influence of the five IPSS clinical variables acquired during the

TABLE 70.7 Median Survival of Each Risk Group in Four Prognostic Scoring Systems for Primary Myelofibrosis

Risk Group	Lille	IPSS	DIPSS	DIPSS Plus
Low	93 months	135 months	Not reached	185 months
Intermediate-1	26 months	95 months	170 months	78 months
Intermediate-2		48 months	48 months	35 months
High	13 months	27 months	18 months	16 months

DIPSS, Dynamic international prognostic scoring system; IPSS, international prognostic scoring system.

course of disease rather than at presentation. The IPSS variables were analyzed as time-dependent covariates in a multivariate Cox proportional hazard model. Anemia was found to have the most significant hazard ratio (HR) for survival. The advantage of this dynamic IPSS (DIPSS) is its ability to assess real-time prognosis as a patient acquires different clinical features. An age-adjusted DIPSS (aaDIPSS) was also proposed for patients younger than the age of 65 years and may be particularly useful when applied to young patients in the context of risk assessment for SCT. More recently, an attempt to further refine the DIPSS based on the incorporation of unfavorable karyotype, platelet count below 100 × 10⁹/L and transfusional status within the scoring system was reported. A poorer, leukemia-free survival was predicted by the presence of thrombocytopenia or an unfavorable karyotype with a 10-year risk of 31% (HR: 3.3; 95% confidence interval: 1.9–5.6).

Substantial progress has been made during the past few years to allow for the use of cytogenetics as a prognostic indicator. Initially, a group at the MD Anderson Cancer Center performed a retrospective analysis of 256 patients (36% had an abnormal karyotype) and determined that baseline cytogenetic status was useful in predicting survival. Deletions of chromosomes 13 and 20 or trisomy 9 alone or in the presence of other abnormalities were associated with a median survival time similar to those with a normal karyotype (63 and 46 months, respectively). By contrast, abnormalities of chromosomes 5 or 7, or three or more abnormalities were associated with a median survival time of 15 months. In a larger study from the Mayo Clinic, a two-tier cytogenetic risk stratification after a median follow-up of 4 years was developed. Because cytogenetic analysis is not yet incorporated in the IPSS, the following cytogenetic current schema should be carefully considered. Patients with favorable karyotype include chromosome del(13q), del(20q), trisomy 9, alone other single abnormalities, two abnormalities excluding unfavorable types of abnormalities, and a normal karyotype. The 5-year survival rate was 51% with a median survival of 5.2 years observed for patients in the group with favorable karyotypes. Although derivative 1;6 resulting in 1q gain has been considered a favorable prognostic finding, gain of

chromosome 1q, which occurs in 22% of PMF patients, has been reported to be associated with disease progression, and jumping 1q translocations have been observed to be associated with imminent transformation to AML. In PMF, the region on chromosome 1 that is most frequently duplicated or occurring in trisomy is between 1q21-32 and 1q32-44 band regions (see Fig. 70.5). The 5-year survival for patients with an unfavorable karyotype, including trisomy 8, abnormalities of chromosomes 5 or 7, inversion of chromosome 3, isochromosome 17q, deletion 12p or 11q23 rearrangement, as well as two abnormalities including an unfavorable abnormality and a complex karyotype, was 8% with a median survival of 2 years. Moreover, multivariable analysis demonstrated that karyotype and platelet count ($<100 \times 10^9/L$) but not the IPSS status predicted leukemia-free survival. The 5-year leukemic transformation rates for patients with an unfavorable versus favorable karyotype were 46% and 7%, respectively ($p < .0001$). The widespread implementation of this cytogenetically-based scoring system requires more extensive validation. A new cytogenetic risk category, monosomal karyotype (MK), also defines an unfavorable risk category. An MK is defined as having two or more autosomal monosomies or a single autosomal monosomy associated with at least one structural abnormality. This is a rare cytogenetic change associated with median survival of 6 months and a 2-year leukemic transformation rate of 29.4%. At diagnosis of PMF, detection of MK is associated with extremely poor overall and leukemia-free survival.

The mutational profile of a MF patient has also been shown to have prognostic significance. Four risk groups based on mutational status of the driver mutations involving *JAK2*, *MPL*, and *CALR* have been shown to predict different overall and leukemia-free survival. MF patients with *CALR*-positive, *JAK2V617F*-positive, *MPL*-positive, or “triple-negative” disease have a mean OS of 17.7 years, 9.2 years, 9.1 years, and 3.2 years, respectively. In fact, the incorporation of these molecular markers into modern risk-adapted treatment stratification has been proposed by some investigators. Additionally, MF patients harboring both *CALR* and *ASXL1* mutations have been shown to have a good prognosis compared with patients harboring an *ASXL1* mutation alone.

Most studies have indicated that the OS of patients with *JAK2V617F*-positive and -negative PMF are similar; however, patients with *JAK2V617F*-positive disease and a low allele burden ($<25\%$) have been shown to have a shorter survival time. In addition, mutations in *MPL* or *TET2* do not appear to influence overall or leukemia-free survival. A number of investigators have attempted to correlate the presence of a variety of additional mutations with disease outcomes. See Table 70.2 for a list of documented recurrent acquired mutations associated with MF. *EZH2* mutations have been identified in 6% of patients with PMF, 3% of PV patients, 3% of patients with post-PV MF, and 9.4% of patients with post-ET MF. More than 40% of the patients with *EZH2* mutations were *JAK2V617F*-positive, 6% have a *TET2* mutation, and, 22% harbored an *ASXL1* mutation. Concurrent *EZH2* mutations and *MPL* mutations have not been observed. *EZH2* mutations are usually present at the diagnosis of chronic MPN and are maintained universally in the leukemic blasts at the time of transformation to AML. *EZH2*-mutated patients are characterized by more profound leukocytosis and larger spleens, and have a higher percentage of blasts. The survival of patients with *EZH2* mutations was clearly inferior because they are clustered in patients with high-risk IPSS scores. In addition, IDH mutations, albeit rare in PMF patients, have been associated with inferior survival in *JAK2V617F*-positive patients, raising the possibility of the cooperation between *IDH* mutations and *JAK2V617F* in leukemic transformation.

Therapy

The treatment of the PMF patient was thought until recently to be largely a futile exercise, but with reports of curative nonmyeloablative (MA) aSCT for a subpopulation of PMF patients, and the approval of a small-molecule JAK2 inhibitor that is effective in reducing the

degree of splenomegaly and alleviating systemic symptoms, therapy for PMF patients has become much more effective. The therapeutic strategies employed for an individual patient are currently based on an assessment of the patient's clinical characteristics, performance status, and prognosis estimated using one of the prognostic scoring systems described above. A conservative approach to management is generally recommended for low-risk patients, with observation of asymptomatic patients and therapeutic intervention reserved for patients with intermediate/high-risk disease or individuals with especially burdensome symptoms.¹⁰

In general, therapy is indicated for PMF patients with the following conditions: symptoms attributable to anemia, pressure symptoms related to splenomegaly, bleeding problems, life-threatening thrombocytopenia, significant hyperuricemia, bone pain, systemic symptoms (fevers, night sweats, and weight loss), and portal hypertension and life-threatening gastrointestinal bleeding. Hyperuricemia should be aggressively treated in all patients with PMF. Hydration and chronic administration of allopurinol (300 mg/day) are suggested.

Patients with the prefibrotic form of MF or low-risk MF, particularly if they are young, are particularly challenging for most physicians. These patients are largely asymptomatic but are at a risk of their disease eventually evolving to a symptomatic form of MF or acute leukemia. Many patients are eager to entertain options that might prevent the evolution of such disease but at present there is no data to indicate that any approach can successively achieve this goal. Also aSCT is not an option for such patients due to the morbidity and mortality associated with its implementation. During the last decade several investigators have promoted IFN- α therapy as an agent that might be capable of delaying disease progression by decreasing the rate of fibrosis if administered chronically during the early course of this disease. Others have not reported such effects in patients with more advanced phases of the disease. In one series, only four of 11 patients were able to complete 1 year of therapy; the other seven patients discontinued the drug because of unacceptable toxicity or the development of severe cytopenias. A clinically significant improvement (degree of BM fibrosis, osteosclerosis, or angiogenesis) was not observed in any of these patients. A small phase II pilot study in PMF patients demonstrated responses in patients with a prefibrotic form of PMF treated with low doses of IFN- α -2b over an extended period (median duration: 3 years). Four patients with *JAK2V617F*-positive PMF were followed over time, and although each had clinical responses, only one had a significant reduction in mutant allele burden. The drug was generally well tolerated at doses between 1 and 2 million units weekly, and responses in the BM included reduction in the degree of reticulin fibrosis and abnormal cellular morphology. Eleven patients with PMF were treated with a pegylated form of IFN- α -2b (PEG-IFN- α -2b) at starting dose between 2 and 3 $\mu g/kg/week$; only a single patient responded. Although the pegylated form of this drug allows for weekly injections, the toxicity profile was found to be similar to the standard formulation and for many patients limited the duration of therapy. The most common grade 3/4 toxicity was fatigue and thrombocytopenia. Because of the recent encouraging results reported with PEG-IFN- α -2a (Pegasys) in PV patients, this form of IFN- α has also been evaluated in MF patients. The French Groupe d'Etudes des Myelofibroses (GEM) and France Intergroupe des Syndromes Myeloproliferatifs conducted a study of 18 patients with PMF and post-ET/PV MF treated with Pegasys. Of the four PMF patients included in this study, one had a complete response, two had a minor response, and one had no response. Responses were associated with improvement in the degree of anemia, leukocytosis, and thrombocytosis, but not splenomegaly, and appeared to be irrespective of JAK2 status. Comprehensive reviews of the literature suggest that modest benefits may be derived from IFN- α therapy for PMF after patients have entered the more advanced phases of the disease. Further large randomized studies are warranted in patients with the prefibrotic phase of PMF to determine the effects of this modality of treatment on disease-free survival, OS, quality of life, and progression to more advanced phases of PMF or evolution to acute leukemia. Before such trials are completed, IFN therapy at any phase of PMF should be considered an experimental form of

therapy and not embarked upon unless the patient is participating in a clinical trial.¹¹

Treatment of the Anemic Patient

Anemia is a common problem in patients with PMF. It is usually multifactorial in origin; contributing factors are folate deficiency, iron deficiency, ineffective erythropoiesis, erythroid hypoplasia, increased clearance, and hemolysis. Patients with documented nutritional deficiencies should receive folate, iron supplementation, or both. Transfusion therapy with packed RBCs is clearly indicated in patients who are symptomatic from their anemia. Chronic transfusion therapy is frequently required, and the clinician should try to attain a hemoglobin level at which symptoms resolve. Long-term transfusion therapy potentially may lead to the development of iron-overload syndrome. It remains unclear if iron chelation provides a meaningful clinical benefit to patients with MF and the justification of the use of this therapy has mostly been extrapolated from the MDS literature and case reports. Low-dose dexamethasone has been reported to be useful in the treatment of patients with transfusion-dependent PMF.

Corticosteroids (e.g., prednisone 1 mg/kg/day taken orally) have also been successfully used for treatment of the hemolytic anemia associated with PMF. Other therapeutic options for PMF-associated hemolytic anemia can include therapy with intravenous immunoglobulins and recombinant human erythropoietin- α (rHuEPO). Recently, retrospective analysis of single-agent prednisone therapy for 30 intermediate-2 or high-risk PMF patients with anemia/thrombocytopenia was published. The initial dose was 0.5–1 mg/kg daily, with tapering to the minimum effective dose in responders. Twelve patients (40%) achieved an anemia response by IWG-MRT criteria. The median response duration was 12.3 months. Patients with constitutional symptoms or >2% circulating blasts had a lower response rate. Median survival from the initiation of prednisone therapy was significantly longer in anemia responders (5.0 years vs. 1.5 years, $p = .002$). Additional information that supports the use of corticosteroids for the treatment of MF-related anemia is derived from a prospective clinical trial that was constructed to evaluate the efficacy of the immunomodulatory agent, pomalidomide. This study surprisingly revealed that prednisone alone can induce significant responses in unselected MF patients with severe anemia. In this randomized study, the active control arm that included 21 patients consisted of prednisone (30 mg/day during the first 28-day cycle, 15 mg/day the second cycle, 15 mg every other day the third cycle) plus placebo (up to 12 cycles). Overall, four out of 16 (25%) patients assigned to the control arm who completed three cycles of treatment achieved anemia response according to the IWG-MRT criteria. Three of the four responses were short-lived, lasting between 2.3 and 5.5 months. These data are similar to our own experience indicating that prednisone therapy can improve the anemia and thrombocytopenia associated with PMF even after the failure of standard therapies.

It is important to be aware that the hemolytic anemia in patients with PMF may also rarely be a consequence of a coexisting secondary form of paroxysmal nocturnal hemoglobinuria that can be responsive to eculizumab therapy (see [Chapter 32](#)). Furthermore, patients with PMF who receive multiple transfusions are candidates for developing delayed hemolytic transfusion reactions that occasionally may be severe and persistent. The direct antiglobulin test result is usually positive in this setting. It is generally believed that additional transfusions in these patients with delayed hemolytic transfusion reactions should be avoided if possible.

Anemia caused by erythroid cell hypoplasia as well as ineffective erythropoiesis in PMF may respond to anabolic steroids. A good response, as defined by a decrease or total avoidance of transfusion therapy, occurs in about 20–40% of patients. A course of 3–6 months of androgen therapy is indicated to identify responsive patients, but the development of hepatic dysfunction or virilizing side effects may limit long-term androgen administration. Patients with associated chromosomal abnormalities have been reported to be less likely to

respond to androgen therapy. Danazol, a synthetic attenuated androgen, has also been useful in reducing the requirement for RBC transfusion support and correction of thrombocytopenia in 20–40% of treated patients in several series. Variables associated with response were lack of transfusion requirement and higher hemoglobin levels. The experience with the use of rHuEPO in PMF has been reviewed by Cervantes and colleagues in a total of 51 patients, documenting that 28 (55%) of these patients responded to rHuEPO treatment, including 16 complete and 12 partial responses. Endogenous serum EPO levels inappropriately low for the degree of anemia is predictive of a favorable response to rHuEPO. Serum EPO levels below 125 U/L were found to be associated with a favorable response to rHuEPO therapy. Responses can be associated with a limited enlargement of the spleen.

The use of darbepoetin, a novel hyperglycosylated erythropoiesis-stimulating protein, has been reported in 20 PMF patients. With an initial weekly dose of 150 μ g, increased to 300 μ g, when no response was observed after 4–8 weeks, eight patients (40%) responded to treatment, including six complete and two partial responses, and five maintained their response after a median follow-up of 12 months (range: 4–22 months). The median time to response was 2 months. Univariate analysis indicated that older age was the only factor associated with a favorable response to treatment ($p < .006$). None of the patients with elevated serum EPO levels responded. Treatment was usually well tolerated, and patients can be successfully switched from rHuEPO to darbepoetin.

Multiple trials have explored the use of thalidomide in the treatment of anemia in PMF based on the drug's antiangiogenic, immunomodulatory, and antiinflammatory actions. A pooled analysis of five small phase II studies indicated that 29% of patients with moderate to severe anemia experience an increase in hemoglobin or reduction or elimination of blood transfusion requirements with thalidomide therapy at a standard dose of 200–800 mg/day. Nevertheless, most of the patients treated with these doses had adverse effects that resulted in an attrition rate of greater than 50% after 3 months. Moreover, increases of WBC numbers or platelet counts were frequently reported to be associated with such serious adverse events as pericardial effusions secondary to myeloid metaplasia. Using a dose-escalation design and starting with a low dose of thalidomide (50 mg/day), 31% of patients with transfusion-dependent anemia were reported to experience a response after treatment. A combination of low-dose thalidomide (50 mg/day) with prednisone has been reported to be a better-tolerated regimen and equally or more effective than standard-dose treatment. This regimen also had a significant effect on the degree of thrombocytopenia and resulted in a reduction in the degree of splenomegaly in almost 10% of the patients. These responses were frequently maintained after therapy was halted. Higher doses of thalidomide were not more effective than lower doses. A prospective phase IIB, randomized, double-blind, multicenter trial compared therapy with 200–400 mg of thalidomide with placebo and documented that in the thalidomide group, only 10 out of 26 patients completed 6 months of treatment and that no difference was observed between the thalidomide and placebo groups as regards to improvement of hemoglobin levels or reduction of the number of RBC transfusion required. In addition, experience with thalidomide therapy in a two-stage phase II dose-escalation trial in 44 patients with advanced PMF has been reported. Starting at 200 mg/day and increasing to 800 mg as tolerated, the median tolerated dose was 400 mg for a median duration of 3 months, and 20% of the patients experienced improvement in their degree of anemia (21% became transfusion independent). A more potent thalidomide analog, lenalidomide, was evaluated in 68 symptomatic patients with PMF at two institutions. Oral lenalidomide was administered at a dose of 10 mg/day if the platelet count was greater than 100,000/ mm^3 or at a dose of 5 mg/day if the platelet count was less than 100,000/ mm^3 for 3–4 months. The overall response rates were 22% for patients with anemia, 33% for patients with splenomegaly, and 50% for thrombocytopenia. Several patients normalized their hemoglobin levels or became RBC transfusion independent. The most common associated toxicities were grade 3 and 4 neutropenia and

thrombocytopenia, which occurred in approximately 30% of patients but resolved with discontinuation of therapy. In several patients with del(5)(q31)-associated PMF or post-PV MF, lenalidomide therapy was associated with reduction of the numbers of cells with a marker chromosome as assayed by FISH and reduction of the *JAK2V617F* burden. Lenalidomide therapy in combination with prednisone therapy in PMF has been evaluated in a phase II trial within the Eastern Cooperative Oncology Group and appears to be modestly active and myelosuppressive. Forty two MF patients with anemia were treated with lenalidomide at 10 mg/day in combination with a 3-month prednisone taper. Grade 3 and higher myelotoxicity was noted in 88% of patients, and a response rate of 23% by IWG-MRT was obtained (19% clinical improvement in anemia or 10% clinical improvement in spleen size). Whether either of these immunomodulatory drugs (IMiDs) is superior to the other is the subject of speculation, which would require a large randomized clinical trial. The mechanism by which these agents achieve these clinical responses also remains of larger speculation.

Because IMiDs as a class have shown activity in MF and their use is often undermined by neurotoxicity or myelosuppression, recent interest in the structurally related but more potent pomalidomide in the treatment of MF-associated anemia has led to the completion of several early-phase studies and a randomized phase III study. The first study to evaluate the response of pomalidomide in MF was a phase II randomized, double-blind, placebo-controlled adaptive design study with four treatment arms. This study reported an overall response in anemia of 24% (10 patients), and 15 of these patients achieved transfusion independence that was durable at 7.5 months. Pomalidomide at 0.5 mg/day with or without a prednisone taper was found to have better anemia responses with less toxicity compared with pomalidomide at 2 mg/day with or without prednisone. Grade 3/4 myelosuppression and neurotoxicity were not frequent adverse events. A single-center phase II study of low-dose pomalidomide was conducted at Mayo Clinic. A cohort of 58 patients were treated with pomalidomide at 0.5 mg/day. Of the 42 transfusion-dependent *JAK2V617F*-positive MF patients, 10 had significant responses in anemia, with nine patients achieving transfusion independence. Although there were no spleen responses, a 58% response in thrombocytopenia for those with baseline platelets below 100×10^9 cells/L was noted. The anemia response was predicted by peripheral blood basophilia within the first month of therapy and the absence of massive splenomegaly, and was restricted to MF patients who were *JAK2V617F* positive. Pomalidomide was also evaluated in a dose-escalation phase I/II setting with the purpose of determining if higher doses of pomalidomide were more effective in reversing the anemia associated with MF. Doses of 3 mg/day given for 21 out of 28 consecutive days were found to be the maximum tolerated dose, and myelosuppression the dose-limiting toxicity without any added response in anemia. The placebo-controlled, randomized, phase III RESUME trial compared pomalidomide at 0.5 mg/day with prednisone with an opportunity to cross over, and were enrolled both *JAK2* mutated and WT MF patients with documented anemia. The primary endpoint of anemia response was not met in this large global trial; however, 21% of patients achieved clinical improvement in platelet count. Whether this trial would have had positive results if eligibility had been restricted to MF patients with *JAK2V617F* and limited splenomegaly, remains conjecture. The responses to prednisone therapy in anemic MF patients have been previously discussed and raise the possibility that this was not the appropriate control group in this randomized pomalidomide study.

Treatment of Spleen-Related and Systemic Symptoms

Pressure symptoms caused by splenic enlargement have been treated historically with cytotoxic chemotherapy. Busulfan, melphalan, and hydroxyurea have each been used for this purpose. A significant reduction in spleen size with relief of pressure symptoms occurs in occasional patients receiving chemotherapy.⁴ Responses are unfortunately short lived, lasting a median of only 4.5 months. Only 16%

of patients with long-term maintenance therapy enjoy sustained relief of symptoms. Hematologic toxicity often necessitates cessation of therapy. Inhibition of the activated JAK-STAT pathway is an attractive therapeutic target in PMF and has led to the development of oral small-molecule inhibitors. Ruxolitinib, a selective JAK1 and JAK2 tyrosine kinase inhibitor, was approved in 2011 for the treatment of patients with MF; this is the first drug approved by the United States Food and Drug Administration (US FDA) where the indication for use is intermediate- or high-risk MF. The phase I/II study determined the optimal starting dose of 15 mg twice daily, and that thrombocytopenia and worsening anemia were dose-limiting toxicities. A dose-dependent suppression of phospho-STAT3 was seen in both WT and mutated *JAK2* patients treated with ruxolitinib, demonstrating that drug activity does not discriminate between mutated and WT *JAK2* in its inhibitory activity. Fifty two percent of treated patients achieved a greater than 50% reduction in splenomegaly for greater than 12 months, which was irrespective of their *JAK2* mutational status. The debilitating symptoms associated with MF were dramatically improved, and this was correlated with reduction in inflammatory cytokines believed to be mediated through inhibition of JAK1 signaling. This compound was then evaluated in two randomized phase III trials, COMFORT 1 (United States, Canada, and Australia), in which ruxolitinib therapy was compared with a placebo control, and COMFORT 2 trial (Europe), in which ruxolitinib therapy was compared with the best available therapy.^{12,13} The results of each of these trials are remarkably similar, and each trial was adequately powered. Patients with intermediate-2 or high-risk MF as assessed using the IPSS were eligible regardless of *JAK2* mutational status. All patients had platelet counts over 100×10^9 /L and had a spleen palpated at least 5 cm below the left costal margin. In COMFORT 1, the primary endpoint of 35% or greater reduction in spleen volume was met at 24 weeks in 41.9% of the ruxolitinib-treated cohort and only 0.7% in the placebo group. This response was maintained 48 weeks or more in 67% of treated patients. Fig. 70.10 shows the percent change in spleen volume from baseline at week 24 for individual patients on both arms of this trial and depicts the contrast of spleen reduction in ruxolitinib-treated patients compared with the majority of patients in the placebo arm who had an increase in spleen volume. There were 13 deaths in the ruxolitinib arm and 24 deaths in the placebo arm, revealing a modest survival benefit for MF patients treated with ruxolitinib. Although grade 3/4 anemia and

Fig. 70.10 REDUCTION IN SPLENIC VOLUME WITH RUXOLITINIB THERAPY IN THE COMFORT 1 TRIAL. The waterfall plot shows the percent change from baseline in spleen volume at week 24 (in 139 patients in the ruxolitinib group and 106 in the placebo group) or at the last evaluation before week 24 (in 16 patients in the ruxolitinib group and 47 in the placebo group). Data for one patient with a missing baseline value are not included on the graph. Most patients in the ruxolitinib group (150 out of 155) had a reduction in spleen volume, but most patients in the placebo group had either an increase in spleen volume (102 out of 153 patients) or no change (15 out of 153 patients). (From Verstovsek S, Mesa RA, Gotlib J, et al: A double-blind, placebo-controlled trial of ruxolitinib for myelofibrosis. *N Engl J Med* 366:799, 2012.)

thrombocytopenia were frequent in the ruxolitinib arm (45.2% and 12.9%, respectively), discontinuation for these events was extremely rare. The primary endpoint in the COMFORT-2 trial was met at 48 weeks, with 28% of patients in the ruxolitinib arm and 0% in the BAT arm achieving at least a 35% reduction in spleen volume. The mean length of palpable spleen decreased by 56% at 48 weeks compared with an increase of 4% in the BAT arm. Sophisticated disease-specific quality-of-life tools were used to evaluate the effects of ruxolitinib therapy on the systemic symptoms that have been presumed to be a consequence of the increased elaboration of inflammatory cytokines modulated by JAK1 signaling. The effects of ruxolitinib were, however, limited in that reversal of histomorphologic abnormalities, including BM fibrosis or osteosclerosis, significant reduction in the *JAK2V617F* allele burden, and loss of marker cytogenetic abnormalities indicating that the underlying malignant potential of PMF is not affected by this therapy. In addition, abrupt discontinuation of ruxolitinib therapy was associated with rapid return to baseline levels of splenomegaly and severity of the systemic symptoms that at times can be disabling. More gradual tapering of this agent or the use of a short steroid taper is recommended to avoid this complication. Ruxolitinib is an important agent for the palliation of symptomatic splenomegaly and the debilitating symptoms seen in patients with PMF. The survival data from the COMFORT 1 trial, although modest, are intriguing and suggest that even if an appreciable impact on abnormal BM histopathology or molecular or cytogenetic responses is not seen with ruxolitinib, pharmacologic suppression of the JAK pathway decreases the risk of death, perhaps simply by improving the overall performance status, and reversing cancer cachexia of an individual. The use of ruxolitinib has been demonstrated to be safe in patients with a minimum platelet count of $50 \times 10^9/L$. The need to treat patients who are asymptomatic with limited splenomegaly is not apparent since treatment does not appear to affect the underlying malignant disorder. With a median follow-up of 3 years, the mature results of the COMFORT-1 trial demonstrate a durable response in spleen reduction and symptom improvement in those subjects that remain on treatment. The absence of new/unexpected toxicities or late-onset emergent hematologic adverse events was also appreciated. However, it should be noted that a 50% discontinuation rate was reported in the arm originally randomized to ruxolitinib, and the potential for leukemic transformation with sites of extramedullary leukemia have also been reported. Patients treated with ruxolitinib have been noted to have an increased incidence of infectious complications, including toxoplasmosis, cryptococcal pneumonia, reactivation of latent herpes simplex virus and hepatitis B, and disseminated tuberculosis. An almost threefold increase in the incidence of herpes zoster infections has been observed, suggesting that the drug may promote clinically significant suppression of cell-mediated immunity. A profound and prolonged reduction in T-regulatory and natural killer cells has been observed in patients treated with ruxolitinib, which is likely a consequence of downregulation of inflammatory cytokine expression. The determination of how prevalent these infectious complications are will require careful long-term follow-up of large cohorts of patients being treated with this drug for prolonged periods of time.

A number of other small-molecule inhibitors of JAK2 are under various phases of clinical development, and all appear to be generally effective in reducing splenomegaly and improving symptom burden. It is important to note that none of the currently tested JAK2 inhibitors have been shown to clearly achieve complete BM pathologic responses or induce cytogenetic/molecular remissions. Additionally, data to support the superiority of one agent over another do not exist. Momelotinib (JAK1/JAK2 inhibitor) and pacritinib (JAK2/FLT3 inhibitor) are currently being evaluated in phase III registration trials, and have the potential to be used as either first-line agents in ruxolitinib-naïve patients with significant baseline cytopenias, or as second-line agents for patients experiencing ruxolitinib-associated cytopenias or loss of clinical response. These agents have different target specificities and toxicity profiles, and require further evaluation in mature clinical trials to ultimately determine their utility in comparison to ruxolitinib.

Phase I/II data of momelotinib (CYT387, Gilead) in patients with MF is notable for the potential durable anemia response reported (70% transfusion independence). Headache and elevated lipase levels were determined to be the dose limiting toxicities of momelotinib treatment. Pacritinib (SB1518, CTI Biopharma) has been evaluated in a phase I/II trial in which treatment-emergent myelosuppression was limited and appears to be effective in safely reducing splenomegaly in patients with low baseline platelet levels. The results of the phase III PERSIST-1 trial were recently presented and confirmed the beneficial effects of this JAK2/FLT3 inhibitor in 327 ruxolitinib-naïve, intermediate/high-risk MF patients with any baseline platelet count. Compared with the best available therapy arms (excluding ruxolitinib), pacritinib was superior in achieving the primary endpoint of spleen reduction (19.1% vs. 4.7%) without a significant increase in hematologic toxicity. Gastrointestinal toxicity was more frequently observed with pacritinib therapy (diarrhea 50%) but mostly grade 1/2 and not a frequent reason for drug discontinuation. Additionally, RBC transfusion independence was achieved in 25% of transfusion-dependent patients at baseline. Fedratinib (SAR302503, Sanofi Aventis) was a selective JAK2 inhibitor with positive results reported in two phase III trials conducted in MF patients, but was unfortunately found to be associated with the emergence of Wernicke encephalopathy in several patients. This drug is no longer in clinical development and joins several other JAK2 inhibitors that are no longer being tested due to concerns regarding treatment-related toxicity such as XL019, AZD1480, and BMS-911543.

Splenic irradiation has frequently been used in the past for treatment of the painful large-spleen syndrome, but is now considered a last-resort option with the approval of JAK1/2 inhibitor therapy. Irradiation in fractions of 0.15–1 Gy administered daily or by an intermittent fractionation schedule (i.e., two or three times a week) to a total dose per treatment course of 2.5–6.5 Gy may be effective. Responses are transient, lasting an average of 3.5 months, and hematopoietic toxicity is frequently significant. Splenic irradiation is especially useful for treatment of splenic pain of sudden onset and for treatment of ascites caused by implants of hematopoietic tissue. Radiation therapy should be considered as a temporary measure to be used in patients who are too ill to tolerate splenectomy or chemotherapy. Splenic irradiation is limited by myelosuppression with significant prolonged cytopenias, which is not predictable and is not correlated with the doses of radiation administered.

Radiotherapy offers a viable treatment option and sometimes may be the therapy of choice for the treatment of patients with symptomatic hepatomegaly, peritoneal and pleural implants or pulmonary infiltration leading to ascites or pleural effusions, and EMH in vital organs leading to organ dysfunction. Because of the inherent sensitivity of myeloid tissue to radiation and profound BM suppression that may occur after irradiation, therapy is usually initiated at low doses (20–25 cGy/day), with modification of the dose as the clinical situation dictates. An alternative approach using intraperitoneal administration of cytosine arabinoside has been used to treat ascites in PMF. Low-dose, single-fraction, whole-lung radiotherapy has also been useful in treating pulmonary artery hypertension associated with PMF.

Splenectomy remains a viable option even in the face of the recent availability of JAK2 inhibitors in patients with hemolysis, thrombocytopenia, painful splenomegaly, recurrent splenic infarction, and portal hypertension refractory to other therapeutic modalities or in individuals with leukopenia or thrombocytopenia that prevents one from resorting to therapy with chemotherapeutic agents or a JAK2 inhibitor. Splenectomy in patients with PMF is associated with a postoperative morbidity rate of 15–30% and a mortality rate of almost 10%. The appropriate implementation of splenectomy can result in the improved quality of life of PMF patients who frequently do not have other therapeutic options available. Because splenectomy is associated with significant morbidity and mortality, the physician should only resort to this strategy if thrombocytopenia, anemia, or symptomatic splenomegaly is unresponsive to less invasive approaches such as JAK2 inhibitor treatment. Progressive hepatomegaly and marked thrombocytosis occurred, respectively, in 16% and 22% of

patients after splenectomy and can be controlled with ruxolitinib therapy.

Allogeneic Stem Cell Transplantation

aSCT is a potentially curative option in patients with PMF who have an appropriate donor available. Successful transplantation is associated with gradual resolution of BM fibrosis, reduction in splenomegaly, and normalization of hematopoiesis (see box on [Algorithm for Selection of Appropriate Patients for Stem Cell Transplantation Stratified According to Risk Status](#)).

Most of our understanding of the role of aSCT in primary and post-PV/ET MF with conventional MA conditioning regimens comes from two retrospective series of transplants with more than 50 patients performed between 1979 and 2002. The median age of transplanted patients was 42 and 43 years; treatment-related mortality (TRM) was 27% and 33%, with 5-year survival of 47% and 58%, respectively. The 5-year probability of treatment failure caused by nonengraftment, relapse or persistent disease after transplantation was 36%, and the failure of sustained engraftment was 10.7%, which occurred solely in patients receiving BM transplants from mismatched or unrelated donors. The probability of grade III–IV acute graft-versus-host disease (GVHD) was 33% and 21%, and extensive chronic GVHD was 35% and 50%, respectively. Older age and factors associated with more advanced disease (Hgb <10, increased number of RBC transfusions, presence of osteomyelosclerosis, increased number of clonal abnormalities) adversely affected the outcome. The Seattle group has updated their 15-year experience with 95 PMF and post-PV/ET MF patients who received MA busulfan and/or TBI-containing regimens. The 7-year actual survival rate was 61%, although 10% of patients died of recurrent or a persistent disease. Non-TBI-containing regimen of targeted busulfan/cytosine resulted in an improved probability of survival of 68%. These retrospective reports of MA allo-HSCT in PMF provided evidence that engraftment can be achieved and that a complete and durable remission of the disease can occur in approximately 50% of patients. However, owing to the poor transplant outcomes in older patients, enrollment to this procedure represents a major therapeutic dilemma in PMF patients who are primarily diagnosed at ages in excess of 60 years.

The advent of non-MA, reduced-intensity conditioning (RIC) regimens for aSCT has resulted in decreased TRM and has expanded the use of this treatment modality to older patients. Rondelli and coworkers provided one of the initial retrospective reports on the outcome of 21 intermediate- to high-risk PMF patients (without leukemic transformation) with a median age of 54 years (range: 27–68 years) who underwent RIC preparation and utilized a peripheral blood stem cell (PBSC) source in 18 cases and related donors in 18 cases. This trial was conducted at multiple institutions belonging to the MPD-Research Consortium (MPD-RC). Predominantly fludarabine-based RIC regimens allowed engraftment in all but one patient with TRM of 10% and 2-year OS rates of 87%. Durable remission was achieved in 17 out of 18 patients alive 12–122 months (median: 31 months) after transplant. Three patients relapsed, with two of them able to achieve remission following second transplantation and donor lymphocyte infusion. Thirty three percent of patients developed acute GVHD grades II–IV (9% grade III–IV), and 72% developed chronic GVHD, with 44% being extensive.

Recent CIBMTR retrospective data derived from an analysis of 223 patients who underwent RIC fludarabine-based allogeneic transplantation between 1997 and 2010 showed the probability of 5-year survival to be 47%. Donor type was the only significant factor to impact survival, with 5-year OS in the related donor arm of 56% versus matched unrelated donor of 48% and mismatched unrelated donor of 34%. A trend toward decreased mortality was observed in patients with low/intermediate-1 DIPSS score versus intermediate-2/high-risk DIPSS.

The use of RIC PBSC transplantation in patients with advanced MF has been evaluated prospectively in two phase II trials by the European Group for Blood and Marrow Transplantation (EBMT)

and MPD-RC. An EBMT trial included 103 MF patients transplanted from related ($n = 33$) or unrelated donors ($n = 70$), with 21% of donors having at least one allele or antigen mismatch using a fludarabine/busulfan/ATG regimen. Although all but two patients achieved initial engraftment, secondary graft failure or poor graft function occurred in 11% of patients. The estimated 5-year event-free survival (EFS) and OS was 51% and 67%, respectively. One-year nonrelapse mortality was 16%—similar among related and unrelated donor transplants but significantly higher in mismatched transplants (38% vs. 12%). One third of patients developed grade II–IV acute GVHD (11% grade III–IV), with half of patients affected by chronic GVHD (24% extensive). Relapse rate/treatment failure at 3 and 5 years was 22% and 29%, respectively. As can be seen in [Fig. 70.11](#), age over 55 years, human leukocyte antigen (HLA) mismatching, and advanced disease are associated with decreased PFS and OS. However, even in this high-risk group, the OS was approximately 40%. Remarkably, patients younger than 55 years of age had a 5-year OS rate of 82%. Elimination of *JAK2V617F* after transplant was associated with a reduced incidence of relapse.

The prospective, multicenter phase II MPD-RC 101 trial included two parallel cohorts of patients: related donors ($n = 32$, 94% HLA matched) and unrelated donors ($n = 34$, 74% HLA matched). Fludarabine/melphalan was used as a conditioning regimen with rabbit anti-thymocyte globulin (rATG) added in the unrelated donor group. Patient characteristics were similar in the two groups, with 63 out of 66 patients having intermediate- to high-risk disease based on Lille score. After a median of 25 months follow-up, OS was 75% (median not reached) in the related donor cohort and 32% (median: 6 months) in the unrelated donor. Nonrelapse mortality at 59% was significantly higher in the unrelated group compared with 22% in the related group. Graft failure occurred in 36% (24% primary) of unrelated transplants and 6% (3% primary) of related. The unrelated cohort had double the rate of severe acute GVHD grade III–IV (21% vs. 12%) but comparable rates of chronic GVHD (38% vs. 36%), including extensive form (20% vs. 25%). Patients who were able to achieve sustained stem cell engraftment experienced an overall response rate of 93% in the related group and 69% in the unrelated group, with only four patients experiencing progression of disease. Neither disease diagnosis (primary or secondary MF), HLA mismatch, presence of *JAK2V617F* mutation, nor age >57 years showed a statistically significant effect on survival. The only factor that correlated with improved survival was related donor type, as seen in [Fig. 70.12](#). The low/intermediate-1-risk patients in the unrelated group had better survival than the intermediate-2/high-risk patients, whereas there was no difference in survival between these two DIPSS groups in the related group.

The German group has analyzed the effect of multiple risk factors related to patient, disease, and transplant characteristics on survival after RIC SCT and developed a predictive model based on three risk factors: age ≥ 57 , *JAK2* WT status, and presence of constitutional symptoms. Five-year OS in the absence of any risk factors was 90%. The presence of one or two risk factors reduced 5-year OS to 74% and 51%, respectively. Patients who had all three risk factors did extremely poorly after RIC SCT, with a 1-year OS of 25%. Despite inferior outcomes in older patients, SCT is feasible, as demonstrated by a retrospective study of aSCT of 30 PMF patients between the ages of 60 and 78 (median: 65) years transplanted at four major United States academic centers with 3-year OS and PFS rates of 45% and 40%, respectively.

One of the limitations of widely applying aSCT to more patients with PMF is the lack of access to appropriate donors. Takagi and coworkers from Japan reported surprisingly positive results with umbilical cord blood (UCB) grafts for RIC allogeneic transplantation in adults (median age: 57.5 years) with various hematologic disorders associated with extensive BM fibrosis (PMF, post-MPN AML, and MDS-related AML). The estimated probability of survival at 4 years for this group was 28.6%, which is modest but considerably superior to that which would be anticipated with presently available chemotherapy regimens for such high-risk disease. Retrospective analysis of 35 high-risk MF patients (20% blast-phase myelofibrosis, median

Fig. 70.11 Survival of patients with myelofibrosis after reduced-intensity allogeneic stem cell transplantation according to age (A), donor (B), and Lille risk profile (C). MMUD, mismatched unrelated donor; MUD, matched unrelated donor.

age: 54 years) who underwent UCB transplantation reported to Eurocord showed a 2-year OS and EFS of 44% and 30%, respectively. Conditioning using TBI, cyclophosphamide and fludarabine was associated with the best results in terms of blood count recovery and EFS. These studies provide the rationale for the further evaluation of RIC allogeneic transplant for eligible PMF patients lacking an HLA-matched sibling or unrelated donor with the use of alternative sources of grafts such as UCB or possibly haploidentical donors.

Occasionally, patients with PMF after allogeneic transplant can experience relapse of their underlying disease, failure of engraftment, or graft failure. Relapse can frequently be treated with donor lymphocyte infusions. Second RIC allogeneic transplants should be considered for individuals who do not respond to donor lymphocyte infusions or experience difficulty with engraftment or late graft failure. In *JAK2V617F*-positive patients, monitoring allele burden following SCT can help predict patients at risk for relapse and prompt early intervention. The feasibility of utilizing aSCT as the front-line therapy for all intermediate- and high-risk patients is limited by the presence of competing comorbidities or a poor performance status due to the systemic effects of the underlying PMF. Although the JAK2 inhibitors are largely palliative, they do reduce the degree of splenomegaly and often improve the performance status of such patients, frequently resulting in weight gain, and improve their candidacy for transplant. The reported outcomes with JAK2 inhibitor therapy as a component of the conditioning regimen for allogeneic transplantation have resulted in conflicting results, and will require rigorous testing to determine its effect on immediate and long-term survival and transplant-related complications. This approach is currently being evaluated within the MPD-RC as a phase II trial of preconditioning ruxolitinib treatment (MPD-RC 114).

The fact that allogeneic RIC transplant is curative in appropriate patients is undeniable, and the improvements in the design of conditioning regimens and supportive therapy make this a viable first-line approach for individuals with HLA-matched donors and advanced disease. Whether such an approach should also be implemented in patients with earlier phases of the disease is a point of contention that requires further careful investigation. This decision is especially important in young patients with early forms of PMF because their disease is likely to eventually progress, and the best results with allogeneic transplant have been reported in lower risk patients, especially if they do not have a related donor. The flaw in the argument to proceed with immediate transplant in young patients with early PMF is the exposure to significant mortality and morbidity in a patient population that frequently can anticipate a decade or more of a good-quality life with no or minimal therapeutic interventions. New molecular markers such as *JAK2V617F*, *EZH2*, *ASXL1*, and *CALR* mutations will help further refine risk stratification and likely better guide treatment decision.

Many unresolved issues remain to be clarified concerning the optimal strategy for aSCT in PMF. The need for splenectomy before aSCT remains a major issue. Splenectomy before aHSCT in PMF results in faster hematopoietic recovery but at the cost of potentially prolonged and complicated postoperative recovery. Although some analyses suggest improved survival with pretransplant splenectomy, it has also been associated with a potential increased risk of relapse. Moreover, even extensive splenomegaly (>30-cm longitudinal size by computed tomography scan) does not appear to prolong hematologic reconstitution after transplant.

The establishment of valid complete remission criteria of PMF after aSCT remains a major issue because the conventional criteria for response after aSCT are often influenced by GVHD, infections, or poor graft function, and cannot be used. Conversely, normal blood counts and disappearance of disease-related symptoms do not exclude residual disease. In *JAK2V617F*-positive patients, the mutational allele burden following transplantation may serve as a surrogate parameter for complete remission assessment and as a guide for instituting adoptive immunotherapy.

Investigational Therapeutic Options

The identification of various epigenetic defects in PMF has provided novel therapeutic targets, and preclinical studies are actively being translated into early-phase clinical trials. This class of agents leads to accumulation of acetylated histones, which in turn leads to increased tumor-suppressor gene expression. The DNA methyltransferase inhibitor 5-azacitidine has been evaluated in a phase II study in 34 MF patients. The overall response rate was 24% after a median of 5

Fig. 70.12 Survival for patients with myelofibrosis after receiving reduced-intensity allogeneic hematopoietic stem cell transplantation was worse in the unrelated donor cohort compared with the related donor cohort irrespective of diagnosis subtype, degree of HLA matching, *JAK2* mutational status, and age. Final results from the multicenter phase II MPD-RC 101 trial. *ET-MF*, essential thrombocythemia myelofibrosis; *HLA*, human leukocyte antigen; *NEG*, negative; *PMF*, primary myelofibrosis; *POS*, positive; *PV-MF*, polycythemia vera myelofibrosis. (Data from Rondelli et al: MPD-RC 101 prospective study of reduced-intensity allogeneic hematopoietic stem cell transplantation in patients with myelofibrosis. *Blood* 124:1183, 2014.)

Algorithm for Selection of Appropriate Patients for Stem Cell Transplantation Stratified According to Risk Status

months of treatment, and grade 3/4 myelosuppression was seen in 29% of patients, requiring dose reduction in 47% of the cases. Interestingly, there was no difference in global hypomethylation between responders and nonresponders. This finding could argue that the mechanism of action of this drug in responding MF patients may not be directly through induction of DNA promoter site demethylation. Studies designed to evaluate the methylation status of specific genes thought to be silenced by this epigenetic modification (e.g., *p15^{INK4b}* and *p16^{INK4a}*) need to be done in the future. A modified 5-day course of 5-azacitidine was also tested in a group of 10 MF patients, and was found to have even less of a response rate than the full 7-day course. Case series highlight the potential role of decitabine in the treatment of MF in blast phase, and initial reports of subcutaneous low-dose decitabine in advanced MF also appears to hold promise and is currently being evaluated in larger studies. LBH589 (panobinostat) is a potent pan-deacetylase inhibitor that has also been evaluated in PMF patients in two separate trials with thrombocytopenia as the dose-limiting toxicity and the demonstration of a signal

of clinical activity that is associated with enhanced histone acetylation. A report of the results of long-term administration of low-dose panobinostat in MF patients demonstrated the potential to alleviate constitutional symptoms, reduce splenomegaly, improve anemia, eliminate peripheral blood leukoerythroblastosis, reduce BM reticulin and collagen fibrosis, and restore normal BM morphology in a small number of patients. A phase II study of panobinostat at a dose of 25 mg orally thrice weekly is currently ongoing, and studies combining this agent with ruxolitinib are ongoing, and the results are highly anticipated. The therapeutic potential for the use of chromatin-modifying agents for the treatment of PMF patients is an exciting approach and requires further careful evaluation in ongoing, well-designed clinical studies.

A novel and exciting therapeutic approach to the treatment of MF was recently reported by the Mayo Clinic group, in which a pilot study at this single institution was conducted evaluating an infusional telomerase inhibitor. Imetelstat is a 13-mer lipid conjugated oligonucleotide competitive inhibitor of telomerase RNA (hTR) resulting in telomere shortening and cell cycle arrest and apoptosis. Thirty three patients were treated either with weekly infusion and then every 3 weeks infusion or every 3 weeks from the start. The majority of patients discontinued due to suboptimal response or progressive disease, and three patients died on study. However, after a median of five cycles of treatment, seven responses were documented (four complete response and three partial response; three complete molecular responses) and appeared to be durable for a median of >9 months). Additionally, anemia responses ($n = 4$) and 50% reduction in spleen size ($n = 9$) were reported. The occurrence of transaminitis was a cause initially for temporary study hold and now a large multicenter phase II trial will evaluate imetelstat in MF patients and molecular determinants of therapy response will be prospectively assessed.

FUTURE DIRECTIONS

More rational therapies for PMF are evolving from increased understanding of the cellular and molecular biologic abnormalities underlying PMF. Studies defining the relative contributions of acquired genetic mutations, epigenetic events, as well as the influence of the BM and splenic microenvironment on the origins of PMF, disease progression, and events leading to leukemic transformation are ongoing. Because PMF originates at the level of the HSC, the identification of novel drugs that eliminate such malignant stem cells is likely the most direct route to potentially curative pharmacologic strategies. Also, further delineation of the therapeutic potential of IFN as well as histone deacetylase inhibitor therapies must be pursued to define their potential use in the management of PMF patients. The evaluation of the use of combinations of active agents, including the JAK2 inhibitors, TGF- β inhibitors, IMiDs, histone deacetylase inhibitors, telomerase inhibitors, and pegylated forms of

IFN are anticipated to lead to significant clinical improvements in the outcomes of PMF patients. The evaluation of these combination therapies will certainly require the use of novel strategies for the design of clinical trials that will evaluate the effects of several active agents administered either simultaneously or sequentially. Overall, the implementation of any therapeutic approach by the practicing community of hematologists should only occur after evidence is provided by the completion of well-planned and adequately powered phase III trials comparing the experimental approach to the standard of care. aSCT with RIC and PBSC grafts remains the only potentially curative therapy available for patients under 70 years of age with an acceptable performance status and a suitable available donor. Although there is a reluctance to expose PMF patients to the risks of aSCT, if their underlying disorder is associated with a sufficiently poor prognosis, this risk appears to be warranted. Because early forms of PMF are associated with survival of well over a decade, many individuals have been even more reluctant to expose such patients to experimental therapeutic agents or aSCT. Unfortunately, progression to more advanced forms of MF is anticipated in younger patients. Exploration of therapeutic agents that can delay or even prevent disease progression or identification of the appropriate role of SCT in this low-risk group will require additional study. Such trials will be time consuming due to the prolonged survival of such patients with low-risk disease. The decision to proceed to transplant requires a detailed discussion of the risks and benefits of such a high-risk but potentially curative procedure. The recent establishment of multiinstitutional cooperative groups to evaluate such novel therapies and treatment strategies for PMF patients has met the need of insuring rapid evaluation of candidate therapeutic agents. No single institution has sufficient numbers of patients to perform this ever-growing number of required investigative efforts. Only with the completion of such rigorous evaluations of individual therapeutic strategies will one be able to determine the value of a continuously growing number of potentially active agents used alone or in combination. Each new therapy will likely be evaluated using not only a number of clinical endpoints, but also surrogate biomarkers and consideration of the immediate and long-term toxicities associated with their use documented. Independently developed objective criteria by which responses to experimental therapeutic agents can be judged must be implemented for the evaluation of promising agents. Furthermore, quality-of-life tools have become more widely used in the evaluation of such experimental therapeutic agents. Because it is likely that a large number of such agents will be evaluated in patients with PMF in the future, it is recommended that a uniform standard be adopted so that the relative efficacy of any new therapeutic approach can be more easily judged. The integration of these new classes of agents can also be incorporated into the conditioning regimens that are used before aSCT; this approach will also likely contribute to significant improvements in outcomes in PMF patients undergoing aSCT.

How Should PMF Patients With Thrombocytopenia Be Treated?

Platelet Count 50–100 $\times 10^9/L$:

It is important to be certain that vitamin B₁₂ or folate deficiencies and/or sustained suppression from prior chemotherapeutic agents have not contributing to the development of a low platelet count. Chemotherapeutic agents such as hydroxyurea can be used in patients with marked splenomegaly, which can result in an improvement in the platelet count as the spleen volume is reduced. Patients can also be treated with thalidomide or lenalidomide in combination with prednisone. These first-generation immunomodulatory drugs (IMiDs) can sometimes improve cytopenias and reduce splenomegaly in primary myelofibrosis (PMF) patients, and in some cases, this response can persist even after drug discontinuation. Lenalidomide can induce cytopenias to a greater extent than thalidomide, which needs to be taken into consideration before this agent is used in the thrombocytopenic patient. In a randomized

phase III trial, pomalidomide failed to meet the primary endpoint of anemia response (transfusion independence: ≥ 84 days), but the platelet response rate was 22% in the treatment arm. This finding supported the previous phase II findings of a response rate of 58% in increasing the baseline platelet count by greater than 50% in patients with baseline platelets above 50 $\times 10^9/L$. This second-generation IMiD has not been evaluated in patients with platelet counts below 50 $\times 10^9/L$. A course of prednisone therapy should also be considered, since 30–40% of patients have been reported to respond to this agent alone. Ruxolitinib has more recently been shown to be safe and effective in patients with baseline platelet counts as low as 50 $\times 10^9/L$, and the FDA label has been expanded to include such myelofibrosis patients. Sustained thrombocytopenia with ruxolitinib therapy is an indication for a dose reduction or discontinuation of the drug. Patients can also be enrolled

How Should PMF Patients With Thrombocytopenia Be Treated?—cont'd

in other JAK2 inhibitor clinical trials in which reduced platelet counts are acceptable (such as the PERSIST-2 phase III pacritinib trial) or in clinical trials with other agents in development. If thrombocytopenia worsens with the current treatment plan, then proceed with the strategy outlined below.

Platelet Count $20\text{--}50 \times 10^9/\text{L}$:

Thalidomide or lenalidomide in combination with prednisone can be used to correct anemia in these PMF patients but rarely improve the platelet counts in a clinically meaningful way. Most clinical trials involving a variety of therapeutic agents including JAK2 inhibitors will require baseline platelets above $50 \times 10^9/\text{L}$. In patients who are experiencing life-threatening bleeding, in addition to aggressive immediate platelet transfusions, splenectomy is a reasonable therapeutic option.

Platelet Count $<20 \times 10^9/\text{L}$

The treatment choices are truly limited for these patients. Intervention is also dependent on the clinical picture, with emphasis on addressing bleeding. Supportive therapy with frequent platelet transfusions is a possibility, but it is likely not sustainable in the long term. It is our practice to transfuse if the platelet count is below $10 \times 10^9/\text{L}$ unless there is no evidence of mucosal bleeding or life-threatening hemorrhage. Occasionally, patients may have an improvement in the degree of thrombocytopenia

with steroids. About 20–30% of patients with severe thrombocytopenia will have significant improvement in platelet counts after a splenectomy. Aggressive platelet transfusional support is necessary before, during, and after splenectomy in many cases. However, splenectomy in patients with PMF is associated with a postoperative morbidity rate of 15–30% and a mortality rate close to 10%. These numbers, however, are highly dependent on the institutional experience and the operating surgeon. Splenectomy can also result in extramedullary hematopoiesis in the liver, causing hepatomegaly, which may require the administration of judicious amount of chemotherapeutic agents (hydroxyurea, busulfan, cladribine) or a JAK2 inhibitor. Severe thrombocytopenia is an adverse prognostic feature. Such patients who are eligible for stem cell transplantation (SCT) and have available donors should be considered for transplantation. Thrombopoietin mimetics have been associated with increased bone marrow fibrosis when used for the treatment of immune thrombocytopenia purpura and have not been evaluated in the setting of PMF-associated thrombocytopenia. Additionally, patients with extreme thrombocytopenia and signs of leukemic transformation can be considered for therapy with decitabine or azacytidine with aggressive platelet transfusional support, and then ideally should proceed to allogeneic SCT if a donor is available and the patient's performance status is appropriate.

Which Patients Should Be Considered for Allogeneic Hematopoietic Stem Cell Transplantation?

Allogeneic stem cell transplantation (aSCT) is the only potential curative treatment option for primary myelofibrosis (PMF). Patients with poor risk features and decreased probability for survival should be considered for SCT because of the not insignificant risk of transplant-related morbidity and mortality. All patients younger than 70 years of age and their siblings should be human leukocyte antigen typed at the time of diagnosis to determine if there is a potential match. Patients between the ages of 65 and 70 years with available related donors should be evaluated based on their performance status and presence of comorbid conditions. Patients younger than 70 years of age with good performance status and available donors (either related or fully matched unrelated) should be encouraged to undergo evaluation for SCT soon after the diagnosis and preferably within a clinical trial. Patients with high- or intermediate-risk disease with available

donors should consider transplantation before developing debilitating symptoms or significant worsening in their performance status. Patients with low-risk disease can be closely monitored without intervention but should proceed to transplantation with evidence of disease progression. For patients with available donors but poor performance status because of symptoms of myelofibrosis, a course of treatment with ruxolitinib can be considered with a goal of improvement in performance status associated with reduction of splenomegaly and constitutional symptoms. These patients may become more viable transplant candidates with this pretransplant treatment approach. Splenectomy before transplant is not essential to ensure adequate engraftment. Currently, SCT using reduced-intensity conditioning regimens, haploidentical donors, and cord blood grafts are being actively evaluated.

Which PMF Patients Are Appropriate for JAK2 Inhibitor Therapy?

Not all primary myelofibrosis (PMF) patients require treatment with JAK2 inhibitor therapy. Patients with symptomatic splenomegaly or debilitating myelofibrosis (MF)-related symptoms are potential candidates for treatment with ruxolitinib. Inhibition of JAK1/2 is associated with myelosuppression and could further compromise existing cytopenias. In patients with isolated splenomegaly and adequate blood counts, a course of hydroxyurea should be considered. If the patient fails hydroxyurea or has debilitating symptoms, then ruxolitinib would be the appropriate agent. Ruxolitinib is currently approved for patients with intermediate- and high-risk MF, and has yet to be explored in cases of symptomatic patients with low-risk disease. Additionally, the use of this drug is not advised in MF patients with platelet counts below $50 \times 10^9/\text{L}$. Whether Ruxolitinib should be used in patients with poor performance status before allogeneic stem

cell transplantation (SCT) as a means to improve their performance status and promote weight gain in an attempt to optimize them for SCT, is under prospective evaluation within the MPD-Research Consortium. Although the COMFORT 1 trial reported a modest improvement in survival at a median of 51 weeks of treatment with ruxolitinib, the exact mechanism that underlies this survival benefit remains, and this agent should not be given with the primary goal of disease process modification and promoting increased survival. Patients started on ruxolitinib need to have frequent monitoring of blood counts, and if discontinued, the dose should be either tapered or a pulse of concurrent steroid therapy considered to avoid the rapid reappearance of systemic symptoms and splenomegaly, which can occur at times.

How Does Characterizing the Mutational Profile of a PMF Patient Influence Care?

Assessing the status of the primary myelofibrosis driver mutations *JAK2*, *MPL*, and *CALR* can help refine prognostication and influence therapeutic decision-making. Retrospective studies suggest that molecular risk stratification can further refine the individual risk for leukemic transformation and shortened overall survival. Patients with triple-negative status (lacking mutations of *JAK2*, *MPL*, and *CALR*) or with an *ASXL1* mutation are at highest risk for a poor outcome and should be evaluated for early stem cell transplantation (SCT) or experimental therapy, even if they are assessed to have low-risk disease by conventional risk-stratification tools. Such patients should be sent for transplant at the earliest time of evidence of disease evolution. Proposed molecular stratification tools

have recently been proposed but not yet validated in prospective trials. It is also important to remember that *JAK2* wild type status, and *MPL*- and *CALR*-mutated patients respond equally well to ruxolitinib therapy. The characterization of nearly 20 recurrent gene mutations in PMF patients has been reported by various groups and implicates a complex and heterogeneous molecular pathophysiology that will likely not allow for a single therapeutic target drug approach. Whether the presence of certain gene mutations will ultimately predict for therapeutic response with differing agents has yet to be shown. The presence of these mutations can also be used to detect minimal residual disease after SCT

EOSINOPHILIA, EOSINOPHIL-ASSOCIATED DISEASES, EOSINOPHILIC LEUKEMIAS, AND THE HYPEREOSINOPHILIC SYNDROMES

Peter Valent, Andreas Reiter, and Jason Gotlib

Eosinophils are highly specialized granulocytic effector cells that produce and store numerous biologically active mediators, including cytotoxic proteins, lipid mediators, chemotactic peptides, and cytokines (Table 71.1). Under various pathologic conditions, blood eosinophils transmigrate through the endothelial layer and invade various target organs, where they secrete their products into the surrounding tissues, thereby triggering inflammation, toxic damage, and tissue remodeling.¹ Since their initial characterization by Paul Ehrlich in 1879, eosinophilic granulocytes have been implicated in a growing number of systemic diseases and conditions characterized by blood and/or tissue eosinophilia (Table 71.2). During the past few years, researchers have also gained a better understanding of the unique features and functions of activated eosinophils, and of the specific roles some of their granule proteins and inducible lipid mediators may play in the pathogenesis of allergic, parasitic, neoplastic, and other diseases.¹ In addition, recognition of the eosinophil as a major proinflammatory and tissue-remodeling effector cell has fueled a surge of interest in this granulocyte in recent years.

Studies of the biochemistry, biologic activities, and tissue localization of distinct enzymatic and nonenzymatic cationic proteins derived from eosinophils have provided convincing evidence for their role in the pathogenesis of inflammation and tissue damage in eosinophil-associated diseases. The five cationic granule proteins that may play a role in eosinophil-related pathologies include two major basic proteins (MBP-1, MBP-2), eosinophil peroxidase (EPX), and two ribonucleases, namely eosinophil cationic protein (ECP) and eosinophil-derived neurotoxin (EDN; see Table 71.1). Eosinophils also have the capacity to express toxic oxidative intermediates and other mediators of inflammation, as well as mediators of thrombosis and fibrosis. In addition, eosinophils are a rich source of DNA traps that may facilitate fibrin deposition as well as the killing of microbial invaders.² A clinically important aspect is that the various mediators produced and released by (activated) eosinophils often act together to trigger thrombosis and tissue damage, especially when eosinophil expansion and activation is chronic and “treatment-resistant”.

The process of determining the cause of eosinophilia is often frustrating for both the physician and the patient, and in many instances, the resulting diagnosis is “eosinophilia of unknown etiology”. Depending on laboratory standards and local guidelines, eosinophilia is defined as more than 450–500 eosinophils/ μ L blood, confirmed by visual microscopy. Diurnal variations in eosinophil counts are well documented, with minimum numbers appearing early in the morning and greatest numbers appearing late at night, mirroring circadian rhythms in adrenal corticosteroids. Although these variations are usually limited to a certain extent, basal eosinophil counts should be routinely measured during daytime. Transient mild eosinophilia is commonly seen in allergic reactions, during and shortly after a bacterial infection, and in many other reactive states. Sometimes, transient eosinophilia may be substantial or even excessive. Such transient (<4 weeks) form of reactive eosinophilia per se, if present, is considered harmless in most instances, but should prompt the physician to search for certain underlying diseases, such as an occult allergy or an unrecognized infection.

Eosinophil disorders and related syndromes are a heterogeneous group of diseases characterized by marked expansion and persistent accumulation of eosinophils in the peripheral blood (PB) and other organ systems. In general, eosinophil disorders can be divided into (A) neoplastic states where eosinophils are found to be monoclonal, and (B) reactive states where eosinophil expansion is considered to be “poly-clonal” and triggered by eosinotropic cytokines, such as interleukin-5 (IL-5).³ In both instances, hypereosinophilia (HE), defined by a persistent eosinophil count of $\geq 1.5 \times 10^4$ /L blood, is typically present. Depending on the underlying disease and other factors, the HE state may or may not be accompanied by specific (HE-mediated) organ damage, also referred to as *hypereosinophilic syndrome* (HES). In many instances, HES-related organ damage manifests as overt thromboembolism (thrombosis) or fibrosis. In other patients, organ damage is associated with less specific findings, and may involve the skin, gastrointestinal (GI) tract, or the CNS. Based on the underlying condition, both HE and HES can be divided into familial, primary (neoplastic), and secondary (reactive) forms (Table 71.3).³ Apart from these classical forms of HES, more specific syndromes associated with HE and HE-related organopathy have been described. Some of these syndromes are associated with a genetic (germ-line) defect, whereas others are accompanied by distinct immunological abnormalities (Table 71.4A). Finally, HE may develop in the context of organ-restricted inflammatory conditions such as eosinophilic pneumonia or eosinophilic colitis (Table 71.4B).

A thorough examination of all clinical and laboratory parameters, including radiologic and imaging studies, bone marrow (BM) investigations, cytogenetics, and molecular studies, are required in order to establish the correct diagnosis (underlying disease and organ damage) in patients with initially unexplained HE.³ The current chapter provides an overview on the epidemiology, pathogenesis, course, prognosis, and clinical features of various eosinophil disorders. We also discuss recent developments in the field and the impact of molecular markers and targets. In addition, this chapter provides diagnostic algorithms and recommendations for the management and treatment of patients with eosinophil disorders.

EPIDEMIOLOGY

Little is known about the prevalence and incidence of primary eosinophil disorders (eosinophil neoplasms) and HE-related syndromes, including HES. Based on the available literature, most eosinophil neoplasms and all types of HES are rare, and the same holds true for other HE-related conditions, such as the Gleich syndrome or Churg-Strauss syndrome (CSS). In an attempt to estimate the incidence of HES, data collected by the Surveillance, Epidemiology and End Results (SEER) database, sponsored by the National Cancer Institute, have been reviewed. A crude incidence of 0.035 cases per 100,000 person-years was found, and the male-to-female ratio was reported to be 1.47 to 1. The average age at diagnosis was 52.5 years, and the peak incidence was recorded in individuals aged 65–74 years. Childhood cases of HES have been reported but are very rare. Unfortunately, all these data have serious limitations and

TABLE 71.1**Eosinophil-Derived Molecules and Their Potential Role in Health and Disease**

Eosinophil Product/ Molecule	Relevant Function(s)	Eosinophil Product/ Molecule	Relevant Function(s)
Eosinophil-Related Enzymes		Growth Factors/Cytokines	
Nonspecific esterase	Cytotoxic effects (microbes and tissue cells)	Interleukin-1- α (IL-1 α)	Endothelial activation, inflammation
Catalase	Cytotoxic effects (microbes and tissue cells)	Interleukin-2 (IL-2)	Activation of T lymphocytes
Acid phosphatase	Cytotoxic effects (microbes and tissue cells)	Interleukin-3 (IL-3)	Amplification of eosinophil accumulation/ activation and basophil activation
Lysophospholipase	Tissue inflammation	Interleukin-4 (IL-4)	B-cell maturation and mast cell differentiation
Phospholipase D	Migration, adhesion, vesicle transport, secretion	Interleukin-5 (IL-5)	Amplification of eosinophil accumulation/ activation
Hexosaminidase	Tissue inflammation and tissue remodeling	Interleukin-6 (IL-6)	Lymphocyte maturation
Arylsulphatase B	Lysosomal hydrolase	Interleukin-13 (IL-13)	Bronchial hyperreactivity, mucus production, B-cell maturation
5-Lipoxygenase	Leukotriene production, angiogenesis	GM-CSF	Leukocyte/eosinophil accumulation/activation
Leukotriene C4 synthase	Leukotriene production	TGF- α	Fibrosis, growth inhibition
Cyclooxygenase	Prostaglandin production	TGF- β	Fibrosis, growth inhibition
Histaminase	Histamine degradation	TNF- α	Endothelial activation, inflammation, cachexia
Eosinophil Basic Proteins		Oncostatin-M (OSM)	Fibrosis, angiogenesis, paracrine mobilization of eosinophils via upregulated SDF-1 production in fibroblasts
Eosinophil peroxidase (EPX)	Cytotoxic effects (parasites, microbes, tissue cells)	Lipid Membrane-Derived Substances	
Major basic protein-1 (MBP-1)	Cytotoxic effects (parasites, microbes, tissue cells)	PAF	Bronchoconstriction, edema formation
Major basic protein-2 (MBP-2)	Cytotoxic effects (parasites, microbes, tissue cells)	TXB2	Platelet aggregation
Eosinophil cationic protein (ECP)	Cytotoxic effects, mucus secretion, fibrosis	LTC4	Mucus secretion
Eosinophil-derived neurotoxin (EDN)	Cytotoxic effects (antiviral, RNase activity)	15-HETE	Diverse effects on blood and tissue cells
Chemokines		PGE1 and PGE2	Diverse effects on platelets, endothelial cells, fibroblasts and other tissue cells
Interleukin-8 (IL-8)	Leukocyte recruitment and activation	Antifibrinolytic Mediators	
MIP-1-alpha (CCL3)	Leukocyte recruitment and activation	PAI-2	Antifibrinolytic and prothrombotic
RANTES (CCL5)	Leukocyte recruitment and activation	Extracellular DNA traps	Fibrin deposition, antibacterial effect
Eotaxin (CCL11)	Further eosinophil recruitment		

CCL, chemokine (C-C motif) ligand; GM-CSF, granulocyte/macrophage colony-stimulating factor; LTC4, leukotriene C4; MIP-1-alpha, macrophage inflammatory protein-1-alpha; PAF, platelet-activating factor; PAI-2, plasminogen activator inhibitor-2; RANTES, regulated on activation, normal T-cell expressed and secreted; TGF, transforming growth factor; TNF, tumor necrosis factor; TXB2, thromboxane B2.

TABLE 71.2**Conditions Associated With Eosinophilia**

Reactive Conditions	Endocrinologic Conditions
Helminth infections (filariasis, toxocariasis, schistosomiasis, trichinosis, onchocerciasis, fascioliasis, strongyloidiasis, ascariasis, hookworm, echinococcus/hydatid disease)	Addison disease
Fungal infections (aspergillosis, coccidioidomycosis, cryptococcosis)	Neoplastic Conditions Involving the Hematopoietic System
Scabies and other infestations	Myeloid neoplasms
Bacterial infections (convalescent phase of pneumococcal pneumonia, chlamydial pneumonia, scarlet fever, other bacterial infections)	Mast cell neoplasms
Viral infections (HIV infection, chronic active hepatitis)	Lymphoid neoplasms
Allergic reactions (asthma, rhinitis, bronchitis, urticaria, Atopic diseases (atopic asthma, atopic dermatitis)	Paraneoplastic Conditions
Drug reactions (allergic, toxic)	Solid tumors/malignancy
Administration of IL-2, IL-3, or GM-CSF	Lymphoproliferative neoplasms (B- or T-cell lymphoma, Hodgkin disease)
Autoimmune diseases/connective tissue diseases/vasculitis (Sjögren syndrome, rheumatoid arthritis, lupus erythematoses, hypersensitivity vasculitis, bullous pemphigoid, others)	Langerhans cell histiocytosis
Acute and chronic graft-versus-host disease	Idiopathic Forms
Angioblastic lymphoid hyperplasia (Kimura disease)	Idiopathic eosinophilia ^a
Lymphocytic/lymphoid variant HES (HES _L)	HE of uncertain (undetermined) significance (HE _{US})
	Idiopathic hypereosinophilic syndrome (HES)
	Hereditary HE of unknown etiology

^aIdiopathic mild eosinophilia (500–1500 eosinophils/ μ L blood = less than HE) of unknown etiology.

HE, Hypereosinophilia; HES, hypereosinophilic syndrome; HES_L, idiopathic HES; HES_L, lymphoid variant HES; HE_{US}, hypereosinophilia of undetermined (unknown) clinical significance; GM-CSF, granulocyte-macrophage colony-stimulating factor; HIV, human immunodeficiency virus; IL-2, interleukin-2; IL-3, interleukin-3.

TABLE 71.3 Classification of Hypereosinophilia and Hypereosinophilic Syndromes

HE Variant	Abbreviation	Associated HES Variant
Familial/hereditary HE	HE _{FA}	Familial HES = HES _F
HE of undetermined/ Unknown Significance	HE _{US} ^a	Idiopathic HES = HES _I ^a
Neoplastic/primary HE	HE _N	Neoplastic HES = HES _N
Reactive/secondary HE	HE _R	Reactive HES = HES _R Lymphocytic variant = HES _L ^b

^aIn patients with HE_{US}, the presence of HES is excluded by definition; as soon as HES is diagnosed in a patient with HE_{US}, the diagnosis changes to HES_I, unless an underlying etiology (condition/disease) is also found.

^bHES_L is regarded a special variant of HES_R.

HE, Hypereosinophilia; HES, hypereosinophilic syndrome; HES_F, familial HES; HES_I, idiopathic HES; HES_L, lymphocytic variant HES; HES_N, primary (neoplastic) HES; HES_R, reactive HES; HE_{US}, hypereosinophilia of undetermined (unknown) clinical significance.

TABLE 71.4A Rare HES-Like Syndromes Accompanied by Hypereosinophilia

Syndrome	Characteristic Features and Laboratory Abnormalities
Gleich syndrome	Cyclic recurrent angioedema, fever, weight gain, elevated polyclonal IgM, increased IL-5 production, evidence of clonal T cells (CD3 ⁺ T cells) ^a
Churg-Strauss syndrome (CSS) = eosinophilic granulomatosis with polyangiitis (EGPA)	Stage I: Asthma and rhinosinusitis (isolated) Stage II: Eosinophilic phase (HES-like) Stage III: Vasculitic phase defined by necrotizing (small-vessel) vasculitis and HE with pulmonary infiltrates and/or neuropathy (ANCA+ and ANCA- subvariants).
Eosinophilia myalgia syndrome (EMS)	Severe myalgia ± fever (flu-like), edema, fatigue, weight loss, neurologic symptoms, skin abnormalities Epidemic cases have been reported to result from exposure to L-tryptophan (toxic oil syndrome).
Eosinophilic fasciitis (EF) = Shulman syndrome	Scleroderma-like condition with painful swelling of the skin and chronic induration (limbs and trunk) as well as laboratory signs of systemic inflammation
Omenn syndrome (OS)	Severe combined immunodeficiency (SCID) with well-populated lymphatic organs (OS paradox) Autosomal recessive genetic (pediatric) disease (recurrent mutations in <i>RAG1</i> or <i>RAG2</i>) Clinical findings: erythroderma, hepatosplenomegaly, lymphadenopathy, increased IgE, diarrhea, weight loss (GVHD-like condition with autoreactive T cells)
Hyper-IgE syndrome (HIES)	Hereditary immunodeficiency syndrome with elevated IgE, recurrent severe infections, often with skin eczema and facial anomalies Known recurrent gene mutations: Autosomal dominant variant: <i>STAT3</i> mutations Autosomal recessive variant: <i>DOCK8</i> mutations <i>PGM3</i> mutations

^aEGPA/CSS with clonal T cells is often regarded as special variant of lymphoid variant HES (HES_L).

ANCA, Anti-neutrophil cytoplasmic antibodies; DOCK8, dedicator of cytokinesis 8; GVHD, graft-versus-host disease; HE, hypereosinophilia; HES, hypereosinophilic syndrome; IgE, immunoglobulin E; PGM3, phosphoglucomutase 3; *RAG*, recombination-activating gene; *STAT3*, signal transducer and activator of transcription-3.

TABLE 71.4B Organ-restricted (Inflammatory) Conditions Accompanied by Eosinophilia

Eosinophilic gastrointestinal disorders (EGIDs)
Eosinophilic esophagitis
Eosinophilic gastritis
Eosinophilic gastroenteritis
Eosinophilic colitis
Eosinophilic pancreatitis
Eosinophilic hepatitis
Eosinophilic ascites
Pulmonary eosinophilic syndromes
Eosinophilic asthma
Eosinophilic bronchitis
Eosinophilic pneumonia
Eosinophil pleuritis
Eosinophilic nephritis
Eosinophilic cystitis
Eosinophilic endometritis and myometritis
Eosinophilic mastitis
Eosinophilic ocular disorders
Eosinophilic myocarditis
Eosinophilic synovitis
Skin diseases/conditions associated with eosinophilia ^a
Allergic contact dermatitis
Atopic dermatitis
Drug reactions
Bullous pemphigoid and pemphigoid variants
Eosinophilic cellulitis (Wells syndrome)
Radiotherapy-related eruptions associated with eosinophilia
Eosinophilic pustular folliculitis
Infestations (parasitic) and infections (bacterial, viral, fungal) involving the skin
Mycosis fungoides
Pachydermatous eosinophilic dermatitis
Kimura disease (skin and lymph nodes)
Eosinophilic panniculitis

^aMany other skin abnormalities can be accompanied by eosinophilia, especially when a systemic inflammatory disease process is present and triggers eosinophilia.

emphasize the need for more comprehensive epidemiologic studies using currently available diagnostic criteria and robust registries. A complicating issue is that HES may coexist with an underlying primary eosinophil disorder, a lymphoma, but also an allergy or another reactive condition.³ In eosinophilic leukemia presenting with the *FIP1L1-PDGFR* fusion gene (*F/P*), a clear male predominance is found. As a consequence, any HES registry including patients with *F/P*+ eosinophilic leukemia and/or other *F/P*+ myeloproliferative neoplasms (MPNs) with eosinophilia (MPN-eo) will report on an overall male predominance of HES, even if other HES types are evenly distributed in males and females. Indeed, no clear gender predominance has been reported in other groups of HE or HES. Familial forms of HE and HES have been described, but are very rare. In these cases, a hyper-immunoglobulin (Ig)E syndrome or Omenn syndrome (OS) have to be excluded. No cases of familial *F/P*+ leukemia have been reported to date.

MORPHOLOGY AND PHENOTYPE OF EOSINOPHILS

Eosinophils contain three granule populations, namely (1) electron-dense, round, primary progranules present mainly at the promyelocyte and myelocyte stages, (2) specific (secondary) eosinophilic granules with an electron-dense crystalloid core, specifically found in mature eosinophils, and (3) small-sized granules, which may contain catalase, acid phosphatase, and arylsulfatase.¹ The large, specific granule is the major source of cytotoxic and proinflammatory cationic proteins. Eosinophils also contain lipid bodies that may serve as a source of

eosinophil eicosanoid-forming enzymes, including 5-lipoxygenase, leukotriene C4 synthase, and cyclooxygenase (see [Table 71.1](#)).

The immunophenotype of human eosinophils is well established and may assist in eosinophil detection and enumeration by flow cytometry. In common with all leukocytes, eosinophils express leukosialin (CD43), the homing cell adhesion molecule HCAM (CD44), and the pan-leukocyte tyrosine phosphatase C (CD45).⁵ In addition, eosinophils express several myeloid differentiation antigens, including LFA-1 (CD11a/CD18) and Siglec-3 (CD33). These cell surface antigens are also expressed on other myeloid cells, including monocytes and basophils. However, a few cell surface structures are largely restricted to eosinophils and thus serve as cell-specific markers through which eosinophils can be detected and isolated. One of these markers is Siglec-8, an inhibitory receptor that, when crosslinked, mediates eosinophil apoptosis.⁶ Apart from eosinophils, basophils also display Siglec-8 ([Fig. 71.1](#)). Eosinophils also express several cytokine receptors, such as the IL-5 receptor, granulocyte-macrophage colony-stimulating factor (GM-CSF) receptor, and IL-3 receptor. Moreover, eosinophils exhibit various chemokine receptors, including eotaxin receptors and CXC-chemokine receptor 4 (CXCR4), a receptor for stromal cell-derived factor (SDF)-1 ([Table 71.5](#)). Finally, eosinophils express diverse complement receptors (CRs), such as CR3 (CD11b/CD18) and C5aR (CD88), adhesion receptors, and immunoglobulin (Fc) receptors. Several of these cell surface markers have been considered as potential targets of therapy. However, no aberrantly expressed or disease-specific markers for neoplastic eosinophils or reactive eosinophils have been identified yet. Several studies have shown that eosinophils in HES patients may express increased amounts of CD11b, CD16, CD25, or/and HLA-DR. However, overexpression of these antigens is not disease-specific.

Apart from cell surface antigens, eosinophils also express more or less specific marker antigens in their cytoplasm by which these cells can be detected in various tissues by immunohistochemistry (IHC). Useful eosinophil IHC stains include ECP, EPX, and MBP ([Fig. 71.2A](#)). Depending on the condition and underlying neoplasm, these antibodies may also react with (immature) basophils. Otherwise, however, the staining reaction appears to be largely specific for eosinophil granulocytes. Another important aspect is that some of the eosinophil proteins, like MBP, can be detected in tissue sections as deposit material after complete degranulation of eosinophils and even after their subsequent destruction (disappearance), which is often seen in the context of chronic HE-related tissue damage (HES).⁷ Therefore, the definition of tissue HE includes not only the detection of a local eosinophil (cellular) infiltrate, but also the presence of eosinophil protein deposits, even in the absence of eosinophil infiltrates.

Eosinophils from the PB and tissues of patients with HE may differ from their normal counterparts by morphologic, biochemical, and functional characteristics. The most important morphologic distinction is that between immature and mature eosinophils. In most instances, this distinction is a straightforward approach, as immature forms exhibit distinct nuclear and cytoplasmic morphologic features ([Fig. 71.2B and C](#)). However, sometimes the distinction may be challenging, especially in reactive states with massive inflammation and in certain myeloid neoplasms. In immature myeloid neoplasms, eosinophil precursor cells may exhibit dark basophilic granules that must not be confused with the specific granules of blood basophils. These immature eosinophils may also be misinterpreted as mixed-lineage cells.

Immature eosinophils also differ from mature eosinophils in several other aspects, including density, nuclear shape, protein composition, and cell surface antigens. A difficult task is to differentiate normal eosinophils from activated (sometimes immature) eosinophils in reactive states. In previous years, researchers focused on cell density. In particular, a distinction was made between the “normodense” (normal-density) and the “hypodense” (light-density) eosinophil. The blood of normal individuals contains less than 10% eosinophils with densities less than 1.082 g/mL, whereas patients with eosinophilia can have markedly increased numbers of hypodense cells. Hypodense eosinophils appear to be cytokine-activated cells that are characterized

Fig. 71.1 EXPRESSION OF SIGLEC-8 ON PERIPHERAL BLOOD EOSINOPHILS. Peripheral blood cells were obtained from a patient suffering from a myeloproliferative neoplasm with eosinophilia (MNP-eo). Cells were stained with an antibody against Siglec-8, as well as antibodies against CD203c (for basophil detection) and CD14 (for monocyte detection), and analyzed by multicolor flow cytometry. As visible, Siglec-8 is expressed on eosinophils (detected by their characteristic side-scatter properties and auto-fluorescence) as well as on blood basophils, whereas monocytes (like most other leukocytes) lack Siglec-8.

by increased vacuolization, decreased granule size, decreased content of granule cationic proteins, and increased numbers of cytoplasmic lipid bodies. The numbers of surface receptors for a variety of eosinophil agonists, including complement components, immunoglobulins, and PAF, are expressed at higher levels by hypodense eosinophils. Functionally, hypodense eosinophils show increased metabolic activity and oxygen consumption, an increased capacity for the synthesis and secretion of LTC4 and certain cytokines, enhanced chemotaxis, and augmented cytotoxicity. So far, no clear relationship between the percentage of hypodense eosinophils and the etiology of eosinophilic disorders has been established. The percentage of these cells increases in most reactive forms of HE and HES, but also in patients with primary HES. Ultrastructurally, HES eosinophils may show a selective loss of secondary granule components (crystalloid MBP-containing core or granular matrix, or both), a decreased number and size of granules, and increased numbers of cytoplasmic lipid bodies and tubulovesicular structures that may be involved in eosinophil secretion during the process of piecemeal degranulation.

TABLE 71.5 Receptors and Ligands Regulating Growth and Function of Eosinophils

Receptor (R) on Eosinophils	Ligand	Effects on Eosinophils
IL-2RA/CD25 ^a	IL-2	Activation? ^a Migration? ^a
IL-3R/CD123 + CD131	IL-3	Differentiation, survival, adhesion, migration, activation, priming
IL-4R/CD124	IL-4	Priming for effects of chemotaxins
IL-5R/CD125 + CD131	IL-5	Differentiation, survival, adhesion, migration, activation, priming
GM-CSFR/CD116 + CD131	GM-CSF	Differentiation, survival, adhesion, migration, activation, priming
IL-10R	IL-10	Inhibitory (activation, survival)
IL-12R	IL-12	Inhibitory (activation)
IL-13R	IL-13	Unknown
CD4	IL-16 (LCF)	Activation, priming
IL-25R	IL-25	Survival, activation
IL-27R	IL-27	Survival, activation
IL-33R/ST2	IL-33	Activation, survival
VEGFR-1/FLT-1	VEGF	Chemotaxis, activation
Tie-2/TEK	Angiopoietin-1	Chemotaxis, activation?
PDGFRA/B	PDGF	Activation and growth?
FGFR	FGF	Activation?
TGFβ1R	TGFβ1	Inhibitory (differentiation)
TGFβ2R	TGFβ2	Inhibitory (differentiation)
IFN-α-R	IFN-α	Inhibitory (growth)
IFN-γ-R	IFN-γ	Inhibitory (growth, migration)
CCR3 (CD193)	RANTES (CCL5)	Chemotaxis, activation
	MCP-3 (CCL7)	Chemotaxis, activation
	MCP-4 (CCL13)	Chemotaxis, activation
	Eotaxin-1 (CCL11)	Chemotaxis, activation
	Eotaxin-2 (CCL24)	Chemotaxis, activation
	Eotaxin-3 (CCL26)	Chemotaxis, activation
CXCR4 (CD184)	SDF-1 (CXCL12)	Chemotaxis
PAF-R	PAF	Chemotaxis, activation
C5aR (CD88)	C5a	Chemotaxis, activation
TLR1, 4, 7, 9, 10	Toll-like R-ligands	Survival, activation
Corticosteroid R	Corticosteroids	Inhibitory (activation)

^aEosinophils derived from patients with hypereosinophilic syndromes (activated eosinophils) may express CD25. However, the role of CD25 in eosinophil function remains unknown.

CCL, Chemokine ligand; CCR, chemokine receptor; FGF, fibroblast growth factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; LCF, lymphocyte chemoattractant factor; MCP, monocyte chemoattractant protein; PAF, platelet-activating factor; PDGF, platelet-derived growth factor; TGF, transforming growth factor; VEGF, vascular endothelial growth factor.

ORIGIN, DIFFERENTIATION, RECRUITMENT, AND ACTIVATION OF EOSINOPHILS

Eosinophilopoiesis

Eosinophils originate from pluripotent and granulocyte-committed, CD34⁺, hematopoietic progenitor cells that are detectable in the BM,

Fig. 71.2 IMMUNOHISTOCHEMICAL AND MORPHOLOGIC PROPERTIES OF NEOPLASTIC EOSINOPHILS. (A) Expression of major basic protein (MBP) in neoplastic eosinophils in a patient suffering from a myeloid neoplasm with eosinophilia. Paraffin-embedded bone marrow sections were stained with an antibody against MBP by indirect immunohistochemistry. (B) Wright-Giemsa-stained bone marrow smear in a patient with chronic eosinophilic leukemia. Note the presence of atypical eosinophils, some of which contain multi-lobed nuclei. (C) Wright-Giemsa-stained bone marrow smear in a patient with an acute eosinophilic leukemia. As visible, the smear contains a mixture of immature and mature eosinophils. Some of the immature eosinophils exhibit a blast-like morphology. Other immature forms contain “basophilic” dark-blue granules, but these cells still belong to the eosinophil lineage.

in the PB, and various extramedullary organs. Eosinophil development from their multipotent and lineage-restricted progenitors is controlled by a network of transcription factors, including GATA-1, GATA-2, C/EBP-A, and C/EBP-E. Lineage-specific signaling as well as transcription factor expression is controlled by a network of cytokines and cytokine receptors. In fact, eosinophils develop from their progenitors in response to T-cell-derived growth factors,

including IL-3, GM-CSF, and IL-5. The most potent and specific eosinophilopoietic growth factor is IL-5. Eosinophils are derived from multipotent or bipotent colony-forming progenitor cell units (CFUs). Bipotent CFUs giving rise to eosinophils and basophils (CFU-eo/ba) are frequently detected in the BM and PB in healthy individuals, as well as in various disease states.⁸ By contrast, progenitor cells selectively giving rise to eosinophils and mast cells (CFU-eo/mast) are very rare. At an early stage of progenitor cell development, eosinophil-committed progenitors exhibit CD34 and CD38, and coexpress receptors for IL-3, GM-CSF, and IL-5. Later, CD34 is diminished, whereas the interleukin receptors continue to be expressed, and several additional, functionally important cell surface antigens are acquired by maturing eosinophils.

IL-3, GM-CSF, and IL-5 promote eosinophil differentiation in hematopoietic progenitor cells and eosinophil maturation of lineage-restricted precursors, as well as the recruitment, priming, activation, and survival of mature eosinophils.⁹ Whereas IL-3 and GM-CSF also affect other hematopoietic lineages, including basophils, IL-5 acts as a more lineage-restricted (eosinophil-targeting) cytokine. Therefore, IL-5 and IL-5 receptors have been recognized as major targets of therapy in diseases associated with (reactive) HE. The high-affinity receptor for IL-5 is composed of an IL-5–specific alpha chain (CD125) and a beta chain (CD131) that mediates intracellular signaling and is shared also by the high-affinity receptors for GM-CSF (CD116/CD131) and IL-3 (CD123/CD131; see [Table 71.5](#)). Expression of high-affinity IL-5 receptors is an important prerequisite for specific cellular responses to “physiologic doses” of IL-5. Overexpression of IL-5 is observed in many reactive conditions and disease states associated with (reactive) HE. Correspondingly, IL-5 transgenic mice develop profound eosinophilia, and IL-5 knockout mice do not develop HE in response to allergic stimuli or a helminth infection. Under various reactive conditions accompanied by HE, IL-5 is produced primarily by activated Th2-type helper cells. However, although activated T cells are considered a primary and most important source of eosinophilopoietic cytokines, like IL-5, other cell types, such as mast cells, macrophages, natural killer (NK) cells, and stromal cells, also produce these cytokines. In myeloid neoplasms with HE, clonal expansion of eosinophils usually is a growth factor-independent process. Moreover, depending on the underlying disease, neoplastic eosinophils may produce eosinophilopoietic cytokines in an autocrine manner, thereby augmenting tissue and blood HE.

Mobilization and Migration of Eosinophils to Sites of Inflammation

In healthy individuals as well as in reactive states, eosinophils circulate only briefly in the PB, and then transit to extravascular sites. Depending on environmental factors and demand, eosinophils localize preferentially in tissues and organs exposed to external environments, principally the submucosal membranes and loose connective tissues of the skin, GI tract, genital tract, and lungs. During an acute or chronic inflammatory process, larger numbers of eosinophils may be recruited actively into local tissue sites.⁹ The mobilization of eosinophils from the vasculature into (vascularized) tissues is a multistep process that involves their rolling on vascular endothelial cells and their subsequent adhesion to endothelium via L-selectin, followed by binding to intercellular adhesion molecule-1 (ICAM-1 = CD54) through a CD18/CD11a/b-dependent mechanism.⁴ Expression of selectins on endothelial cells is triggered by histamine and other mediators, whereas expression of ICAM-1 on endothelial cells is induced by various proinflammatory cytokines, such as tumor necrosis factor- α (TNF- α). As both histamine and TNF- α are produced and are rapidly provided by (activated) mast cells, these cells are considered to play a crucial role in eosinophil recruitment in various allergic and other inflammatory reactions. However, the recruitment of eosinophils is a complex process involving many different mechanisms and molecules, such as E-selectin, endothelial-leukocyte adhesion molecule 1 (ELAM-1 = CD62E) or vascular cell

adhesion molecule-1 (VCAM-1 = CD106).⁴ Selective recruitment of eosinophils is mediated by adhesion to VCAM-1 via the β 1 integrin very late activation antigen-4 (VLA-4 = CD49d/CD29), which is expressed by eosinophils but not by blood neutrophils.

Eosinophil migration is regulated by several different chemotactic factors, including various chemokines (SDF-1, eotaxins, IL-8, regulated on activation, normal T-cell expressed and secreted [RANTES], and others), the complement fragment C5a, platelet-activating factor (PAF), and several eosinotropic cytokines, such as IL-5 or GM-CSF, which also prime eosinophils for enhanced migratory responses to PAF and IL-8. In addition, IL-2, leukotriene B₄, and the lymphocyte chemoattractant factor (LCF = IL-16) can induce eosinophil migration. At least for neoplastic eosinophils, a most potent chemoattractant appears to be SDF-1, a stromal cell-derived chemokine that binds to CXCR4 (CD184) on normal and neoplastic eosinophils.¹⁰ Other potent chemoattractants for (neoplastic) eosinophils are the eotaxins (eotaxin-1, -2, -3) that bind to and signal through the chemokine receptor CCR3 (CD193; see [Table 71.5](#)).⁹ Depending on the underlying disease, the cell type(s) involved, and the presence of comorbidities (triggering, e.g., local or systemic inflammation) all these chemotactic factors may act together to trigger eosinophil recruitment and accumulation in the affected (often inflamed) tissue sites. Likewise, in several reactive conditions, IL-5 and eotaxin reportedly cooperate locally to promote eosinophil migration and tissue HE.

The primary source of eosinophil chemotactic factors often remains unknown. In many disease states accompanied by HE, eosinophil chemotactic factors may be produced by microenvironmental cells, including fibroblasts, endothelial cells, macrophages, and mast cells. Several of these chemotaxins, like SDF-1, are produced by stromal cells in a paracrine fashion. For example, in neoplastic eosinophils, the *F/P* mutant triggers expression and release of oncostatin M (OSM), which in turn induces fibroblast and endothelial cell proliferation but also the expression and release of SDF-1 from these cells, thereby augmenting the accumulation of additional eosinophils.¹¹ In this regard, it is noteworthy that the SDF-1 receptor CXCR4 is not only expressed on mature eosinophils, but also on pluripotent stem cells and eosinophil-committed precursor cells. Depending on the type of underlying neoplasm, eosinophil chemotactic cytokines may also be produced in an autocrine manner.

Role of Mast Cells in Eosinophil Recruitment and Accumulation

In various inflammatory and allergic reactions, several different interactions between eosinophils and mast cells have been postulated. For example, mast cells provide the immediate stimuli upon activation to initiate allergic inflammation, resulting in eosinophil recruitment during the later phases following an allergen encounter. In addition, mast cells and eosinophils are often increased in numbers in allergic reactions, but also in nonallergic inflammatory conditions and even in neoplastic states. Both cell types express a similar profile of chemotactic receptors, such as CCR3, and both respond to eotaxins and RANTES (CCL5), leading to their recruitment into local tissue sites. Mast cells and eosinophils also interact with each other via cell–cell contact and through several different soluble mediators. Likewise, mast cell-derived heparin binds and stabilizes various chemokines, including the eotaxins. In addition, mast cells are a source of various cytokines involved in the regulation of eosinophil adhesion, migration, and function. As previously mentioned, mast cells express and release histamine and TNF- α , and thereby facilitate eosinophil recruitment. Mast cell proteases appear to have a dual action on eosinophil functions. Mast cell-derived chymase suppresses eosinophil apoptosis and induces the release of IL-6 and various chemokines (CXCL1, CXCL8, CCL2) from eosinophils. Beta-tryptase, on the other hand, can cleave eotaxin and RANTES, and thereby may limit eosinophil chemotaxis. Apart from these interactions, eosinophils and mast cells may sometimes also derive from the same stem or progenitor cell compartment, and therefore may express the same driver mutant,

which has been documented for cases of *F/P+* chronic eosinophilic leukemia (CEL) with accompanying mast cell expansion, as well as for patients with *KIT D816V+* systemic mastocytosis (SM) with concomitant HE. Therefore, mast cells and eosinophils may often appear as a dual target cell population, both in reactive and neoplastic states, which is a critical point when considering the development of specific therapies. For example, simultaneous downregulation of eosinophil and mast cell activation might be achieved by certain inhibitory surface molecules, such as CD300a or Siglec-8.¹² Several other target receptors, such as Siglec-3 (CD33) are expressed on eosinophils, mast cells, and basophils. In *F/P+* cases, imatinib can induce apoptosis in both eosinophils and mast cells, as both cell types express the mutant platelet-derived growth factor receptor (PDGFR) target in this neoplasm.

MONITORING OF EOSINOPHIL NUMBERS AND ACTIVITY IN HEALTH AND DISEASE

In the PB, eosinophils can easily be measured by microscopy or flow cytometry based on their characteristic side scatter properties and their autofluorescence. In case of atypical (immature) cells or questionable results, immunophenotyping can be performed to confirm the presence of eosinophils. In tissue sections, the quantification of eosinophils is a more difficult task that makes routine clinical evaluations somewhat impractical. Alternative approaches such as analysis of tissue secretions from affected organs (e.g., bronchoalveolar lavage [BAL]) have been used with success in evaluating local eosinophil numbers and function in asthma. In addition to routine histochemical identification and enumeration of eosinophils and the immunochemical localization of secreted eosinophil granule cationic proteins in tissue biopsies, two other methods have been employed to demonstrate and monitor eosinophil activation and involvement, (1) the identification of activated eosinophils by staining with anti-ECP antibody EG2 recognizing a secreted (deglycosylated) form of the protein, and (2) measurement of eosinophil granule proteins, such as MBP or ECP by radioimmunoassay (RIA) or enzyme-linked immunosorbent assay in various body fluids, including serum, plasma, urine, sputum, nasal lavage, and BAL. Indeed, these antigens may serve as reliable biomarkers of eosinophil involvement and activation in allergic, parasitic, and inflammatory diseases. In addition, treatment responses can be demonstrated and measured with these assays.

ETIOLOGY AND PATHOBIOLOGY OF HE

In patients with documented HE, four etiologies have to be considered: (1) myeloid (and rarely myeloid/lymphoid) neoplasms where eosinophils are usually derived from neoplastic stem and progenitor cells, (2) lymphoid neoplasms or nonhematopoietic (solid) tumors where HE is a paraneoplastic phenomenon, (3) reactive conditions, such as an allergy, infection or an autoimmune disease where HE is a reactive process, and (4) rare syndromes accompanied by HE, including rare inherited disorders (see Table 71.4A).³ In patients with clonal (primary) HE, eosinophils and their progenitors often display rearrangements in *PDGFRA*, *PDGFRB*, or *FGFR1* genes.¹³ Therefore, the World Health Organization (WHO) has employed these mutations as primary criteria to describe (classify) hematopoietic neoplasms accompanied by HE (Table 71.6).¹⁴ The resulting “fusion proteins” act as protooncogenic drivers and are considered to contribute to cytokine-independent differentiation of eosinophil progenitor cells. The most frequently detected molecular abnormality is the *F/P* fusion gene, a mutant gene created by an 800-kb interstitial deletion on chromosome 4q12. The fusion gene is detectable by polymerase chain reaction (PCR) as well as by fluorescence in situ hybridization (FISH; deleted *CHIC2* gene) but not by conventional karyotyping. However, conventional cytogenetics may reveal translocations, deletions, or inversions on chromosome 5q31-33, indicating rearrangements of *PDGFRB*, or abnormalities on chromosome band

TABLE
71.6

Molecular Classification of Eosinophil-Related Neoplasms Proposed by the WHO and Related Molecular and Cytogenetic Defects^a

1. Myeloid and lymphoid neoplasms with eosinophilia and abnormalities of *PDGFRA*, *PDGFRB* or *FGFR1*
Myeloid and lymphoid neoplasms with *PDGFRA* rearrangement
Most common variant: *FIP1L1-PDGFRA*⁺ CEL
Myeloid neoplasms with *PDGFRB* rearrangement
Most common variant: *ETV6-PDGFRB*⁺ leukemia (aCML, CMML or others)
Myeloid and lymphoid neoplasms with *FGFR1* rearrangement
Most common variant: *ZMYM2-FGFR1*⁺ disease
2. Chronic eosinophilic leukemia, not otherwise specified
BCR-ABL1 and abnormalities in *PDGFRA*, *PDGFRB*, or *FGFR1* are excluded
Other MPN-related molecular lesions, such as *JAK2* mutations, or certain cytogenetic defects, such as +8 or i(17q), support the diagnosis of CEL
3. WHO-defined myeloid neoplasms with HE, not included in “1” or “2”
 - a. Ph⁺ (*BCR-ABL1*⁺) chronic myeloid leukemia (CML-eo)
 - b. *JAK2 V617F*⁺ myeloproliferative neoplasms (MPN-eo)
 - c. *KIT D816V*⁺ systemic mastocytosis (SM-eo)
 - d. *CBFB*-fusion gene-related acute myeloid leukemia (AML-eo/M4-eo)
 - e. Myelodysplastic syndromes with HE (MDS-eo)
 - f. Other WHO-defined myeloid neoplasms with HE

^aThe table refers to the WHO classification of eosinophil neoplasm.¹⁴

aCML, Atypical chronic myeloid leukemia; CEL, chronic eosinophilic leukemia; CMML, chronic myelomonocytic leukemia; FGFR, fibroblast growth factor receptor; HE, hypereosinophilia; MDS, myelodysplastic syndrome; MPN, myeloproliferative neoplasm; PDGFR, platelet-derived growth factor receptor; Ph⁺, Philadelphia chromosome positive; SM, systemic mastocytosis; WHO, World Health Organisation.

8p11-12, indicating a rearrangement of the *FGFR1* gene. From a clinical point of view, it is of great importance to screen for these rearrangements in all patients using the correct techniques, as many of them, including *F/P*, are responsive to imatinib or other tyrosine kinase inhibitors (TKIs). However, clonal HE may also be triggered by other mutations, including *BCR-ABL1*, rearranged *JAK2* or *FLT3*, or *KIT D816V*.¹⁴ In a substantial subset of patients with MPN-eo, no mutation is found.

In paraneoplastic and reactive states, HE is usually triggered by eosinophilopoietic cytokines, including IL-5, IL-3, or GM-CSF. These cytokines, especially IL-5, may be detected in the serum of these patients and are considered to be produced by activated T cells or other activated immune cells. In a few patients with HE and HES, activated (clonal) T cells are detectable by phenotyping and PCR, but no underlying lymphoma or other underlying condition is found. In these cases, the lymphoid variant of HES (HES_L) is diagnosed.¹⁵ In some of these patients, an overt T-cell lymphoma or Sézary syndrome may develop in the follow-up. A number of different reactive conditions and disorders, including helminth infections, fungal infections, autoimmune disorders, allergies, or drug reactions, can lead to reactive HE and reactive HES (HES_R). These conditions are listed in Table 71.2.

Pathogenesis of Eosinophil-Associated End-Organ Damage in Patients With HES

Regardless of the underlying etiology (neoplastic or reactive), sustained HE may lead to typical end-organ damage defined as HES. Even in patients with idiopathic HE, such organ damage may occur and is then called *idiopathic HES* (HES_I).³ However, not all patients presenting with HE develop organ damage even if followed over a

longer time period. For example, patients with an underlying allergic disease, an inherited disorder accompanied by HE, or those with organ-specific HE syndromes, such as eosinophilic pneumonia, usually fail to develop the cardiac damage seen in patients with typical HES. When neither an underlying disease nor HE-related organ damage is found, the diagnosis HE of undetermined significance (HE_{US}) is established.³ In general, the risk of HES is lower in reactive forms of HE, especially when the underlying disease can be treated successfully. Correspondingly, IL-5 transgenic mice with massive HE do not develop significant end-organ damage, suggesting that other factors (in addition to IL-5) are likely necessary for the occurrence of a HE-related organ damage. In patients with an underlying MPN or other underlying myeloid neoplasm, the risk of HE-related organ damage (HES) is relatively high. The highest risk is found in patients with mutations in *PDGFR* genes. Likewise, most untreated patients with *F/P+* MPN-eo or CEL may develop HES with cardiac involvement over time. Additional risk factors may also contribute in these patients: these factors include, among others, an additional prothrombophilic state, late detection of the disease, and late initiation of specific (anti-CEL) therapy. There may also be a certain genetic predisposition for early occurrence of tissue HE in patients with *F/P+* CEL (*F/P+* MPN-eo). In particular, the severity (extent) of tissue HE seems to correlate with a polymorphic variant (SNP in the 5'-UTR) in the *IL-5RA* gene.¹⁶ However, it remains unclear whether this SNP predisposes to HES development or progression, and thus is relevant clinically. Today, the general recommendation is to initiate therapy with imatinib early in all *F/P+* patients, regardless of genetic, molecular or other factors, in order to prevent any HES occurrence as well as disease progression (to acute leukemia).

A number of different organ systems are affected in patients with HES. The most common manifestations are summarized in Table 71.7. Although multiple organ systems are involved and the manifestation patterns are quite complex with varying courses and outcomes, some common pathogenetic factors have been described. One common feature is the mobilization of the tissue microenvironment by eosinophil-derived mediators and cytokines, which leads to tissue remodeling, fibrosis, and increased angiogenesis. Another common factor is tissue inflammation, which is typically triggered by eosinophil-derived cytokines and chemokines. Finally, HE-related organopathies may often result from direct cytotoxic damage that is induced by the various toxic mediators produced and released by (reactive and neoplastic) eosinophils. With regard to thrombosis, several different eosinophil-derived mediators have been implicated, including TNF- α , plasminogen activator inhibitors (PAIs), and eosinophil-derived DNA traps (see Table 71.1).¹⁷ In addition, ECPs have the capacity to alter thrombomodulin activity. A number of different compounds produced by eosinophils, including cationic proteins and various cytokines, may induce fibrosis. Among these cytokines, OSM may play a particular role as a HES-related profibrogenic cytokine.¹¹ HE-related neoangiogenesis may be triggered by IL-8, OSM, and vascular endothelial growth factor (VEGF). All these cytokines are produced and secreted by normal/reactive and also by neoplastic eosinophils. However, neoplastic eosinophils produce some of these cytokines in excess over their normal counterparts. For example, *F/P+* eosinophils express and release huge amounts of OSM, IL-8, and VEGF. The *F/P* mutant induces the production and secretion of these mediators in neoplastic cells in a STAT5-dependent manner. Concerning the mobilization of the microenvironment in various organs in patients with HES, a most critical *F/P* target gene may be *OSM*. Notably, OSM initiates not only fibrosis and angiogenesis by triggering fibroblast proliferation and tube formation in endothelial cells, but also by inducing the production of multiple cytokines and chemokines in stromal cells. Among these mediators are IL-8, SDF-1, and other chemotactic factors that can recruit additional CXCR4+ precursor cells and eosinophils to local tissue sites.¹¹

An unresolved question is why HE-related fibrosis and thrombosis affect certain tissues and organs, including the heart, whereas the same organs are spared by other thrombophilia-inducing MPN types,

such as the *JAK2*-mutated variants. One explanation may be that eosinophils invade heart and lung tissues via “physiologic” routes, which may not be the case in other MPNs where HE usually does not occur. An additional explanation may be that eosinophil-derived mediators are toxic to certain (tissue-specific) cell types such as cardiomyocytes. Indeed, as noted earlier, eosinophils express a number of different cationic proteins capable of inducing endothelial and endocardial damage and neurotoxicity. In addition, the eosinophil has the capacity to generate reactive oxidative species that can augment tissue damage.

DEFINITION AND CLASSIFICATION OF HE AND HES

The term HES was initially proposed for a syndrome characterized by idiopathic HE and HE-related organ damage, as well as by exclusion of various conditions and diseases that are typically accompanied by HE. More recently, the definition of HES has been refined as any type of HE (not just idiopathic) associated with typical HE-related end-organ damage.³ According to the proposal of an international working group on eosinophil disorders (ICOG-EO), the term HES should be reserved for clinical syndromes fulfilling HES criteria, but not for underlying (hematologic) malignancies or immunological disorders presenting with HE.³ In other words, the diagnosis HES must prompt the physician to search for (detect) an underlying (HES-triggering) disease. Accordingly, the final diagnosis is either idiopathic HES or HES based on a recognized underlying disorder, and both need to be documented in the final diagnosis. In previous WHO classifications, the term HES was sometimes used as a synonym of CEL, and sometimes to discriminate CEL from other less well-defined myeloid neoplasms with HE. However, in the 2008 edition of the WHO monograph, the term HES was no longer recommended as a synonym of WHO-defined neoplasms, a distinction that is in agreement with the proposal of the ICON group and the proposal of the ICOG-EO group.³

Definition of HE

HE is currently defined as a persistent, microscopically confirmed increase in PB eosinophils above $1.5 \times 10^4/L$. In previous definitions, persistent eosinophilia over 6 months was required to establish the diagnosis HE. However, based on improved diagnostics and treatment, and the necessity to introduce such treatment rapidly to avoid organ damage, the proposed definition of HE has recently been revised to a 4-week observation interval by the ICOG-EO group.³ The term “tissue HE” has also been proposed by several experts, and it may be useful to apply it in certain conditions, especially in the context of (to demonstrate) HE-related organ damage (HES). However, isolated tissue HE (without blood HE) is rare, and the documentation of tissue HE often requires special immunostains directed against eosinophil granule proteins.⁷ Therefore, the presence of tissue HE is often overlooked or is not documented, and PB HE clearly remains the key diagnostic marker in daily practice. In some of these patients, criteria for blood HE are not met, but molecular and clinical signs are strongly indicative of a particular eosinophil disorder with or without accompanying HES. These patients should be followed closely, as they may progress to an overt eosinophil disease (neoplasm) over time. The same holds true for WHO-based neoplasms presenting with *PDGFR* or *FGFR1* fusion genes without overt HE.¹⁴

Diagnostic Algorithm

When arriving at the provisional diagnostic “checkpoint” HE, two critical questions have to be addressed in order to approach to a final diagnosis: (1) is there any underlying disease or condition triggering HE? and (2) are there clinical signs and symptoms or laboratory abnormalities that point to the presence of HE-induced organ damage, so that the additional diagnosis of HES can be established? For example, the hematologic work-up in a patient with HE revealed CEL, and staging investigations showed endocardial thrombus formation: the final diagnosis in this patient is CEL with concomitant primary HES (HES_N). A diagnostic algorithm is shown in Fig. 71.3. In patients with typical HES and typical clinical manifestation, histopathologic evaluation is generally not warranted to confirm the presence of tissue HE. However, in patients with rare or atypical manifestations, such as renal failure, isolated myocarditis or bloody diarrhea, a tissue biopsy is required to document the presence of tissue HE and to confirm HE-induced organ damage, so that the diagnosis HES can be

established. The demonstration of extensive extracellular deposition of eosinophil-derived proteins supports the conclusion the organ damage is “HE-related”.⁷

Classification of HE and HES

The classification of HE and HES is essentially based on the related disease and underlying etiology. Accordingly, HE and HES are both divided into a familial variant (HE_F, HES_F), a primary/neoplastic form (HE_N, HES_N), and reactive entities (HE_R, HES_R; see Table 71.3).³ In a smaller fraction of patients, the etiology of HE and HES remains uncertain or two different causative factors are detected. When the etiology of HE remains uncertain after a thorough investigation and appropriate testing and no organ damage is detected, the final diagnosis is HE of uncertain (undetermined) significance (HE_{US}); and if HES is diagnosed, but no underlying disease is detected, the final diagnosis is idiopathic HES (HES).³

In general, four major groups of underlying disorders (conditions) have to be considered in HE (HES) patients: (1) myeloid (and rarely myeloid/lymphoid) neoplasms including eosinophilic leukemias (HE_N; HES_N), (2) lymphoid or nonhematopoietic neoplasms (paraneoplastic HE, a special variant of HE_R), (3) common allergic, reactive, or immunologic conditions (HE_R and HES_R), and (4) clinically defined, rare syndromes and conditions accompanied by HE, including rare inherited disorders and organ-restricted inflammatory diseases with tissue HE.^{3,17} Overall, the classification of HE/HES remains an important step in the diagnostic algorithm (Fig. 71.3). Using generally accepted criteria and parameters, this approach should lead to a final diagnosis concerning the presence or absence of HES and the presence or absence of an underlying disease.

CLINICAL MANIFESTATIONS OF HES IN VARIOUS ORGAN SYSTEMS AND DIFFERENTIAL DIAGNOSIS

Depending on the type of disease and other factors, a number of different organ systems may be involved in patients with HES. The most commonly involved organs are the skin, lungs, GI tract, heart, and the CNS (see Table 71.7). In some patients, the relationship between HE and the typical clinical signs and symptoms are pathognomonic, whereas in other cases a tissue biopsy may be required to confirm HE-related organopathy.

Cardiac Manifestations in Patients With HES

Prior to the advent of improved diagnostics and management, and novel therapeutic approaches, cardiac disease was the leading cause of morbidity and mortality in patients with HES. Endomyocardial thrombosis and fibrosis are often documented in HES_N, particularly in association with the *F/P* fusion gene, but are also seen in other variants of HES, including tropical forms induced by (persistent) parasitic infections and other reactive forms of HES. A thorough cardiac evaluation including an ECG and echocardiogram is mandatory in all patients with HE, and cardiac magnetic resonance imaging (MRI) may be helpful in distinguishing a HE-related cardiac disease from other etiologies. In uncertain cases, troponin levels and B-type natriuretic peptide levels may be helpful parameters. An endomyocardial biopsy may be required in some of these patients in order to establish the definitive diagnosis, but biopsies are usually not performed in daily practice.

The cardiac damage seen in HES usually progresses from early necrotic changes through thrombosis and fibrosis. The presence of eosinophils in the myocardium is always abnormal and highly suggestive of eosinophil-mediated organopathy. Identical forms of cardiac pathology can develop in patients with HES forms of diverse etiologies, including tropical eosinophilias caused by parasitic infections, drug reactions, eosinophilic leukemias, MPN-eo, solid tumors,

Fig. 71.3 DIAGNOSTIC ALGORITHM FOR PATIENTS WITH EOSINOPHIL DISORDERS. The first important step in the algorithm is to confirm the presence of HE, defined by a persistent (>4 weeks) increase in eosinophils above 1500/ μ L blood. The next important question is whether HE is reactive (HE_R) or neoplastic (clonal = HE_N) in nature. In patients with HE_N , WHO criteria should be applied in order to define the underlying molecular lesion. In addition, morphologic and histopathologic criteria are used to arrive at a final diagnosis regarding the underlying disease. In patients with HE_R , an underlying disease must also be defined. In both groups of patients, the next important question is whether (or not) HE-related organ damage is present. If such organopathy is found, it is appropriate to diagnose the (additional) presence of HES. According to the underlying etiology (disease), HES is classified again into HES_R and HES_N . In some patients with HES, a clonal T-cell population, but no lymphoproliferative disease, is detected. In these patients, the HES_L variant is diagnosed. If no clonal T cells and no underlying reactive or neoplastic condition is detected in a patient with HES, the (provisional) diagnosis of an HES_I is established. If no underlying disease and no HES is detected, the patient has HE_{US} by definition. Familial cases of HE or HES are very rare, and the same holds true for hereditary syndromes and mono-organ syndromes accompanied by HE. HE, Hypereosinophilia; HES, hypereosinophilic syndrome; HES_F , familial HES; HES_I , idiopathic HES; HES_L , lymphoid variant of HES; HES_N , primary (neoplastic) HES; HES_R , reactive HES; HE_{US} , HE of undermined (unknown) significance; WHO, World Health Organisation.

CSS and lymphomas. However, some of these patients may never go on to develop cardiac involvement, suggesting that disease manifestation likely involves as yet undefined factors required for HE-related tissue damage. The histopathology of cardiac involvement in HES is well characterized and can evolve through three sequentially defined stages in which eosinophils and eosinophil-derived mediators may be involved. These include (1) an initial acute necrotic stage of short duration (a few weeks) involving active endomyocarditis, (2) a later thrombotic stage (several months) with mural thrombus formation over endocardial lesions, and (3) a late fibrotic stage (after approximately 2 years of illness) with development of endomyocardial fibrosis. The early necrotic stage of cardiac disease is usually not recognized clinically. Echocardiography and angiography may fail to detect abnormalities at this early stage because ventricular thickening has not yet occurred and endomyocardial biopsies, generally from the right ventricle, are required to make the correct diagnosis of cardiac involvement. In the second stage, thrombi form over the damaged endocardium in either of the ventricles or the atrium,

generally with sparing of the aortic and pulmonary valves. Progressive scarring at sites of mural thrombus formation ultimately leads to the late fibrotic stage, with endomyocardial fibrosis resulting in a restrictive cardiomyopathy and mitral or/and tricuspid valve regurgitation (see Table 71.7). The more common clinical manifestations in the later progressive stages of endomyocardial fibrosis include dyspnea, chest pain, signs of left or right ventricular congestive heart failure, or both, murmurs from mitral valve regurgitation, cardiomegaly, and T-wave inversions. Most patients who progress to this stage of HES-related cardiopathy have echocardiographic abnormalities, with thickening of the left ventricular wall being a common finding. However, electrocardiographic and MRI changes in these patients are not specific to HES. Differential diagnoses include infectious etiologies (endomyocarditis), CSS, autoimmune disorders such as rheumatoid arthritis, Marfan syndrome, thyroid disorders, and ischemic heart disease. Although various imaging techniques are helpful in evaluating HES-related cardiopathy, endomyocardial biopsy from the right and left ventricle remains a

gold standard in diagnostic evaluation in patients with HE-related cardiopathy.

Pulmonary Manifestations

Approximately 50% of HES patients have pulmonary involvement, with the most common symptom being a chronic and persistent (nonproductive) cough. In order to confirm pulmonary manifestation in HES, a number of studies may be helpful, including pulmonary function tests, chest radiography and/or CT scan, and bronchoscopy with BAL studies and a tissue biopsy if necessary. The physiologic basis of pulmonary involvement in HES remains unknown. As in the heart, several different eosinophil-derived (cytotoxic and stroma-targeting) mediators and cytokines may act together to induce tissue damage and tissue remodeling, as well as fibrosis and thrombosis. Some of the pulmonary features may also reflect changes secondary to congestive heart failure. Although bronchospasm has been noted in some patients, full-blown asthma is rare in HES patients. Transudative pleural effusions are mostly seen in patients with frank congestive heart failure. In contrast to chronic eosinophilic pneumonia, the pulmonary infiltrates seen in HES patients are either diffuse or focal, without any preference for particular regions of the lung. Pulmonary infiltrates in HES often clear with prednisone treatment, but not all patients are responders. Pulmonary fibrosis is rare, but can develop in patients with endomyocardial fibrosis. The differential diagnosis of HES_R with pulmonary involvement includes drug allergy, CSS, chronic eosinophilic pneumonia, severe allergic bronchial asthma with eosinophilia, allergic bronchopulmonary aspergillosis, and other eosinophilic lung infections.

Cutaneous Manifestations

The skin is frequently involved in HES, with cutaneous lesions present in over 50% of all cases. In these patients, the cutaneous lesions fall into three categories: (1) angioedematous and urticarial lesions; (2) erythematous, pruritic papules and nodules; and (3) mucosal ulcerations (see Table 71.7).¹⁸ Patients with angioedema and urticaria are more likely to have a benign disease that is responsive to corticosteroids, without the development of cardiac or neurologic symptoms. A subgroup of patients with cyclical angioedema and eosinophilia are considered to have a syndrome (episodic angioedema with eosinophilia = Gleich syndrome) that is distinct from classical HES. These patients have a disorder with recurrent attacks of angioedema and urticaria accompanied by fever and weight gain. In HES patients with papular or nodular lesions, dermal biopsies usually show mixed cellular infiltrates, including eosinophils, without signs of vasculitis. Perivascular eosinophilic infiltrates are also found in these lesions. In a group of HES patients with skin involvement, the erythematous pruritic eruptions and indurated papules and nodules may respond to psoralen and ultraviolet light A. In other patients with HES-associated pruritus, the nodular lesions may respond to dapsone and corticosteroids. Oral sodium cromoglycate (cromolyn sodium), administered before meals, has also been reported to be efficacious, although neither dapsone nor cromolyn is able to reduce eosinophil counts in the blood. Severe and sometimes incapacitating mucocutaneous ulcerations may be a prodrome to HES and indicate a subset of HES patients with a poor prognosis. These lesions can appear at multiple sites, including the mouth, nose, pharynx, penis, esophagus, stomach, and anus. The lesions can flare up independently of other clinical manifestations of HES. Biopsies of the ulcerative lesions usually show mixed cellular infiltrates, without a predominance of eosinophils or any evidence of vasculitis or microthrombi. These ulcers are usually resistant to treatment with corticosteroids, colchicine, and hydroxyurea (HU), but they usually respond to interferon- α (IFN- α), with complete and durable remissions in most patients. There are a number of differential diagnoses that have to be considered in HES patients with suspected skin involvement, including drug reactions, local infections, and atopic eczema.

Neurologic Manifestations

Neurologic involvement is quite common in HES, affecting approximately 50% of all patients. In these cases, three different types of manifestations have been described. The first form of neurologic involvement is caused by thromboemboli, which may originate from intracardiac thrombi in the left ventricle but may also develop locally in cerebral vessels. Some of these thromboembolic episodes may occur before an overt cardiac manifestation has been documented. Patients with thrombotic complications may experience embolic strokes or transient ischemic attacks that may be multiple and recurrent, and these episodes may occur even though the patient is adequately anticoagulated. The second type of neurologic manifestation is primary diffuse CNS involvement. These patients may variably exhibit changes in behavior, confusion, ataxia, and loss of memory. The third neurologic abnormality noted in HES is the development of peripheral neuropathy, which can occur in approximately 50% of HES patients exhibiting neurologic involvement. This includes symmetric or asymmetric sensory polyneuropathies, including sensory deficits, painful paresthesias, or mixed sensory and motor defects (see Table 71.7). These neuropathies may improve with corticosteroid administration or other treatments, and may be stable or continue to progress despite therapy, or may improve or even resolve with time. The histopathology of the involved nerves usually shows varying degrees of axonal loss, without evidence of vasculitis or direct or peripheral eosinophil infiltration. Whether eosinophil-derived EDN and/or ECP, known to cause neurotoxicity in experimental animals, are involved in the development of neuropathies in HES remains unknown. Based on immunohistochemical studies, these proteins are not detectable at the sites of ongoing neuropathology in HES patients. All in all, the etiology of HES-related neuropathy remains poorly defined. Differential diagnoses of HES-related neuropathies are manifold and include, among others, neurodegenerative disorders, multiple sclerosis, and CNS infections.

Gastrointestinal Manifestations

Compared to lung or skin, GI tract involvement is less common in patients with HES. Although any form of HES can present with GI tract manifestation, GI tract symptoms are mostly recorded in patients with HES_R or the idiopathic form of HES. In these patients, a wide variety of symptoms and findings have been described, including abdominal pain, vomiting, diarrhea, or ulcerative disease, but also ascites or an overt colitis (see Table 71.7). These patients may also report bloody diarrhea and weight loss. Histologically, GI tract involvement with HES is characterized by an infiltration of the mucosa and submucosa with eosinophils. Immunohistochemical examination may reveal a huge infiltration with eosinophils as well as extensive deposition of extracellular eosinophil proteins in the gastric mucosa. In most patients with reactive HES, the GI tract disease component responds to treatment with oral corticosteroids. Differential diagnoses of GI tract involvement with HES include localized (organ-restricted) inflammatory disorders, such as eosinophilic esophagitis, eosinophilic gastroenteritis, eosinophilic colitis, autoimmune diseases, chronic inflammatory bowel disease, GI infections, GI tract lymphomas, and GI tract involvement in patients with SM. Especially in patients with SM, the underlying disease is often overlooked, since neoplastic mast cells are outnumbered by the infiltrating eosinophils. In these cases, the use of mast cell-related immunohistochemical markers, such as tryptase, KIT (CD117), or CD25, may be helpful to diagnose an underlying SM.

Hematologic Manifestations and BM Involvement

In HES patients suffering from an underlying myeloid neoplasm (HE_N, HES_N), the BM is almost always involved. In these patients, the BM is often hypercellular and shows a substantial increase in eosinophil numbers. In addition, alterations in the BM

microenvironment, including neoangiogenesis and BM fibrosis, is usually detected in these patients. Depending on the underlying neoplasm, other hematopoietic lineages may also be affected and may show typical morphological or phenotypic aberrations. Depending on the underlying neoplasm, eosinophils may be mature or (rather) immature cells (Fig. 71.2B and C). The BM is also affected in patients with reactive or idiopathic HES. However, in these patients eosinophils are usually mature cells and no major alterations in the BM microenvironment or abnormalities in other hematopoietic lineages are found.

Apart from eosinophilic leukemias, a number of different underlying BM neoplasms may be identified, such as a MPN, myelodysplastic syndrome (MDS), MDS/MPN overlap syndrome, acute myeloid leukemia (AML), or, rarely, a lymphoid malignancy.¹⁷ In these patients, various blood count abnormalities may be present, such as neutrophilia, monocytosis, basophilia, thrombocytosis, a left-shifted white blood count, or an increase in blasts. In some cases, anemia or/and thrombocytopenia with or without increased blast cells or dysplasia is found, consistent with the diagnosis of an overt MDS, a MDS/MPN overlap syndrome, or AML. In rare cases, a stem cell neoplasm with involvement of both the myeloid and lymphoid lineage is detected. In these patients, an *FGFR1*-rearranged neoplasm (previously referred to as *8p11 myeloproliferative syndrome* or *stem cell leukemia/lymphoma syndrome*) may be diagnosed.¹³ The prognosis is poor in these patients. In some patients with CEL, a massive leukocytosis is found. In these cases, eosinophilia of more than 90% may be seen, and total leukocyte counts may exceed 50,000 or even 100,000/mm³. Extremely high leukocyte (eosinophil) counts are more commonly seen in patients with HES_N in the context of CEL and are considered to be associated with a more unfavorable prognosis. Blood smears from patients with HES_R and HES_I generally show more or less normal, mature eosinophil morphologies, including typical bilobed nuclei and granule-rich cytoplasm. However, hypodense eosinophils and eosinophilic precursor cells may be recorded, although less commonly, and eosinophils may also exhibit morphologic abnormalities, including nuclear hypersegmentation, decreased size and/or numbers of secondary granules, and cytoplasmic vacuolization. Mast cells may be increased in number in HES patients, especially in *F/P+* cases, where these cells usually belong to the neoplastic clone. The presence of myeloblasts and/or dysplastic findings in the PB may suggest AML or MDS. Splenomegaly is present in a substantial subset of patients with HES, mostly in those with an underlying myeloid neoplasm, but sometimes also in cases with a reactive form of HES or idiopathic HES. In patients with markedly enlarged spleens, hypersplenism may develop and may contribute to thrombocytopenia and anemia. In these patients, splenic pain induced by capsular distention or infarction are well-known complications.

Underlying Hematologic Disorders and Differential Diagnoses

Although various hematologic neoplasms may be accompanied by eosinophilia, only a few of these are associated with persistent HE (HE_N) and HE-related organ damage (= HES_N). For example, mild-to-moderate eosinophilia may be detected in Philadelphia chromosome-positive (Ph⁺; BCR-ABL1⁺) chronic myelogenous leukemia (CML) and various Ph⁻ MPNs, but marked HE is unusual and HES is rarely found in these patients. However, in a few patients with CML or MPNs, excessive HE may develop. In these patients, HE is usually responsive to BCR-ABL1 kinase inhibitors in CML, and to conventional cytostatic drugs, such as HU or IFN- α , in MPN. In a few myeloid neoplasms substantial or even excessive HE is a typical finding. These malignancies include the rare variant of acute eosinophilic leukemia (AEL), the more common variant of CEL that is often associated with a *F/P* fusion gene, and other forms or CEL or MPN-eo with rearrangements involving *PDGFRA*, *PDGFRB*, or *FGFR1*.¹³ Other patients with CEL may fulfill the criteria of the WHO category CEL, NOS (see Table 71.6).¹⁴ Rarely, HE_N is found in patients with MDS. In most cases with dysplastic BM and HE,

however, additional signs of myeloproliferation are found, consistent with a diagnosis of a MDS/MPN overlap syndrome or frank MPN. Another myeloid neoplasm that is often accompanied by HE is SM.¹⁹ In fact, HE_N is frequently seen in patients with advanced SM, including aggressive SM and mast cell leukemia (see Table 71.6). Most of these patients develop HE without HE-related organ damage (HES). In rare cases, lymphoid neoplasms may also present with HE. In these patients, a T-cell lymphoma is most commonly detected as underlying disease during initial staging investigations or during follow-up. In most patients with T-cell lymphomas accompanied by HE, eosinophils are nonclonal cells. By contrast, in patients with fusions involving *FGFR1*, where stem cells are considered to give rise to malignant cells, both eosinophils and lymphocytes are clonally involved. The prognosis in these patients is grave.

Several different concepts by which to classify eosinophil neoplasms have been proposed in the recent past.²⁰ The WHO has classified eosinophil-related disorders according to the presence of certain molecular lesions, including abnormalities in the *PDGFR* or *FGFR* genes (see Table 71.6).¹⁴ The advantage of this approach is that it refers to molecular targets of therapy. As a result, therapeutic decisions may be directly based on a WHO-based diagnosis. However, independent of the clinical presentation and markers, the WHO classification has to be complemented by a final histopathologic diagnosis, which in turn is based on thorough morphologic, histopathologic, and immunohistochemical studies of the BM.^{3,17} Based on a proposal of the ICOG-EO group,³ the following underlying neoplasms have to be delineated (see Table 71.8A):

Acute Eosinophilic Leukemia

This type of leukemia is defined by HE, more than 19% ($\geq 20\%$) myeloblasts and greater than 29% ($\geq 30\%$) eosinophils in BM smears (see Table 71.8A).³ Other classical types of MPN and CML must be excluded. AEL is an extremely rare disease. Eosinophils in these patients may be quite immature, hypogranulated cells, or represent a

TABLE 71.8A

Histopathologic Classification and Criteria of Eosinophilic Leukemias and Other Myeloid Neoplasms Presenting With Hypereosinophilia

Neoplasm(s)	Abbreviation	Definition/Criteria
i. Acute eosinophilic leukemia	AEL	HE and eosinophils $\geq 30\%$ and myeloblasts $\geq 20\%$
ii. Chronic eosinophilic leukemia	CEL ^a	HE and eosinophils $\geq 30\%$ and myeloblasts $< 20\%$ and no underlying stem cell-, myeloid or lymphoid neoplasm found
iii. Other myeloid neoplasm (MN) or stem cell neoplasm with HE: MPN-eo, MDS-eo, SM-eo,	MN-eo	MN or stem cell neoplasm by WHO or FAB criteria and HE, but eosinophils $< 30\%$

The histopathological classification of eosinophil disorders assists the WHO-based delineation of neoplasms presenting with eosinophilia (HE). In a first step, the diagnosis is based on the WHO definition as molecular and cytogenetic abnormalities are examined. In a second step, the final histomorphologically defined diagnosis needs to be established using the criteria depicted in this table.³ Values for eosinophils and blast cells refer to the bone marrow smear. In rare cases (acute leukemia), eosinophils may be quite immature and may escape conventional morphological identification. In these cases, immunophenotyping or electron microscopy may be required.

^aIn order to diagnose CEL, the following cytogenetic and molecular defects have to be excluded as primary reason of HE: *BCR-ABL1*, *inv(16)*, *t(16;16)*, *JAK2 V617F*.

FAB, French–American–British Cooperative Study Group; HE, Hypereosinophilia; MDS, myelodysplastic syndromes; MPN, myeloproliferative neoplasm; WHO, World Health Organization.

mixture of mature and immature eosinophils. In some of these patients, a prodrome of MDS or MPN without HE occurs. In addition, *F/P+* patients with CEL or *F/P+* MPN-eo may progress to AEL during their terminal phase. However, no (other) recurrent cytogenetic or molecular marker has been identified in AEL patients. The clinical course in AEL is unfavorable. Chemotherapy and stem cell transplantation are usually recommended. Major differential diagnoses are AML M4-eo with *inv16*, CEL with signs of progression, and SM-AHN-eo (e.g., SM-AML-eo).

Chronic Eosinophilic Leukemia

In patients with CEL, eosinophils comprise $\geq 30\%$ of all nucleated BM cells and/or blood leukocytes. As per definition, patients with CEL have overt HE_N and less than 20% myeloblasts in their BM and/or blood smears (see Table 71.8A).³ Usually, blast counts are below 5%. In most patients, neoplastic cells exhibit rearrangements (mutations) in genes coding for *PDGFRA*, *PDGFRB*, or *FGFR1*. Therefore, most patients also fit into the WHO category of “myeloid or lymphoid neoplasms associated with eosinophilia and abnormalities of *PDGFRA*, *PDGFRB*, or *FGFR1*”. Other BM neoplasms need to be excluded by BM examination. Major differential diagnoses include AEL, MPN-eo, MPN/MDS-eo, SM-eo, SM-AHN-eo, and reactive forms of HE/HES. Progression from CEL to AEL is an extremely rare event. However, in untreated patients with *PDGFR* mutations and those with *FGFR1* mutations, progression of CEL to AEL or even AML may occur. The prognosis in CEL depends largely on the molecular lesions detected. In patients with CEL exhibiting *PDGFR* mutations, the prognosis is excellent, as in most cases the disease responds to imatinib. By contrast, in patients with *FGFR1* mutations, the diagnosis is dismal, even when treated with chemotherapy and early allogeneic hematopoietic stem cell transplantation (HSCT) should be considered.

MPN-eo, MPN/MDS-eo, MDS-eo, and SM-eo

The exact nomenclature of myeloid or mast cell neoplasms with marked eosinophilia (HE) is still under debate.²⁰ The ICOP-EO group has recently proposed the use of the appendix “-eo” for patients in whom HE_N is detected but criteria of AEL or CEL are not met.³ In fact, in these patients an underlying MPN, MPN/MDS, MDS, or SM is diagnosed, and HE is present. However, eosinophils comprise less than 30% of all nucleated BM and PB leukocytes. In patients with MPN-eo, MPN/MDS-eo, or MDS-eo, HE may be detected at diagnosis or may develop during the follow-up period. In a small group of patients, mutant forms of *PDGFRs* or the *FGFR* are found. In other patients, karyotype abnormalities are detected, but *PDGFR* or *FGFR* mutants are not found. The molecular mechanisms underlying HE development in these patients usually remains unknown. Differential diagnoses include Ph^+ CML, CEL, AEL, and SM-AHN-eo. The overall prognosis depends on the underlying neoplasm, especially on blast cell counts, karyotypes and the expression of *PDGFR* or *FGFR1* mutants. Therefore, it is important to apply all markers and diagnostic tests in order to define the exact final diagnosis. In MDS and MPN/MDS, the presence of eosinophilia is an independent prognostic factor and indicative of poor survival, especially when HE is accompanied by blood basophilia.²¹ Treatment of patients depends largely on the type of underlying malignancy, but also on the presence of distinct molecular lesions and targets. In advanced stages of the disease, a complex karyotype and complex mutational patterns are often found. These patients are candidates for intensive treatment, including HSCT.

Lymphoid Neoplasms, Lymphomas

A number of different lymphomas may produce eosinophilia, mostly through the generation of eosinophilopoietic cytokines in neoplastic

cells. An exception is the 8p11 myeloproliferative syndrome (*FGFR1*-rearranged neoplasm), where eosinophils are derived from the malignant clone even if the primary tumor was classified as a lymphoma.¹³ Most lymphoma patients with paracrine HE also suffer from a (peripheral) T-cell non-Hodgkin lymphoma (NHL). In these patients, clonal T cells are considered to represent the primary source of eosinophilopoietic cytokines, such as IL-5. A prephase of HES_L or HE_{US} may be present in these patients. The prognosis of patients with peripheral T-cell NHLs is poor, even when treated with chemotherapy, such as cyclophosphamide, hydroxydaunomycin, vincristine (Oncovin), and prednisone. Therefore, allogeneic HSCT is usually recommended for these patients, provided that the patient has an acceptable performance status and a suitable donor is available, and the same holds true for lymphoma patients presenting with an *FGFR1* rearrangement. Relapsing disease after HSCT has an extremely poor outcome. These patients are treated with investigational agents and palliative cytoreduction. A summary of BM neoplasms presenting with HE is provided in Table 71.8B.

Reactive, Immunologic and Paraneoplastic Conditions associated With HE

A number of different nonhematologic malignancies may be accompanied by HE. These include, among others, solid tumors of the GI tract, adenocarcinomas of the lung, carcinomas in other internal organs, skin cancer, urogenital malignancies, and stromal cell-derived tumors. In several of these patients, the cancer cells or the cancer-related microenvironment (e.g., fibroblasts) may produce eosinophilopoietic cytokines. In many cases, PB HE but also tissue eosinophilia (tissue HE) may be recorded. In some of these cancer patients, the tumor cells are tightly surrounded and sometimes even outnumbered by the infiltrating eosinophils. So far, it remains unknown whether tissue HE and eosinophil-derived mediators contributes to tumor formation (through neoangiogenesis or tissue remodeling) or even

hinder tumor formation in these patients. As mentioned earlier, lymphomas may also be accompanied by reactive/paracrine HE.

A number of different immunologic and other reactive conditions can cause reactive HE (HE_R). These include infectious diseases (e.g., helminth infections, HIV, and certain fungal infections), allergic disorders (e.g., asthma, food allergy, atopic dermatitis, and drug reactions), chronic inflammatory reactions, and autoimmune processes (see Table 71.2).¹⁷ Treatment of the underlying disease is usually followed by resolution of HE_R, thereby confirming the etiology of HE. In most reactive conditions, HE is triggered by cytokines derived from activated immune cells, such as T cells or mast cells. In some of these patients, an underlying disease is not detectable, but clonal T lymphocytes and/or lymphocytes with an aberrant surface immunophenotype are present. In such cases, HE-related organ damage may also be seen, which leads to the diagnosis of the lymphoid variant of HES (HES_L).¹⁵

Specific Syndromes and Conditions Associated With HE

Several specific conditions and syndromes defined by HE and organ damage may fulfill the criteria of a HES, but based on traditional views and their unique etiologies, these syndromes are still regarded as distinct entities that should be discriminated from the classical HES variants. In the future, however, most or all of these syndromes may be regarded as a special form of HES. These syndromes include, among others, episodic angioedema and eosinophilia (Gleich syndrome), CSS, eosinophilia myalgia syndrome (EMS), OS, and hyper-IgE syndrome (see Table 71.4A).

Gleich syndrome is characterized by recurrent angioedema associated with eosinophilia (HE), elevated serum cytokine (IL-5) levels, and increased (polyclonal) IgM production.²² The episodes of angioedema and eosinophilia typically occur at monthly intervals and often resolve spontaneously without therapy. Patients with Gleich syndrome may suffer from fever and increasing body weight. The clinical course is usually benign without involvement of internal organs, thereby contrasting the typical HES variants. In a subset of patients, the symptoms and HE persist. These patients usually respond to low-dose corticosteroids. So far, little is known about the pathogenesis of Gleich syndrome. Several lines of evidence suggest that multiple cell types are involved, including neutrophils, mast cells, eosinophils, and T lymphocytes. Whereas most of these cells are considered to be cytokine-mobilized cells, T cells are often found to be clonal in these patients. In fact, in many patients with Gleich syndrome, T-cell phenotyping reveals an abnormal phenotype of CD4⁺ lymphocytes, with decreased or absent CD3 expression (see Table 71.4A).²² In addition, in several of these patients a clonal T-cell receptor rearrangement has been found. Therefore, Gleich syndrome has also been considered as a special (cycling) subvariant of HES_L.

CSS, also known as *eosinophilic granulomatosis with polyangiitis* (EGPA), is defined by a disseminated necrotizing vasculitis that is accompanied by asthma and (tissue) eosinophilia (HE).²³ CSS is a small-vessel vasculitis characterized by the formation of extravascular granulomas and the production of antineutrophil cytoplasmic antibodies (ANCA). Both, tissue HE and the ANCAs produced in these cases are considered to play an active role in the pathogenesis of CSS. However, the exact etiology of CSS remains unknown. More recent data suggest that CSS/EGPA may be a Th2-mediated disease. Clinically, CSS develops in three distinct phases: the initial (early) phase is characterized by asthma and rhinosinusitis, the eosinophilic phase is defined by HE_R and HE-related organ involvement, and the late ("vasculitic") phase is defined by clinical manifestations originating from the small-vessel vasculitis (see Table 71.4A). CSS is a systemic disease that may affect a number of different organ systems, including the lungs, skin, kidneys, nerves, and heart. Criteria for CSS have been proposed by various expert groups. According to the American College of Rheumatology, the following criteria define CSS: asthma, eosinophilia (>10%), neuropathy (mononeuropathy or

polyneuropathy), pulmonary infiltrates, paranasal sinus abnormalities, and extravascular eosinophil infiltrates on tissue biopsies. When four out of these six criteria apply, the diagnosis CSS can be established. Based on the considerable clinical overlap with classical HES variants, CSS is also regarded as a special HES variant, defined by an ANCA+ vasculitis. The prognosis of patients with CSS depends on a number of clinical variables, including lung involvement, duration of disease, and response to therapy. Treatment of patients with CSS is based on the individual situation in each case and the presence or absence of prognostic factors. A combination of high-dose corticosteroids and cyclophosphamide remains a standard for treatment. More recently, antibody-based drugs, such as rituximab or mepolizumab, have been proposed as therapeutic alternatives and should be considered in cases resistant to cyclophosphamide.

EMS is a flu-like condition defined by recurrent episodes of myalgia and persistent eosinophilia. In many patients, neurological symptoms and skin abnormalities are found. In addition, patients may suffer from fever, weight loss, edema, and severe fatigue. The etiology of EMS remains uncertain. A clue to pathogenesis was the detection of a relationship between EMS and exposure to contaminated L-tryptophan or rapeseed oil (toxic oil syndrome). EMS is an incurable disease, but fatal cases are rare. As in Gleich syndrome and CSS, the clinical overlap with HES is obvious, and many experts believe that EMS could be regarded as a special subvariant of HES.

Eosinophilic fasciitis (EF) is a scleroderma-like syndrome with HE, polyclonal hypergammaglobulinemia, and signs of systemic inflammation. The etiology of EF remains unknown, but most authors regard EF as an immunologic hyperreactivity disorder manifesting in the skin. Painful swelling of the skin with progressive induration and thickening of the skin and soft tissues of the limbs and trunk are typical clinical findings. Corticosteroids are usually prescribed and have been shown to be efficacious in EF patients. In a subset of patients, spontaneous improvement is found. Again, based on clinical findings and HE, it is difficult to differentiate between EF and skin involvement in HES_R.

OS is a rare, autosomal recessive form of severe combined immunodeficiency (SCID) associated with leukocytosis, HE, elevated IgE levels, and a high mortality rate. Recognition in early childhood is required in order to initiate life-saving therapy. OS is caused by hypomorphic missense-mutations in the recombination-activating genes *RAG1* and *RAG2* (see Table 71.4A). Unlike patients with typical SCID, patients with OS have well-populated lymphatic organs and usually suffer from diarrhea, hepatosplenomegaly, lymphadenopathy, and weight loss. In addition, severe erythroderma, increased IgE levels, and eosinophilia are found in most cases. HE and inflammation observed in these patients may result from the activity of clonally expanded T cells, which are predominantly of the Th2 type. Overall, the disease presents very similar to a graft-versus-host reaction, which is due to patients producing T cells with limited recombination ability (mutant *RAG* genes) and a specific affinity for self-antigens, making them autoreactive T lymphocytes. Other SCID-related mutations may also lead to an OS-like disease, including certain mutations in the *IL-7 receptor (IL-7R)* gene. The treatment of choice in OS is allogeneic HSCT. For patients who cannot be transplanted or need a bridging therapy prior to allogeneic HSCT, cyclosporine A (CSA) may be considered.

Hyper-IgE syndromes (HIES) are a group of rare hereditary immunodeficiency syndromes characterized by elevated IgE levels, severe recurrent infections, and HE. In many cases, skin eczema and facial anomalies are found. So far, little is known about the pathogenesis of the HIES. The disease can manifest as an autosomal dominant or autosomal recessive variant. Several different genes may be affected. In the autosomal dominant variant, *STAT3* mutations are most commonly described. Since *STAT3* acts as a key transcription factor downstream of multiple cytokine receptors regulating diverse immunologic responses, impaired *STAT3* function is likely to cause immunodeficiency. In the autosomal recessive HIES variants, mutations in *DOCK8* and, less commonly, in the phosphoglucomutase 3 (*PGM3*) gene, have been reported (see Table 71.4A). The natural course of HIES patients is variable, but overall the long-term

prognosis is poor. Therefore, early allogeneic HSCT should be considered whenever possible.

Organ-Restricted HE Syndromes

There are other clinical conditions and syndromes accompanied by HE-related organ damage that cannot be classified (diagnosed) as typical HES. A special group of such disorders are organ-restricted inflammatory conditions, such as eosinophilic colitis, eosinophilic pneumonia, or eosinophilic esophagitis (see Table 71.4B). In these patients, cytokine production and disease manifestations are typically restricted to one single-organ system, in contrast to the classical forms of HES and most of the above-described specific syndromes. The etiology of these organ-restricted HE syndromes remains largely unknown. In many instances, infectious or toxic agents or specific allergens are felt to play a pathogenetic role. In addition, genetic or epigenetic factors may contribute to disease manifestations. Depending on disease severity, suspected etiology, and presence of comorbidities, a treatment-plan is established. In many cases, corticosteroids are prescribed. In those with suspected allergy, additional drugs, such as antihistamines or leukotriene antagonists, have been recommended. The prognosis is variable and depends largely on the underlying etiology and response to treatment. Most patients respond to corticosteroids. In some patients, an underlying (initially unrecognized) systemic disease, infectious disease, or local tumor is diagnosed during follow-up. In these patients, the prognosis and treatment depends on the type and stage of the underlying disease.

TREATMENT ALGORITHM, TREATMENT OPTIONS AND PROGNOSIS

When establishing the management plan for a patient with HE, several important questions have to be addressed. First, the final diagnosis concerning the presence or absence of HES, and the presence and nature of the underlying disease, if present, has to be firmly established. Second, it is important to decide whether the patient needs symptomatic or/and interventional therapy. In some of these HE patients, a wait-and-watch strategy may be acceptable, whereas in other cases (when HES is diagnosed) specific therapy needs to be introduced quickly. Finally, the optimal treatment plan and most useful drugs need to be defined. The type of therapy varies depending on the underlying condition and the type of HES.²⁴

Primary Management and Algorithm

In many cases, treatment of HES is a straightforward approach. For example, reactive HES is often managed (and resolved) quite easily by treating the underlying disease, such as a helminth infection or an autoimmune disease. In cases with idiopathic HE or HES and those with advanced or aggressive disease, however, treatment should always be performed in collaboration with a specialized center and in an interdisciplinary approach involving hematologists, immunologists, pathologists, and/or laboratory specialists, as needed.

In patients with HE_{US} and HE_B, it seems appropriate to follow the patient without treatment provided there are no signs or symptoms of eosinophil-related organ damage despite careful medical monitoring. However, both HE_{US} and HE_B must be regarded as provisional diagnoses, and in both conditions organ damage may develop over time. In addition, a hematologic or other underlying disease may be detected during follow-up of these cases. In the reactive form of HES, it is important to define and to treat the underlying condition. Additional symptomatic therapy, often in the form of corticosteroids, may be required to control eosinophil activation in these patients, especially when eosinophil counts are high or/and cells undergo rapid lysis, which may occur during treatment with cytotoxic drugs.²⁴

In the past, most patients with HES received corticosteroids as front-line therapy. However, this strategy has changed with more

extensive knowledge about the pathogenesis of HE and HES etiologies, and the advent of novel drugs such as PDGFR-targeting TKIs. Notably, today, front-line therapy is largely dependent on the underlying disease and the molecular targets detectable in neoplastic cells.²⁴ In patients in whom eosinophils display mutated forms of PDGFRs, imatinib is considered standard front-line therapy. By contrast, in patients with idiopathic HES (HES_I) and those with HES_L, corticosteroids remain standard front-line therapy. However, there are also patients in whom an initial staging and grading and/or molecular studies suggest that neither steroids nor imatinib will work. These cases include, among others, patients with an advanced myeloid neoplasm without a *PDGFR* mutation (e.g., AML-eo, MDS-eo, or SM-eo) and patients with rearranged *FGFR* genes. In many of these cases, the primary treatment plan includes intensive chemotherapy and allogeneic HSCT.

All in all, a number of different therapeutic approaches for the treatment of HES and of the underlying (eosinophil) disorder(s) detected in these patients are available. In the following sections, these treatment approaches are briefly reviewed and discussed.

Corticosteroids

In patients with idiopathic HES (HES_I) and HES_L, corticosteroids are considered standard front-line therapy. By contrast, in patients with HES_R and HES_N, corticosteroids should only be considered as an adjunct to more specific treatment, in order to stop eosinophil activation and eosinophil recruitment as early as possible. In patients with a (suspected) infection, diabetes mellitus, an ulcerative GI tract disease, or arterial hypertension, corticosteroids should be administered with caution and with recognition of potential side effects and the related risk. In patients with HES_I and HES_L, corticosteroid therapy, usually in form of prednisone at 1 mg/kg/day (initial dose) is usually effective in reducing eosinophil counts to normal levels, with overall response rates of >75% in HES_I. In contrast, most patients with HES_N do not respond to corticosteroid therapy.

The mechanisms of action by which corticosteroids suppress HE in HES_I and HES_L patients are only partly understood. Steroids act through specific corticosteroid receptors that are present in the cytoplasm of eosinophils and eosinophil precursor cells, but also in the cytoplasm of T lymphocytes and mast cells. It has also been described that steroids effectively block the production of various eosinotropic cytokines by T lymphocytes. In addition, corticosteroids effectively counteract T-cell expansion. Based on these effects, corticosteroids may act directly and indirectly to block HE in HES patients, namely by (1) inducing growth inhibition and apoptosis of eosinophils and their precursor cells, by (2) directly blocking eosinophil recruitment and migration, and by (3) inhibiting the production and release of eosinophilopoietic cytokines by T lymphocytes and other immune cells.

As mentioned earlier, long-term treatment with steroids is associated with a risk of (severe) side effects. Therefore, steroids should be tapered down (and discontinued) whenever possible, especially in cases with HES_R and HES_N. However, in many patients with HES_I, maintenance therapy with corticosteroids is required to control disease activity. In these patients, the steroid dose applied should be reduced to a minimum. In fact, even though corticosteroids are “natural” substances and very effective in reducing eosinophil counts in HES_I, chronic use of steroids is associated with the risk of serious adverse events and long-term toxicity. Once reduction of the eosinophil count to below 1500/mm³ and symptom control have been achieved, the corticosteroid dose should be tapered. Increases in eosinophil numbers on a prednisone dose greater than 10 mg daily and/or reappearance of symptoms or signs of organ damage are indications for the addition of other agents to the steroid regimen. A number of different drugs may be useful as steroid-sparing agents in patients with HES. These drugs include, among others, conventional cytostatic agents such as HU or cyclophosphamide, IFN- α , and the IL-5-targeting antibody mepolizumab.²⁵

Conventional Cyto reduction and Chemotherapy

Several studies have shown that HU (0.5–2 g/day), is efficacious in steroid-nonresponsive patients with HES, including those with HES_I and HES_N. In patients with HES_I, HU is administered as an alternative drug or in conjunction with corticosteroids as a steroid-sparing medication. A typical starting dose is 500–1000 mg daily. In combination with corticosteroids, the overall response rate exceeds 50%. Eosinophil counts begin to decrease 7–14 days after starting HU treatment. Depending on the dose, HU may induce cytopenias. Otherwise, HU is usually well tolerated unless very high doses are administered, and is therefore also used as a palliative drug in HES_N patients resistant to targeted drugs and chemotherapy. However, not all patients with HES may respond to HU. Historically, a number of cytotoxic agents have been used to treat HES refractory to steroids and HU, including vincristine, etoposide (VP-16), and chlorambucil. However, each of these agents can produce cytopenias and other side effects, and their use should be limited to select patients with HES in whom neoplastic cells develop resistance against other agents including HU. In patients with advanced, resistant CEL or AEL, but also in patients with AML-eo, other advanced myeloid neoplasms with *FGFR1* rearrangement (8p11 myeloproliferative syndrome), intensive polychemotherapy and allogeneic HSCT are usually recommended. These chemotherapy regimens are usually the same as applied in patients with refractory leukemias without HE/HES. Chemotherapy before allogeneic HSCT is often a preferable initial approach for two reasons: first, debulking may result in remission, and patients in remission have in general a better overall outcome after allogeneic HSCT. In addition, chemotherapy can provide some indication as to whether a patient can tolerate intensive therapy. On the other hand, multiple cycles of chemotherapy increase the risk of infections, which may be problematic in the context of a planned allogeneic HSCT.

Interferon- α

IFN- α has been used for the treatment of HES for more than 25 years, both as monotherapy and in combination with other agents. A number of studies have shown that this type of therapy can successfully counteract HE and HES in patients in whom treatment with prednisone and HU has failed. Response rates to IFN- α vary depending on the underlying disease and dose, but may be approximately 50% when used as monotherapy and 75% in combination with other agents. Usually, therapy is initiated at a dose of 1 million units three times a week, and is titrated up to 4 million units three times weekly. In the responding patients, eosinophil counts decrease, and improvement in splenomegaly and hepatomegaly has been reported. Moreover, the risk of cardiac and thromboembolic complications can be reduced by treatment with IFN- α . Finally, mucosal ulcerative lesions and other skin manifestations may substantially improve. The unprocessed and the pegylated form of IFN- α may be equally effective. However, despite efficacy, the administration of IFN- α is problematic because of side effects. These side effects are often dose dependent and include fever, a flu-like syndrome, fatigue, impotence, depression, suicidal ideation, and psychosis. In addition, IFN- α therapy may lead to exacerbations of autoimmune disorders, such as autoimmune thyroiditis, psoriasis, ulcerative colitis, and others, but also to exacerbation of depression or other psychiatric diseases. Other serious adverse events observed with IFN- α include excessive suppression of blood counts, retinopathy, sarcoidosis, and left-sided heart failure. All these (potential) side effects have to be taken into account, especially when prescribing IFN- α on a long-term basis at relatively high doses. On the other hand, IFN- α is non-mutagenic and is considered a drug that can be prescribed even during pregnancy. The mechanism of action of IFN- α is not well understood. Receptors for this cytokine are expressed on multipotent hematopoietic progenitor cells, eosinophil-committed precursors, and mature blood eosinophils. Therefore, in contrast to corticosteroids, IFN- α works in HES patients with diverse etiologies, including HES_I, but also in HES_N and even in HES_I. IFN- α inhibits eosinophil activation and the

release of various toxic mediators from eosinophils. However, IFN- α may also exert an antiinflammatory effect on other cell types that may contribute to tissue damage in HES.

Cyclosporine A (CSA)

CSA, an immunosuppressant that interferes with multiple functions and growth of immunocompetent T lymphocytes, has been reported to be effective in a subset of patients with HES. The goal of CSA treatment in HES is to inhibit production of eosinophilopoietic cytokines, including IL-5, by T cells in these patients. CSA has been used as a single agent or in conjunction with low-dose corticosteroids. In those with steroid-sensitive disease, CSA may act as a steroid-sparing agent. However, good responses may only be seen in distinct variants of HES, namely those HES variants where T-cell activation is a causative etiology. Another important point is that efficacy has so far only been described for CSA in short-term-treated HES patients (10 months), whereas long-term efficacy has not been determined so far. In each case, the side effects and immunosuppressive effects of CSA have to be taken into account. In patients with HES_N, CSA should not be administered.

Targeted Treatment Approaches Using Tyrosine Kinase Inhibitors

Several different oncogenic kinases have been detected in primary eosinophilic disorders (mostly CEL and MPN-eo) and serve as targets of therapy.¹³ The most relevant and most frequent target kinase detectable in patients with CEL is *F/P*. This fusion gene product is a target of imatinib and also sensitive to other TKIs, such as nilotinib, dasatinib, PKC412 (midostaurin), or ponatinib. A number of other oncoproteins may also serve as targets of imatinib and are detectable in primary eosinophil disorders. Most of these fusion genes involve *PDGFRA* or *PDGFRB*, whereas *FGFR1* mutants are imatinib resistant. The hematologic benefit of imatinib in *F/P*-positive neoplasms and *PDGFRB*-rearranged neoplasms has been confirmed in several clinical trials.^{26,27} Therefore, imatinib is regarded as standard first-line therapy in these patients. Given the poor prognosis in patients with overt organ damage (HES_N), patients with an *F/P*+ neoplasm or another mutation involving *PDGFRA* or *PDGFRB* genes should be treated with imatinib, even in the absence of end-organ damage, in order to prevent any HES occurrence. Although the optimal dosing strategy for imatinib has not been fully defined, a number of studies have shown that a daily dose of 100 mg appears to be sufficient to induce complete hematologic and molecular remission in most patients.²⁶ Moreover, 100 mg imatinib/day appears to be a safe approach in all patients, including those who suffer from cardiac involvement. Therefore, 100 mg/day is regarded a standard dose of initial therapy with imatinib in *F/P*+ CEL. However, in a few patients with *PDGFRA*- or *PDGFRB*-rearranged neoplasms, higher doses of imatinib (400 mg daily) are required to induce a durable remission. In those who enter a hematologic and molecular remission, imatinib is usually maintained, as discontinuation is often followed by a relapse.²⁸ However, it remains unknown whether all patients need to continue on their initial dose on a life-long basis. In fact, it has been described that many of these patients do not relapse when lowering the dose of imatinib or even when imatinib is discontinued. In other patients, however, resistance against imatinib may occur. In relapsing patients, *F/P* point mutations associated with decreased (or loss of) drug-binding capacity may be detected. For these patients, novel TKIs, such as sorafenib, nilotinib, midostaurin, or ponatinib may be considered. The most commonly detected mutant, T674I, is sensitive in vitro to a number of different TKIs, including PKC412, sorafenib, and ponatinib. Other secondary mutations in *F/P*+ disease, such as D842V, are very rare. However, once these secondary mutations occur during treatment with multiple TKIs, they usually exhibit pan-resistance. In fact, durable responses to TKIs with either the T674I or D842V mutation are not generally observed, and especially

the *F/P* D842V mutant is resistant to almost all available TKIs. More recently, it has been described that ponatinib can kill neoplastic eosinophils exhibiting all types of *F/P* mutations *in vitro* at clinically achievable drug concentrations. Whether this also holds true *in vivo* in patients with TKI-resistant CEL or acute leukemias exhibiting this *F/P* mutant, presently remains unknown. Another approach in patients with TKI-resistant eosinophil neoplasms is to apply cytoreductive agents (IFN- α , HU) or experimental drugs. In patients who transform to an acute leukemia, polychemotherapy and allogeneic HSCT is usually recommended.

A number of different markers have been proposed for the monitoring of treatment responses in patients with *F/P*+ CEL. A close hematologic follow-up is recommended for the first weeks of therapy, where a rapid decline in eosinophils (and leukocytes) is usually observed, and is regarded a good prognostic sign. After a few months, the BM should be examined in order to document and confirm the hematologic response. A complete remission is obtained in most patients, even if the initial BM revealed marked involvement at diagnosis, including fibrosis and/or increased blast cells. In patients with a complete hematologic remission, molecular monitoring and a repeat PCR and FISH analysis is recommended in order to define the molecular response. Quantitative measurement of the *F/P* mRNA burden by reverse-transcriptase-PCR is available in many centers and can be employed to define the depth of the remission. In those with an initially elevated serum tryptase, serial determinations of tryptase are also useful to document the response to imatinib or other TKIs. Finally, in those with end-organ damage, including cardiac disease, reinvestigation of all involved organ systems is recommended to demonstrate potential reversion of end-organ damage. In high-risk patients (e.g., cardiac history), echocardiography and troponin as well as B-type natriuretic peptide levels before initiating therapy may be recommended to gauge the potential risk.

Although imatinib and other TKI therapies in CEL patients is generally well tolerated, all these agents can produce severe side effects. Even imatinib may produce severe side effects, especially when applied to HES patients with cardiopathy at 400 mg daily. In fact, in a few cases severe left ventricular dysfunction has been reported soon after initiation of imatinib therapy. Therefore, close monitoring of these patients is recommended during this time period and prophylactic steroids (during the first week of treatment) should be considered. The second- and third-generation TKIs used to treat CML and CEL may also produce severe side effects, and many of them may affect the cardiovascular system or metabolic parameters, which is relevant clinically in the context of HES. The most relevant side effects of dasatinib are pleural and pericardial effusion, and the most relevant adverse events observed with nilotinib and ponatinib are arterial occlusive events that may occur as a result of a rapidly progressive form of atherosclerosis. In the case of nilotinib, increasing fasting glucose levels and cholesterol levels have been documented during therapy.

Targeted Antibodies

A number of targeted antibodies and antibody-toxin conjugates have been considered for patients with HE-related disorders and HES.²⁹ These antibodies are either directed against (neoplastic) eosinophils and their precursor cells or against eosinotropic cytokines, such as IL-5. Antieosinophil antibodies are considered useful in neoplastic states and should ideally be directed against both eosinophils and their precursor cells, or even neoplastic stem cells. One such antibody is alemtuzumab. This humanized antibody is directed against CD52 (= Campath-1), a surface receptor expressed on neoplastic stem cells in various leukemias as well as on eosinophils and their precursor cells. Alemtuzumab therapy in patients with drug-resistant eosinophil disorders has been reported in a limited number of studies. In about 80–90% of the patients the drug induced remission. However, in over 80% of these patients relapses occurred after cessation of therapy. In addition, alemtuzumab produced substantial side effects, including severe hematological toxicity with subsequent opportunistic infections. Several other antibodies directed against cell

surface receptors expressed by eosinophils are currently in preclinical development. The epidermal growth factor-like modul-containing, mucin-like hormone receptor 1 (EMR1) is expressed specifically on human blood eosinophils and may serve as a potential target of therapy. A novel, humanized afucosylated anti-EMR1 IgG1 antibody has recently been shown to augment NK cell-mediated killing of eosinophil granulocytes. Benralizumab is an antibody directed against the IL-5 receptor on eosinophils and their precursor cells. So far, benralizumab has been tested in normal subjects and patients with asthma, and is currently being tested in patients with HES. BM studies have shown that this antibody induces a remarkable depletion of eosinophils and their precursor cells. It is noteworthy that the IL-5 receptor is also expressed on basophils, albeit at lower levels. Another interesting target receptor is Siglec-8. This antigen is expressed on eosinophils and mast cells, but not on neoplastic stem cells. Remarkably, Siglec-8 crosslinking induces eosinophil apoptosis and inhibits IgE-mediated mast cell activation, thereby providing a common mechanism to limit inflammation caused by the coexistence and functional interactions of these cells.⁶ Whether this concept is clinically effective, remains at present unknown. Since Siglec-8 is not expressed on immature eosinophilic progenitor cells or neoplastic stem cells, the drug may not be useful in eosinophil malignancies. By contrast, Siglec-3 (CD33), another established drug target, is displayed by normal and neoplastic eosinophils and even by neoplastic stem cells. Gemtuzumab ozogamicin is a humanized CD33 antibody conjugated with calicheamicin. Although the drug is highly effective in targeting myeloid cells and their progenitors in AML, the drug has been withdrawn from the market because of toxicity issues. However, when used at limited doses and at reasonable time intervals, the toxicity of such antibodies may be acceptable.

Another approach is to target eosinotropic cytokines using specific antibodies, which is a strategy that is recommended for patients with reactive HE and HES (HES_R) as well as HES_L, where overproduction of such cytokines is known to play a pathogenetic role. These agents include antibodies directed against IL-5, against eotaxin, or other cytokine agonists. Mepolizumab is a fully humanized IgG1 antibody that binds IL-5 and prevents its binding to the IL-5 receptor alpha chain.²⁹ In 2008 a randomized, double-blind, placebo-controlled trial showed that mepolizumab is effective as a corticosteroid-sparing agent in patients with severe (drug-resistant) HES_R.²⁵ Adverse events were tolerable and similar in the treated and in the placebo groups. Mepolizumab has been recently FDA approved for the treatment of eosinophilic asthma and tested in HES patients in clinical trials. Reslizumab is a humanized IgG4 anti IL-5 antibody that is currently being tested in clinical trials for eosinophilic esophagitis and in pediatric patients for eosinophilic asthma, but it has not been studied in the context of HES.²⁹ Initial results suggest that the drug is effective in reducing eosinophil counts and clinical symptoms. Bertilimumab is a human anti-eotaxin-1 antibody that is currently being tested in a phase II clinical trial for ulcerative colitis, but has not been tested yet in HES patients. Together, more controlled clinical trials in HES patients are needed in order to learn which antibodies directed against eosinophilic receptors and eosinotropic cytokines are most effective in patients with primary or reactive eosinophil disorders and HES.

Leukapheresis

Leukapheresis has no defined role in the management of HES. However, leukapheresis may be useful in emergency situations for patients with excessively high eosinophil counts. Since cell counts rebound rapidly to pretreatment levels, such a maneuver should always be combined with cytoreductive therapy in order to keep eosinophil counts under control.

Anticoagulation and Antiplatelet Agents

Thromboembolic complications may be life-threatening in HES patients. Therefore, prophylactic anticoagulation may be considered

in patients with HES, especially in those in whom the risk for thromboembolic complications is high, such as in patients with a *F/P+* disease, cardiac involvement, or neurologic symptoms. In patients with overt HES and associated thromboembolic events, anticoagulation is a standard approach. Commonly used agents are warfarin, antiplatelet agents, and heparin. The efficacy of these drugs has not been formally established in HES, and some of the patients may continue to have thrombotic events, despite adequate anticoagulation. Therefore, it is always important to also treat the underlying disease if possible, in order to stop the thromboembolic state.

Splenectomy

Splenectomy is usually not required in patients with MPN-eo, AEL, or CEL. However, in rare cases, splenomegaly has been performed to correct hypersplenism-related cytopenias, or to avoid splenic infarction and pain induced by capsular distention.

Allogeneic Hematopoietic Stem Cell Transplantation

Although the experience with allogeneic HSCT in patients with advanced BM neoplasms accompanied by HE (with or without HES) is quite limited, allogeneic HSCT should be considered in certain groups of patients, especially those who are (1) young and fit, (2) have a suitable transplant donor, and (3) have a progressive and treatment-resistant form of an underlying myeloid or lymphoid neoplasm. More or less definitive indications in this regard include *FGFR1*-rearranged neoplasms, drug-resistant cases of AEL or CEL, chemotherapy-resistant peripheral T-cell lymphomas accompanied by HE/HES, and treatment-resistant (progressive) cases of MPN-eo, AML-eo, or MDS-eo. If possible, debulking therapy should be introduced prior to conditioning and HSCT, especially when the burden of neoplastic cells is high or excessive. Such debulking may be performed with polychemotherapy or with experimental drugs. Several but not all transplanted patients may enter a complete remission. Transplant-related mortality rates may not be higher compared with age-matched patients with other advanced hematopoietic neoplasms. As in other BM neoplasms, age, comorbidities, and the disease status are major risk factors concerning survival and transplant-related mortality. In this regard, it should be noted that the presence of HES-related organ damage, such as overt cardiomyopathy or thromboembolism, but also neuropathies or GI disease, may count as relevant comorbidities, and if severe in nature, may represent a contraindication to allogeneic HSCT. In those who are successfully transplanted, the clinical course may be complicated by graft-versus-host disease requiring treatment with corticosteroids, cyclosporin-A, or/and other immunosuppressive drugs. Little is known about long-term outcomes after allogeneic HSCT. In smaller case series and single cases reports, long-term survivors have been described. However, relapses have also been reported in most groups of patients.

Cardiac Surgery

In a subset of patients with HES, surgical intervention of cardiac lesions is required. Interestingly, such intervention does not appear to carry a major risk for disease recurrence at the operative sites. Indications for surgery include a significant compromise of valvular function and the presence of a clinically significant thrombotic mass. Cardiac surgery has the capacity to provide a substantial clinical and quality-of-life benefit in these patients. In fact, successful mitral valve and/or tricuspid valve repair or replacements have been reported in HES patients in several studies. For mitral valve replacements, mechanical valves have proven problematic because of recurrent thrombosis despite adequate anticoagulation, suggesting the use of porcine valves whenever possible. HES patients who have received valve replacements have generally experienced long-term

improvement in cardiac function, provided the underlying disease and the related HE can be kept under control.

SUMMARY AND FUTURE PERSPECTIVES

The diagnosis, classification, and management of patients with persistent HE remains a challenge in clinical practice, especially when no underlying disease is identified and/or HE-related organ damage (HES) develops. Because of disease heterogeneity and the power and specificity of novel markers and targets, each case needs to be investigated and managed using the full battery of diagnostic markers and assays, and according to contemporary diagnostic and therapeutic algorithms.^{3,14} Depending on the overall situation, initial investigations include BM studies (histology, cytology, and cytogenetics with FISH), molecular analyses, immunologic parameters, and a complete staging of all potentially involved end-organ systems. In benign disease variants, the course can sometimes be monitored without specific treatment. However, in patients with (1) advanced hematopoietic neoplasms, (2) overt HE-related end-organ damage (HES), (3) an active underlying (systemic) immunologic, infectious, or allergic disease, (4) evidence of a specific clinical syndrome with systemic organ involvement, or (5) organ-restricted marked inflammation associated with eosinophilia, such as eosinophilic colitis or eosinophilic pneumonia, specific treatment needs to be initiated. In reactive conditions, symptomatic treatment and corticosteroids are usually administered. In addition, it is of utmost importance to treat and eradicate (or control) the underlying disease, such as a NHL, helminth infection or IgE-dependent allergy, in these patients. Such treatment is often followed by complete resolution of reactive HE and of the related HES. In treatment-resistant patients in whom reactive eosinophilia is likely to be triggered by eosinophilotropic cytokines such as IL-5, anti-cytokine therapy, such as mepolizumab, may be considered. This drug has shown promising results in patients with steroid-resistant reactive HES and other HE-related conditions, such as eosinophilic esophagitis. In advanced hematopoietic neoplasms, treatment with targeted drugs or less specific cytoreductive agents is recommended. In *F/P+* patients and those with related *PDGFR* fusion genes, imatinib is an undisputable standard of therapy. For patients with imatinib-resistant *F/P+* CEL or MPN-eo, MPN-eo without a *PDGFR* mutant, or HE-related malignancies expressing *FGFR1* or *JAK2* fusion genes, novel TKIs are available. In patients in whom secondary mutations in *F/P* are detectable, novel *PDGFR*-targeting TKIs such as ponatinib may work. In cases with *FGFR1*-rearranged neoplasms, novel FGFR blockers may overcome resistance, and in patients with *JAK2*-mutated MPN-eo, ruxolitinib may elicit clinically meaningful responses. In rapidly progressive and/or drug-resistant cases, high-dose chemotherapy and allogeneic HSCT need to be considered. In patients who are TKI resistant and not eligible for allogeneic HSCT, HU, other cytostatic agents, or IFN- α serve as palliative drugs. Current research aims at exploring the evolution of HES and at defining mechanisms regulating the development of HE-mediated end-organ damage, which should lead to more selective and improved therapies in the future. Clinically relevant targets for these efforts are likely to include (1) neoplastic stem cells producing eosinophil neoplasms such as CEL or MPN-eo, (2) molecular targets created specifically by neoplastic cells, such as mutant forms of *PDGFRs* or *FGFRs*, (3) eosinophilotropic cytokines and their receptors, (4) underlying T-cell clones triggering eosinophil expansion and/or activation through production of eosinopoietic cytokines, (5) adhesion receptors and other molecules mediating eosinophil homing and redistribution, such as VLA-4, and (6) signaling molecules responsible for cytokine-dependent or -independent eosinophil proliferation, migration, adhesion, or/and activation. Another aim for the future is to better understand cellular interactions and related molecular mechanisms underlying HE-induced organ damage (HES) in various organ systems. There is hope that an improved knowledge of mechanisms regulating end-organ damage will lead to the development of new treatment concepts and better therapies for patients with HES.

MAST CELLS AND MASTOCYTOSIS

Jason Gotlib, Hans-Peter Horny, and Peter Valent

INTRODUCTION

The year 2015 marked a century since the death of Paul Ehrlich, who used his 1878 doctoral thesis to characterize a new cell type—the mast cell (MC)—based on its reactivity to aniline dyes and the metachromatic appearance of its cytoplasmic granules.¹ He referred to MCs as *Mastzellen* and he speculated that their intracellular granules contained phagocytosed materials or nutrients. Ehrlich also described a close relationship in tissues between MCs and blood vessels, nerves, gland excretory ducts, as well as their proximity within the environment of tumors and chronic inflammation. In 1894, the pathobiologic association of MCs with lesions of urticaria pigmentosa was reported, and from the 1930s forward, basic incremental discoveries about normal MC functions were made. Their capacity to undergo degranulation in response to various stimuli, their source of histamine and heparin, and their important role in anaphylaxis was examined.²

Perturbations of MC growth and function may lead to mastocytosis, a condition defined by pathologic expansion and accumulation of MCs in diverse tissues such as the skin, bone marrow (BM), spleen, liver, lymph nodes, and gastrointestinal tract. In 1949 the first case report of systemic mastocytosis (SM) was published. Later, between 1950 and 1980, several different subtypes of SM were described, including a leukemic variant termed *mast cell leukemia* (MCL). The first classification of mastocytosis was created by the Kiel group of pathologists, and in 1991 the first consensus classification was published. Criteria for SM and other variants of the disease were established between 1990 and 2000. In 2000 these criteria were discussed by a consensus group and were employed to establish a robust consensus classification of mastocytosis,³ that was adopted by the World Health Organization (WHO) in 2001 and also in 2008.⁴ In consecutive years, the consensus group published treatment response criteria and established a widely accepted update of the classification of mastocytosis in 2007.⁵ In this updated classification, the smoldering state is defined as a separate category of SM which was confirmed by the WHO in 2016. In 2002 the European Competence Network on Mastocytosis (ECNM) was founded. Since then, the ECNM has facilitated basic science and translational research dealing with mastocytosis and related MC disorders. This chapter provides an overview of normal MC physiology and highlights contemporary issues related to the classification, diagnosis, and treatment of SM.

ORIGIN AND DEVELOPMENT OF MAST CELLS

The marrow origin of MCs was first demonstrated by engrafting BM cells into irradiated mice. Human MCs can be generated from a CD34⁺ hematopoietic progenitor cell in response to stimulation with stem cell factor (SCF). In vitro MC differentiation models showed that circulating MC progenitors express CD13, CD34, and KIT, but lack CD14 and CD17.⁶ MC progenitors are released from the BM into the circulation in a primitive state and undergo terminal maturation and differentiation after their migration to tissues. Although shared histomorphologic and biologic features of MCs and basophils include cytoplasmic basophilic granules, expression of high-affinity immunoglobulin (Ig)E receptors (FcεRI), and release of histamine upon stimulation, basophils exhibit several distinctive characteristics. Basophils circulate as mature cells, which are incapable

of proliferation, and subsequently undergo apoptosis after their recruitment and activation in the tissues. Differential expression of the transcription factor CCAAT-enhancer-binding protein (CEBP)α may be a primary determinant of whether development is skewed toward basophil progenitors (CEBPα present) or MC progenitors (CEBPα absent). Although eosinophils and basophils have been found to share a common bipotential progenitor in humans, definitive data for a similar progenitor giving rise to both basophils and MCs are lacking. Rather, based on colony assays, MCs are directly derived from multilineage and lineage-restricted progenitors, but not from such a bi-potent precursor cell.⁶ In line with this observation, evidence against a bilineage basophil/MC progenitor also came from tracking lineage involvement of *KIT* D816V in patients with SM, where *KIT* D816V was only found in basophils in a small subset of patients, namely those with multilineage involvement of the mutation. In addition, when highly enriched by cell sorting, neither mature blood basophils nor mature blood monocytes give rise to MCs in vitro.⁶

KIT and Stem Cell Factor (KIT Ligand)

KIT

Kit is the cellular homolog of the *v-Kit* oncogene of the Hardy-Zuckerman 4 feline sarcoma virus. The human *KIT* gene on chromosome 4q11–12 was found to be allelic to the white spotting locus (*W*) in mice, in which over 30 mutations have been identified. The common theme of mutant alleles at the *W* locus is decreased kit kinase activity either through missense mutations that generate kinase-defective kit (e.g., *W*⁴² [*kit* D790N]; *W*³⁷ [*kit* E582K]; *W*^v [*kit* T660M]; and *W*⁴¹ [*kit* V831M]) or decreased expression of kit on the cell surface (e.g., the *W* allele, caused by a 78-amino acid deletion that involves the transmembrane region of the kit protein).

Double mutants at the murine *W* locus not only result in markedly decreased MC numbers, but also in pleiotropic phenotypes, including white coat color/spotting, sterility, and anemia, that respectively relate to the failure of melanocytes, germ cells, and hematopoietic progenitors to migrate and/or proliferate effectively during development. Heterozygosity or homozygosity for the different alleles at the *W* locus results in variable phenotypic effects on hematopoiesis, pigmentation, and fertility. Mutations at the *W* locus can also result in abnormalities of the interstitial pacemaker cells of Cajal, leading to functional gut abnormalities, such as megacolon. Intriguingly, some of these clinical correlates can also be seen in patients undergoing long-term treatment with a strong KIT inhibitor, like imatinib: these individuals can develop MC deficiency, depigmented skin areas, cytopenias, and fertility problems.

KIT is a member of the type III receptor tyrosine kinases (TKs) that also include platelet-derived growth factor receptor (PDGFR)-α and -β, FMS-like tyrosine kinase-3 (FLT3), vascular endothelial growth factor receptor 2 (VEGFR2), and the receptor for macrophage colony-stimulating factor (FMS).⁷ These TKs share common structural motifs including an extracellular domain containing five Ig-like motifs that bind their specific ligands, a short transmembrane (TM) domain that anchors KIT to the cell membrane, a cytoplasmic TK domain that is split by an insert sequence into ATP-binding and phosphotransferase regions, and a juxtamembrane (JM) domain that

lies between the TM and TK domains. KIT is expressed on hematopoietic stem/progenitor cells and is also essential for gametogenesis and melanogenesis. KIT expression is lost when hematopoietic cells undergo differentiation. However, the exception is MCs, which retain persistent and high-level expression of KIT (CD117). This can be exploited for the purposes of MC identification by immunohistochemistry and/or flow immunophenotyping (in conjunction with other surface and cytoplasmic markers).

The two major splice variants of KIT differ by the presence or absence of four amino acids (GNNK) at the extracellular JM region. In NIH3T3 cells, the GNNK⁻ isoform induced loss of contact inhibition, anchorage-independent growth, and tumorigenicity in mice, whereas the GNNK⁺ isoform did not exhibit most of these characteristics. Also, despite similar binding of SCF to KIT, the GNNK⁻ isoform displayed more rapid and extensive tyrosine autophosphorylation and faster internalization. Preferential expression of the GNNK isoform has been noted in small cohorts of patients with SM and germ cell tumors, but larger series are needed to determine the relevance of these KIT isoforms to disease pathogenesis.

Stem Cell Factor

SCF (KIT ligand) was identified by three groups in 1990 as the principal growth and differentiation factor for human MCs. In fact, SCF was found to induce MC differentiation from CD34⁺ cells or blood/BM mononuclear cells. SCF is produced by fibroblasts and endothelial cells, and promotes the proliferation, differentiation, survival, and migration of hematopoietic progenitors, melanocytes, MCs, and germ cells.

Loss-of-function mutations at the *Sl* (steel) locus on chromosome 10 in mice were found to phenocopy mutations at the *W* locus. Ultimately, the gene product of the *Sl* locus was found to be the ligand for kit, SCF. In the case of mutations affecting the *W* (kit) locus, transplantation of BM cells from congenic +/+ mice into *W/W^v* mice corrected MC deficiency and anemia, consistent with an intrinsic progenitor/stem cell defect. In contrast, skin and BM engraftment experiments demonstrated that mutations at the *Sl* locus were cell extrinsic (e.g., microenvironmental) in nature. When skin from either *W/W^v* or *Sl/Sl^d* mice was transplanted onto the backs of congenic +/+ mice, MCs were capable of engrafting the skin from *W/W^v* mice but not the skin from *Sl/Sl^d* mice. In addition, hematologic abnormalities in *Sl/Sl^d* mice failed to correct with transplantation of BM cells from congenic +/+ animals. These experiments formally established that SCF is a physiologically relevant ligand of kit and that development is critically dependent on this ligand-receptor interaction. Therefore SCF has also been termed *mast cell growth factor*.

Alternative splicing results in two isoforms of membrane-bound SCF with different susceptibility to proteolytic cleavage: a longer isoform that retains exon 6 and contains a cleavage site that results in soluble SCF, and a shorter isoform lacking the cleavage site, which remains membrane-bound and serves as a stem cell homing receptor in the BM niche. Both the membrane-bound and soluble form of SCF (which exists in a homodimeric confirmation) are capable of binding to and inducing homodimerization of KIT, which, in turn, leads to autophosphorylation of tyrosine residues located in intracellular portions of the molecule. A cascade of signaling events ensues via downstream effector molecules, including Src kinases, c-Jun N-terminal kinase (Jnk), mitogen-activated protein (MAP) kinases, and the Janus-activated kinase (JAK)-signal transducer and activator of transcription and phosphatidylinositol 3-kinase (PI3K)/AKT pathways. In addition to promoting MC differentiation and survival, SCF can regulate MC adhesion to extracellular matrix proteins as well as mediator release via IgE-dependent and IgE-independent mechanisms. Likewise, when applied at relatively high concentrations for 90 min, SCF is capable of directly inducing mediator secretion from human MCs. Whereas in mice several different cytokines are involved in the regulation of growth and activation of MCs, SCF seems to be a rather specific cytokine for human MCs. Other studies

have shown that certain cytokines or hormonal factors exert inhibitory effects on MCs (e.g., interferon [IFN]- γ), and some cytokine pairs counterbalance each other's effects (e.g., T-helper 2 [Th2] cytokine interleukin [IL]-4 vs. regulatory T cell cytokine TGF- β 1) on MC homeostasis. Expression of the death receptor tumor necrosis factor-related apoptosis-inducing ligand and inhibitor receptors CD300a and Siglec-8 may also contribute to downregulation of MC activation, survival, and IgE-mediated responses.

MAST CELL ACTIVATION AND FUNCTION

MCs commonly reside at the interface between the host and environment, usually in the skin, or in the mucosa lining the lungs or gastrointestinal tract. Migration and homing of MCs to various sites is regulated by the interaction between surface expression of numerous types of chemokine receptors (e.g., CXC chemokine receptor 2) and integrins (e.g., α 4 β 7, α 4 β 1) on MCs to tissue-specific endothelial binding sites such as mucosal vascular address in cell adhesion molecule-1 (MAdCAM-1) and vascular cell adhesion molecule-1 (VCAM-1). In addition to playing a primary role in mediating allergic responses and inflammation, MCs act as one arm of the adaptive immune system by playing a role in host defense against pathogens such as bacteria, fungi, and viruses.

MCs serve as a rich source of a variety of biologically active molecules (Table 72.1). These include preformed mediators such as vasoactive amines (histamine), anionic proteoglycans (heparin, chondroitin sulfate), and proteases (trypsin, chymase, and carboxypeptidase).² Activated MCs also contribute to de novo synthesis of lipid-derived mediators that constitute the slow-reacting substance of anaphylaxis (SRS-A). These mediators include lipoxygenase-derived metabolites of arachidonic acid—the cysteinyl leukotrienes LTC₄,

TABLE 72.1 Human Mast Cell Cell-Derived Mediators

Class	Mediators	Physiologic Effects
Preformed mediators	Histamine, serotonin, heparin, neutral proteases (trypsin and chymase, carboxypeptidase, cathepsin G), major basic protein, acid hydrolases, peroxidase, phospholipases	Vasodilation, vasoconstriction, angiogenesis, mitogenesis, pain, protein processing/degradation, lipid/proteoglycan hydrolysis, arachidonic acid generation, tissue damage and repair, inflammation
Lipid mediators	LTB ₄ , LTC ₄ , PGE ₂ , PGD ₂ , PAF	Leukocyte chemotaxis, vasoconstriction, bronchoconstriction, platelet activation, vasodilation
Cytokines	TNF- α , TGF- β , IFN- α , IFN- β , IL-1 α , IL-1 β , IL-5, IL-6, IL-13 IL-16, IL-18	Inflammation, leukocyte migration/proliferation
Chemokines	IL-8 (CXCL8), I-309 (CCL-1), MCP-1 (CCL2), MIP-1 α S (CCL3), MIP1 β (CCL4), MCP-3 (CCL7), RANTES (CCL5), eotaxin (CCL11), MCAF (MCP-1)	Chemoattraction and tissue infiltration of leukocytes
Growth factors	SCF, M-CSF, GM-CSF, bFGF, VEGF, NGF, PDGF	Growth of various cell types, vasodilation, neovascularization, angiogenesis

The mediators in the table are examples only. In addition, many mediators are identified in mouse mast cells, human mast cell lines or primary cultures of human mast cells and may not be produced in vivo.

From Metcalfe DD: Mast cells and mastocytosis. *Blood* 112:946, 2008.²

LTD4, and LTE4, and cyclooxygenase-derived prostaglandin (PG) D2. These substances are involved in mediating vasodilation and vasopermeability, smooth muscle constriction, mucus secretion, and other proinflammatory sequelae. IgE- and non-IgE-dependent mechanisms (e.g., IgG, complement [C3a, C5a], neuropeptides, narcotics, physical stimuli, and activation of Toll-like receptors by bacterial products) can induce MCs to release a variety of cytokines (e.g., TNF- α , macrophage inflammatory protein [MIP]-1 α and -1 β , monocyte chemoattractant protein [MCP]-1, IFN- α , β , and γ , and various interleukins) and growth factors (see Table 72.1) that are implicated in the aforementioned physiologic roles of inflammation, allergic responses, and host defense. MCs mediate early-phase (e.g., anaphylaxis, acute asthma) and late-phase allergic responses, as well as non-type I hypersensitivity reactions through their proinflammatory mediators. Furthermore, MCs mediate upregulation of Th2 responses and allergen-specific IgE biosynthesis, which contribute to host defense against parasitic infections. MCs have also been implicated in the pathogenesis of various nonallergic conditions such as infectious or autoimmune diseases (e.g., multiple sclerosis, psoriasis, rheumatoid arthritis, inflammatory bowel disease), and also in repair after tissue injury, such as wound healing, thrombolysis, or tissue remodeling.

Coupling of MCs and eosinophils often occurs in the same tissue niches in allergic/inflammatory and neoplastic disorders such as eosinophilic esophagitis, chronic gastritis, gastrointestinal neoplasms, parasitic infections, and inflammatory bowel disease.⁸ MCs can initiate the allergic inflammatory cascade, resulting in recruitment of eosinophils during the later phases of an allergen encounter. Both MCs and eosinophils express CCR3 and respond to eotaxins and RANTES (CCL5), leading to recruitment of both cell types into inflamed tissue. Moreover, MC-derived heparin can bind and stabilize eotaxins. In addition, MCs and eosinophils can interact with each other through soluble mediators or via direct cell-to-cell contact. At least in the murine system, MCs can also be induced to produce IL-3 and IL-5, which can potentiate eosinophil recruitment in tissues. The two principle MC-derived proteases exert dual actions on eosinophils. For example, MC-derived chymase suppresses eosinophil apoptosis and induces release of IL-6, CXCL8, CCL2, and CXCL1 from eosinophils. In contrast, β -tryptase can cleave eotaxin and RANTES, and can limit eosinophil chemotaxis. Eosinophils in turn produce SCF, which can attract more tissue MCs and protect them from apoptosis.

IgE-mediated hypersensitivity reactions (e.g., allergic rhinitis or asthma, anaphylaxis) are mediated by binding of allergen-specific IgE to the high-affinity Fc ϵ RI receptor, which is constitutively expressed at a high level on MCs. Engagement of Fc ϵ RI leads to its inclusion in lipid rafts, and phosphorylation of its β - and γ -chain immunoreceptor tyrosine-based activation motifs (ITAMs) by Lyn kinase and subsequent activation of Syk kinase through its binding to the ITAMs.⁹ These proximal signaling events also activate Fyn kinase, which is important for phosphorylation of the adaptor protein Gab2 and activation of the PI3K pathway. Lyn kinase also regulates phosphorylation of the protein scaffolds LAT and NTAL, which coordinate multiple signaling pathways including Ras/MAP kinase, TEC family kinases, and PLC γ activation. PLC γ , in turn, is a critical mediator of MC cytokine production and degranulation. Experimental data indicate that the functions of KIT and Fc ϵ RI in MCs are interdependent. It has been observed that SCF enhances Fc ϵ RI-mediated MC degranulation, and that phosphorylation of the membrane adaptor molecule NTAL is a crucial link between the signaling cascades following KIT activation and Fc ϵ RI aggregation. In addition, BTK is a mediator of Fc ϵ RI-mediated MC degranulation and plays a critical role in the amplification of Fc ϵ RI activation by KIT.

TOOLS TO STUDY HUMAN MAST CELLS

The challenges of studying MCs relate to heterogeneity in their morphology and function between different species, and also within

different tissues of the same organism. Although several techniques, including flow cytometry-based cell sorting, exist for ex vivo isolation of BM MCs, yields are typically low, reflecting the low numbers of MCs in the BM and the difficulties in isolating them from other tissues, such as the lung. Ex vivo generation of human cord blood–derived or peripheral blood–derived MCs from their CD34⁺ or CD133⁺ progenitor cells using SCF and IL-6, can generate large numbers of functionally mature MCs that can be interrogated for various types of biologic investigations. Many studies of MCs and/or mastocytosis have relied on MC lines such as the SCF-dependent cell lines LAD1/LAD2, derived from patients with MC sarcoma with *KIT* D816V (this cell line actually has normal *KIT* despite its origin, and is SCF dependent); the LUVA cell line (derived from CD34⁺ cells, growth factor–independent, normal *KIT*, and tendency to lose Fc ϵ RI expression with long-term culture); and the SCF-independent human mast cell line HMC-1 derived from a patient with MCL. Two HMC-1 subclones are available—HMC-1.1, which contains the *KIT* V560G mutation, and HMC-1.2, which expresses both *KIT* V560G and D816V. Both clones have been useful for in vitro evaluation of the differential sensitivity of different small-molecule inhibitors of KIT. None of these human MC lines, however, express both a functional IgE receptor and *KIT* D816V. However, more recently, a human cord blood–derived cell line that is SCF dependent and Fc ϵ RI⁺ (ROSA^{KIT WT}), and that converts to SCF independence and tumorigenic growth with transfection by *KIT* D816V (ROSA^{KIT D816V}), has been established, and should be a useful tool for studying the biology and pharmacologic aspects of mastocytosis.¹⁰

Mouse Models to Study Human Mastocytosis

A number of murine models of mastocytosis are available, including several transgenic models and xenotransplantation models. First, all the cell lines described earlier have been applied successfully in xenotransplantation models. In most instances, NSG mice were employed. In addition, several transgenic models have been established. In one model, transgenic mice harboring a fusion transgene consisting of the 571-bp primate chymase gene (Δ 571-bchm) promoter fragment and the human Kit proto-oncogene cDNA with the codon 816 Asp→Val substitution were generated. These mice were found to slowly develop a MC disease-like condition with focal accumulations of MCs in the spleen and other organs, resembling indolent SM (ISM). In another model, a transgenic mouse exhibiting murine *KIT* D814V was established. These mice developed gastrointestinal MC accumulations. Both models may not reflect all aspects of the human disease, but may be helpful in basic science.

FIP1L1-PDGFR α - and NPM-ALK-Based Murine Models

Expression of the *FIP1L1-PDGFR α* fusion alone in murine BM cells was not sufficient to cause eosinophilia, but only a general myeloproliferative disease. However, overexpression of IL-5 together with *FIP1L1-PDGFR α* produced typical features closely resembling HES, including tissue infiltration by eosinophils. However, a phenotype of mastocytosis in addition to eosinophilia developed in another murine model by introducing *FIP1L1-PDGFR α* into hematopoietic stem cells and progenitors with T-cell overexpression of IL-5. Transplantation of *NPM-ALK* (nucleophosmin-anaplastic lymphoma kinase)–transduced progenitors into normal mice or IL-9–transgenic mice without *NPM-ALK* each result in MC hyperplasia; however, both “single-hit” models are insufficient to generate a histopathologic picture of SM. SM is only observed when *NPM-ALK* is transduced into mouse BM progenitors of lethally irradiated IL-9 transgenic mice. Similar to the model of *FIP1L1-PDGFR α* and IL-5, this model of the *NPM-ALK* fusion and IL-9 highlights the biologic interdependence of a fusion oncogene and cytokine-related pathways in promoting the full expression of neoplastic MC growth.

Germline Susceptibility to Mast Cell Disorders and Familial Mastocytosis

In general, mastocytosis behaves as an acquired, somatic disease. However, a few familial cases have been reported. In most of these families, a *KIT* mutation (various codons affected) can be detected in the germline. However, in a few families, the *KIT* mutation was only expressed in hematopoietic cells, but not in the germline of the affected individuals, suggesting that predisposing germline factors may contribute to disease development. However, so far, little is known about what gene polymorphisms serve as susceptibility alleles. In one study, polymorphisms within certain cytokine genes have been identified as exerting a potential predisposition to development of SM. In particular, a polymorphism in the promoter of the *IL-13* gene, -1112C/T , was significantly more frequent in SM patients versus both cutaneous mastocytosis (CM) patients and healthy controls. In addition -1112C/T was associated with increased serum tryptase levels and adult-onset disease. MCs express IL-13 receptors and IL-13-containing medium provides enhanced support for the growth of MCs. However, it remains unclear how -1112C/T relates to these specific biologic findings. In contradistinction to the *IL-13* -1112C/T germline allele, the *IL-4* chain receptor Q576 polymorphism was associated with more limited forms of mastocytosis. IL-4 modulates the growth and differentiation of MCs, and induces IgE receptor expression in MCs. Polymorphisms in the IL4 receptor have been implicated in allergic and inflammatory conditions. In a study of patients with cutaneous and systemic forms of mastocytosis, this polymorphic allele was significantly more associated with cutaneous disease, childhood-onset disease, and lower levels of serum tryptase and soluble CD117. The Q576 polymorphism in the *IL4* chain receptor therefore appears to protect against MC hyperplasia and more aggressive forms of the disease. The Asp358Ala polymorphism in the *IL-6* receptor was associated with a 2.5-fold lower risk for mastocytosis compared with those with the AC or CC genotypes. However, no association was found between the *IL-6* 174G/C polymorphism and increased susceptibility to SM.

EPIDEMIOLOGY AND CLASSIFICATION OF MASTOCYTOSIS

In 2008, SM was included in the WHO category of myeloproliferative neoplasms (MPNs).⁴ However, based on the complex clinical picture, biology and pathology, SM has been again defined by the WHO as a separate unique myeloid neoplasm in 2016. SM is an orphan disease and sparse data exist regarding its incidence or other epidemiologic features. A slight male predominance has been observed, and in one study, the median age at time of SM diagnosis was 55 years. A retrospective study from Denmark that canvassed the years from 1997 to 2010 estimated the incidence of SM at 0.89 per 100,000 persons per year, with an estimated prevalence of 9.59 per 100,000 individuals. A Dutch analysis estimated the prevalence of ISM to be 13 cases per 100,000 inhabitants.

The first diagnostic checkpoint is to distinguish SM from CM, which is characterized by predominant skin involvement. Criteria to diagnose SM are not fulfilled in these patients. However, in rare cases with CM, a discrete involvement of the BM by clonal cells may be detected, and serum tryptase levels may be slightly elevated. SM primarily occurs in adults, whereas CM is more common in children and its natural history is typically defined by spontaneous resolution of skin lesions usually at the time of puberty. CM variants include urticaria pigmentosa/maculopapular CM, diffuse CM, and solitary mastocytoma of the skin. In the overwhelmingly majority of adults with cutaneous involvement, systemic disease (SM) is diagnosed. However, absence of skin lesions does not exclude the presence of SM. Skin involvement occurs in over 80% of all patients with adult SM. However, sometimes, no BM examination is performed for some time, especially when the patient has not been referred to a hematologist. In such cases, cutaneous lesions are referred to as *mastocytosis in the skin* (MIS).

Diagnostic criteria for SM were initially formulated by a working group of MC disease experts at a consensus conference in Vienna in 2000,³ and adopted by the WHO in both 2001 and 2008.⁴ In the 2008 WHO Classification of hematolymphoid neoplasms, mastocytosis was classified as one of the disease subtypes under the major category of “Myeloproliferative Neoplasms (MPNs)”. However, in the revised 2016 WHO classification, mastocytosis is now classified as its own major category distinct from MPNs. Minimal diagnostic criteria for SM requires at least one major plus one minor criterion, or at least three minor criteria (Table 72.2). The major criterion is the presence of multifocal dense aggregates of MCs (>15 MCs in aggregates) in sections of BM or other extracutaneous organ(s); minor criteria include: (1) >25% of the MCs in the infiltrate or in the BM smear are of spindle shape or of otherwise atypical morphology; (2) activating mutation at codon 816 in the *KIT* gene in an extracutaneous organ; (3) expression of CD2 and/or CD25 in/on MCs; and (4) serum tryptase level >20 ng/mL, unless there is an associated myeloid disorder that makes this parameter not valid.

SM is further divided into several subtypes that reflect the presence or absence of certain clinical or laboratory findings (Tables 72.3 and 72.4). The most common form of SM in adults is ISM, characterized by a slightly to markedly increased burden of neoplastic MCs in the BM and/or other extracutaneous organ(s). By definition, ISM patients do not exhibit MC-related organ damage or an associated hematologic disorder, and life expectancy in this variant is similar to that of an age-matched healthy population (Fig. 72.1).¹¹ However, ISM patients often experience mediator symptoms related to MC degranulation (e.g., flushing, pruritis, diarrhea, abdominal cramping, neuropsychiatric complaints). Although triggers may not always be identifiable, known provokers of MC activation and/or anaphylaxis include non-IgE and IgE-mediated causes: physical or emotional stress, exercise, hot or cold temperature stimuli, medications such as aspirin, NSAIDs, opioid analgesics, or antibiotics, alcohol, radiocontrast dye, and IgE-mediated allergies. One critical comorbidity is Hymenoptera venom allergy. In particular, these patients are at high risk of developing severe or even fatal anaphylaxis upon exposure to the venom. Cutaneous involvement usually develops in conjunction with the ISM subtype, both in younger individuals as well as in older patients. Bony disease (e.g., localized bone pain, diffuse osteopenia, osteoporosis with or without pathologic fractures, osteosclerosis) is also well described in ISM, but can cause morbid complications across the spectrum of SM variants.

In the 2008 WHO classification, smoldering SM (SSM) was designated as a subvariant of ISM. However, based on the current

TABLE 72.2 World Health Organization Diagnostic Criteria for Systemic Mastocytosis^a

Major criterion	Multifocal dense infiltrates of mast cells (>15 mast cells in aggregates) detected in sections of bone marrow and/or other extracutaneous organ(s)
Minor criteria	- In biopsy sections of bone marrow or other extracutaneous organs, >25% of the mast cells in the infiltrate are spindle shaped or have atypical morphology or, of all mast cells in bone marrow aspirate smears, >25% are immature or atypical - Detection of an activating point mutation at codon 816 in <i>KIT</i> in bone marrow, blood, or another extracutaneous organ - Mast cells in bone marrow, blood, or other extracutaneous organs express CD2 and/or CD25 in addition to normal mast cell markers - Serum total tryptase persistently exceeds 20 ng/mL (unless there is an associated clonal myeloid disorder, in which case this parameter is not valid)

^aRequires at least 1 major + 1 minor criteria or 3 minor criteria.

TABLE 72.3 2016 World Health Organization Variants of Mastocytosis

1. Cutaneous mastocytosis (CM)
 - a. Maculopapular CM
 - b. Diffuse CM
 - c. Mastocytoma of skin
2. Indolent systemic mastocytosis (ISM)
3. Smoldering systemic mastocytosis (SSM)
4. Systemic mastocytosis with an associated hematologic neoplasm (SM-AHN)*
 - a. SM-MDS
 - b. SM-MPN (e.g. PV, ET, MF, CML)
 - c. SM-MDS/MPN (e.g. CMML, MDS/MPN-unclassified)
 - d. SM-CEL
 - e. SM-AML
 - f. SM-lymphoid neoplasm (e.g. NHL, CLL, multiple myeloma)
5. Aggressive systemic mastocytosis (ASM)
6. Mast cell leukemia (MCL)
 - a. Aleukemic MCL
7. Mast cell sarcoma (MCS)

*SM-AHN is a new term that may be used in lieu of, or interchangeably with the previously used term, SM-AHNMD (systemic mastocytosis with an associated non-mast cell lineage disease). AML, Acute myeloid leukemia; CEL, chronic eosinophilic leukemia; CLL, chronic lymphocytic leukemia; CML, chronic myeloid leukemia; CMML, chronic myelomonocytic leukemia; ET, essential thrombocythemia; MDS, myelodysplastic syndrome; MF, myelofibrosis; MPN, myeloproliferative neoplasm; NHL, non-Hodgkin lymphoma; PV, polycythemia vera.

classification proposed by the consensus group, SSM is now included in the revised 2016 WHO classification as a separate variant of SM, which is meaningful because these patients exhibit a higher chance of progression to more advanced disease. SSM is defined by two or more “B” findings (Table 72.5), e.g., (1) hepatomegaly without impairment of liver function, and/or palpable splenomegaly without hypersplenism, and/or lymphadenopathy on palpation or imaging; (2) BM MC burden >30% and serum tryptase level >200 ng/mL; and (3) signs of dysplasia or myeloproliferation, in non-MC lineage(s), but insufficient criteria for definitive diagnosis of an additional hematopoietic neoplasm, with normal or only slightly abnormal blood counts. Compared with ISM, SSM patients often exhibit clonal multilineage involvement of the *KIT* D816V mutation, which is also a prognostically relevant variable.

SM with an associated hematologic neoplasm (SM-AHN) comprises 30% of SM variants, although this figure may vary because of referral patterns. In the revised 2016 WHO classification, the term “SM-AHN” can be used interchangeably with or in lieu of the prior term “SM-AHNMD” (SM with an associated hematologic non-mast cell lineage disease). The vast majority of AHNs are myeloid neoplasms: myelodysplastic syndrome (MDS), MPNs, MDS/MPN overlap disorders such as chronic myelomonocytic leukemia (CMML) or MDS/MPN-unclassified, chronic eosinophilic leukemia (CEL), and acute myeloid leukemia (AML).¹² Rarely, lymphoid neoplasms such as chronic lymphocytic leukemia, myeloma, or lymphomas have been found in association with SM. Identifying a concomitant myeloid neoplasm may depend on several factors, including the expertise of the evaluating pathologist, and whether one disease is masked by the presence of another. For example, in cases of SM-AML, MC aggregates may only be unmasked after induction chemotherapy with achievement of BM hypoplasia, because neoplastic MCs may persist after such therapy. Distinguishing nonhematologic or hematologic organ damage because of the SM component versus the associated myeloid disease can be very difficult, if not impossible, in some patients. Even when a biopsy of the involved extramedullary organ is analyzed to elucidate the burden of neoplastic MCs versus associated myeloid neoplasm, it is sometimes impossible to define the relative impact of the SM versus AHN component on organ

TABLE 72.4 2016 World Health Organization Diagnostic Criteria for Variants of (Systemic) Mastocytosis

1. **Indolent systemic mastocytosis (ISM):** Meets criteria for SM. No “B” or “C” findings. No evidence of associated clonal hematologic malignancy/disorder. In this variant, the mast cell burden is usually low; skin lesions are almost invariably present.
 - *Bone marrow mastocytosis:* As above, with bone marrow involvement, but no skin lesions.
2. **Smoldering systemic mastocytosis (SSM):** Meets criteria for SM. Two or more “B” findings and no “C” findings.
3. **Systemic mastocytosis with an associated hematologic neoplasm (SM-AHN)*:** Meets criteria for SM and criteria for an associated hematologic neoplasm (MDS, MPN, MDS/MPN, CEL, AML, lymphoma, or other hematologic neoplasm that meets the criteria for a distinct entity in the WHO classification).
3. **Aggressive systemic mastocytosis (ASM):** Meets criteria for SM. One or more “C” findings. No associated clonal hematologic neoplasm. No evidence of mast cell leukemia.
4. **Mast cell leukemia (MCL):** Meets criteria for SM. Bone marrow biopsy shows diffuse infiltration, usually interstitial pattern, by atypical, immature mast cells. Bone marrow aspirate smears show 20% or more mast cells. Cases in which <10% of circulating WBCs are mast cells are referred to as ‘aleukemic mast cell leukemia’.
5. **Mast cell sarcoma (MCS):** Unifocal mast cell tumor. No evidence of SM. No skin lesions. Destructive growth pattern. High-grade cytology.

*SM-AHN is a new term that may be used in lieu of, or interchangeably with the previously used term, SM-AHNMD (systemic mastocytosis with an associated non-mast cell lineage disease). AML, Acute myeloid leukemia; CEL, chronic eosinophilic leukemia; MDS, myelodysplastic syndrome; MPN, myeloproliferative neoplasm; WBC, white blood cell; WHO, World Health Organization.

TABLE 72.5 “B” Findings: Indication of High Mast Cell Burden

1. Infiltration grade (mast cells) greater than 30% in bone marrow in histology and serum total tryptase levels greater than 200 ng/mL
2. Hypercellular marrow with loss of fat cells, discrete signs of dysmyelopoiesis without substantial cytopenias, and without WHO criteria for an MDS or MPN
3. Organomegaly: palpable hepatomegaly, splenomegaly, or lymphadenopathy (on CT or ultrasound) greater than 2 cm without impaired organ function

MDS, Myelodysplastic syndrome; MPN, myeloproliferative neoplasm; WHO, World Health Organization.

dysfunction, especially when both disease components are of an aggressive type.

Although the prognosis of SM-AHN frequently relates to the AHN component, the burden of SM as well as the type and stage of the associated myeloid neoplasm need to be considered on an individual basis. Treatment plans are tailored to the histopathologic and molecular findings and the clinical sequelae that are felt to be attributable to each disease component. A commonly cited therapeutic approach has been to treat the SM component as if the myeloid neoplasm were not present, and to treat the myeloid neoplasm as if SM were not present. Because the *KIT* D816V mutation may be present in the cells belonging to both disease compartments, small molecule inhibitors of dysregulated KIT may provide benefit for both the SM and AHN in selected cases.

Aggressive systemic mastocytosis (ASM) comprises 5%–10% of SM variants and is defined by one or more “C findings” (Table 72.6) reflecting organ dysfunction because of neoplastic MC infiltrates. Examples of C findings include marked cytopenias because of extensive BM involvement (defined by an absolute neutrophil count

Expected US survival compared to all systemic mastocytosis patients

B

Fig. 72.1 SURVIVAL OF SYSTEMIC MASTOCYTOSIS PATIENTS. (A) The observed Kaplan-Meier survival for systemic mastocytosis patients (red) compared with the expected survival of the age- and sex-matched US population (blue). (B) The observed Kaplan-Meier survival for patients with systemic mastocytosis, classified by disease subtypes ISM (red), ASM (green), SM-AHN (yellow), and MCL (purple) compared with the expected survival of the age- and sex-matched US population (blue). ASM, Aggressive systemic mastocytosis; ISM, indolent systemic mastocytosis; MCL, mast cell leukemia; SM-AHN, systemic mastocytosis with an associated hematologic neoplasm; US, United States; WHO, World Health Organization.

[ANC] $<1 \times 10^9/L$, hemoglobin <10 g/dL, and/or platelet count $<100 \times 10^9/L$ and/or hypersplenism; hepatomegaly with liver dysfunction, and/or portal hypertension or ascites; hypoalbuminemia, which may relate to liver dysfunction and/or gut infiltration by neoplastic MCs; weight loss; and severe bone disease manifested by significant osteopenia and/or pathologic fractures. In a majority of patients with ASM, the percentage of MCs in the BM smear is below 5%, which is a favorable prognostic sign. Notably, in the less frequent ASM patients in whom MCs comprise $\geq 5\%$ of all nucleated BM cells on a Giemsa-stained BM smear, the prognosis is poor, as many of these patients progress and transform to MCL or an ASM-AHN. Therefore these patients have recently been described as ASM in transformation (ASM-t; see later also under diagnostic evaluation of mastocytosis).¹³ As soon as the percentage of MCs in these patients increase to $\geq 20\%$ in the BM smear, the diagnosis changes to MCL.

MCL is a very rare form of SM (~1% of SM variants) and is defined by MCs comprising $\geq 20\%$ of nucleated cells on BM aspirate smears. On the core biopsy, MCs form a diffuse, compact infiltrate with usually low levels of fibrosis. High-grade cytologic features of MCs can be observed in MCL, including multilobed or clefted

TABLE 72.6 “C” Findings: Indication of Organ Damage Attributable to Neoplastic Mast Cell Infiltration

1. Cytopenia(s): Absolute neutrophil count $<1000/\mu L$ or hemoglobin <10 g/dL or platelets $<100,000/\mu L$
2. Hepatomegaly with ascites and/or impaired liver function
3. Palpable splenomegaly with hypersplenism
4. Malabsorption with hypoalbuminemia and weight loss
5. Skeletal lesions: large-sized osteolyses or severe osteoporosis causing pathologic fractures
6. Life-threatening organopathy in other organ systems that is definitively caused by an infiltration of the tissue by neoplastic mast cells

nuclei, metachromatic blasts, and mitotic figures. In MCL, circulating MCs ($\geq 10\%$ of nucleated cells) may be found; however, the aleukemic MCL variant ($<10\%$ MCs in the peripheral blood) is more common. MCL may arise de novo or progress from less advanced forms of SM, such as ASM with elevated MC counts on the BM aspirate.¹³ MCL typically has a dismal prognosis with a life expectancy of 6 months or less in most patients (see Fig. 72.1).^{11,13,14} However, a chronic form of MCL has also been described, wherein patients meet histopathologic criteria for the disease, but without C findings (see later).¹³ In these cases, MCs tend to show a more mature morphology. However, even those with the initially more indolent form of (chronic) MCL are expected to show progression over time with development of organ damage (transformation to acute MCL) and limited survival.

MC sarcoma (MCS) is a rare MC tumor that can invade local tissues and has a high potential to develop advanced systemic disease with a fulminant course. In particular, most if not all patients with MCS progress to MCL within a relatively short time period. Extracutaneous mastocytoma is another rare SM variant that typically follows a benign course.

Well-differentiated SM (WDSM) is a more recently described, rare variant of SM that is not yet formally recognized by the WHO (see later for histopathologic characteristics). The major reason for this is that the well-differentiated (WD) morphology of MCs can be found in all WHO subvariants of SM, including ISM, ASM, and MCL. Therefore the WD phenotype should be used as a descriptive term to complement the WHO diagnosis rather than as a tool to formulate a new entity.

Mast Cell Activation Syndromes

During the past few years, diagnostic criteria have been formulated for mast cell activation syndromes (MCAS), which are clinical conditions defined by MC activation but are not regarded as subtypes of SM (Table 72.7).¹⁵ Patients with MCAS exhibit symptoms (e.g., anaphylaxis) and/or biochemical evidence of massive MC degranulation, with an event-related increase in serum tryptase. Other mediators produced by MCs may also increase during anaphylaxis. These mediators include plasma histamine, 24-h urine *N*-methylhistamine, PGD₂ or metabolite 11- β PGF₂. Several different variants of MCAS have been described (Table 72.8). In patients with reactive MCAS, an underlying allergy is most commonly detected, whereas no signs of MC clonality are found. By contrast, in patients with primary (clonal) MCAS, MC monoclonality can be demonstrated. In these patients, MCs in the BM may be increased, often with atypical morphology, and evidence for their clonality can be established by identification of *KIT* D816V or cell surface expression of CD25. In patients with primary MCAS, there are two subsets of patients. One group of patients fulfills the criteria of an underlying MC disease, usually in form of SM (criteria to diagnose SM are fulfilled). In the second group of patients, the burden of MCs is very low, and despite the documented presence of clonal MCs, neither SM nor CM can be diagnosed. In these patients, one or two minor

TABLE 72.7 Criteria for the Diagnosis of Mast Cell Activation

- A. Typical symptoms (see below)
- B. Increase in serum total tryptase by at least 20% above baseline plus 2 ng/mL during or within 4 h after a symptomatic period
- C. Response of clinical symptoms to histamine receptor blockers or MC-targeting agents, e.g., cromolyn

Typical Symptoms

Flushing
Pruritis
Urticaria
Angioedema
Nasal congestion
Nasal pruritis
Wheezing
Throat swelling
Headache
Hypotension
Diarrhea

MC, Mast cell.

Modified from Valent P, Akin C, Arock M, et al: Definitions, criteria and global classification of mast cell disorders with special reference to mast cell activation syndromes: a consensus protocol. *Int Arch Allergy Immunol* 157:215, 2015.

TABLE 72.8 Classification of Mast Cell Activation Syndromes

Category and Variants	Proposed Criteria
Primary MCAS = (mono) clonal MCAS Mastocytosis Primary MCAS without evidence of mastocytosis	MCA criteria fulfilled and MC (mono) clonality proven (CD25 ⁺ MC and/or <i>KIT</i> D816V) ^a
Secondary MCAS Allergy Other underlying disorder ^b	MCA criteria fulfilled and criteria for the diagnosis of allergy or other diseases that can produce MCA fulfilled as well
Idiopathic MCAS ^c	MCA criteria fulfilled, but no disease that could lead to MCA diagnosed

^aCD25⁺ MCs plus *KIT* D816V detectable, or *KIT* D816V detectable, but MCs cannot be demonstrated to express CD25.

^bDisorders associated with MCA include autoimmune diseases, certain bacterial infections, and some adverse drug reactions.

^cIdiopathic MCAS is a final diagnosis but needs an extensive workup in order to exclude all potential underlying conditions. Idiopathic and secondary MCA episodes may occur at different time points in the same patient.

MC, Mast cell; MCA, mast cell activation; MCAS, mast cell activation syndrome. From Valent P, Akin C, Arock M, et al. Definitions, criteria and global classification of mast cell disorders with special reference to mast cell activation syndromes: a consensus protocol. *Int Arch Allergy Immunol* 157:215, 2012.

SM criteria are typically present. However, at the time of diagnosis, a diagnosis of an underlying MC disease cannot be established.¹⁶ In both instances, the diagnosis is primary (clonal) MCAS. Because of the very low numbers of MCs, techniques to enrich for MCs and/or use of sensitive techniques to detect *KIT* D816V (e.g., allele-specific PCR) may be necessary to detect neoplastic MCs in these patients. Currently, there is no evidence that these two entities are “prodromal” SM conditions with a defined rate of progression to systemic MC disease. If neither an underlying allergy or another underlying reactive process nor a clonal population of MCs can be detected in an MCAS patient, the final diagnosis is idiopathic MCAS.¹⁵ Criteria for MCAS include an event-related increase in serum tryptase, typical clinical symptoms, and response of these symptoms to drugs targeting MC activation, MC-derived mediators, or their specific receptors.¹⁵ All three MCAS criteria must be fulfilled to characterize the condition as MCAS. The minimal increase in tryptase is defined by the following formula: 20% of baseline plus absolute 2 ng/mL. Example: if in

an SM patient with 100 ng/mL baseline tryptase, an anaphylactic response to a bee sting is followed by an increase to 150 ng/mL, the reaction is called MCA ($100 + 20 + 3 = 123$; this means any value above 123 qualifies as a MCAS criterion).¹⁵ It is important to know that after such an anaphylactic reaction, it takes at least 24–48 h (after complete resolution of symptoms) until the baseline of tryptase is again reached.

In patients with IgE-mediated hymenoptera venom anaphylaxis, particularly individuals with an elevated baseline tryptase level (separate from the acute rise after a sting), the suspicion for an underlying clonal MC disorder is increased. The differential diagnosis for MCAS includes less severe allergic or toxic reactions, endocrinologic disorders, cardiac diseases or severe infectious diseases (septicemia) leading to shock.

Diagnostic Evaluation of Mastocytosis

Tissue biopsy in conjunction with clinical and pathology expertise are critical in establishing the diagnosis of SM. BM MC burden is best quantified by morphologic analysis and immunohistochemical stains such as tryptase, CD117 (*KIT*), and CD25 on the core biopsy. Multiparameter flow cytometric analysis of BM aspirates can also be used to quantify the percentage of MCs, and generally correlates with SM burden defined by morphologic/immunohistochemical evaluation.¹⁶ Morphologic evaluation of the BM aspirate is additionally important for evaluating dysplasia and excess myeloblasts, and most relevant to MCL, the number of atypical MCs. Based on this evaluation, the presence of MCL can be excluded or can be confirmed during the diagnostic work-up.

The most important morphologic feature of mastocytosis, in particular its systemic variants, is the presence of compact infiltrates consisting of densely packed atypical MCs. Compact MC infiltrates are almost never detected in reactive states, even in those with marked MC hyperplasia. Accordingly, compact MC infiltrates can be regarded as the only major criterion for diagnosis of mastocytosis, which also underlines the important role of the hematopathologist in making these diagnoses. Investigation of an adequate BM biopsy trephine specimen is crucial to assess or exclude a diagnosis of SM. In most patients a few compact infiltrates can be identified even by using conventional stains like Giemsa-Wright or toluidine blue, which both facilitate detection of the pathognomonic metachromatic granules. The MCs are round or spindle shaped, and often exhibit at least some hypogranulation. The nuclei are round or elongated depending on the shape of the cell. Prominent nucleoli are not seen. Almost always such compact infiltrates also contain mature eosinophils, histiocytes, and sometimes large follicle-like aggregates of lymphocytes that are polyclonal in nature. Reticulin fiber density is always increased with the exception of a few very small but diagnostic infiltrates. Larger compact and mixed infiltrates often show patchy collagen fibrosis. The degree of reticulin fibrosis in most cases of MCL is low, which can be used as a criterion that allows one to distinguish MCL from aggressive SM, which usually exhibits marked reticulin or even collagen fibrosis (Fig. 72.2). Immunohistochemistry should be performed in all cases in order to enumerate the numbers of loosely scattered MCs and to detect small but diagnostic compact infiltrates. The degree of MC infiltration should always be documented by the hematopathologist: it is recommended to refer to the section area and to the overall cellularity in this respect. This enables monitoring of the disease during and after therapy. MCs almost always coexpress tryptase and CD117; in most SM cases, MCs also aberrantly express CD25, whereas aberrant expression of other antigens such as CD2 is more rarely encountered and therefore of minor diagnostic importance (Fig. 72.3). Interestingly, it could be shown that MCs may lose immunohistochemically detectable tryptase expression during or after therapy with TK inhibitors such as midostaurin, and MCs in cases of intestinal involvement by SM may lack tryptase expression at diagnosis (e.g., incomplete immunophenotype). However, it can be stated definitively that a cell lacking expression of CD117 (*KIT*) cannot be a MC. Although

Fig. 72.2 AGGRESSIVE SYSTEMIC MASTOCYTOSIS. Core biopsy, hematoxylin and eosin stain. Extremely hypercellular bone marrow with subtotal depletion of fat cells and normal blood cell precursors. Packed infiltration by atypical hypogranulated spindle-shaped mast cells that are embedded in a dense fibrotic stroma is the typical finding in aggressive systemic mastocytosis (ASM). However, only the presence of C-finding(s) qualifies such cases to be subtyped as ASM. Similar pictures can be seen in smoldering systemic mastocytosis with B-findings. Note that the morphologic features of nonspecific fibrosis or granulation tissue may be very similar and appropriate immunostaining is necessary to confirm the diagnosis of SM.

Fig. 72.3 ACUTE MAST CELL LEUKEMIA WITH CD30 EXPRESSION. Core biopsy with positive staining of mast cells for surface CD30. Bone marrow section shows extreme hypercellularity with diffuse-packed infiltration by atypical round mast cells coexpressing tryptase and CD117 (not depicted). A significant number of the mast cells stain positive by an antibody against CD30, among them a few multinucleated giant cells that resemble Reed-Sternberg cells. A diagnosis of Hodgkin lymphoma should not be established in such cases.

ISM and isolated mastocytosis of the BM usually show a minor degree of BM involvement with multifocal compact infiltrates (<10% of the section area), smoldering and aggressive SM but also MCL usually exhibit a more diffuse or packed infiltration occupying more than 30% and up to 100% of the section area. Regarding morphologic and immunophenotypic features of MCs in SM, a broad spectrum of differential diagnoses should be considered.

Fig. 72.4 CHRONIC MAST CELL LEUKEMIA (BY CLINICAL BEHAVIOR). Bone marrow aspirate (Papanheim stain) shows a very unusual picture with an extreme increase of spindle-shaped and often slightly hypogranulated mast cells. Note their elongated nuclei. Nucleoli are inconspicuous. Mast cell number is almost 100% and a diagnosis of mast cell leukemia can easily be established. The prolonged survival of this patient and the unique cytomorphologic aspect qualifies this case to be subtyped as chronic mast cell leukemia.

The following list only contains the main entities and is therefore incomplete:

1. monocytic leukemias (clear cell feature + CD14)
2. histiocytoses (clear cell feature + CD68)
3. clear-cell carcinomas (clear cell feature)
4. basophilic leukemias (metachromatic granules + tryptase)
5. myelomastocytic leukemia (metachromatic granules + tryptase + CD117)
6. Hodgkin lymphoma (CD30)
7. hairy cell leukemia (clear cell feature + CD25)

Evaluation of blood and BM smears is crucial for both identification and subtyping of MCL and separation of MCL from a recently described subtype of ASM, namely ASM-t (see earlier). In almost all patients with ISM and SSM, but also in most cases with ASM, the MC numbers in BM smears are lower than 5%, in ISM and SSM usually even below 1%. Crushed particles with higher numbers of MCs must not be considered in this respect. In a few patients with ASM the number of MCs is unusually high, exceeding 5% but not 19% of all nucleated cells. It is this subgroup of patients that bears a worse prognosis but do not fulfill criteria for MCL and have therefore been termed ASM-t.

Cytomorphologic findings in SM include atypically shaped MCs with spindled appearance (type I) on the one hand and round immature MCs with bilobated or monocytoid nuclei on the other (type II). Atypical type I MCs are usually encountered in ISM, SSM, and often also in ASM, but also in isolated mastocytosis of the BM (BMM), whereas atypical type II MCs dominate the picture in most cases of MCL, and are often found also in patients with ASM and ASM-t. Exceedingly rare cases of MCL with predominance of spindle-shaped cells of type I are associated with a relatively good prognosis and the disease accordingly has been termed *chronic MCL* (see earlier) (Fig. 72.4). There is one peculiar phenotypic variant of SM termed *well-differentiated SM* (; see earlier) that consists exclusively of round hypergranular-appearing MCs that form the typical cohesive clusters in BM smears. Such MC clusters are not seen in all of the subvariants of SM. The feature of well-differentiated SM has been encountered in almost all defined subvariants of SM including

Fig. 72.5 WELL-DIFFERENTIATED SYSTEMIC MASTOCYTOSIS. Core biopsy, Giemsa stain. Bone marrow shows aggregates of exclusively round mast cells with an abundance of metachromatic granules. This is the typical phenotypical appearance of a well-differentiated systemic mastocytosis. The disease was otherwise subtyped as indolent systemic mastocytosis with skin involvement but missing *KIT* D816V mutation and also lack of CD25 expression by the mast cells (not depicted).

MCL. Well-differentiated SM usually lacks aberrant expression of CD25 and does also not show the typical activating point mutations at codon 816 of *KIT* (Fig. 72.5).

CD30 (Ki-1) is a cytoplasmic and membrane-bound antigen expressed by neoplastic cells in Hodgkin lymphoma and anaplastic large-cell lymphoma. Recently, however, CD30 has also been shown to be expressed by neoplastic MCs in SM.¹⁷ Although the antigen was originally reported as an immunohistochemical marker that is primarily expressed in the cytoplasm of MCs in more advanced forms of SM, other studies have detected CD30 by immunohistochemistry in less advanced forms of MC disease, including CM, as well as ISM and SSM. CD30 is not only expressed in the cytoplasm of neoplastic MCs but also on the cell surface, which has clinical implications as a CD30 antibody-toxin conjugate is available and is currently being tested in patients with advanced SM.

Serum Tryptase Level

Tryptase is considered to be a most reliable and robust initial parameter with which to screen patients with suspected SM.^{18,19} Tryptase is a serine protease primarily produced by MCs, and to a lesser extent by mature basophils and myeloid progenitors. Commercially available ELISA-based assays measure total serum tryptase levels which consist of both mature tryptase (β -tryptase) and protryptases (e.g., α -tryptase). The basal serum tryptase level reflects the MC burden in healthy individuals as well as in patients with SM, whereas the event-related (further) increase in tryptase is a marker of MC activation. β -tryptase is stored in MCs and released together with all other granular substances upon degranulation/anaphylaxis (tryptase levels peak 1–2 h after degranulation event and return to baseline after 24–48 h). The α -tryptase form is constitutively produced by MCs and thus more reflects the total burden of MCs. For many centers, the upper normal reference range for the serum tryptase level is 10 or 11.4 ng/mL. However, healthy individuals may exhibit levels in the range of 5–15 ng/mL or higher, which may be confounded by the association between advancing age and increasing serum tryptase levels. Although a serum tryptase level >20 ng/mL serves as a minor diagnostic criterion for SM, a minority of patients with histopathologically proven SM can exhibit values lower than this threshold. In adult patients with MIS or hymenoptera allergy, a serum tryptase

level >20 ng/mL is suggestive of the presence of SM. Conversely, patients with CM usually exhibit a serum tryptase level <20 ng/mL, or it may be within normal range. Other medical conditions besides SM and anaphylaxis that can produce an elevated tryptase level include renal failure, chronic helminth infections (MC hyperplasia), SCF treatment, and myeloid neoplasms, including MDS, MPN, AML, and CEL—notably patients with the *FIP1L1-PDGFR* fusion gene.

Although there is a close correlation between high tryptase levels and advanced SM, serum tryptase levels do not necessarily reflect the aggressiveness of the disease. Likewise, SSM is partially defined by a very high serum tryptase level exceeding 200 ng/mL, and in many of these cases, progression does not occur for many years. Contrasting the smoldering state, most patients with typical ISM have lower serum tryptase levels, although enzyme levels can vary widely among patients according to the MC burden. Patients with ASM and MCL may exhibit serum tryptase levels in the several-hundred range to over 1000 ng/mL. In many of these patients, serum basal tryptase levels increase rapidly over time (in contrast to ISM and SSM). Although discordances can exist between the serum tryptase level and the degree of MC infiltration of the marrow and other organs, it is the most useful and widely available biomarker that can be used to assess changes in the MC burden in response to cytoreductive therapy.

Clinical Manifestations

Organomegaly

Splenomegaly and hepatomegaly, without associated organ damage, have traditionally been referred to as “B” findings and are one of the defining features of SSM. Similarly, SM-related substantial (palpable, >2 cm) lymphadenopathy has been included in the category of “B” findings. Organomegaly by itself does not indicate inexorable progression to advanced SM or organ damage. However, even in the absence of organ damage, symptomatic splenomegaly may warrant therapeutic intervention similar to patients with myelofibrosis or other hematologic neoplasms.

Nonhematologic Organ Damage

The challenge of defining response parameters related to hepatic function is several-fold. First, for patients with SM with associated myeloid neoplasm, it is unclear whether liver dysfunction is related to the SM or the accompanying myeloid disease. Concomitant diseases such as MPN or MDS/MPN such as CMML, CEL, or AML may (also) involve the liver and result in a hepatitis-like syndrome or obstructive liver disease. It is unknown what level of liver involvement by MC consistently results in liver dysfunction. Liver biopsy is sometimes performed and may help to assess the grade and extent of liver involvement by SM. Although liver biopsy may be informative, the potential information gleaned from the procedure must be weighed against potential complications such as bleeding, especially in the setting of severe thrombocytopenia and/or coagulopathy.

Hypoalbuminemia is an adverse prognostic factor for overall survival (OS) in SM^{3,11}; it can reflect worsening synthetic function of the liver, and/or worsening nutritional status or even malabsorption because of gastrointestinal infiltration by neoplastic MCs. The development of ascites in SM usually reflects aggressive liver disease and may be accompanied not only by hepatomegaly but also by abnormal liver function test, often with an elevated alkaline phosphatase and/or portal hypertension. More uncommonly, ascites may develop without evidence for liver disease, or in conjunction with massive abdominal lymphadenopathy. Similar to ascites, pleural effusions may develop in advanced SM, although it is an uncommon event. Every attempt should be made to establish that the ascites or pleural effusion is related to SM and/or the associated

myeloid neoplasm, including evaluation of MC content. Other causes of effusion should be excluded including infection, heart failure, and drugs such as dasatinib that have been used to treat advanced SM.

Hematologic Organ Involvement

The etiology of cytopenias in advanced SM includes compromise of normal marrow reserve by infiltration with neoplastic MCs (often seen in ASM and MCL), ineffective hematopoiesis in the context of SM with an associated myeloid neoplasm, hypersplenism, and other causes such as recent myelosuppressive therapy or gastrointestinal bleeding. The coexistence of another myeloid neoplasm (AHN) often makes it difficult to ascertain the specific cause of the low blood counts. This distinction is not relevant to ISM, where the relatively lower MC burden is not expected to contribute to the development of cytopenias.

Molecular Features of SM

Following the discovery of the somatic *KIT* D816V mutation in MC neoplasms in the mid-1990s,²⁰ it has become evident that this molecular abnormality is found in approximately 80% to 90% of SM patients. *KIT* D816V serves as a minor diagnostic criterion for the disease, and is considered a major driver of SM pathogenesis. Rare codon 816 variants such as D816F/H/I/Y have also been described and are considered functionally equivalent to D816V. Mutations affecting codon 816 are located in exon 17 and affect the second TK domain (TK2) that contains the phosphotransferase site and activation loop of KIT. Other mutations that have been identified in exon 17, for example in cases of ASM and MC sarcoma, include D820G and N822K. *KIT* mutations in exons 8–9 of the extracellular region (del419, S451C, ITD 502–503) and the TM region (exon 10; e.g., F522C), and JM domain (exon 11; e.g., V560G/I) comprise some of the additional rare mutations in *KIT* that have been observed (Fig. 72.6).²¹ With a few exceptions (e.g., V559I), mutations affecting these domains are more likely to exhibit sensitivity to imatinib, whereas codon 816 variants are imatinib resistant. Contrary to other SM subtypes, MCL less frequently exhibits the *KIT* D816V mutation; in a review of MCL, D816V was found in 13 of 28 (46%) evaluable patients. MCL patients may exhibit other variants within *KIT*, or sequencing of the entire *KIT* gene may reveal no mutations. Increasingly sensitive assays, such as allele-specific quantitative PCR for *KIT* D816V, are now available and can detect *KIT* D816V in the peripheral blood of almost all adult patients with SM. Where available, it has been recommended that such sensitive assays be used as a valuable screening test for patients with suspected SM.¹⁹ However, a low MC burden or the presence of other rare *KIT* or non-*KIT* mutations could lead to negative results; therefore a full workup with BM biopsy is warranted in typical cases where clinical symptoms and findings are highly suggestive of the presence of SM.

In a large cohort of pediatric mastocytosis patients, 36% exhibited *KIT* D816V mutations, and three (6%) patients had other codon 816 mutations (D816Y [*n* = 2] and D816I [*n* = 1]). Another 42% demonstrated *KIT* mutations outside exon 17, with half of these being located in exons 8 and 9 (D417-418, D419Y, C443Y, S476I, ITD502-503, K509I) and exon 11 (D572A). When these data were combined with a cohort from Dubreil and colleagues, 76% of the pediatric patients were found to have alterations in *KIT*, all of which resulted in constitutive activation of the TK. Multiple families with hereditary mastocytosis, typically manifesting as cutaneous disease, were found to have germline *KIT* mutations, including K509I, A533D, N822I, M835K, S849I, or deletion of amino acids 419 or 559–560).

SM-AHN cases commonly harbor molecular abnormalities related to the myeloid disease component in addition to *KIT* D816V. For example, *JAK2* V617F has been found in SM with myelofibrosis; *BCR-ABL1* in rare cases of concurrent SM-CML; and in SM-AML,

Fig. 72.6 STRUCTURE OF THE *KIT* GENE AND MUTATIONS IN MASTOCYTOSIS. Representation of the structure of *KIT*, illustrating the localization of the more frequently observed mutations in the *KIT* sequence in pediatric and adult patients with mastocytosis. The receptor is presented under its monomeric form, whereas its WT counterpart dimerizes upon ligation with SCF before being activated in normal cells. In children, the *KIT* D816V PTD mutant (in red) is found in nearly 30% of the patients, whereas the ECD mutants (in blue) are found in nearly 40% of the affected children, the most frequent being the deletion 419. In adults, depending of the category of mastocytosis, the *KIT* D816V mutant (in red) is found in at least 80% of all patients. The complete list of *KIT* mutants retrieved in the literature for mastocytosis is depicted here. In children, the structure of *KIT* is found WT in ~25% of the patients analyzed, whereas in adults, *KIT* is found WT in <20% of all patients analyzed so far. Some of the mutations are found only in a very few number of patients. The symbols indicate the following: ±, mutation found in <10% of the pediatric or adult patients; +, mutations found in 1%–5% of pediatric patients; ++, mutation found in 5%–20% of pediatric patients; +++, mutation found in ~30% of pediatric patients and in >80% of all adult patients. *Mutation also found in children at low frequency. Del, Deletion; ECD, extracellular domain; Ig, immunoglobulin; Ins, insertion; ITD, internal tandem duplication; JM, juxtamembrane domain; KI, kinase insert; PTD, phosphotransferase domain; TK, tyrosine kinase; TM, transmembrane domain. (From Arock M, Sotlar K, Akin C, et al: *KIT* mutation analysis in mast cell neoplasms: recommendations of the European Competence Network on Mastocytosis. *Leukemia* 29:1223, 2015.)²¹

the t(8;21)(q22;q22) *RUNX1/RUNX1T* rearrangement is a well-known association. In cases of *KIT* D816V-positive SM, several reports have now detailed the coexistence of additional myeloid neoplasm-related mutations, which are implicated in differentiation, epigenetic regulation, and control of the spliceosome machinery. The common themes that have emerged are: (1) ISM tends to be more a pure *KIT* D816V-driven disease with absence of, or low frequency of additional (known) molecular abnormalities; (2) *TET2*, *SRSF2*, and *ASXL1* are the most common of the myeloid neoplasm-associated mutated genes (~20%–35% of patients), but mutations in *DNMT3A*, *CBL*, *KINRAS*, *UAF1*, *ZRSF2*, *EZH2*, *RUNX1*, *ETV6*, and *SETBP1* have also been identified; and (3) the presence of one or more of these genes mutations are usually associated with more advanced disease subtypes, particularly SM-AHN. Schwaab et al found that the presence of one or more of these mutations in addition to *KIT* D816V was associated with inferior survival,²² and a separate analysis found that mutation of *ASXL1* had a significant negative impact on OS among a cohort of 62 patients with SM-AHN. Mutations in the ethanolamine kinase gene *ETNK1* were recently found to be enriched in SM patients with eosinophilia, but are commonly present with *KIT* D816V or other myeloid disease-associated mutations (Dr. Andreas Reiter, personal communication). Mutations in *ETNK1* were also identified in ~9% of patients with atypical CML and in <5% of patients with CMML. The basis for the restriction of *ETNK1* mutations to these diseases and how they contribute to their pathogenesis is unknown. In one patient with MCL, exome sequencing revealed an imatinib-resistant *KIT* V654A mutation as well as a mutation in the β -chain of Fc ϵ RI, but the functional consequences of this variant were not explored.

Special research techniques have been used to interrogate the cell-specific distribution of mutations. For example, *KIT* D816V has been demonstrated in both MCs and the AHN component (e.g., monocytes in CMML) by cell laser microdissection; *TET2* and *KIT* D816V have been found together in flow-sorted MCs; the *SRSF2* P95 hotspot mutation has been uncovered in both MCs and monocytes from a case of SM-AHN; and finally, t(8;21) has been identified by FISH in the BM MCs and the leukemic clone of a patient with SM and AML.

In 2003 the *FIP1L1-PDGFR* fusion oncogene was identified in patients with a diagnosis of idiopathic hypereosinophilic syndrome. This molecular abnormality is not visible by standard chromosome analysis and its detection requires either use of reverse-transcriptase polymerase chain reaction or, more commonly, fluorescence in situ hybridization (FISH). Because this genetic lesion results from an interstitial 800-kb deletion on chromosome 4q12, which removes a segment of DNA involving the *CHIC2* gene, the diagnostic test is referred to as “FISH for the *CHIC2* deletion.” Patients with *FIP1L1-PDGFR*-associated eosinophilia present with features of a myeloproliferative disorder: splenomegaly, hypercellular BMs, and clinicopathologic characteristics that overlap with SM, including increased numbers of abnormal-appearing BM MCs, marrow fibrosis, and elevated serum tryptase levels. However, although *FIP1L1-PDGFR*-positive myeloid neoplasms may exhibit increased numbers of BM MCs, they usually form interstitial or loose clusters, and this disease entity is not considered a subtype of SM by the WHO. However, in a smaller subset of patients, criteria for SM may be fulfilled even if a *KIT* mutation is not detected. Notably, in almost all cases with *FIP1L1-PDGFR*-positive myeloid neoplasms, including those who have SM-CEL, MCs do not exhibit *KIT* D816V, even if they express CD25. Although the *FIP1L1-PDGFR* genetic abnormality was once considered mutually exclusive of *KIT* D816V, rare cases with both mutations have now been reported, including their coexistence in tryptase-positive microdissected MCs.

Investigators identified a set of clinical and laboratory features that could reliably distinguish patients with *KIT* D816V-positive SM with eosinophilia from individuals with the *FIP1L1-PDGFR*-positive myeloid neoplasms with eosinophilia (Table 72.9).²³ These criteria may be particularly useful when molecular testing is not readily available. In the D816V *KIT*-positive group, gastrointestinal symptoms, urticaria pigmentosa, thrombocytosis, median serum tryptase

TABLE 72.9

Clinicopathologic Features of Eosinophilia-Associated *FIP1L1-PDGFR*-Rearranged Myeloid Neoplasms Versus *KIT* D816V-Positive Systemic Mastocytosis

Features	<i>FIP1L1-PDGFR</i> -Rearranged	<i>KIT</i> D816V-Positive
Gender	Overwhelmingly male	Less gender skewing
Bone marrow mast cell aggregates	Loose clusters/interstitial	Dense aggregates
AEC/tryptase ratio	>100	≤100
Treatment	Imatinib sensitive	Imatinib-resistant; second-generation TKIs (e.g., midostaurin)
Symptom profile	Cardiac/pulmonary	Gastrointestinal/urticaria pigmentosa/anaphylaxis
Vitamin B ₁₂ level	Elevated	Often normal

AEC, Absolute eosinophil count; TKI, tyrosine kinase inhibitor.

Modified from Maric I, Robyn J, Metcalfe DD, et al: *KIT* D816V-associated systemic mastocytosis with eosinophilia and *FIP1L1/PDGFR*-associated chronic eosinophilic leukemia are distinct entities. *J Allergy Clin Immunol* 120(3):680-687, 2007.

value, and the presence of dense MC aggregates in the BM were statistically significantly increased or more frequently represented compared with patients with the *FIP1L1-PDGFR* gene fusion. Conversely, male sex, cardiac and pulmonary symptoms, median peak absolute eosinophil count, the eosinophil to tryptase ratio, and elevated serum B₁₂ levels were higher or more common in the group with *FIP1L1-PDGFR*. A scoring system incorporating these clinical and laboratory parameters could reliably predict whether patients with peripheral eosinophilia and increased marrow MC burden carried the *FIP1L1-PDGFR* gene fusion or the *KIT* D816V mutation, which is important for guiding targeted therapy options.²³ Treatment of *FIP1L1-PDGFR*-positive myeloid neoplasms associated with eosinophilia is discussed in Chapter 71.

Additional Diagnostic Studies

In all patients with symptomatic SM, a thorough work-up for allergies, including total and specific IgE levels, should be performed. Biochemical studies to evaluate for MC activation/mediator release include 24-h urine evaluation of *N*-methylhistamine, prostaglandin D₂, or 11-B-prostaglandin F₂. Bleeding diatheses have been reported in patients with MCAS or SM, and increased heparin levels can be found in patients with SM or MC activation. Dual energy x-ray absorptiometry (DEXA) scans should be undertaken to screen for osteoporosis, and plain x-ray films (e.g., metastatic skeletal survey) are used to evaluate osteolytic lesions and/or pathologic fractures. MC-related gastrointestinal symptoms such as diarrhea and signs of malabsorption (e.g., hypoalbuminemia and weight loss) can be evaluated with endoscopy/colonoscopy with biopsy using appropriate immunohistochemical stains (e.g., CD117, tryptase, CD25, and CD3 as a control T-cell marker) to highlight abnormal MCs. Ultrasonography, CT and/or MRI of the abdomen/pelvis (with or without volumetric imaging) are utilized to determine the presence and extent of B and C findings such as hepato/splenomegaly, portal hypertension, ascites, and lymphadenopathy.

Diagnostic Decision Making

In patients presenting with MC activation symptoms or anaphylaxis without signs of cutaneous involvement, and a normal or elevated serum tryptase level, the diagnostic workup is centered on establishing whether WHO diagnostic criteria for SM are met (Fig. 72.7). If these criteria are not satisfied, a workup is performed to rule out or

diagnose MCAS, and to document (other) primary and secondary causes of MC expansion or MC activation.

In adult patients with cutaneous MC lesions, the large majority of such patients will ultimately be found to have SM according to WHO diagnostic criteria. A BM biopsy is generally recommended in these patients to establish a diagnosis of SM (see Fig. 72.7). In patients with modest elevations of the serum tryptase level, mild or no symptomatology, nor evidence of blood count abnormalities or other signs of organ damage, diagnostic testing may not elicit short-term changes in management even if SM is found. However, given the differences in OS between adult CM and SM, and the fact that only those with SM may develop severe bone disease (osteoporosis) requiring therapy staging investigations should be extended in SM, BM analysis can be very helpful as an initial “forensic” assessment of these potential disease trajectories. Children with skin lesions rarely have systemic disease. Therefore a BM biopsy is generally not recommended in children unless the serum tryptase level is unusually high

or progressively increasing, or organomegaly and/or blood count abnormalities emerge.

Survival and Prognostic Factors

In a Mayo series of 342 patients with SM (46% ISM, 12% ASM, 40% SM-AHN, 1% MCL), life expectancy in ISM was similar to age- and sex-matched normal controls.¹¹ In contrast, median OS (and leukemia-free survival) was inferior in patients with more advanced forms of SM. For example, the median OS was 41 months and 24 months, respectively for ASM ($n = 41$ patients) and SM-AHN ($n = 138$ patients), and only 2 months for MCL ($n = 4$) patients. In a multivariate analysis, independent adverse prognostic factors included advanced age, weight loss, anemia, thrombocytopenia, hypoalbuminemia, and excess BM blasts.¹¹ In addition to an increased percentage of MCs on marrow aspirate smears, Spanish investigators found that

Fig. 72.7 DIAGNOSTIC DECISION PATHWAYS FOR PATIENTS WITH MAST CELL ACTIVATION SYMPTOMS OR ADULT-ONSET MASTOCYTOSIS IN THE SKIN. For patients with mast cell activation symptoms or anaphylaxis (and/or increased serum tryptase level), or adult-onset MIS, screening to assess whether the diagnostic criteria for SM are met should be the first diagnostic checkpoint. For patients not meeting criteria for SM, evaluation for MCAS (primary vs. secondary vs. idiopathic) and idiopathic anaphylaxis is the next phase of evaluation. Patients with MIS for whom no signs of SM can be found may be categorized as cutaneous mastocytosis. *The serum tryptase level may be below the 20 ng/mL threshold, or only transiently elevated. **Although an evaluation for systemic mastocytosis is generally recommended in adults with MIS with no blood count abnormalities or organ dysfunction, and a normal or mildly increased serum tryptase level, the value of performing a bone marrow biopsy should be discussed with the patient. MC, Mast cell; MCAS, mast cell activation syndrome; MIS, mastocytosis in the skin; SM, systemic mastocytosis; PDGFRα, platelet-derived growth factor receptor A; WHO, World Health Organization. (Adapted from: Pardamani A: *How I treat patients with indolent and smoldering mastocytosis (rare conditions but difficult to manage)*. Blood 2013;121:3085, 2013; Valent P, Akin C, Arock M, et al: *Definitions, criteria and global classification of mast cell disorders with special reference to mast cell activation syndromes: a consensus protocol*. Int Arch Allergy Immunol 157:215, 2012.)

multilineage involvement of the *KIT* D816V mutation in more than just MCs (e.g., other myeloid lineages, and sometimes lymphoid cells) is a poor prognostic factor and leads to an increased risk of progression to advanced SM.²⁴ Many of these patients may suffer from overt SSM. In patients with SM, eosinophilia was also associated with inferior outcomes in one study, and was prognostically neutral in another series. SM patients with eosinophilia tend to suffer from SSM, ASM, or MCL, but even in ISM, eosinophilia may be detected.

TREATMENT

Therapy of mastocytosis centers on addressing symptoms related to MC activation (in all categories), and using cytoreductive agents to reverse organ damage caused by neoplastic MC infiltrates in advanced SM. Fig. 72.8 provides a treatment algorithm for indolent versus advanced stages of SM and the broad therapeutic strategies that are available based on the presence of mediator symptoms, organ damage, and a concomitant AHN.

Mast Cell Activation Symptoms/Anaphylaxis

All adult mastocytosis patients, regardless of prior anaphylactic events, should carry two doses of an adrenaline autoinjector (and should be instructed in its safe use, e.g., by an allergist) to treat potential future episodes of anaphylaxis. In addition, emergency medicines such as diphenhydramine or oral prednisolone should be considered, although their utility for mitigating acute symptoms is less well-established. Because anaphylaxis can also be a feature of MCAS, these patients are candidates for similar therapy even if no overt SM was diagnosed. The treatment of choice for life-threatening Hymenoptera allergy/anaphylaxis is venom immunotherapy that should be undertaken with caution using a multidisciplinary approach led by allergists. Similarly, perioperative management of anesthetics, which can precipitate immediate and delayed MC activation, requires consultation with the surgical, anesthesiology, and allergy teams to minimize the occurrence and severity of anaphylaxis. General guidelines regarding anesthesia and analgesic management in patients with mastocytosis have been published.

The treatment of MC activation symptoms follows a stepwise approach using antimediator drugs and other supportive care

measures.²⁵ These medications include H1-histamine blockers for flushing and pruritis, and H2-histamine blockers for SM-related gastrointestinal (GI) symptomatology such as diarrhea, abdominal discomfort/cramping, and peptic ulcer disease. Leukotriene antagonists such as Montelukast are commonly added to H1-histamine blockers for persistent flushing and pruritis. In rare cases, aspirin can be a alternative therapy for refractory flushing, but needs to be used with caution because of its ability to precipitate MC activation, bleeding tendency, and GI tract ulcerative disease. In general, however, aspirin is not recommended for use in SM. Although the MC stabilizer sodium cromoglycate (Gastrocrom) is geared to persistent GI symptoms such as diarrhea, proton pump inhibitors may be specifically useful for patients with refractory GERD/peptic ulcer disease. Alternative treatments that have been used for refractory mediator symptoms include the off-label antihistamine/MC stabilizer ketotifen, and the anti-IgE antibody omalizumab, which has also been used for anaphylaxis, as well as asthma. Although bisphosphonates (alendronate 70 mg q week; risedronate 35 mg q week; pamidronate 90 mg intravenously (IV) q 4 weeks; and zoledronic acid 4 mg IV q 4 weeks) are recommended for bony disease, reports of their use in SM primarily consists of single cases or small cases series. A generally accepted rule is to start with a bisphosphonate when the T-score drops to below -2.5 . IFN- α has been employed with bisphosphonates and/or as single agent therapy, especially for patients with refractory bony pain and/or MC-related osteoporosis and pathologic fractures. Concerns regarding the cosmetic appearance of cutaneous lesions or skin-related mediator symptoms refractory to the aforementioned therapies can be helped for a limited period of time with phototherapy (UVA₁, narrow-band UVB, and UVA plus psoralen). In addition, occlusion dressings embedded with topical steroids with or without phototherapy, and both topical and oral forms of sodium cromoglycate, have been used with some benefit.

Cytoreductive Agents

IFN- α and cladribine (2-chlorodeoxyadenosine) have typically been used for patients with progressive SSM and for cytoreduction in advanced SM patients (ASM, MCL, and SM-AHN) to reduce or reverse organ damage. In most instances, cladribine is favored over IFN- α to induce debulking of neoplastic MCs in advanced SM patients. The use of both drugs is recommended to treat patients with less rapidly progressive disease (PD). In addition, cladribine and

Fig. 72.8 TREATMENT OPTIONS BASED ON SUBTYPE OF SYSTEMIC MASTOCYTOSIS. Treatment options are listed based on subvariant of SM (indolent vs. advanced forms of disease), whether organ damage is considered related to SM or the associated myeloid neoplasm in patients with SM-AHN, and whether cytoreductive therapy may need to be considered in patients with ISM and refractory mediator symptoms. 2-CdA, 2-Chlorodeoxyadenosine; ASM, aggressive systemic mastocytosis; HSCT, hematopoietic stem cell transplantation; ISM, indolent systemic mastocytosis; IFN- α , interferon- α ; MCL, mast cell leukemia; SM, systemic mastocytosis; SM-AHN, systemic mastocytosis with an associated hematologic neoplasm; SSM, smoldering systemic mastocytosis.

IFN- α are sometimes used to control mediator symptoms, especially when these symptoms are refractory to conventional antimediator-type drugs. In addition, low-dose IFN- α has been suggested for ISM patients with drug-resistant osteoporosis. Otherwise, however, these agents are not recommended for use in ISM or SSM. In patients with rapidly progressive ASM or MCL, more intensive therapy is usually recommended, whereas cladribine alone or IFN- α alone are insufficient to control rapid disease expansion or transformation in SM.

Interferon- α

IFN- α has been used as monotherapy or in combination with corticosteroids, mostly in patients with ASM with slow progression or mono-organ involvement. For example, the drug works effectively in patients with ASM with liver involvement and ascites. Prednisone or prednisolone 0.5–1 mg/kg is initiated with IFN- α (or as a lead-in dose for several days prior) in order to improve its efficacy and tolerability, and tapered over 2–3 months if feasible. In some patients with severe and persistent mediator symptoms or organ damage that is particularly responsive to corticosteroids, a longer term maintenance dose (e.g., ≤ 10 mg daily) may be required. IFN- α dosing has been variable between studies and an optimal dose has not been identified. Starting doses have ranged from 1 million units (MU)/day to 3 MU three times weekly, with median total weekly maintenance doses in the range of 15–30 MU. Because of the (low) risk of anaphylactic reactions, consideration should be given to hospitalization of patients during the first days of treatment, if possible.

In the Mayo experience with IFN- α (with or without prednisone),²⁵ 21 of 40 evaluable patients responded (53%); response rates by subgroup were: six of 10 ISM, six of 10 ASM, and nine of 20 SM-AHN. The 21 responses consisted of one complete remission (CR), six major responses (MRs), and 14 partial responses (PRs). The median duration of response (DOR) was 12 months (range, 1–67) with no statistical difference between responders and nonresponders regarding use of prednisone or the median weekly dose of IFN- α . However, the absence of mediator-related symptoms was associated with a significantly lower response rate.

In the French experience with 20 SM patients (four ISM and 16 ASM), IFN- α -2b was initiated at 1 MU daily and progressively increased as tolerated up to 5 MU/m² daily. Among the 13 patients treated for at least 6 months (mean daily dose: 3.2 MU daily), all had partial or complete resolution of systemic or cutaneous disease manifestations and/or MC mediator levels, but no significant reduction in BM MC burden. The lack of a substantive effect on tumor load and rapid relapse in four responding patients after drug withdrawal suggests that IFN- α exerts a cytostatic effect on MCs.

Responses to IFN- α primarily include amelioration of MC mediator symptoms and associated laboratory markers of MC activation such as levels of histamine or its metabolites. Single cases and small case series, in addition to the aggregate data from the aforementioned larger trials, indicate variable potential to ameliorate skin lesions, osteoporosis, and C findings such as cytopenias, hepato/splenomegaly with liver dysfunction and/or ascites, and weight loss. Toxicities associated with IFN- α such as flu-like symptoms, myelosuppression, transaminitis, hypothyroidism, depression, and bone pain are not uncommon, and result in a moderate proportion of patients requiring dose-reduction or drug discontinuation.

Cladribine

Cladribine has been used off-label across a spectrum of SM subtypes. In 2013 cladribine received orphan designation (not marketing authorization) for the treatment of SM in Europe. Following an initial report indicating that cladribine could elicit improvement of mediator symptoms, urticaria pigmentosa lesions, and reduction of MC burden and the serum tryptase level, Kluin-Nelemans and colleagues published a series of 10 patients, including 3 with ISM, 1 SSM, 3 SM-AHN, and 3 ASM. Cladribine was administered for 5

days every 4–8 weeks at a dose of 0.10–0.13 mg/kg over 2 h IV. Among 9 evaluable patients (1 discontinued because of toxicoderma), the drug elicited improvement in symptoms, and a decrease (often rapid) in urticaria pigmentosa lesions, MC burden, serum tryptase levels, and urine metabolites of MC activation.

In the Mayo Clinic experience,²⁵ cladribine was administered for 5 days at a dose of 5 mg/m²/day (or 0.13–0.17 mg/kg/day) for 5 days IV. A median of 3 cycles (range, 1–9) was administered. The overall response rate was 12 of 22 (55%), consisting of 1 CR, 7 MR, and 4 PR. Responses were observed in 5 of 9 ISM, 1 of 2 ASM, and 6 of 11 SM-AHN patients. Improvement in mediator symptoms, organomegaly, C-findings (e.g., ascites, anemia), and markers of MC burden and/or activation (e.g., serum tryptase level and MC-derived urine metabolites) were observed. The median response duration was 11 months, and inferior outcomes were predicted by leukocytosis, monocytosis, and circulating immature myeloid cells, the latter remaining significant in a multivariate analysis.

The long-term French experience with cladribine in both indolent ($n = 36$) and advanced ($n = 32$) SM patients was recently published.²⁶ Cladribine was administered as an infusion or subcutaneously at a dose of 0.14 mg/kg, for 1–5 days, every 4–12 weeks. A median of 3.7 courses was administered (range, 1–9). The overall response rate was 72%, split between 92% and 50% for indolent and advanced disease, respectively. Among patients with advanced SM, the respective CR, MR, and PR rates were 0%, 37.5%, and 12.5%. Significant decreases in serum tryptase levels was only observed in ISM patients, and changes in BM MC burden were only evaluated in nine patients, precluding a substantive conclusion regarding this endpoint. Median durations of response were 3.71 (range, 0.1–8) and 2.47 (range, 0.5–8.6) years for indolent and advanced SM, respectively. Lymphopenia (82%), neutropenia (47%), and opportunistic infections (13%) were the most common grade 3/4 adverse events. Although cladribine has activity in selected patients with SM, its use in subjects with indolent disease (even those with refractory mediator symptoms) needs to be approached very cautiously because of the potential for substantial high-grade toxicities in these individuals who otherwise exhibit similar survival to age-matched controls.

Tyrosine Kinase Inhibitors

Dasatinib

Multikinase inhibitors with activity against KIT have been evaluated in patients with advanced SM. Dasatinib is a dual SRC/ABL kinase inhibitor that is used as front-line treatment of chronic myelogenous leukemia, or as second- or third-line therapy for patients with intolerance to, or resistance to imatinib (or nilotinib). Dasatinib exerts relatively weak inhibition of KIT D816V and has a short half-life. A case series and a phase II trial of dasatinib (140 mg total daily dose) revealed limited activity in SM. In the phase II trial of 33 patients (ISM, $n = 18$; ASM, $n = 9$; SM-AHN), 11 (33%) responded. Two complete responses were recorded in patients who were negative for the *KIT* D816V mutation, including a patient with *JAK2* V617F-positive SM-PMF and a patient with SM-CEL. The other 9 responses provided symptomatic benefit only, without clinically significant reductions in either BM MC burden or serum tryptase levels. In the context of the CML experience, (which may also pertain to the treatment of SM), side effects of dasatinib have included pleural and pericardial effusions, cytopenias, an increased risk of bleeding, as well as immunosuppression.

Imatinib

Imatinib is currently the only US Food and Drug Administration–approved drug for SM and is indicated for adult patients with ASM without the *KIT* D816V mutation or with unknown *KIT* mutational status. The general utility of imatinib in SM is therefore limited given the high prevalence of the *KIT* D816V mutation, and the increasing

sensitivity and widespread use of assays that can detect this molecular abnormality. Although imatinib lacks activity against KIT D816V in vitro and in vivo, it has led to clinical benefit in patients with alternative *KIT* mutations or wild-type *KIT*. For example, imatinib has elicited excellent responses in cases of the well-differentiated SM variant with either the F522C TM *KIT* mutation²⁷ or wild-type *KIT*; in a patient with familial SM carrying the germline *KIT* K509I mutation; with deletion of codon 419 in exon 8 of *KIT* in pediatric CM; and in a case of MCL with mutation in exon 9 (p.A502_Y503dup). It is also noteworthy that long-term treatment with imatinib (400 mg/day) is associated with an almost complete MC deficiency, which may be of clinical relevance in reactive (nonclonal) MCAS and other MC-dependent diseases.

Masitinib

Masitinib (AB1010), is an inhibitor of Lyn, Fyn, PDGFR- α/β , and wild-type KIT. After an initial study II trial in patients with ISM or CM with symptoms unresponsive to prior therapy, masitinib was studied in a phase III, randomized, double-blind trial of 135 patients with ISM or SSM (108 subjects formally satisfied the WHO criteria for SM). Subjects were randomized to oral masitinib (6 mg/kg daily in two daily doses) or placebo. The primary end-point of the study was based on a 75% or more improvement in one or more symptom categories: pruritis, flushing, depression, or fatigue. Of the patients taking masitinib, 18.7% achieved this endpoint compared to 7.4% of patients taking placebo. At week 24, there was an 18% decrease in the serum tryptase level in the masitinib arm versus an increase of 2.2% in the placebo arm ($P < .0001$). Also, urticaria pigmentosa lesions on masitinib therapy decreased by an average body surface area of 12.3% versus an increase of 15.9% for the placebo group. Masitinib-associated clinical benefits were generally sustained during a two-year extension period. Although treatment was generally well tolerated, there was an excess incidence of diarrhea, rash, and asthenia in 9%, 6%, and 4% of patients, respectively, in the masitinib group. In addition, 24% of patients in the masitinib arm discontinued therapy because of an adverse event, compared with 10% in the placebo arm. For these patients with lower-risk disease who have a normal life expectancy, these side effects need to be weighed against the potential benefits of the drug in alleviating SM-related symptoms.

Midostaurin

Midostaurin (*N*-benzoylstaurosporine; PKC412) is an inhibitor of multiple TKs including wild-type and D816V-mutated KIT, FLT3, PDGFR- α/β , FGFR1, and VEGFR2. In Ba/F3 cells transformed by *KIT* D816V, the IC₅₀ of midostaurin was 30–40 nM compared with greater than 1 μ M with imatinib. A PR with midostaurin in a patient with MCL and an associated MDS/MPN, and encouraging responses in a phase II trial of 26 patients with advanced SM led to a global, multicenter, open-label trial of midostaurin (100 mg twice daily on 28-day continuous cycles) in patients with ASM, MCL, and SM-AHN.²⁸

The trial employed a steering committee and central pathology review to adjudicate eligibility, response, and histopathology. Among 89 evaluable patients, the ORR was 60%, of which 75% were MRs. Responses in organ damage (e.g., normalization of cytopenias/red blood cell or platelet transfusion dependence) and liver function abnormalities, hypoalbuminemia) were observed regardless of *KIT* D816V status, prior therapy, or the presence of an AHN. The median best reduction in serum tryptase level was –58%. In addition, the median change in BM MC burden was –59%, and 57% of patients had a $\geq 50\%$ reduction in BM MCs. After a median follow-up of 26 months, the median DOR and median OS were 24.1 and 28.7 months, respectively. Median OS in responders was 44.4 months compared with 15.4 months in nonresponders. Of the 16 patients with MCL, 8 responded, including 7 MR (44%); among MCL

patients, the median DOR was not reached, with three MRs ongoing at 49, 33, and 19 months at the time of data cut-off. The median OS was 9.4 months among all patients with MCL, but was not reached among responding MCL patients. In addition, the hazard for death was reduced by 95% in MCL responders versus nonresponders. Symptoms and quality of life, measured by the Memorial Symptom Assessment Scale (MSAS) and Short-Form 12 (SF-12) survey, respectively, were significantly improved with midostaurin treatment. Improved symptoms and quality of life may relate to the ability of midostaurin to block IgE-dependent mediator release from MCs in vitro. The drug was generally well tolerated with a manageable toxicity profile consisting mostly of gastrointestinal side effects, including nausea and vomiting, primarily grade 1–2 in nature. These data support further exploration of midostaurin in combination with other agents with activity in advanced SM (e.g., cladribine), and evaluation of the drug in ISM patients with refractory MC activation symptoms.

Other Agents

Phase I/II trials of denileukin diftitox, everolimus (RAD001), daclicumab, thalidomide, and lenalidomide have shown limited or no activity in small numbers of SM patients. Hydroxyurea has been used to control leukocytosis and splenomegaly in patients with a concurrent AHN such as MPN, CEL/HES, or MDS/MPN. Multiagent, intensive chemotherapy is usually reserved for patients with MCL, especially for patients with kinetically active disease, but the results thus far have been disappointing. Anthracycline plus cytarabine-based induction chemotherapy is the standard of care for patients with AML who are suitable for high-intensity therapy, including those in whom SM is also present. In such cases, treatment of the AML almost always takes priority, and the finding of the *KIT* D816V mutation may provide an opportunity to consider the addition of KIT inhibitors such as dasatinib or midostaurin to the induction, consolidation, and/or maintenance phases of treatment. However, the safety and efficacy of this approach has yet to be validated in the context of clinical trials. Other agents have shown activity against *KIT* D816V-mutated MCs in vitro, including the multikinase/KIT inhibitor EXEL-0862, heat shock protein 90 inhibitor STA-9090, proteasome inhibitor MG132, BCL-2 inhibitor obatoclax, hypomethylating agents azacitidine and decitabine, and the alkaloid omacetaxine mepesuccinate (homoharringtonine). However, clinical trial data regarding their activity in patients have not yet been published. Finally, several antibodies and antibody-drug conjugates have been considered for use in advanced SM. For example, the anti-CD30 antibody-drug conjugate brentuximab vedotin induces growth inhibition and apoptosis of CD30⁺ MCs. A clinical trial testing brentuximab has recently been initiated in the United States. Other agents that may be useful for the eradication of neoplastic MCs and possibly also neoplastic stem cells, include CD33, CD44, CD52, and CD123 monoclonal antibodies.

Allogeneic Hematopoietic Stem Cell Transplantation

Until recently, the role of hematopoietic stem cell transplantation (HSCT) in advanced SM remained poorly characterized, and only on a limited number of case reports and series had appeared. In a large, multicenter retrospective analysis published in 2014, Ustun and colleagues evaluated the outcomes of 57 SM patients (SM-AHN, $n = 38$ [AML = 20]; ASM, $n = 7$; and MCL, $n = 12$) who underwent allogeneic HSCT.²⁹ Donor types consisted of HLA-matched identical ($n = 34$) and unrelated ($n = 17$) donors, umbilical cord blood ($n = 2$), and haploidentical ($n = 1$), and three unknown. Responses were observed in 70% of patients, including a 16% CR rate. The remaining 30% of responses were split between stable disease (21%) and primary refractory disease (9%). All 38 patients with SM-AHN achieved CR regarding the AHN component, but 10 subsequently relapsed with AHN, and half of these patients died.

The median OS for all patients at 3 years was 57%, consisting of 74% for patients with SM-AHN, and 43% and 17% for ASM and MCL patients, respectively. The strongest risk factor for a poor OS was a diagnosis of MCL. In addition, inferior survival was observed in patients undergoing reduced-intensity versus fully myeloablative conditioning. However, patient age, donor age, donor type (sibling or unrelated donor), graft source (BM or peripheral HSCT, *KIT* mutation status, karyotype), and total-body irradiation used in myeloablative conditioning had no impact on overall or progression-free survival. Treatment-related mortality at 6 months and 1 year was 11% and 20%, respectively, and was highest in MCL patients. Although a prospective trial is needed to better define the role of HSCT in advanced SM, these data suggest that transplantation can provide extended survival in selected patients, particularly for patients with SM-AHN.

Response Criteria for Advanced SM

Response criteria for advanced SM were first published in 2003 and reiterated in a consensus conference report in 2007.⁵ In this system, evaluation of clinical evidence of organ damage, or “C” findings, was the foundation for distinguishing levels of response. Changes in BM MC burden, serum tryptase level, and hepatosplenomegaly were additionally employed to subcategorize levels of MR. These original criteria or their modified version have been used to adjudicate responses in clinical trials of new agents.

According to prior consensus response criteria, a MR is defined as normalization of one or more “C” findings. In turn, MR is divided into three subcategories: (1) complete remission (resolution of abnormal MC infiltrates in organs, decrease of serum tryptase below 20 ng/mL, and disappearance of SM-associated organomegaly); (2) incomplete remission (decrease of MC infiltrates and/or serum tryptase level, and/or visible regression of organomegaly by >50%), and (3) pure clinical response (without decrease of MC infiltrates, serum tryptase level, or organomegaly). A PR is defined as incomplete regression of one or more “C” findings (good PR; >50% regression of one or more “C” findings; and minor response, ≤50% regression). Progression of one or more “C” findings even in the presence of an improvement of other “C” findings defines PD.

Several shortcomings emerged regarding these SM response criteria. First, achievement of an “MR” is permitted in patients with baseline laboratory values just outside of the normal reference range. Second, responses in C-findings such as ascites, weight loss, and bone lesions are often difficult to quantify. Third, criteria for baseline red blood cell and platelet transfusion dependence were not codified. Lastly, the minimal DOR was not clearly defined, although a minimum response duration of 8 weeks has been incorporated ad hoc into many trials.

In order to overcome these challenges, and to generate response criteria that can be adopted across clinical trials, the International Working Group for Myeloproliferative Neoplasms Research and Treatment (IWG-MRT) and the ECNM established revised response criteria for advanced SM that better characterize nonhematologic and hematologic organ damage findings, and lend more specificity and quantitation to evaluation of clinical and histopathologic improvement.³⁰ First, a minimum of grade 2 (according to NCI Common Terminology Criteria version 4.03) hematologic or nonhematologic organ damage was required to be considered eligible for organ damage adjudication. Resolution of one or more nonhematologic or hematologic organ damage findings without concomitant worsening of other eligible organ damage was defined as “clinical improvement” (CI). Response categories of CR and PR were defined based on the percent reduction of (1) the burden of neoplastic MCs in the BM (and/or extracutaneous organ) and (2) the serum tryptase level. In addition to changes in MC burden and serum tryptase level, achievement of a PR or CR requires that patients also meet criteria for resolution of at least one or all CI findings, respectively. For additional clinical relevance, the duration of CI and histopathologic response need to be maintained for at

least 12 weeks. The criteria for stable disease, PD, and loss of response were also detailed in the report.

FUTURE DIRECTIONS

Several clinical and translational initiatives are being pursued in MC disease and should reach fruition in the near future. Given the relatively low incidence of SM, efforts are currently being led by the ECNM to combine patient data from multiple collaborators into a central registry (e.g., such data should be useful in generating prognostic variables to help risk stratify patient outcomes). Efforts are also underway to validate SM-specific patient-reported outcome tools to qualitatively and quantitatively measure patients’ symptom burden and quality of life. Regulatory health agencies are increasingly focused on these patient measures for drug approval, and validated patient-reported outcomes are critical for stringent adjudication of treatment-related changes in the context of placebo-controlled, double-blind study designs.

Clinical trials are under development to investigate targets and pathways relevant to MC pathobiology. Novel approaches include use of the anti-CD30 antibody-drug immunoconjugate brentuximab vedotin, JAK inhibitors (e.g., ruxolitinib), PI3K inhibitors, and BTK inhibitors such as ibrutinib. In addition, new selective inhibitors of *KIT* D816V entered phase I trials in 2016. Other agents that merit investigation include inhibitors of BCL-2, agonist antibodies against inhibitory receptors such as siglec-8 in order to induce MC apoptosis, and antibodies against other newly described aberrant markers on neoplastic MCs, such as CD123 (IL-3 receptor- α). Biologic correlates of therapeutic response such as changes in *KIT* mutant allele burden, circulating tumor DNA, and cytokine profiles are now being incorporated into trials. Transcriptome and proteomic profiling of purified MCs and AHN cell populations are compelling translational objectives for future protocols.

THE PATHOLOGIC BASIS FOR THE CLASSIFICATION OF NON-HODGKIN AND HODGKIN LYMPHOMAS

Elaine S. Jaffe, Stefania Pittaluga, and John Anastasi

INTRODUCTION AND HISTORICAL BACKGROUND

The classification of malignant lymphomas has undergone significant changes over the past 50 years. The current approach is based on the integration of morphologic, phenotypic, genetic, and clinical features that allows the identification of distinct disease entities (See box on [Principles of the Classification of Lymphomas](#)). This practical approach to lymphoma categorization was initially proposed by the International Lymphoma Study Group in 1994 and formed the basis of the Revised European-American Classification of lymphoid neoplasm (REAL). It was then adopted by the World Health Organization (WHO) classification of neoplasm of the hematopoietic and lymphoid tissues, published in 2001, updated in 2008 and revised again in 2016 ([Table 73.1](#)).^{1,2} The WHO classification represents a significant achievement in terms of cooperation, communication and consensus among pathologists, hematologists, and oncologists. Furthermore, it recognizes that any classification system to be viable and applicable should evolve and incorporate new data resulting from emerging technologies in the field of hematopathology such as results from genome-wide large-scale sequencing studies. These studies have led to the identifications of new prognostic and diagnostic categories, and provide insight into therapeutic targets based on a better understanding of molecular mechanisms of transformation. This chapter will focus on the classification of neoplasms derived from mature B cells, T cells, and natural killer (NK) cells with emphasis on malignant lymphoma. We provide a framework for the subsequent chapters on Hodgkin and non-Hodgkin lymphomas in reviewing the major entities according to the WHO classification.

MATURE B-CELL NEOPLASMS

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

Chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) usually presents in adults with generalized lymphadenopathy, frequent bone marrow and peripheral blood involvement, and often hepatosplenomegaly. Presentation as leukemia, that is, CLL, is more common than as lymphoma, SLL. Even in patients with a lymphomatous presentation, careful examination of the blood may reveal a circulating monoclonal B-cell component. Nevertheless, there are some patients who will present with generalized adenopathy, and whereas progression to CLL is frequent, it does not necessarily occur in all cases.

The increased sensitivity of immunophenotypic/molecular methodologies has resulted in the detection of clonal lymphoid proliferations with a CLL phenotype in the general population, even in the absence of clinical lymphocytosis, a condition now designated monoclonal B-cell lymphocytosis (MBL) (Box on [Early Events in Lymphoid Neoplasia](#)). The International Workshop on CLL proposed new diagnostic criteria that were then included in the WHO classification of 2008. Recent studies have distinguished between high count and low count MBL, with a count of monoclonal B cells greater than $5.0 \times 10^3/L$ being more clinically significant.⁴ Similar to peripheral blood, small clonal populations with a CLL phenotype can be detected in

lymph nodes as an incidental finding, and appear to represent a tissue counterpart of MBL.⁵ Histologically, the lymph node involved by CLL/SLL shows diffuse architectural effacement ([Fig. 73.1](#)), although occasional residual naked germinal centers can be observed. The predominant cell type is a small lymphocyte with clumped chromatin, but a spectrum of nuclear morphology is usually seen. Pseudofollicular growth centers or proliferation centers are present in the majority of cases and contain a spectrum of cells ranging from small lymphocytes to prolymphocytes and paraimmunoblasts. The prolymphocytes and paraimmunoblasts have more dispersed chromatin and more prominent nucleoli usually centrally placed. The presence of proliferation centers is also a helpful criterion in the differential diagnosis with mantle cell lymphoma (MCL), which may show otherwise some overlapping features with CLL. If needed, immunophenotypic studies can be helpful in this differential diagnosis.

CLL/SLL is characterized by CD5⁺, CD23⁺, LEF1⁺ B cells expressing dim CD20, and usually dim surface immunoglobulin (sIg). Cyclin D1 is negative, in contrast to MCL. CLL has been shown to have a greater degree of heterogeneity biologically and different subgroups have been identified based on immunoglobulin heavy chain mutational status, cytogenetics, ZAP-70 expression, and CD38 expression. The latter two have been used as partial surrogate markers for the mutational status. ZAP-70 expression correlates with an unmutated status and poorer prognosis. In fact, ZAP-70 expression has been suggested to be more clinically relevant than mutation status, when the two markers are discordant. The use of CD38 as surrogate marker for mutational status is less useful, but its high expression is also associated with a poor prognosis. Recently, recurrent somatic mutations have been identified in a subset of CLL patients using whole-genome and exome sequencing techniques, and some of them have been associated with clinical outcome and may be useful in the future for risk stratification.⁶ Deletions at 17p, or mutations in TP53 correlate with more aggressive course.⁷

Histologic transformation over time may occur in CLL, a phenomenon known as Richter syndrome. Short of progression to diffuse large B-cell lymphoma (DLBCL), lymph nodes may show an increased number of prolymphocytes and paraimmunoblasts, sometimes referred to as “accelerated phase”. Two forms of Richter transformation with features of classic Hodgkin lymphoma (CHL) have been described. In Type I, Reed–Sternberg (RS) cells and mononuclear variants are seen in a background of small round B lymphocytes, consistent with CLL. The process lacks the rich inflammatory background characteristic of CHL, such as eosinophils, plasma cells, and histiocytes. In other instances, referred to as Type II, the histologic pattern is that of typical CHL, which may be diagnosed at a site not involved by CLL. There is a relatively high incidence of positivity for Epstein–Barr virus (EBV) in both Type I and Type II cases. Treatment with immunosuppressive agents such as fludarabine appears to increase risk.

Lymphoplasmacytic Lymphoma

The definition of lymphoplasmacytic lymphoma (LPL) and its relationship to other B-cell lymphomas associated with plasmacytoid differentiation and monoclonal gammopathy has been clarified in recent years. LPL is frequently, but not invariably, associated with

ALK, Anaplastic lymphoma kinase; CNS, central nervous system; EBV, Epstein-Barr virus; HHV-8, human herpesvirus-8; NK, natural killer; NOS, not otherwise specified.

Principles of the Classification of Lymphomas Based on the Revised European-American Classification of Lymphoid Neoplasm/World Health Organization Classifications

- Each disease is defined as a distinct entity based on a constellation of morphologic, clinical, and biologic features.
- The cell of origin is the starting point of disease definition.
- Some lymphoid neoplasms can be identified by routine morphologic approaches. However, for most diseases, knowledge of the immunophenotype and molecular genetics/cytogenetics plays an important role in differential diagnosis.
- A disease-based approach to classification facilitates discovery of molecular pathogenesis
- The sites of presentation and involvement are important clues to underlying biologic distinctions. Extranodal lymphomas differ in many respects from their nodal counterparts.
- Many lymphoma entities display a range in cytologic grade and clinical aggressiveness, making it difficult to stratify lymphomas according to clinical behavior. A number of prognostic factors influence clinical outcome, including stage, international prognostic index, cytologic grade, gene expression profile, secondary genetic events, and the host environment.

Early Events in Lymphoid Neoplasia

- In recent years, there has been a greater appreciation of early events in lymphoid neoplasia.
- These early lesions can in some ways be considered equivalent to benign neoplasms in the epithelial system, and require special management approaches.
- These are clonal proliferations of B cells or T cells that carry genetic aberrations associated with specific forms of lymphoid neoplasia: CLL, multiple myeloma, follicular lymphoma, and mantle cell lymphoma.
- Examples include: MGUS, MBL, follicular lymphoma in situ, and mantle cell lymphoma in situ; lymphomatoid papulosis, patch stage of mycosis fungoides, primary cutaneous CD4⁺ small medium T-cell lymphoproliferative disease.
- Early lesions appear to lack the secondary and tertiary “hits” seen in lymphoid neoplasms that are clinically significant, and most patients have a very low risk of clinical progression.
- Challenges for the future are:
 - to define the precise genetic features that distinguish early lesions from lymphoma
 - to assess the risk of clinical progression
 - to determine how these patients should be managed clinically

CLL, Chronic lymphocytic leukemia; MBL, monoclonal B-cell lymphocytosis; MGUS, monoclonal gammopathy of undetermined significance.

Fig. 73.1 SMALL LYMPHOCYTIC LYMPHOMA. Low-power view (A) illustrates a diffuse effacement of the lymph node. A monotonous population of small lymphocytes is seen at higher power (B). These have fairly round nuclear contours, condensed nuclear chromatin, and inconspicuous or absent nucleoli. Only rare larger cells are present. Small lymphocytic lymphoma can transform to large cell lymphoma (C) and occasionally to Hodgkin lymphoma (D). Patients can also develop worsening lymphadenopathy from viral infections such as herpes simplex virus, in which the node typically shows focal necrosis (E).

Fig. 73.2 LYMPHOPLASMACYTIC LYMPHOMA (LPL). Lymphoplasmacytic lymphoma and Waldenström macroglobulinemia have nearly identical morphology. There is a diffuse infiltrate (A) of small lymphocytes that have plasmacytoid features or interspersed plasma cells ((B), bone marrow; (C), lymph node). Intranuclear inclusions can sometimes be seen. Evaluation for κ and λ by immunohistochemical stains can demonstrate clonality in the plasma cells and plasmacytoid lymphocytes (D).

Waldenström macroglobulinemia (WM). The 2008 WHO classification adopted the approach advocated at the second international workshop on WM, which defined WM as the presence of an, immunoglobulin M (IgM) monoclonal gammopathy of any concentration associated with bone marrow involvement by LPL.⁸ Hence LPL and WM are not synonymous, with WM defying a subset of LPL.

More recently recurrent mutations in MYD88 (L265P) have been identified in greater than 90% of WM patients and are highly associated with LPL, but infrequently seen in other B-cell lymphomas with plasmacytoid features, such as marginal zone lymphomas.⁹ In addition, nonsense and frameshift mutations involving CXCR4-chemokine receptor 4, similar to those occurring in warts hypogammaglobulinemia infections myelokathexis (WHIM) patients, were reported and are associated with heavy disease burden.

LPL is a disease of adult life that usually presents with bone marrow involvement, and sometimes with nodal and splenic involvement (splenomegaly), vague constitutional symptoms, and anemia. (see Chapter 87) The tumor consists of a diffuse proliferation of small lymphocytes, plasmacytoid lymphocytes, and plasma cells, with or without Dutcher bodies (Fig. 73.2). The growth pattern is often interfollicular, with sparing of the sinuses. The cells have surface and cytoplasmic immunoglobulin (Ig), usually of IgM type, usually lack IgD, and express B-cell-associated antigens (CD19, 20, 22, 79a). They are usually negative for CD5 and CD10. CD25 or CD11c may be weakly expressed in some cases. The lack of CD5 and the presence of strong cytoplasmic Ig are useful in distinction from CLL. The postulated normal counterpart is thought to be a postfollicular medullary cord B-cell-based in part on the presence of somatic mutations in the Ig heavy and light-chain variable region genes.

Mantle Cell Lymphoma

MCL is a distinct entity that has been more precisely defined in recent years through the integration of immunophenotypic, molecular genetic, and clinicopathologic studies.³ The molecular hallmark of MCL is the t(11;14)(q13;q32) involving Cyclin D1 (*CCND1*) and the *IGH* gene. Cyclin D1 overexpression is believed to be essential in the pathogenesis of MCL. However, rare variants negative for Cyclin D1 with similar immunomorphology and gene expression signature have been identified, and most often have translocations involving *CCND2*. Sox11 is overexpressed in most Cyclin D1 positive and negative cases.¹⁰ The postulated normal counterpart is the CD5⁺ “naïve” B cell, sIgM⁺ and sIgD⁺, which can be found in the peripheral blood and in the mantle of reactive germinal centers. Mutational analysis of the rearranged immunoglobulin variable region genes shows few or no somatic mutations; however, similarly to CLL a subset of MCL have mutated *IG* genes.

Recently, because of the widespread use of immunohistochemistry, early involvement of lymph node by cells carrying t(11;14) translocation with subsequent overexpression of Cyclin D1 has been documented in several cases, referred to as “in situ MCL”. Most often these represent an incidental finding, but some cases will eventually progress to overt MCL.⁵ In some cases, in situ MCL is detected in a lymph node involved by another lymphoma type, such as follicular lymphoma. The risk of progression of in situ MCL is difficult to ascertain, as the number of reported cases is few. The preferred term in the revised WHO classification is “in situ mantle cell neoplasia”. In a recent multicentric retrospective study, it was noted that the expression of Sox11 was more frequently associated with progression

Fig. 73.3 MANTLE CELL LYMPHOMA. At low power, mantle cell lymphoma (MCL) can show a diffuse, vaguely nodular, or mantle zone pattern. In the latter, the neoplastic mantle zones are expanded and can become confluent leaving “naked” germinal centers (A). At higher power, the lymphoma cells are small or slightly enlarged (B). They have irregular nuclear contours, especially compared with small lymphocytic lymphoma, and they have dense chromatin. Typically, cases are positive for cyclin D1 expression (C), which is related to the t(11;14) involving IgH and *CCND1*. Some cases can develop a “blastoid” transformation (D), although some cases can present as a “blastoid” variant. Such cases are characterized by cells with an intermediate size, a high mitotic rate, and finely dispersed “blastic” chromatin. Sometimes when the “blastoid” cases develop a leukemic phase, they can be difficult to distinguish morphologically from acute lymphoblastic leukemia. In such cases, flow immunophenotyping is needed to resolve the differential diagnosis. MCL can also present with gastrointestinal involvement (E) as in lymphomatoid papulosis.

to MCL, since the majority of in situ cases lacked Sox11 expression. Also, similar to follicular lymphoma in situ, a distinction should be made between partial involvement by mantle cell lymphoma with a mantle zone pattern and in situ MCL. The latter refers to a reactive lymph node with Cyclin D1 positive cells limited to an otherwise normal appearing follicle mantle; these cases tend not to progress and should not be labeled as lymphomas.

Another newly identified variant is an indolent form of MCL characterized by a leukemic phase without nodal disease, but often with long standing splenomegaly. These patients have an indolent clinical course and do not appear to require aggressive chemotherapy. These cases carry t(11;14) with few additional chromosomal abnormalities and lack expression of Sox11 in contrast to conventional MCL.

MCL occurs in adults (median age 62), with a high male-to-female ratio. Most patients present with advanced stage at diagnosis. Common sites of involvement include lymph nodes, spleen, bone marrow, and lymphoid tissue of Waldeyer ring. Gastrointestinal (GI) tract involvement is frequent and is associated with the picture of lymphomatous polyposis.

The hallmark of MCL is a very monotonous cellular composition. In the typical case, the cells are slightly larger than a normal lymphocyte with finely clumped chromatin, scant cytoplasm, and inconspicuous nucleoli (Fig. 73.3). The nuclear contour is usually irregular or cleaved. Some cytologic variants, blastoid (blastic) and pleomorphic, tend to be associated with a more aggressive course, and adverse biologic features, such as tetraploidy or p53 mutation/deletion. The proliferation rate was previously identified as prognostically important based on scoring of Ki67-positive cells. More recently gene expression profiling (GEP), using genes involved in cell cycle progression and DNA synthesis, has identified a proliferation signature that delineates cohorts with varied prognosis. These correlate to some extent with cytologic subtype. For example, the blastoid variant has a high proliferation rate, utilizing both KI-67 and GEP.

Follicular Lymphoma

Follicular lymphoma (FL) is the most common subtype of non-Hodgkin lymphoma within the United States and accounts for approximately 45% of all newly diagnosed cases. It has a peak incidence in the fifth and sixth decades, and is rare under the age of 20. Men and women are equally affected. FL is less common in black and Asian populations. Most patients have stage 3 or 4 disease at

diagnosis, with generalized lymphadenopathy. Staging evaluation will usually detect bone marrow involvement. Approximately 10% of patients will have circulating malignant cells. However, careful immunophenotypic or molecular analyses may disclose peripheral blood involvement in a higher proportion of patients. A more accurate prognostic index than the international prognostic index (IPI), the follicular lymphoma international prognostic index, has been proposed for FL, and has been widely adopted.

The natural history of the disease is associated with histologic progression in both pattern and cell type (Fig. 73.4). A heterogeneous cytologic composition is one of the hallmarks of FL. Usually, all of the follicle center cells are represented, but in varying proportions. It should be stressed that the variation in cytologic grade is a continuum, and therefore precise morphologic criteria for subclassification are difficult to establish.

According to the WHO classification, all low-grade FL are combined into a single category, Grade 1–2, all containing overall a predominance of centrocytes with fewer than 15 centroblasts/high power field (hpf). FL grade 3 (with >15 centroblasts/hpf) is further subdivided in 3A and 3B based on the presence or absence of centrocytes in the background.

The vast majority of FL (approximately 85%) are associated with a t(14;18) involving rearrangement of the *BCL2* gene. This translocation appears to result in constitutive expression of BCL2 protein, which is capable of inhibiting apoptosis in lymphoid cells. The cells of FL accumulate and are at risk to acquire secondary mutations, which may be associated with histologic progression. It has been postulated that the *BCL2/JH* translocation occurs during immunoglobulin gene rearrangement in the bone marrow at the pre-B cell stage of development. This fact might contribute to the difficulty in eradicating the neoplastic clone with chemotherapy.

Biologically, the pathogenesis of most cases of FL grade 3B differs from that of FL grades 1–2/3A, in lacking the *BCL2/IGH*, but also differs from diffuse large B-cell lymphoma, in having a low incidence of BCL6 aberrations.¹¹ These data provide a biologic explanation for the greater curability of grade 3B FL with aggressive therapy, although some studies have not found support for this hypothesis. Differences in diagnostic criteria might account for this apparent discrepancy, and the correlation between grade 3A versus 3B, and molecular alterations is imprecise. Other phenotypic variants appear to have prognostic significance, such as FL negative for CD10 but positive for MUM1/IRF4. These cases are usually of higher grade and interestingly also lack the *BCL2* translocation. Evolution towards a molecularly defined classification of FL is a possibility for the future.

Fig. 73.4 FOLLICULAR LYMPHOMA (FL). Follicular lymphoma (FL) shows effacement of the normal lymph node architecture because of an accumulation of neoplastic lymphoid follicles that lack the features of reactive follicles (A). They are crowded, show back-to-back localization, lack distinct mantle zones, and show no polarity. The lymphoma cells are highly irregular (B) with elongated, twisted, or clefted nuclear contours and dense chromatin. FL is typically graded into grade 1 or 2 (1/2; C, D), or 3 (E), depending on the number of large cells seen at higher power (see text). FL typically involves the bone marrow with lymphoma cells spreading along the bone (F). This localization is termed “paratrabecular.”

The phenomenon of localization of FL cells to isolated germinal centers within a lymph node has been termed FL in situ.⁵ The revised WHO classification proposes in situ follicular neoplasia as a preferred term. The likelihood of evolution to clinically significant FL is low for these patients, if there is no other evidence of disease at the time of diagnosis. Indeed, this translocation can be found in the peripheral blood and lymphoid organs of healthy individuals, and suggests that the *BCL2/JH* translocation is necessary but not sufficient for the development of FL. “FL in situ” or in situ follicular neoplasia should be distinguished from partial involvement by FL. In the true “in situ” lesion clusters of B cells strongly positive for CD10 and *BCL2* are localized to germinal centers in an otherwise reactive lymph node. It often represents an incidental finding, in a lymph node biopsied for other reasons.

The 2008 WHO classification recognizes other lymphomas of follicle center derivation that may resemble nodal FL, but exhibit significant differences either clinically or biologically.¹² These include diffuse follicular FL, pediatric forms of FL, primary intestinal FL and cutaneous lymphomas of follicle center cell derivation. Intestinal FL, most often presenting in the duodenum, is associated with the *BCL2/IGH* translocation, but usually presents as isolated mucosal polyps with a low risk of dissemination.⁵ FL in the pediatric age group is histologically diverse. Most nodal cases are cytologically high grade, composed of blastoid cells, but are usually localized, and may be cured in a number of instances with surgical excision. This so-called pediatric type of FL may also be seen in adults more rarely, and shows a strong male predominance. Another form of FL seen in children and young adults is associated with translocations involving *IRF4*, and shows overexpression of *MUM1* by immunohistochemistry. These cases frequently present in Waldeyer ring.¹³

There are rare variants of FL with a mainly diffuse growth pattern. These often present as bulky localized inguinal masses, and lack the *BCL2* translocation but often have deletions at 1p36.¹² Primary cutaneous follicle center lymphoma, which also frequently lacks the *BCL2* translocation and *BCL2* expression, is now considered by the WHO classification as a separate entity.² They usually present in the head or upper trunk, and can be managed conservatively with local approaches. However, when *BCL2* expression is detected, the possibility that this may represent a secondary site of involvement should be considered.

Extranodal Marginal-Zone Lymphoma of Mucosa-Associated Lymphoid Tissue Type

Most lymphomas of marginal-zone derivation present in extranodal sites and have the histopathologic and clinical features identified by

Isaacson and Wright as part of the spectrum of mucosa-associated lymphoid tissue (MALT) lymphomas. MALT lymphomas are characterized by a heterogeneous cellular composition that includes marginal-zone or centrocyte-like cells, monocytoid B cells, small lymphocytes, and plasma cells (Fig. 73.5A). In most cases, large transformed cells are infrequent. Reactive germinal centers are nearly always present. When follicular colonization occurs, the process may simulate follicular lymphoma. Clonality is confirmed by molecular and immunohistochemical studies.

MALT lymphomas have been described in nearly every anatomic site but are most frequent in the stomach, lung, thyroid, salivary gland, and lacrimal gland. Other less common sites of involvement include the orbit, breast, conjunctiva, bladder and kidney, and thymus gland. Widespread nodal involvement is infrequent, as is marrow involvement. The clinical course is usually quite indolent, and many patients are asymptomatic. MALT lymphomas tend to relapse in other MALT-associated sites.

MALT lymphomas of the salivary gland and thyroid are usually associated with a history of autoimmune diseases. *Helicobacter* gastritis is frequent in most patients with gastric MALT lymphomas. Other infectious agents have been described in MALT lymphomas involving skin (*Borrelia burgdorferi*), ocular adnexae (*Chlamydia psittaci*), and small intestine (*Campylobacter jejuni*); however, in this latter group a causal relationship has not yet been demonstrated. Chronic antigen stimulation is critical to both the development of a MALT lymphoma and the maintenance of the neoplastic state. Indeed, in some cases antibiotic therapy and the eradication of *Helicobacter pylori* has led to the spontaneous remission of gastric MALT lymphoma in cases lacking genetic aberrations.

By immunophenotype MALT lymphomas are positive for B-cell-associated antigens CD19, CD20, and CD22, but are negative for CD5 and CD10. The absence of cyclin D1 is useful in ruling out MCL, especially in intestinal disease. Rare cases of MALT lymphoma have been reported to be CD5-positive, and in some but not all instances this has been associated with more aggressive disease. The clinical significance of increased transformed cells is still uncertain, and no formal grading system exists for MALT lymphoma. The putative cell of origin of MALT lymphoma is a postgerminal center B-cell.

MALT lymphomas also have several recurring cytogenetic abnormalities, including *t*(11;18)(q21;q21), *t*(1;14)(p22;q32), *t*(14;18)(q32;q21), *t*(3;14)(q27;q32), and *t*(3;14)(p14.1;q32), which are observed with variable frequency, often depending upon the anatomic site. Although several genes are involved in these translocations, at least three of them, *t*(11;18), *t*(1;14), and *t*(14;18), share a common pathway, which leads to the activation of NF- κ B and its downstream targets. By genome-wide DNA profiling integrated with GEP,

Fig. 73.5 MARGINAL ZONE LYMPHOMA. Marginal zone lymphomas commonly occur at extranodal sites arising from mucosa-associated lymphoid tissue (MALT). MALT lymphomas typically infiltrate or invade into epithelial structures, resulting in “lymphoepithelial lesions” (A). They are composed of small to intermediate-sized cells with abundant clear cytoplasm (A, *detail*). The normal lymph node does not have a marginal zone, but primary nodal marginal zone lymphomas (NMZL) can occur. They infiltrate the node in what would be a marginal zone pattern with an expansion of cells peripheral to mantle zone (B). The spleen does have a normal marginal zone, and this can give rise to a splenic marginal zone lymphoma (SMZL). Early on, these show expansion of the marginal zone areas (C) but later can become more diffuse, infiltrating the red pulp. In the case illustrated, the spleen weighed 1700 g.

differences were detected among the three different main types of marginal zone lymphomas lending support to the current WHO classification, which separates these three entities.¹⁴

Nodal Marginal-Zone B-Cell Lymphoma

Nodal marginal zone lymphoma (NMZL) is a primary nodal disease, which resembles other marginal zone lymphomas, extranodal or splenic types. These patients often present with bone marrow involvement, and tend to have a more aggressive clinical course than those with extranodal MALT. The neoplastic proliferation is polymorphous and composed of monocytoid B cells, plasmacytoid cells, with interspersed large blast-like cells. There is an expansion of the marginal-zone area, often with preservation of the nodal architecture (see Fig. 73.5B). The mantle zone may be intact, attenuated, or effaced. The immunophenotype is similar to other MZL, that is, CD20-positive, CD10-negative, CD5-negative, with variable expression of IgD (weak to negative). Because there are no precise immunophenotypic or genotypic markers of NMZL, the diagnosis is sometimes one of exclusion. The differential diagnosis with LPL may be problematic; however, the MYD88 (L265P) somatic mutation is detected infrequently in MZL lymphomas and its presence should raise the possibility of LPL. More stringent criteria are needed to separate these two entities. A variant of nodal MZL occurs in children; these cases show a striking male predominance, present with localized disease, and can be managed with local therapies.¹

Splenic Marginal-Zone Lymphoma

Splenic marginal-zone lymphoma (SMZL) presents in adults and is slightly more frequent in females than males. The clinical presentation is splenomegaly, usually without peripheral lymphadenopathy. The majority of patients have marrow involvement, but there is usually only a modest lymphocytosis, with elevations in the lymphocyte count usually less than that seen in CLL. Some evidence of plasmacytoid differentiation may be seen and patients may have a small M component. The abundant pale cytoplasm evident in tissue sections may also be seen in blood smears. The course is indolent, and splenectomy may be followed by a prolonged remission.

Histologically, the spleen shows expansion of the white pulp, but usually some infiltration of the red pulp is also present (see Fig. 73.5C). A characteristic biphasic pattern in the neoplastic white pulp has been described, with the neoplastic cells surrounding regressed follicles. The immunophenotype of these cells resembles that of other marginal-zone B-cell lymphomas; however, IgD expression is more

frequently observed. Progression to diffuse large B-cell lymphoma can be seen.

Although the molecular pathogenesis of SMZL has not been fully delineated, a frequent cytogenetic alteration involving deletions of the region 7q(22-32) has been reported.¹⁵ Mutations in *NOTCH2* are the most common event but other genes in the NOTCH pathway may be targeted.¹⁶ Many of the affected genes appear to play a role in marginal zone B-cell development. The differential diagnosis of SMZL includes other unspecified B-cell lymphomas of the spleen, including splenic lymphoma with villous lymphocytes (SLVL), and hairy cell variant. The latter have been grouped together under splenic B-cell lymphoma/leukemia unclassifiable, and the interrelationship among these disorders is not fully resolved.

Diffuse Large B-Cell Lymphoma, Not Otherwise Specified

DLBCL is one of the more common subtypes of non-Hodgkin lymphoma, representing up to 40% of cases. It has an aggressive natural history but responds well to chemotherapy. The complete remission rate with modern regimens is 75% to 80%, with long-term disease-free survival approaching 50% or more in most series. This lymphoma may present in lymph nodes or in extranodal sites. Frequent extranodal sites of involvement include bone, skin, thyroid, GI tract, and lung.

DLBCL represents one of the most heterogeneous categories in the WHO, and attempts to identify prognostic groups based on morphology and phenotype have shown limited usefulness and reproducibility (Boxon [Varied Basis for the Recognition of Diverse Entities](#)). To address these issues, DLBCLs were among the first cases to be analyzed by complementary DNA (cDNA) array technology, and more recently also by genome-wide analysis.¹⁷ By GEP three groups were identified based on the differential expression of a large set of genes, namely germinal center-like group (GCB), activated B-cell-like group (ABC), and primary mediastinal (thymic) large B-cell lymphoma (PMBL). PMBL is now recognized as a separate entity, and adaptations in GEP now allow profiling of formalin fixed paraffin-embedded (FFPE) biopsies.¹⁸ The ABC subtype frequently exhibits mutations in the BCR-signaling and NF- κ B pathways providing new insight in the pathogenesis of DLBCL and new potential therapeutic targets.¹⁹ Recurrent mutations in the GCB type of DLBCL appear to target histone-modifying genes.¹⁷ Somatic mutations in *EZH2* also have been identified in FL, another tumor of germinal center derivation.

DLBCLs are composed of large, transformed lymphoid cells with nuclei at least twice the size of a small lymphocyte (Fig. 73.6). The

Fig. 73.6 DIFFUSE LARGE B-CELL LYMPHOMA. The low-power illustration demonstrates the diffuse nature of the process (A). At high power (B), there are sheets of large cells. Those with a vesicular nuclear chromatin and variable numbers of nucleoli along the nuclear membrane are referred to as centroblasts. These typically have a germinal center gene expression profile and a germinal center immunophenotype with expression of CD10 and BCL6 (C and D). Those cases composed of large cells with a single prominent nucleolus (E) are called immunoblastic and commonly have an activated B-cell (ABC) gene expression profile and an ABC phenotype with expression of MUM-1, CD138 (F and G), and IFR-4. The correlation of morphology and immunophenotype is not always exact.

Varied Basis for the Recognition of Diverse Entities Among Aggressive B-Cell Neoplasms

- Cell of origin, in part as determined by gene expression profiling
Activated B cell versus germinal center B cell
Thymic B cell of PMBL
- Clinical factors
Anatomic site, e.g., CNS, mediastinum, intravascular
Advanced age, background of chronic inflammation
- Etiologic factors
EBV, HHV-8
- Molecular pathogenesis
BCL6, *C-MYC*, *ALK*, *BCL2*, *MYD88* (translocations, amplification, mutation)

CNS, Central nervous system; EBV, Epstein-Barr virus; HHV-8, human herpesvirus-8; PMBL, primary mediastinal large B cell lymphoma;

nuclei generally have vesicular chromatin, prominent nucleoli, and basophilic cytoplasm, resembling the centroblasts of the normal germinal center. The immunoblastic variant is characterized by cells with prominent central nucleoli, and abundant deeply staining cytoplasm. Although there is no absolute correlation between morphology and GEP, the majority of centroblastic DLBCL falls into the GCB group, and the majority of immunoblastic into the ABC group.

Algorithms based on immunophenotype have been proposed as surrogates for cDNA microarray using CD10/BCL6 positivity for GCB and MUM1/IRF-4 for ABC with the addition of BCL2 in combination with IPI and may improve the stratification of DLBCL. Because of emerging differences in the treatment of GCB versus ABC (or non-GCB) DLBCL, it is recommended to include the subtype by integrating GEP and/or immunohistochemistry (IHC) results in the report with clarification of the method used and the type of algorithm.¹⁸ As noted, newer GEP methods may be applicable to FFPE material.

Diffuse Large B-Cell Lymphomas, Other Variants and Subtypes.

The spectrum of aggressive B-cell lymphomas has broadened in recent years, incorporating new entities based on unique clinical features such as age or anatomic site, viral pathogenesis (EBV, human herpesvirus [HHV]-8), or distinctive pathologic features.²⁰ *T cell/histiocyte-rich large B-cell lymphoma (THRLBCL)* has distinctive morphologic and clinical features. It is associated with aggressive

clinical behavior, and often presents with advanced stage and bone marrow involvement. The relevance of the microenvironment and recruitment mechanism of the inflammatory cells, which are the main histologic component, has been the focus of recent studies.²¹

The WHO classification recognizes that some lymphomas arising in certain anatomic sites may have distinctive features both clinically and biologically. Among these are *primary DLBCL of the central nervous system (CNS)* and *DLBCL of the testis*. DLBCLs in these sanctuary sites differ at the genomic level from usual nodal DLBCL.^{22,23} Both primary CNS DLBCL and intraocular large B-cell lymphomas commonly have mutations in MYD88.

Primary cutaneous DLBCL, leg type, has a GEP resembling the ABC type of DLBCL, presents most often in older adult females, and generally has an aggressive clinical course. As with nodal DLBCL, BCL2 expression is an adverse prognostic factor.

EBV-positive DLBCL was a provisional entity in the 2008 WHO classification, and was first recognized in the older adult.²⁴ More recent studies have shown a wider age distribution. Decreased immune surveillance in the older adult, or a tolerogenic immune microenvironment may facilitate tumor development.²⁵ The morphologic spectrum is broad, but most cases have a prominent inflammatory background. The prognosis in the older adult is poor but younger patients have a good outcome. EBV-positive DLBCL should be distinguished from EBV-positive mucocutaneous ulcer, which affects mainly cutaneous sites, and often has a self-limited clinical course. These lesions arise in a setting of decreased immune surveillance, most often in the elderly, and frequently with iatrogenic immune suppression.

Lymphomatoid granulomatosis is an EBV-positive B-cell lymphoproliferative disorder (LPD) associated with an inflammatory background rich in T cells. The lung is nearly always involved, with skin, kidney, liver and brain being frequently affected as well. *DLBCL associated with chronic inflammation* was first described in association with chronic pyothorax, but now has been associated with EBV-driven large B-cell proliferations in diverse clinical settings, usually associated with a confined anatomic space and a background of chronic inflammation. These cases appear to have a good prognosis if successfully resected.

There are several LPDs associated with HHV-8/Kaposi sarcoma-associated herpesvirus (KSHV). These include *primary effusion lymphoma (PEL)* and *multicentric Castelman disease (MCD)*. The cells of PEL are usually coinfecting with EBV, and the disease is most often diagnosed in the setting of human immunodeficiency virus (HIV) infection and immunosuppression. While pleural or peritoneal effusions are most common, extracavitary PEL can present as a tumor mass, usually in extranodal sites. PEL has a phenotype resembling that of terminally differentiated B-cells, i.e., plasmablastic (Fig. 73.7).

Fig. 73.7 DIFFUSE LARGE B-CELL LYMPHOMA, VARIANTS AND SUBTYPES. T-cell/histiocyte-rich large B-cell lymphoma is illustrated in (A), where a CD20 immunostain (*right*) identifies scattered large B cells, which are associated with a prominent background of small reactive T cells (CD3; *left*). Sometimes there are numerous histiocytes in the background or an admixture of reactive T cells and histiocytes. Primary diffuse large B-cell lymphoma (DLBCL) of the central nervous system usually shows a perivascular distribution (B). Epstein-Barr virus (EBV)-positive DLBCL can have variable morphologic features. The illustrated case is monomorphic and composed of large cells, which are positive for EBV-encoded RNA (EBER) (C, *bottom and top*). Lymphomatoid granulomatosis (D) also has a perivascular distribution and is composed of a mix of malignant large EBV-positive B cells and reactive T cells. Primary effusion lymphoma is usually diagnosed from cytologic preparations (E) and by flow cytometric and molecular techniques. Although the tumor cells do not generally form masses, extracavitary primary effusion lymphoma can present as a tumor mass, usually in extranodal sites. ALK-positive large B-cell lymphomas are rare, and show ALK positivity as a consequence of a translocation of *ALK* (F). *ALK*, Anaplastic lymphoma kinase; *RNA*, ribonucleic acid.

Two other lymphomas with a plasmablastic phenotype include *plasmablastic lymphoma* (PBL), and *anaplastic lymphoma kinase* (*ALK*)-positive large B-cell lymphoma. PBL is usually positive for EBV, most often extranodal, and associated with immunosuppression from either HIV infection or advanced age. Recent studies have identified a high incidence of *MYC* translocation in PBL.²⁶ *ALK*-positive large B-cell lymphomas show overexpression of *ALK*, usually as a consequence of translocation. They mainly affect older individuals, but can occur at any age. Interestingly, IgA is most often expressed.

Intravascular Large B-Cell Lymphoma

Intravascular large B-cell lymphoma is a rare form of DLBCL characterized by the presence of lymphoma cells only in the lumens of small vessels, particularly capillaries. These cells are nearly always of B-cell phenotype, often with aberrant expression of CD5 (Fig. 73.8). The tumor cells are large, with vesicular nuclei and prominent nucleoli, resembling centroblasts or immunoblasts. Lymph node involvement is rare, and the tumor presents in extranodal sites, most readily diagnosed in the skin. Neurologic symptoms associated with plugging of small vessels in the CNS are common. The disease is often not diagnosed until autopsy, because of the lack of definitive radiologic or clinical evidence of disease, and diverse symptomatology.

Primary Mediastinal (Thymic) Large B-Cell Lymphoma

Primary mediastinal large B-cell lymphoma (PMBL) has emerged in recent years as a distinct clinicopathologic entity, typically arising in young women, with a peak incidence in the fourth decade. Patients present with a mediastinal mass, with frequent superior vena cava syndrome. Regional lymph nodes may be involved but spread to

distant nodal sites is uncommon. Frequent extranodal sites of involvement, particularly at relapse, include the liver, kidneys, adrenal glands, ovaries, GI tract, and central nervous system.

Histologically, PMBL is characterized by fine compartmentalizing sclerosis, and large lymphoid cells with abundant pale cytoplasm (see Fig. 73.8B). An origin from medullary thymic B cells is proposed. The cells express CD20 and CD79a, but do not express surface Ig. Recently, expression of the *MAL* gene has been detected in PMBL and not in other DLBCLs.²⁷ PMBL usually lack rearrangement for *BCL2*, *BCL6*; however, *REL* amplification is a common feature. A common cytogenetic abnormality seen in approximately 50% of cases includes gains in 9p, which may be associated with amplification of *JAK2* and *PDL1/PDL2* as well as translocations involving MHC class II transactivator (*CIITA*). Recently, gene expression profiling studies have found that PMBL bears a distinct molecular signature that differs from that of other DLBCLs and shares features of CHL; however, the same signature is not restricted to mediastinal sites since it can also be detected in other DLBCL-not otherwise specified (NOS) at nonmediastinal sites.

B-Cell Lymphoma, Unclassifiable, With Features Intermediate Between Diffuse Large B-Cell Lymphoma and Classic Hodgkin Lymphoma

This lymphoma is sometimes referred to as mediastinal gray zone lymphoma, since the mediastinum is the most common site of presentation. A close relationship between PMBL and CHL was supported by gene expression profiling. TRAF1 expression and c-REL amplification were also seen in both types of neoplasms and could be detected with suitable immunohistochemical studies.

Gray zone lymphomas are more common in males than females, present with bulky mediastinal masses, and appear to have a more aggressive clinical course than PMBL or CHL. A recent study using

Fig. 73.8 DIFFUSE LARGE B-CELL LYMPHOMA VARIANTS (INTRAVASCULAR, MEDIASTINAL, GRAY ZONE). In intravascular lymphoma, also known as angiotropic lymphoma, the large B cells are confined to the lumens of small vessels (A). Paradoxically, they do not spread to the blood. Primary mediastinal (thymic) large B-cell lymphoma typically shows large B cells in a finely sclerotic background (B, *top* and *bottom*). So-called “gray zone lymphoma” has features intermediate between large B-cell lymphoma and Hodgkin lymphoma. In the case illustrated (C), the male patient presented with a mediastinal mass. The cells were CD30⁺ and only variably positive for CD45 as in Hodgkin lymphoma, but they were strongly and uniformly positive for CD20 and PAX5. They also strongly expressed the B-cell transcription factors OCT2 and BOB1.

Fig. 73.9 BURKITT LYMPHOMA. At low power, Burkitt lymphoma gives a classic “starry sky” appearance because of numerous histiocytes or tingible body macrophages with clear cytoplasm (*stars*), in a background of darkly stained tumor cells (A). At high power, the cells exhibit a very high mitotic rate and are intermediate in size with finely clumped nuclear chromatin (B). On a Wright-stained touch preparation or in the blood or bone marrow aspirate, the cells also have a characteristic appearance with deep blue cytoplasm typically with vacuoles (C). Fluorescence in situ hybridization with a probe that spans *MYC* will show a break-apart signal (D) indicating that *MYC* has translocated to a partner chromosome.

methylation profiling identified gray zone lymphomas as having a signature distinct from both CHL and PMBL. However, by fluorescence in situ hybridization, gray zone lymphomas, PBMCL and CHL share a number of common cytogenetic aberrations including gains at 2p16.1 (*REL/BCL11A* locus), 9p24.1 (*JAK2/PDL2*) and rearrangements of 16p13.13 (*CIITA*). It is not clear how these patients should be approached therapeutically, but they appear to benefit from combined modality therapy (systemic chemotherapy and radiation).

Burkitt Lymphoma

Burkitt lymphoma (BL) is most common in children and accounts for up to one-third of all pediatric lymphomas in the United States. It is the most rapidly growing of all lymphomas, with 100% of the cells in cell cycle at any time. It usually presents in extranodal sites. In nonendemic regions, such as the United States, frequent sites of presentation are the ileocecal region, ovaries, kidneys, or breasts. Jaw presentations, as well as involvement of other facial bones, are common in African or endemic cases and are seen occasionally in nonendemic regions. Bone marrow involvement is a poor prognostic sign.

BL is one of the more common tumors associated with HIV. It can present at any time during the clinical course. In some patients

with HIV infection, BL may be the initial acquired immunodeficiency syndrome-defining illness.

The pathogenesis of BL is related to the translocations involving the *MYC* oncogene, which are seen in virtually 100% of cases and often constitute the sole karyotypic abnormality. Most cases involve the IG heavy-chain gene on chromosome 14, and less frequently the light-chain genes on chromosomes 2 and 22. In endemic BL, genomic instability is thought to be promoted by Plasmodium infection.²⁸ EBV is closely linked to BL in endemic regions but is less frequently seen (15%–20%) in sporadic cases. In other regions, characterized by low socioeconomic status and EBV infection at an early age, BL is often EBV-positive, in the range of 50% to 70%. These data support the concept that the EBV is a cofactor for the development of BL. Cytologically, BL is monomorphic (Fig. 73.9). The cells are medium in size with round nuclei, moderately clumped chromatin, and multiple (2–5) basophilic nucleoli. The cytoplasm is deeply basophilic and moderately abundant. These cells contain cytoplasmic lipid vacuoles, which are probably a manifestation of the high rate of proliferation and high rate of spontaneous cell death. The starry sky pattern characteristic of BL is a manifestation of the numerous benign macrophages that have ingested karyorrhectic or apoptotic tumor cells.

BL has a mature B cell phenotype. The cells express CD19, CD20, CD22, CD79a, and monoclonal surface Ig, nearly always IgM.

Fig. 73.10 B-CELL LYMPHOMA, UNCLASSIFIABLE WITH FEATURES INTERMEDIATE BETWEEN DIFFUSE LARGE B-CELL LYMPHOMA AND BURKITT LYMPHOMA. Examples of diffuse large B-cell lymphoma (DLBCL) (A) and Burkitt lymphoma (BL) (B) are for comparison. In (C), the lymphoma cells are intermediate in size and not as large as the DLBCL but without the typical characteristics of BL cells. The cells had a high Ki67 rate (D) and a B-cell phenotype with CD10 and BCL2 expression (not shown). The karyotype had a $t(14;18)$ as in follicular lymphoma, *MYC* translocation as in BL, but was complex with multiple aberrations. (E). The karyotype was as follows: 51,XY,+X,+1,dup(1)(q32q44),der(1)del(1)(p21p36.3)dup(1)(q32q44),t(6;8)(p21.1;q24.1),+7,+del(?8) (p11.2p23),der(8)i(8)(q10)t(8;11)(q24.1;q13),9,der(11)t(8;11)(q24.1;q13), t(14;15)(q32;q15), t(14;18)(q32;q21.3),+21,+mar[13]/46,XY[1]. (The karyotype was kindly provided by Dr. Yanming Zhan of Northwestern University.)

CD10 is positive in nearly all cases, and CD5, CD23, and BCL2 are consistently negative.

High Grade B-Cell Lymphoma, With *MYC* and *BCL2* and/or *BCL6* Rearrangements

Historically, it has been difficult for pathologists to distinguish some DLBCL with a very high growth fraction from BL with atypical cytology. In addition, there are cases that carry a *C-MYC* translocation, but carry additional cytogenetic abnormalities, most often involving *BCL2* or *BCL6*. These double hit and triple hit lymphomas have a very aggressive clinical course, and will be separately delineated in the revised WHO classification²⁹ (Fig. 73.10). The clinical impact of *MYC* overexpression in DLBCL has not been fully resolved; in some series, it has been associated with a more aggressive clinical course. For the time being, an otherwise typical DLBCL with a *C-MYC* translocation should still be classified as DLBCL. Cases of BL with atypical cytologic features, are retained under the heading of BL, and have a better prognosis when treated appropriately.

T AND NATURAL KILLER-CELL LYMPHOMAS

Overview of the Classification of T-Cell Neoplasms

Although the definition of precursor T-cell or lymphoblastic neoplasms is straightforward, the classification of peripheral T-cell lymphomas has been controversial. These are uncommon, representing less than 15% of all non-Hodgkin lymphomas. Most previously published classification schemes for the malignant lymphomas in the United States or Europe have been based on B-cell malignancies, as these are far more common than their T-cell counterparts. T-cell and NK-cell lymphomas show significant variation in incidence in different geographic regions and racial populations.

The classification of T-cell and NK-cell neoplasms proposed by the WHO emphasizes a multiparameter approach, integrating morphologic, immunophenotypic, genetic, and clinical features. Clinical features play particular importance in the subclassification of these tumors, in part caused by the lack of specificity of other parameters (See Box on [Natural Killer and T-cell Subsets](#)).

In contrast to B-cell lymphomas, specific immunophenotypic profiles are not associated with most T-cell lymphoma subtypes. Although certain antigens are commonly associated with specific disease entities, these associations are not entirely disease-specific. Presently, specific genetic features have not been identified for many of the T-cell and NK-cell neoplasms, although there are few exceptions.

Natural Killer and T-Cell Subsets and the Classification of Peripheral T-Cell and Natural Killer-Cell Neoplasms

Innate Immune System	Adaptive Immune System
Does not require antigen sensitization	Characterized by specificity and memory
NK-cells, NK/T-cells, $\gamma\delta$ T-cells	Effector and memory T-cells
Cell-mediated cytotoxicity	Act principally through cytokines and chemokines
Mainly cutaneous and other extranodal sites	Mainly nodal lymphomas
Children and adults	More often in adults
NK, Natural killer.	

Angioimmunoblastic T-Cell Lymphoma

Angioimmunoblastic T-cell lymphoma (AITL) was initially proposed as an abnormal immune reaction or form of atypical lymphoid hyperplasia with a high risk of progression to malignant lymphoma. Because the majority of cases show clonal rearrangements of T-cell receptor genes, it is now regarded as a variant of T-cell lymphoma. The median survival is generally less than 5 years.

AITL presents in adults; most patients have generalized lymphadenopathy, hepatosplenomegaly, skin rash, and prominent constitutional symptoms. There is usually polyclonal hypergammaglobulinemia and other hematologic abnormalities such as Coombs-positive hemolytic anemia. Rituximab has been used in some recent clinical trials, in an attempt to control some of the effects of B-cell hyperactivity in this disease. Patients may also show evidence of immunodeficiency with recurrent opportunistic infections that may ultimately lead to their demise.

The nodal architecture is generally effaced, but peripheral sinuses are often open and even dilated. At low power, there is usually a striking proliferation of high endothelial venules (HEV) with prominent arborization (Fig. 73.11). Follicles are typically regressed, but there is a proliferation of dendritic cells around HEV. The atypical T-cells have clear cytoplasm, and are associated with small lymphocytes, immunoblasts, plasma cells, and histiocytes. The abnormal cells are usually positive for CD3, CD4, CD10, and CD279 (PD-1), a phenotype characteristic of follicular T-helper cells. This relationship is also confirmed by recent gene expression profiling data. CXC-chemokine ligand 13, a chemokine involved in B-cell trafficking into the germinal centers, is also expressed in AITL.

EBV-positive large B-cell blasts, sometimes with Reed–Sternberg (RS) like features, are nearly always present in the background, and

Fig. 73.11 PERIPHERAL T-CELL LYMPHOMAS. In angioimmunoblastic T-cell lymphoma, the lymph node shows effacement with an arborizing vascular proliferation of postcapillary venules and clustered large cells with clear cytoplasm in the background of plasma cells, immunoblasts, and small lymphocytes (A). The peripheral blood in adult T-cell leukemia/lymphoma has classic “flower-cells” (B). Peripheral T-cell lymphoma, not otherwise specified is heterogeneous, but typically there is a mixture of small and large neoplastic T cells (C).

progression to EBV-positive DLBCL has been reported in rare cases. Atypical B-cell proliferations that are negative for EBV also occur, presumably related to the T-helper follicular function of the neoplastic cells in promoting the activation and migration of bystander B cells. However, the exact role of EBV in AITL remains uncertain. Recently recurrent mutations have been reported in AITL; these include mutations in *IDH2*, *TET2*, and *RHOA*.

The biologic spectrum of AITL is greater than previously thought and other entities related to follicular T-helper cells are considered within the same group. Indeed, peripheral T-cell lymphoma (PTCL)-NOS, follicular variant shares some of the underlying genetic changes and has overlapping gene expression profile characteristics. These changes will be reflected in the updated version of the WHO classification.³⁰

Adult T-Cell Leukemia/Lymphoma

Adult T-cell leukemia/lymphoma (ATL) is a distinct clinicopathologic entity associated with the retrovirus human T-lymphotropic virus-1 (HTLV-1), which is found clonally integrated in the T cells. HTLV-1 infection is endemic in Southwestern Japan and in the Caribbean basin. The disease has a long latency, and affected individuals are usually exposed to the virus very early in life. The virus may be transmitted in breast milk, and through exposure to blood and blood products. The cumulative incidence of ATL is estimated to be 2.5% among HTLV-1 carriers.

The median age of affected individuals is 45 years. Patients may present with leukemia or with generalized lymphadenopathy. Other clinical findings include lymphadenopathy, hepatosplenomegaly, lytic bone lesions, and hypercalcemia. Cutaneous involvement is seen in the majority of patients. The acute form of the disease is associated with a poor prognosis and a median survival of less than 2 years. Complete remissions may be obtained but the relapse rate is nearly 100%.

Chronic and smoldering forms of the disease are seen less commonly, and are associated with minimal lymphadenopathy. The predominant clinical manifestation is skin rash, with only small numbers of atypical cells in the peripheral blood.

The cytologic spectrum of ATL is extremely diverse (see Fig. 73.11B). The cells are often markedly polylobated, and have been referred to as flower cells. Peripheral blood involvement is very common, but often in the absence of bone marrow disease. Immunophenotypically, the neoplastic cells are positive for mature T cell antigens, such as CD2, CD3, and CD5; they are typically CD4/CD25-positive, a phenotype that resembles regulatory T (Treg) cells. Some cases express FoxP3, but usually in a minority of tumor cells. The function of the tumor cells as Treg cells may correlate with the associated immunodeficiency.

Peripheral T-Cell Lymphomas, Not Otherwise Specified

PTCL, NOS is a diagnosis of exclusion and is admittedly a heterogeneous category with most cases being nodal in origin. Therefore, not unexpectedly the cytologic spectrum is very broad.³⁰ (see Fig. 73.11C). An inflammatory background is frequent, consisting of eosinophils, plasma cells, and histiocytes. If the epithelioid histiocytes are numerous and clustered, the neoplasm fulfills the criteria for the *lymphoepithelioid cell variant* of PTCL. The *T-zone variant* is composed of small to medium-sized cells that preferentially involve the paracortical regions of the lymph node.

Clinically, PTCL, NOS most often presents in adults with generalized lymphadenopathy, hepatosplenomegaly, and frequent bone marrow involvement. Constitutional symptoms, including fever and night sweats, are common, as is pruritus. The clinical course is aggressive, although complete remissions may be obtained with combination chemotherapy. However, the relapse rate is higher than in aggressive B-cell lymphomas, including DLBCL.

PTCL, NOS, as defined in the WHO classification, remains heterogeneous. It is likely that individual clinicopathologic entities will be delineated in the future from this broad group of malignancies. Thus far immunophenotypic criteria have not been helpful in delineating subtypes. Most cases have a mature T-cell phenotype, and express one of the major subset antigens: CD4 greater than CD8. These are not clonal markers, and antigen expression can change over time. Loss of one of the pan T-cell antigens (CD3, CD5, CD2, or CD7) is seen in 75% of cases, with CD7 most frequently being absent. GEP studies have shown some cases with a profile resembling AITL. Cases with a high proliferation signature appear to have a more aggressive clinical course, but GEP has not led to the delineation of distinctive subtypes as independent entities.

Anaplastic Large Cell Lymphoma, ALK-Positive

Anaplastic large cell lymphoma (ALCL) is characterized by pleomorphic or monomorphic cells, which have a propensity to invade lymphoid sinuses (Fig. 73.12). Because of the sinusoidal location of the tumor cells, and their lobulated nuclear appearance, this disease when first observed was suspected to be of histiocytic origin. A consistent feature is the strong expression of CD30 antigen, a diagnostic hallmark. However, CD30 expression is not specific for ALCL and can be seen in a variety of conditions, including of course, CHL. Systemic ALCL is associated with a characteristic chromosomal translocation, t(2;5)(p23;q35) involving *NPM/ALK* genes, respectively. A number of variant translocations have been identified that involve partners other than *NPM*. All lead to overexpression of *ALK*, although the cellular distribution of *ALK* varies according to the gene partner.

Fig. 73.12 ANAPLASTIC LARGE CELL LYMPHOMA. Anaplastic large cell lymphoma can show a wide spectrum in cell size, and there is a small cell variant in addition to the more typical common form. The cells (A) include “wreath cells” (center) and “hallmark cells” (bottom right). (B), The presence of ALK staining with nuclear and cytoplasmic localization (right) is associated with the t(2;5). A translocation of ALK can be identified with a break-apart probe that spans *ALK* but is split when *ALK* is translocated to one of a number of partners. A cell with a translocated *ALK* is pictured in (C) and a normal cell in (D). *ALK*, Anaplastic lymphoma kinase.

The cells of classic ALCL have large, often lobulated nuclei with small basophilic nucleoli, so called hallmark cells. The cytoplasm is usually abundant, amphophilic, and there are distinct cytoplasmic borders. A prominent Golgi region is generally visible. Small cell and lymphohistiocytic variants constitute part of the entity, and appear to be associated with a more aggressive clinical course.

The cells exhibit an aberrant phenotype with loss of many of the T-cell associated antigens. Both CD3 and CD5 are negative in greater than 50% of cases. CD2 and CD4 are positive in the majority of cases. CD8 is usually negative. ALCL cells, despite the CD4-positive/CD8-negative phenotype, exhibit positivity for the cytotoxic associated antigens TIA-1, granzyme B, and perforin. In addition, clusterin is generally present in ALCL and represents another useful diagnostic marker. By molecular studies, in most of the cases, a T-cell receptor rearrangement is found, confirming a T-cell origin.

ALCL is most common in children and young adults, with a marked male predominance noted. Although most patients present with nodal disease, a high incidence of extranodal involvement has been reported (involving skin, bone, and soft tissue). Approximately 75% of cases present with advanced-stage and systemic symptoms. Although these lymphomas have an aggressive natural clinical history, they respond well to chemotherapy. Overall survival and disease-free survival are significantly better among ALK-positive versus ALK-negative cases. Both ALK+ and ALK ALCL have a better prognosis than other PTCLs, with a plateau in the survival curve seen in both groups.³¹

Anaplastic Large Cell Lymphoma, ALK-Negative

It has been controversial whether ALCL negative for ALK is a separate entity or part of the spectrum of PTCL, NOS. Part of the controversy relates to the lack of absolute criteria to recognize these cases. They should be morphologically (i.e., sinusoidal and cohesive growth pattern, presence of hallmark cells) and phenotypically similar to ALK+ ALCL, with strong CD30 expression. A cytotoxic phenotype is common but is not essential. They occur in an older age group than the ALK+, and as noted earlier, appear to have a better prognosis than other PTCL, NOS. Recent molecular/cytogenetic studies have identified candidate genes *TP63* and *DUSP22*; the latter is associated with a more favorable outcome. Both ALK+ and ALK ALCL appear to share activation of the JAK/STAT pathway.

Primary Cutaneous Anaplastic Large Cell Lymphoma

The primary cutaneous form of ALCL is closely related to lymphomatoid papulosis, and differs clinically, immunophenotypically, and at the molecular level from the systemic form. Lymphomatoid

papulosis (LYP) and cutaneous ALCL are part of the spectrum of CD30-positive cutaneous T-cell lymphoproliferative diseases. Small lesions are likely to regress. Patients with large tumor masses may develop disseminated disease with lymph node involvement. However, primary cutaneous ALCL is a more indolent disease than other T-cell lymphomas of the skin. Because the skin nodules may show spontaneous regression, usually a period of observation is warranted before the institution of any chemotherapy. Cutaneous ALCL is CD30-positive but ALK-negative, lacking translocations involving the *ALK* gene. However, recent studies have identified rearrangements of *DUSP22* in a subset of cutaneous ALCL.

Mycosis Fungoides/Sézary Syndrome

Mycosis fungoides/Sézary syndrome (MF/SS) are now regarded as separate diseases, but are closely related and often considered together from a clinical and biologic standpoint.³² Both are primary cutaneous T-cell malignancies derived from mature CD4 positive skin-homing T cells. Skin involvement may be manifested as multiple cutaneous plaques or nodules (Fig. 73.13). SS is characterized by erythroderma and a leukemic phase. Lymphadenopathy is usually not present at presentation and, when identified, is associated with a poor prognosis. In early stages, enlarged lymph nodes may only show changes (Category I). If malignant cells are present in significant numbers and are associated with architectural effacement (Category II or III), the prognosis is significantly worse.

Cytologically, the small cells of MF demonstrate cerebriform nuclei with clumped chromatin, inconspicuous nucleoli, and sparse cytoplasm. Epidermotropism is usually a prominent feature. SS presents with exfoliative erythroderma and circulating cerebriform lymphocytes known as Sézary cells. The typical phenotype is CD2⁺, CD3⁺, CD5⁺, CD4⁺, and CD8⁺. However, CD8-positive variants of MF have been described, and are more common in children. The absence of CD7 is a constant feature but may also be seen in reactive conditions, and therefore is of limited diagnostic value. Aberrant expression of other T-cell antigens may be seen but mainly occurs in the advanced (tumor) stages. Inactivation of p16 (*CDKN2A*) and *PTEN* has been identified in some cases and may be associated with disease progression.

Subcutaneous Panniculitis-Like T-Cell Lymphoma

Subcutaneous panniculitis-like T-cell lymphoma (SPTCL) usually presents with subcutaneous nodules, primarily affecting the extremities and trunk. The nodules range in size from 0.5 cm to several centimeters in diameter. In its early stages the infiltrate may appear deceptively benign, and lesions are often misdiagnosed as panniculitis. However, histologic progression usually occurs and subsequent

Fig. 73.13 CUTANEOUS T-CELL LYMPHOMAS: MYCOSIS FUNGOIDES/SÉZARY SYNDROME AND SUBCUTANEOUS PANNICULITIS-LIKE T-CELL LYMPHOMA. In mycosis fungoides, there is a dermal infiltrate with some malignant T cells infiltrating into the epidermis (Pautrier microabscesses) (A). Sézary cells with convoluted nuclear folding are seen in (B). The peripheral nuclear outline is fairly rounded, but the internal nuclear detail shows complex nuclear folding giving rise to a convoluted and cerebriform look. A case of subcutaneous panniculitis-like T-cell lymphoma is illustrated and shows an abnormal lymphoid infiltrate in the subcutaneous fat (C). Fat necrosis is usually evident.

biopsies show more pronounced cytologic atypia, permitting the diagnosis of malignant lymphoma.

Atypical lymphoid cells rim individual fat cells. Admixed reactive histiocytes are frequently present, particularly in areas of fat infiltration and destruction. Vascular invasion may be seen in some cases, and necrosis and karyorrhexis are common (see Fig. 73.13C).

The neoplastic cells are CD8-positive T alpha-beta cells, with tumors composed of gamma-delta T-cells now included under primary cutaneous gamma-delta T-cell lymphomas. The cells display an activated cytotoxic immunophenotype (positive for TIA-1, granzyme-B, and perforin). These proteins may be responsible for the cellular destruction seen in these tumors.

A hemophagocytic syndrome is less often seen in SPTCL than in panniculitis-like tumors of gamma-delta T-cell derivation, but whenever seen, is associated with an adverse prognosis.³³ Patients present with fever, pancytopenia, and hepatosplenomegaly. The cause of the hemophagocytic syndrome appears related to cytokine production by the malignant cells.

Primary Cutaneous Gamma-Delta T-Cell Lymphoma

Primary cutaneous gamma-delta T-cell lymphoma is considered a distinct entity, which can involve the subcutis, the dermis, or with epidermal infiltration. These are clinically aggressive tumors. The cells have a cytotoxic phenotype, and like normal gamma delta T-cells, lack CD5, are positive for TCR-gamma and express cytotoxic molecules. They may be CD8-positive, or more often, double negative for CD4 and CD8. It is important to rule out MF and LYP before rendering a diagnosis of primary cutaneous gamma-delta T cell lymphoma, since there are newly recognized forms of LYP that share morphologic and phenotypic features. While skin is the most common presenting site, lymphomas of gamma delta T-cell origin can present in other mainly extranodal sites. The cells are invariably EBV-negative, and show clonal rearrangement of T-cell receptor genes.

Primary Cutaneous CD8-Positive Aggressive Epidermotropic Cytotoxic T-Cell Lymphoma and Primary Cutaneous CD4-Positive Small/Medium T-Cell Lymphoproliferative Disorder

Primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma is an aggressive cutaneous neoplasm that shares many clinical features with primary cutaneous gamma delta T-cell lymphomas, but is derived from cytotoxic alpha-beta T cells. As the term implies, the neoplastic cells show prominent epidermotropism.

Primary cutaneous CD4-positive small/medium T-cell lymphoproliferative disorder (LPD) most often presents with localized skin lesions. It is associated with an excellent prognosis, and requires only limited localized therapy, unless multiple skin lesions are present. The term LPD rather than lymphoma is used, reflecting the indolent nature of the proliferation. The lesions are rich in B cells, and the proliferating T cells have a T_{FH} phenotype, with clonality usually evident by molecular testing.

Enteropathy-Associated T-Cell Lymphoma

Two variants of Enteropathy-associated T-cell lymphoma (EATL) were recognized in the WHO 2008, EATL Type I and Type II. The classic Type I form of EATL, is associated with either overt or clinically silent gluten-sensitive enteropathy, and is largely seen in patients of European extraction, whereas the Type II form has a more worldwide distribution. In recognition of its distinction from EATL Type I, the proposed term in the revised WHO classification is “monomorphic epitheliotropic intestinal T-cell lymphoma.” Patients usually present with abdominal symptoms, including pain, small bowel perforation, and associated peritonitis. The clinical course is aggressive, and most patients have multifocal intestinal disease.^{30,34}

In EATL, Type I, the cytologic composition is somewhat varied; the neoplastic cells show prominent invasion of the mucosa and are cytotoxic T cells most often of alpha-beta origin. The cells also express the homing receptor CD103 (HML-1) (Fig. 73.14). Cells with anaplastic features positive for CD30 may be present. In EATL, Type II, the adjacent small bowel usually shows villous atrophy associated with celiac disease. In EATL Type II, (now monomorphic epitheliotropic intestinal T-cell lymphoma), the infiltrate is monomorphic and composed of medium-sized cells with clear cytoplasm showing prominent epitheliotropism. They are CD56-positive, CD8-positive, and most often of gamma-delta T-cell derivation. An association with celiac disease is seen only rarely, and this form of intestinal lymphoma is relatively common in Asia. Both EATL Types I and II share some genetic aberrations, including chromosomal gains on 9q33–34 as well as activating mutations involving the JAK/STAT pathway.

Other PTCL can present with intestinal disease, and should be distinguished from EATL. These include the EBV-positive extranodal T/NK cell lymphomas, PTCL, NOS, and a rare indolent form of T-cell lymphoproliferative disorder of the GI tract.³⁵

Hepatosplenic T-Cell Lymphoma

Hepatosplenic T-cell lymphoma (HSTCL) presents with marked hepatosplenomegaly in the absence of lymphadenopathy. The great

Fig. 73.14 OTHER T-CELL AND NATURAL KILLER-CELL LYMPHOMAS. In enteropathy-associated T-cell lymphoma (A), there is an abnormal T-lymphoid proliferation with infiltration into the gastrointestinal glandular elements (*center right*). Hepatosplenic gamma delta T-cell lymphoma in the bone marrow is illustrated with a CD2 stain showing the characteristic sinusoidal distribution (B). Extranodal natural killer cell/T-cell lymphoma typically has marked necrosis (C). The malignant cells are Epstein-Barr virus (EBV)-positive by in situ hybridization for EBV encoded RNA (*insert*). RNA, ribonucleic acid.

majority of cases are of gamma-delta T-cell origin. Most patients are male, with a peak incidence in young adults. Although patients may respond initially to chemotherapy, relapse has been seen in the vast majority of cases, and the median survival is less than 3 years. Rare long-term survival has been seen following allogeneic hematopoietic cell transplantation.

The cells of HSTCL are usually moderate in size, with a rim of pale cytoplasm. The nuclear chromatin is loosely condensed, with small inconspicuous nucleoli. The pattern of infiltration mimics the homing pattern of gamma-delta T cells with marked sinusoidal infiltration in liver and spleen. Abnormal cells are usually present in the sinusoids of the bone marrow but may be difficult to identify without immunohistochemical stains. The neoplastic cells also have a phenotype that resembles that of normal resting gamma-delta T cells. They are often negative for both CD4 and CD8, although CD8 may be expressed in some cases. CD56 is typically positive. The neoplastic cells express markers associated with cytotoxic T cells, such as TIA-1. However, perforin and granzyme B are usually negative, suggesting that these cells are not activated. Isochromosome 7q is a consistent cytogenetic abnormality, and is often seen in association with trisomy 8. In addition, activating mutations involving STAT5B and less frequently STAT3 have been described.³⁶

Extranodal Natural Killer/T-Cell Lymphoma, Nasal-Type

Extranodal NK/T-cell lymphoma, nasal type, is a distinct clinicopathologic entity highly associated with EBV. It is much more common in Asians than in Europeans.³⁴ Clusters of the disease also have been reported in Central and South America in individuals of Native American heritage, suggesting that ethnic background i.e., genetic risk factors, may play a role in the pathogenesis of these lymphomas. It affects adults (median age 50) and the most common clinical presentation is a destructive nasal or midline facial lesion. Palatal destruction, orbital swelling, and edema may be prominent. NK/T-cell lymphomas have been reported in other extranodal sites, including skin, soft tissue, testis, upper respiratory tract, and GI tract. The clinical course is usually aggressive, with a slightly improved median survival in patients with localized disease, in which local radiation therapy may be useful.³⁷ A hemophagocytic syndrome is a common clinical complication, and adversely affects survival.

Extranodal NK/T-cell lymphoma, nasal type, is characterized by a broad cytologic spectrum (see Fig. 73.14C). Although the cells express some T cell-associated antigens, most commonly CD2, other T-cell markers, such as surface CD3, are usually absent. The cells express cytoplasmic CD3, but lack T-cell receptor gene rearrangement. In support of an NK-cell origin the cells are usually CD56-positive, but do not express CD57 or CD16. EBV is positive in 100% of cases by in situ hybridization.

Aggressive NK-cell leukemia is a closely related entity. It presents at a younger age than extranodal NK/T-cell lymphoma, is associated with systemic disease, and a fulminant clinical course. It has a similar phenotype, EBV association, and epidemiology.

There are other EBV+ T-cell and NK-cell proliferations that are seen mainly in children. These include *systemic EBV+ T-cell lymphoma*, *hydra-like lymphoma*, and *mosquito bite allergy*, the latter usually being derived from NK-cells. All are seen most often in Asian children but are also reported in Central and South America, in individuals of Native American origin. The latter two conditions affect mainly the skin and have a more indolent clinical course, whereas the systemic disease has a very aggressive clinical course with survival measured in weeks. Systemic EBV+ T-cell lymphoma may arise in a background of chronic active EBV-infection.

Hodgkin Lymphomas

Hodgkin and non-Hodgkin lymphoma have long been regarded as distinct disease entities based on their differences in pathology, phenotype, clinical features, and response to therapy. It is now accepted that the malignant cell of HL is an altered B cell. Therefore, it is not surprising that both biologic and clinical overlaps should occur between these two lymphoma groups, as also shown by GEP in PMBL and cell lines derived from CHL. Although we have become aware of this closer relationship from the histogenetic point of view (hence the name Hodgkin lymphoma), these disorders are still treated with different modalities.

The diagnosis of CHL depends on the identification of Hodgkin and Reed-Sternberg (HRS) cells in an appropriate inflammatory background composed of small T lymphocytes, plasma cells, histiocytes, and granulocytes (often eosinophils). All cases of CHL share certain immunophenotypic and genotypic features. Neoplastic cells are CD30⁺, CD15^{+/−}, CD45[−], and EMA[−]. Expression of B-cell-associated antigens is seen in up to 75% of cases. However, when present, CD20 staining is weaker than that seen in normal B cells with variable in intensity among individual tumor cells. CD79a is usually negative. IG and T-cell receptor genes are usually germline, caused by the paucity of tumor cells in the inflammatory background, but using microdissection and polymerase chain reaction (PCR) amplification clonal rearrangement of the Ig genes can generally be shown. In addition, the presence of somatic mutations indicates transit through the germinal center.

Sufficient evidence has emerged in recent years to warrant the recognition of nodular lymphocyte-predominant HL (NLPHL) as a distinct entity. Although it resembles other types of HL in having a minority of putative neoplastic cells on a background of benign inflammatory cells, it differs morphologically, immunophenotypically, and clinically from classic HL. The preferred term of Hodgkin lymphoma over Hodgkin disease reflects current knowledge concerning the nature of the neoplastic cell as a lymphocyte.

Fig. 73.15 NODULAR LYMPHOCYTE PREDOMINANT HODGKIN LYMPHOMA. Low-power illustration shows vague expansile nodules that efface the lymph node architecture (A). The nodules can be accentuated with a stain for follicular dendritic cells, CD21 (B). The neoplastic cells are the so-called “LP” cells (previously called “L&H” cells or “popcorn” cells) (C). Unlike the neoplastic cells of classic Hodgkin lymphoma, these LP cells stain brightly for CD20 (D) and are typically CD45⁺, CD30⁺, and CD15⁺.

Nodular Lymphocyte-Predominant Hodgkin Lymphoma

NLPHL usually has a nodular growth pattern, with or without diffuse areas; it is rarely purely diffuse (Fig. 73.15). Nodularity may be more easily recognized using immunohistologic stains with anti-B-cell or antifollicular dendritic cell (FDC) antibodies. Progressively transformed germinal centers are often seen in partially involved lymph nodes or other lymph node sites. The atypical cells have vesicular, polylobated nuclei, and small nucleoli. These had been called lymphocytic and/or histiocytic (L&H) cells, or “popcorn” cells, but the term LP cell is now preferred. Although these cells may be very numerous, usually no diagnostic HRS cells are found. The background is predominantly lymphocytes with or without epithelioid histiocyte clusters. Plasma cells are infrequent, and eosinophils and neutrophils are rarely seen. Occasionally sclerosis may cause lesions to resemble nodular sclerosis.

The atypical cells are CD45⁺-expressing B-cell-associated antigens (CD19, 20, 22, 79a), CDw75⁺, EMA^{+/−} CD15[−], CD30^{+/−} and usually SIg[−] by routine techniques, although one study reported light-chain restriction. Neoplastic cells positive for IgD are more often found in young males. J chain has been demonstrated in many cases. Small lymphocytes in the nodules are predominantly B cells with a mantle-zone phenotype. However, numerous T cells are present, with T cells positive for CD57 and PD-1 (CD279) surrounding the LP cells. The proportion of T cells tends to increase over time in sequential biopsies. A prominent meshwork of FDC is present within the nodules. LP cells, when isolated by microdissection, have clonally rearranged Ig genes with evidence of somatic hypermutation.

NLPHL occurs at all ages, in adults more commonly than in children, and in males more than in females. It usually involves peripheral lymph nodes, with sparing of the mediastinum. It is usually localized at diagnosis, but may be rarely disseminated. Survival is long, with or without treatment, for localized cases. However, when disseminated the prognosis is often poor. Patients with advanced stage disease may benefit from treatment regimens used for aggressive B-cell lymphomas. Late relapses have been reported to be more common than in other types of HL; it may be associated with, or progress to, large B-cell lymphoma. Progression to a process resembling T-cell/histiocyte rich large B-cell lymphoma may also be seen, and recent data suggest that these diseases may be different ends of a spectrum, with a close biologic relationship.³⁸

Classic Hodgkin Lymphoma, Nodular Sclerosis

This variant is most common in adolescents and young adults, but can occur at any age; female cases equal or exceed those in males. The mediastinum is commonly involved; stage and bulk of disease have

prognostic importance. Nodular sclerosis classical Hodgkin lymphoma (NSCHL) is often curable; however, in long-term survivors the risk of secondary malignancies is increased, especially in those receiving both radiation and chemotherapy. NSCHL of the mediastinum is thought to be closely related to PMBL, and both types of tumors can be seen in the same patient, either as composite malignancy, or sequentially.³⁹

The tumor has at least a partially nodular pattern, with fibrous bands separating the nodules in most cases (Fig. 73.16). Diffuse areas may be present, as is necrosis. The characteristic cell is the lacunar-type RS cell, which may be very numerous. Diagnostic RS cells are usually also present. The background contains lymphocytes, histiocytes, plasma cells, eosinophils, and neutrophils. It can be graded according to the proportion of the tumor cells and the presence of necrosis: Grades I and II. However, grading is considered optional. The immunophenotype and genotype are characteristic of CHL. However, EBV is infrequently positive, less than 15% of cases.

Classic Hodgkin Lymphoma, Mixed Cellularity

Patients are usually adults; males outnumber females and the stage is often advanced. The course is moderately aggressive but is often curable. Classic Hodgkin lymphoma, mixed cellularity (CHLMC) has a bimodal age distribution, with a peak in young children, and again in older adults. It is often EBV-positive, seen in up to 75% of cases. Both CHLMC and the lymphocyte depleted form can be associated with underlying HIV-infection. The infiltrate is diffuse, without band-forming sclerosis, although fine interstitial fibrosis may be present (see Fig. 73.16C). HRS cells are of the classic type.

Classic Hodgkin Lymphoma, Lymphocyte Depletion

This is the least common variant of CHL and is most common in older people, in HIV-positive individuals, and in nonindustrialized countries. It frequently presents with abdominal lymphadenopathy, spleen, liver, and bone marrow involvement, without peripheral adenopathy. The stage is usually advanced at diagnosis. It shares many features with CHLMC, and appears to represent a continuum with this variant, associated with more frequent neoplastic cells and fewer normal T cells. The infiltrate is diffuse and often appears hypocellular, owing to the presence of diffuse fibrosis and necrosis. Relative to the number of normal lymphocytes there are large numbers of HRS cells and occasional bizarre ‘sarcomatous’ variants, with a paucity of other inflammatory cells. The immunophenotype is characteristic of CHL. Since the histologic differential diagnosis often includes B or T-large-cell lymphoma or ALCL, immunohistochemistry should be performed in most cases. EBV is positive in the majority of cases.

Fig. 73.16 CLASSIC HODGKIN LYMPHOMA, NODULAR SCLEROSIS, AND MIXED CELLULARITY SUBTYPES. In nodular sclerosis Hodgkin Lymphoma, broad bands of sclerosis typically divide the lymph node into cellular nodules (A). The nodules contain a mixed cellular infiltrate and scattered neoplastic cells with lobular nuclei and retracted cytoplasm (B). In mixed cellularity Hodgkin lymphoma, the lymph node is usually diffusely effaced with only fine fibrosis (C). Classic mononuclear, binuclear, and multinuclear Hodgkin and Reed-Sternberg cells are present (D). Both the lacunar and Hodgkin and Reed-Sternberg cells are typically CD45, CD30⁺, CD15⁺, weakly PAX5⁺, and CD20⁺. The B-cell transcription factors OCT2 and BOB1 are variable but often negative (E).

Classic Hodgkin Lymphoma, Lymphocyte-Rich

This type of CHL may be nodular or diffuse and contains relatively infrequent HRS cells, which are of the classic type, rather than the LP variants seen in NLPHL. There are infrequent eosinophils or plasma cells. In the nodular form the HRS cells are seen at the periphery of B cell-rich nodules, mainly in the marginal zone. The neoplastic cells have the immunophenotype of classic HRS cells, but morphologically may be difficult to distinguish from LP cells in some cases. Thus, in the past many cases were misdiagnosed as NLPHL. The genetic features are similar to those of the other variants of CHL. Patients usually present with localized disease, and tend to be older than patients with NLPHL.

ORIGIN OF HODGKIN LYMPHOMA

Ralf Küppers

INTRODUCTION

More than 150 years ago, Thomas Hodgkin described several cases of a lymphoproliferative disease, later named Hodgkin disease. For a long time this malignancy, now called *Hodgkin lymphoma* (HL), has been one of the most enigmatic forms of lymphomas. This is due to several key features of the disease: First, the pathognomonic and suspected tumor cells of HL, the mononuclear Hodgkin and the bi- or multinucleated large Reed-Sternberg cells, are very rare in the tumor tissue, often accounting for only about 1% of the cells. Thus the molecular analysis of these cells was hampered until methods became available to isolate these cells by microdissection from tissue sections. Second, the Hodgkin and Reed-Sternberg (HRS) cells have a very unusual immunophenotype that does not resemble any normal cell in the hematopoietic system. Therefore immunophenotyping, which was very informative in revealing the cellular derivation of most other lymphoid malignancies, did not help to uncover the cellular origin of HRS cells. Third, only a few cell lines could be established from patients with HL, these lines were rather heterogeneous, and for hardly any of these lines was the derivation from the HRS cells in the patient unequivocally shown. Hence it was initially difficult to draw firm conclusions from the study of such lines. Although HL still harbors many secrets, exciting novel insights into the cellular origin of the HRS cells and the pathogenetic processes in their generation have been obtained in recent years, which will be discussed in this chapter.

CLASSIFICATION OF HODGKIN LYMPHOMA

HL is subdivided into classical HL, which accounts for about 95% of cases, and nodular lymphocyte predominant HL (NLPHL). The tumor cells are called *HRS cells* in classical HL and *lymphocyte predominant (LP) cells* in NLPHL (until recently the tumor cells in NLPHL were called *lymphocytic and histiocytic [L&H] cells*). Classical HL and NLPHL differ in the histologic picture, the morphology and immunophenotype of the tumor cells, and multiple clinical features. Classical HL is further subdivided into four subforms: nodular sclerosis, mixed cellularity, lymphocyte-rich classical, and lymphocyte depletion HL. Again, differences in the histologic picture and HRS cell morphology are the basis for this subtyping (see [Chapter 73](#) for a detailed description).

B-cell Development and Differentiation

Because we now know that HRS and LP cells are derived from B cells (see later), a brief outline of B-cell development and differentiation is given first. B cells are generated in the bone marrow from hematopoietic stem cells in a multistep developmental process. The key determinant for B-cell development is the generation of a functional B-cell receptor (BCR) that is composed of two identical immunoglobulin (Ig) heavy chains and two identical light chains, the latter of which can be of the κ or λ type. B-cell development is initiated when common lymphoid progenitors undergo gene rearrangements at the Ig gene heavy chain locus. The variable part of the antibody heavy chain is composed of three gene segments: variable (V), diversity (D), and joining (J). First, a randomly selected D_H gene segment

is rearranged to one J_H gene segment. In the next step, a V_H gene segment is rearranged to a D_H - J_H joint. A heavy chain can be expressed and the developmental stage of a pre-B cell is reached if the rearrangement is in-frame and productive. In the next step, V_K to J_K rearrangements occur to generate a κ light chain. If this is not successful, V gene rearrangement processes take place at the λ light chain locus. B cells expressing a functional (and nonautoreactive) BCR are released into the periphery and express their BCR as IgM and IgD receptors—that is, two different classes of the heavy chain constant region. The first D_H - J_H rearrangements are not completely specific for B-lineage cells, but V_H - D_H - J_H rearrangements and light chain gene rearrangements are highly specific for B cells. Thus their detection in a cell unequivocally defines that cell as a B cell. Moreover, because of the availability of multiple V, D, and J gene segments and additional diversity generated at the joining sites of the rearranging gene segments, a V(D)J rearrangement (in particular for the heavy chain locus) is unique for each B cell and thus can be used as a clonal marker for B cells deriving from the same mature B cell.

If B cells are activated through binding of antigen to their BCR and through cognate help from T-helper cells, the cells undergo a T-dependent immune response in specific histologic structures, the germinal centers (GC), in lymph nodes or other secondary lymphoid organs. In these follicles, activated B cells undergo massive clonal expansion and further diversify their BCR through two processes: somatic hypermutation and class switching. The process of somatic hypermutation introduces point mutations and some deletions and duplications at a very high rate into the Ig heavy and light chain V region genes. This randomly modifies amino acids in the V regions, and in a selection process involving follicular dendritic cells and follicular T-helper cells, B cells expressing mutated BCR with increased affinity to the stimulating antigen are positively selected, whereas B cells acquiring unfavorable mutations undergo apoptosis within the GC microenvironment ([Fig. 74.1](#)). Unfavorable mutations include clearly destructive mutations, such as nonsense mutations and deletions or duplications causing reading frame-shifts that prevent expression of a BCR as such. Other disadvantageous replacement mutations still allow BCR expression, but reduce the affinity to the antigen. After multiple rounds of proliferation, mutation, and selection, positively selected B cells expressing a high-affinity BCR differentiate into long-lived memory B cells or plasma cells and exit the GC. Many GC B cells also undergo class switching before they are selected into the memory or plasma cell pool. In class switching, the originally expressed $C\mu$ and $C\delta$ heavy chain constant region genes (encoding IgM and IgD, respectively) are replaced by downstream located $C\gamma$, $C\alpha$, or $C\epsilon$ genes, encoding IgG, IgA, and IgE heavy chains, respectively, so that antibodies with altered effector functions are generated. At all stages of their development, B lineage cells are selected for expression of the appropriate BCR, and cells failing this selection are eliminated.

Cellular Origin of Lymphocyte Predominant Cells in Nodular Lymphocyte Predominant Hodgkin Lymphoma

LP cells in NLPHL express multiple typical B cell markers, such as the surface molecules CD20 and CD79 and the transcription factors PAX5, OCT-2, and BOB1 ([Table 74.1](#)).¹ LP cells mostly lack expression of markers of other hematopoietic cell lineages, thus their

Fig. 74.1 THE GERMINAL CENTER REACTION AND A SCENARIO FOR HODGKIN AND REED-STERNBERG AND LYMPHOCYTE PREDOMINANT CELL DERIVATION. Antigen-activated B cells that receive costimulatory signals from T-helper cells establish germinal center (GC) reactions in T-dependent humoral immune responses. In the GC, the activated B cells undergo massive clonal expansion in the dark zone. The proliferating GC B cells are called *centroblasts*. In the centroblasts, the process of somatic hypermutation is activated, which introduces somatic mutations at a very high rate into rearranged Ig V genes. Centroblasts migrate into the light zone and become resting centrocytes. Centrocytes are then selected based on their BCR. Most Ig V gene mutations will be disadvantageous (e.g., when they cause premature stop codons or lead to amino acid changes that reduce the affinity of the BCR to the immunizing antigen) and will cause apoptotic death of the respective B cells. GC B cells acquiring affinity-increasing mutations will be positively selected by interaction with T-helper cells and follicular dendritic cells (not shown). Positively selected centrocytes may either return to the dark zone for further rounds of proliferation, mutation, and selection, or they differentiate into memory B cells or plasma cells and exit the GC. LP cells of NLP HL express functional Ig V genes and proliferate in a follicular microenvironment resembling GC. Thus these cells are likely derived from selected GC B cells. HRS cells in classical HL often carry destructive Ig V gene mutations, indicating that they derive from GC B cells that normally would have undergone apoptosis (i.e., preapoptotic GC B cells). Initial transforming events in HRS cell pathogenesis might have occurred already at a pre-GC B cell differentiation stage, or they might happen in the GC. In EBV-positive cases, EBV is a good candidate for a factor that allows GC B cells with destructive Ig V gene mutations to escape from apoptosis.

immunophenotype suggests a B-cell origin. Moreover, LP cells are located in follicular structures in close association with follicular dendritic cells and GC-type T-helper cells, suggesting a close relationship with GC B cells. Indeed, LP cells express the transcription factor BCL6, the main regulator of the GC B cell differentiation program. They also express activation-induced cytidine deaminase (AID), an enzyme that regulates somatic hypermutation and class switching in GC B cells. Thus all of these phenotypic features point to a GC B cell origin of LP cells (Table 74.1), and this was further corroborated at the genetic level when clonally rearranged and productive Ig V region genes were amplified from isolated LP cells. These rearrangements were always somatically mutated. In some cases, intraclonal diversity of V region genes was observed, indicating ongoing somatic hypermutation during clonal expansion. Therefore the Ig V gene analysis further strongly supported a GC B cell origin of LP cells (Fig. 74.1). The detection of the same V gene rearrangements in all LP cells of a given NLP HL case was also important because this firmly established for the first time the monoclonality of the LP cells, a hallmark for tumor cells. A gene expression profiling study of primary LP cells indicated that LP cells have partly downregulated a fraction

of typical B cell genes and that their gene expression pattern indicates a relationship to late GC B cells on the way to becoming post-GC memory B cells.²

Cellular Origin of Hodgkin and Reed-Sternberg Cells in Classical Hodgkin Lymphoma

As mentioned earlier, HRS cells show a peculiar immunophenotype that does not resemble any normal hematopoietic cell type. HRS cells express markers of different cell lineages in a fraction or even most cases, including B cell genes (e.g., PAX5, IRF4), T cell genes (e.g., NOTCH-1, GATA3), natural killer cell genes (ID2), myeloid genes (e.g., CD15, CSF1R), and dendritic cell markers (e.g., CCL17, fascin, restin) (Table 74.1).^{1,3,4} Therefore immunohistochemical studies could not resolve the cellular origin of HRS cells. In addition, the first cell lines established from patients with HL and presumed to be derived from HRS cells were either of B-cell origin, T-cell, or nonlymphoid origin (discussed in further detail later). The origin of HRS cells was finally clarified when HRS cells microdissected from

TABLE 74.1 Comparison of Phenotypic and Genetic Features of Hodgkin and Reed-Sternberg Cells of Classical Hodgkin Lymphoma and Lymphocyte Predominant Cells of Nodular Lymphocyte Predominant Hodgkin Lymphoma

Feature	Hodgkin and Reed-Sternberg Cells	Lymphocyte Predominant Cells
Somatically mutated Ig V genes	Yes (very rare exceptions)	Yes
Crippling Ig V gene mutations	Yes (>25% of cases)	No
Ongoing somatic hypermutation	No	Yes (moderately)
Presumed cellular origin	Pre-apoptotic GC B cells	Positively selected, mutating GC B cells
Rare cases with a T-cell origin	Yes (<5%)	No
B-cell receptor expression	No	Yes
Expression of B-cell transcription factors (e.g., OCT2, BOB.1, PU.1, PAX5, E2A)	Rarely and/or at low levels	Yes
Expression of B-cell surface antigens (e.g., CD19, CD20)	No or rarely	Yes
Expression of GC B cell markers (e.g., BCL6, AID, HGAL, GCET)	No or rarely	Yes
Expression of molecules involved in antigen presentation and interaction with T-helper cells (e.g., CD40, CD80, CD86, MHC class II)	Yes	Yes
Expression of markers of nonB cells (e.g., CCL17, NOTCH1, GATA3, ID2, CSFR1)	Yes	No
EBV infection of tumor cells	Yes (30–40%)	No

tissue sections were analyzed for rearranged Ig V region genes. These studies revealed that HRS cells in nearly all cases carry clonal Ig heavy and light chain gene rearrangements.^{1,5} Because such rearrangements are highly specific for B cells, this established their B-cell nature. Moreover, with rare exceptions, the rearranged V region genes were highly mutated, pointing to a derivation from GC or post-GC B cells.^{4,5} Intracлонаl V gene diversity was not observed, showing that the process of somatic hypermutation is no longer active in these cells. There is also indication that many HRS cell clones underwent class-switch recombination, a further antigen-driven and B cell-specific process. Thus, these genetic features of the rearranged Ig genes unequivocally demonstrate that the HRS cells are derived from mature B cells that had been activated by antigen. Although some initial studies reported polyclonality of HRS cells, these results could not be verified, and additional analyses firmly established the monoclonality of the HRS cells in a given case.

Surprisingly, in about a quarter of the cases of classical HL, the Ig V gene rearrangements carried clearly destructive mutations that rendered originally functional V region genes nonfunctional.^{1,5} Such “crippling” mutations included deletions and insertions causing loss of the correct reading frame, as well as nonsense mutations. As discussed earlier, destructive mutations regularly happen in mutating GC B cells, but this normally results very efficiently in the removal of the cells by apoptosis. Thus, it is highly likely that the GC B cells that acquired the destructive mutations already carried some transforming events that allowed them to escape apoptosis (Fig. 74.1). Of note, most disadvantageous mutations that cause apoptosis of normal GC B cells are likely replacement mutations that reduce affinity to the antigen or interfere with the proper folding and/or pairing of the Ig heavy and light chains. These mutations cannot be easily recognized by looking at the V gene sequences. Thus, the clearly crippling mutations likely represent only the “tip of the iceberg,” and we have speculated that HRS cells, as a rule, derive from the pool of pre-apoptotic GC B cells (Fig. 74.1).^{1,5} Rare cases of classical HL with unmutated V region genes have also been described. In such cases, the HRS cells may stem from pre-GC B cells. However, because GC B cells acquire their apoptosis proneness upon entering the GC even before starting to undergo hypermutation, it is also conceivable that such cases may originate from GC founder cells.

Decisive steps in HL pathogenesis, therefore, become effective or take place in GC B cells. Thus, although some final transforming events may well occur when HRS precursor cells have already left the GC microenvironment, for the reasons discussed earlier, classical HL is considered as a GC B cell–derived malignancy.

T Cell–Derived Classical Hodgkin Lymphoma

The observation that in a fraction of cases the HRS cells express several T cell markers (e.g., CD3, granzyme B, perforin, T cell intracellular antigen 1) prompted studies aimed to clarify whether in such cases the HRS cells might derive from T cells. Analysis of HRS cells from several cases with T cell marker expression showed that most of these cases nevertheless are B cell–derived. However, several cases were identified that lacked Ig V gene rearrangements and that showed clonal T-cell receptor gene rearrangements.^{6,7} Thus, these cases have a T cell origin. Because the cellular origin of a lymphoma clone is a key factor for current lymphoma classification, it is a matter of debate whether lymphomas with HRS cells of T cell origin should be called *HL* or whether they should be considered a rare, separate type of T-cell lymphoma. Given that these cases are very rare (likely accounting for less than 5% of classical HL) because it is currently not possible to identify them by immunohistochemistry, and because it is unclear whether such cases differ in their clinical behavior from B cell–derived classical HL, there is currently no easy way to resolve this issue. Notably, in gene expression studies of HL cell lines, HDLM-2 (a T cell–derived HL cell line) clustered more closely to B cell–derived HL cell lines than to other T-cell lymphoma lines, suggesting that B cell– and T cell–derived HRS cells have a similar gene expression pattern.

Hodgkin Lymphoma Cell Lines

Tumor cell lines are valuable tools for detailed genetic, biochemical, and functional studies of a malignancy. Thus, there have been many attempts to establish such lines from patients with HL. However, this has proved to be a very difficult task, and less than 10 HL cell lines exist. A main reason for the difficulty in growing HRS or LP cells in culture is most likely their dependence on survival signals from the cellular microenvironment in the disease-affected lymph nodes. Of note, all of the existing HL lines are derived from patients at end-stage and were not established from lymph nodes, but rather from peripheral blood, bone marrow, or pleural effusions. This suggests that only when the HRS cells have become independent from the lymph node microenvironment in the patient do they also have a chance to survive in suspension culture. The existing and available HL lines are L428, L540, L591, L1236, KM-H2, HDLM-2, UHO-1, SUP-HD1, and DEV (Table 74.2). Most lines are of B-cell origin, but HDLM2 and L540 are T cell–derived. L591 is the only HL line that is Epstein-Barr

TABLE 74.2 Characteristics of Hodgkin Lymphoma Cell Lines^a

Cell Line	Hodgkin Lymphoma Subtype	Cellular Origin	Known Genetic Lesions in Oncogenes or Tumor Suppressor Genes	Remarks
L428	Classical	B cell	B2M, NFKBIA, NFKBIE, PTPN1, SOCS1, TP53	
L540	Classical	T cell	PTPN1	
L591	Classical	B cell		Only EBV-positive line
L1236	Classical	B cell	CD95, PTPN1, SOCS1, TNFAIP3, TP53	Only line with proven origin from HRS cells in patient
KM-H2	Classical	B cell	CIITA (translocation), CYLD, NFKBIA, TNFAIP3	
HDLM-2	Classical	T cell	SOCS1, TNFAIP3, TNFSF7, TNFSF9, TP53, UTX	
UHO-1	Classical	B cell	PTPN1, TNFAIP3, TRAF3	
SUP-HD1	Classical	B cell	PTPN1, PTPN2, TNFAIP3	
DEV	NLPHL	B cell	B2M, BCL6 (translocation), SOCS1	

^aA few additional lines have been published (HO, ZO, HD-70, HKB-1), but these have not been used in published studies in recent years, so it is unclear to the author whether they still exist, and very little is known about their phenotypic, functional, and genetic features.

virus (EBV)-positive. Among primary cases of classical HL, approximately 30% to 40% show EBV infection of the HRS cells (see further details later). Notably, L591 cells do not have the typical EBV gene expression pattern of primary EBV-infected HRS cells, which should be kept in mind when using this line for gene expression or functional studies. The DEV line was originally reported as being derived from a case of classical HL, but subsequent more detailed phenotypic and gene expression studies indicated that this is indeed the only existing cell line from a patient with NLPHL. Although the phenotype and genotype of these lines fits well with their presumed origin from HRS cells (or LP cells in the case of DEV), L1236 is the only cell line that the derivation from the HRS cell clone of the patient from which it was established was unequivocally proven. In 1998 a line from a pediatric patient with HL was established (HKB-1), but no further studies with this line were reported. Originally, the CO line was also published as an HL cell line. However, later studies showed that this line represents a cell culture contamination. Also the HD-Myz line was for a long time considered to be a classical HL cell line. However, it was later discovered that the phenotype of the line differs in key aspects from the phenotype of the primary HRS cells of the respective patient. Even more important, HD-Myz lacks Ig- and T-cell receptor gene rearrangements and is presumably of myeloid origin. Considering that all informative HL cases studied in detail for a lymphoid origin have turned out to be B cell-derived, or in rare cases T cell-derived, the nonlymphoid origin of HD-Myz argues against its derivation from HRS cells; thus this line should no longer be used as a model for HL.

Although the HL cell lines are a valuable (and practically the only) tool for functional studies with HRS cells, it needs to be taken into consideration that the cells are adapted to growth in suspension culture in the absence of their normal microenvironment. Indeed, a comparison of the gene expression pattern of primary HRS cells and classical HL cell lines revealed more than one thousand differentially expressed genes, including many genes regulating the extracellular matrix, proliferation, and chemokine production and signaling.⁸

Relationship Between Hodgkin Cells and Reed-Sternberg Cells

The population of HRS cells is always composed of a mixture of mononuclear Hodgkin cells and bi- or multinucleated Reed-Sternberg cells. It is thus an intriguing question how these two types of cells are related to each other. It was proposed that fusion of two independent cells might be involved in the generation of Reed-Sternberg cells from Hodgkin cells. It was also discussed whether the whole HRS cell clone could derive from a cell fusion (e.g., a fusion of a B cell with a non-B cell). Such a scenario was attractive because it might

have provided an explanation for the mixed immunophenotype and the usually aneuploid karyotype of the HRS cells. However, generation of the HRS cell clone through fusion of two separate cells was excluded by molecular studies.⁹ Indeed, there is now firm evidence from studies of HL cell lines that Reed-Sternberg cells develop from mononuclear Hodgkin cells through a process of incomplete cytokinesis.¹⁰ When Hodgkin cells attempt to undergo cell division, the final separation of the daughter cells often fails, and these cells undergo refusion, giving rise to a binucleated Reed-Sternberg cell.¹⁰ Reed-Sternberg cells have little further proliferative potential, so that the mononuclear Hodgkin cells are the principal proliferative compartment of the HRS cell clone.

Potential Hodgkin and Reed-Sternberg Precursor or Stem Cells

Another interesting question is whether the rare CD30⁺ HRS cells represent the whole tumor cell clone in the HL tissue or whether further tumor clone members are present among the smaller, CD30⁻ cells in the microenvironment. In a single-cell Ig V gene analysis of EBV-positive HRS cells and EBV-infected CD30-negative cells, it was found that the HRS cells and the small CD30⁻ EBV-infected B cells carried distinct V gene rearrangements in nearly all instances.¹¹ Because EBV infection of HRS cells is a clonal event, so that in EBV⁺ HL cases all members of the tumor clone should carry the virus, this finding was taken as an argument that the HRS cell clone does not have additional members among CD30-negative lymphocytes.

In several types of tumors, cancer stem cells were identified. These cells are defined as rare cells that have a particular proliferative potential and that sustain the tumor clone, whereas the bulk of the tumor clone lacks the potential to regrow to a full tumor. One study described the existence of HRS precursor cells in HL that fulfill at least some key features of cancer stem cells. In that work, it was reported that CD20⁺BCR⁺CD30⁻ cells belonging to the HRS cell clone exist in the peripheral blood of patients with HL and that these cells express the stem cell marker aldehyde dehydrogenase.¹² However, this finding was criticized because the markers for a clonal relationship between the HRS and non-HRS cells were unreliable and even argued, in part, against a relationship of the cells.¹³ Moreover, a previous highly sensitive study that searched for HRS clone members in the peripheral blood failed to identify such cells.¹⁴ Thus there is currently no convincing evidence for the existence of CD20⁺BCR⁺ HRS stem cells. In any case, it needs to be considered that HRS cells carry clonal and somatically mutated Ig V gene rearrangements; thus if HRS stem cells exist, they must be mature GC-derived B cells that carry the same Ig gene rearrangements and mutation pattern as the HRS cells.

Fig. 74.2 SCENARIO FOR THE GENERATION OF COMPOSITE LYMPHOMAS. Composite lymphomas are very rare combinations of two distinct lymphomas, often a classical HL and an NHL. Detailed molecular analysis of rearranged Ig V genes in several combined HL and B-cell derived NHL revealed that, in most instances, the two lymphomas are clonally related. Notably, the pattern of both shared and distinct V gene mutations in the majority of these cases revealed that the two lymphomas share a common precursor, but developed separately from this precursor. The direct clonal relationship of HRS cells with typical GC B cell–derived NHL is a further strong argument for a GC derivation of HRS cells. The horizontal line within the cells indicates an Ig V region gene; the vertical lines indicate somatic Ig V gene mutations. (Modified from Bräuninger A, Hansmann ML, Strickler JG, et al: Identification of common germinal center B-cell precursors in two patients with both Hodgkin's disease and non-Hodgkin's lymphoma. *New Engl J Med* 340:1239, 1999.)

The issue of potential subpopulations among the HRS cell clone with specific features in terms of proliferative potential and chemotherapy resistance was also addressed by searching for *side population cells*, which are defined as cells that extrude the Hoechst dye 33342, usually because they express drug transporters of the ABC family, such as the multidrug resistance 1 gene. In several types of tumors, side population cells were shown to share features with cancer stem cells (e.g., increased proliferative potential and chemotherapy resistance). Side population cells were indeed detected at low frequency (about 0.5% of cells) in some HL cell lines, and these cells showed increased resistance to chemotherapeutic drugs.^{15,16} The side population cells had the phenotype of small Hodgkin cells and they were positive for CD30 and negative for CD19 and CD20. Hence these cells are different from the cells identified earlier as potential HRS stem cells. Notably, side population cells were able to reestablish the full HRS cell clone upon subcloning. However, not all HL cell lines showed side population cells,^{15,16} arguing against a general role of these cells in the maintenance of the HRS cell clone. Moreover, although side population cells were also identified in cell suspensions of HL lymph nodes, it remains to be clarified whether these cells belong to the HRS cell clone. Thus, there are exciting developments regarding the potential existence of subpopulations among the HRS cell clones with specific biologic features, but additional studies are needed to characterize these cells and reveal their relevance for the HRS clone in vivo.

Lessons From Composite Lymphomas

Composite lymphomas are very rare lymphomas in which two distinct lymphomas, often an HL and a non-Hodgkin lymphoma (NHL), occur in the same patient. In a strict definition of composite lymphoma, this happens concurrently, but there are also cases where an HL may

occur either before or after an NHL in the same patient. There are a few cases where the two lymphomas are not related to each other and hence represent the chance occurrence of two unrelated malignancies developing in parallel in a patient. However, in most composite and sequential HL and NHL that have been molecularly studied for their clonal relationship, it was found that the lymphomas share a common origin, even in instances where sequential lymphomas occurred several years apart from each other.¹⁷ The detailed study of the rearranged Ig V genes of such cases revealed that although, in many cases, the clonally related V region genes of the lymphomas share a number of somatic mutations, there are often additional mutations that were present only in the HRS cells and others only in the NHL B cells.¹⁷ This showed that the two lymphomas have a common precursor, most likely a mutating GC B cell, and that the two lymphomas most likely developed from two distinct members of the GC B cell clone (Fig. 74.2). Thus these composite lymphomas usually do not represent the transformation of one lymphoma into the other but, rather, the parallel development of the two malignant clones from a common, premalignant precursor cell. It is likely that some transforming events were already present in the common precursor, but distinct daughter cells of this GC B cell later acquired different mutations, leading to the generation of the two distinct B-cell malignancies (Fig. 74.2). Therefore composite lymphomas are intriguing models to study the multistep transformation process in lymphomagenesis. In initial studies of several composite lymphomas for shared and distinct transforming events, examples for such genetic lesions were indeed identified.

A further important aspect of the molecular studies of composite lymphomas is that they provide further evidence for the derivation of HRS cells in classical HL from GC B cells, because the clonal relationship with shared and distinct somatic Ig V gene mutations of an HRS cell clone and a typical GC B cell–derived lymphoma (e.g., follicular lymphoma or diffuse large B-cell lymphoma) strongly supports a common GC B-cell origin of both malignancies.

The Role of Epstein-Barr Virus in Classical Hodgkin Lymphoma

In about 40% of cases of classical HL in the Western world, and in about 90% of childhood HL cases in Central and Southern America, HRS cells are infected by EBV. Molecular analyses of EBV⁺ cases showed that EBV infection of HRS cells is a clonal event (i.e., EBV infected or was already present in the founder cell of the HRS cell clone). EBV-positive HRS cells typically show a latency II gene expression pattern characterized by expression of the EBV nuclear antigen 1 (EBNA1) and the two latent membrane proteins 1 and 2a (LMP1 and LMP2a, respectively). EBNA1 is essential for the replication of the EBV episome in proliferating cells. LMP1 is an oncogene, and one of its main functions is to cause constitutive NFκB activation by mimicking an activated CD40 receptor. LMP2a has a cytoplasmic motif that resembles the signaling motif of the BCR. LMP2a can, on the one hand, diminish BCR signaling by recruiting BCR signaling components away from the BCR, but on the other hand, it mimics a tonic BCR signal. Strikingly, all HRS cell clones with clearly destructive Ig V gene mutations that prevent the expression of a BCR were found to be EBV-positive.¹⁸ Hence it appears that in GC B cell precursors of HRS cells that acquired BCR-destructive mutations, EBV is essential to rescue these cells from apoptosis upon loss of BCR expression. This scenario is supported by studies showing that EBV can rescue BCR-deficient GC B cells from apoptosis, and that LMP2a has an important role in this process.¹⁹ Whether the BCR-mimicking function is still important in the established HRS cell clone is unclear. The downregulation of most components of BCR signaling in HRS cells indicates that LMP2a does not have this role in the established HRS cell clone.

Genetic Lesions in Hodgkin and Reed-Sternberg and Lymphocyte Predominant Cells

The molecular analysis of HRS and LP cells for genetic lesions is hampered by the rarity of these cells. Nevertheless, we are now aware of a number of transforming events, especially for HRS cells. The recognition of constitutive activity of the NFκB transcription factor, which is normally only transiently activated in lymphocytes, prompted studies of whether gene mutations cause this deregulated activity. Inactivating mutations in the gene NFKBIA, which encodes the main inhibitor of NFκB (i.e., IκBα) were detected in 10% to 20% of cases of classical HL (Fig. 74.3).¹ Also, mutations in the NFKBIE gene were found. Genomic gains of the REL gene, encoding one of the NFκB factors, are present in about 40% of classical HL. Inactivating mutations in TNFAIP3, a further negative regulator of NFκB, were detected in 40% of HRS cell clones.^{20,21} Interestingly, most cases with TNFAIP3 mutations were EBV-negative,²¹ suggesting that EBV infection and TNFAIP3 mutations are alternative mechanisms in HL pathogenesis, thereby further supporting a pathogenetic role of EBV in HL development. Reestablishing wild-type TNFAIP3 in HL cell lines reduced NFκB activity and survival, establishing that TNFAIP3 functions as a tumor suppressor gene in this lymphoma.²¹ For CYLD, another tumor suppressor gene and negative regulator of NFκB, inactivating mutations were found in one HL cell line, but not in several primary cases of HL studied, indicating that mutations in this gene also occur in HRS cells, albeit at a low frequency. Rare mutations were recently also found in TRAF3, a negative regulator of the noncanonical NFκB pathway. Finally, the NIK kinase gene (MAP3K4), encoding a major activating factor for the noncanonical NFκB pathway, shows gains in 20% of classical HL.

Although LP cells of NLP HL also show constitutive NFκB activity,² no destructive mutations were found in TNFAIP3 and NFKBIA in these cells, and LP cells are not infected by EBV. In some NLP HL REL gains were found. Thus, the mechanisms causing NFκB activation in HRS and LP cells are largely different.

A second signaling pathway that shows constitutive activity in HRS cells and mutations in various pathway members is the JAK/STAT pathway, the main pathway for cytokine signaling. Upon activation of cytokine receptors, JAK kinases bind to the receptors and become activated. The activated JAKs then phosphorylate and thereby activate STAT factors, which upon phosphorylation and dimerization translocate into the nucleus and function as transcription factors. Frequent genomic gains of JAK2 and also rare translocations involving this gene have been detected in HRS cells. However, activating point mutations in the JAK2 gene, although they are frequent in other types of hematologic diseases, are absent in HRS cells. SOCS1, a main inhibitor of this signaling pathway, is inactivated by somatic mutations in the HRS cells in about 40% of cases of classical HL.²² Recently, destructive mutations in the PTPN1 gene were detected in HRS cells in 20% of cases.²³ PTPN1 is a phosphatase that, among other functions, negatively regulates STAT activity.

Notably, the genomic region on 9p24, which harbors the JAK2 gene and shows gains in HRS cells, also encompasses the gene JMJD2C that encodes a histone demethylase, and the programmed death 1 (PD-1) ligand genes PD-L1 and PD-L2.^{24,25} PD-1 ligands inhibit PD-1-expressing T cells and may contribute to the immunosuppressive microenvironment in HL.²⁴ A functional role of JMJD2C in HRS cells is indicated from the finding that downregulation of its expression in HL cell lines is toxic for these cells.²⁵ Thus, a single genetic lesion, the genomic gain on 9p24, affects four genes with pathogenetic roles in HRS cells.

Because disturbed apoptosis seems to be a key aspect of classical HL pathogenesis, numerous regulators of apoptosis were also studied in HL cell lines and/or primary HRS cells. Mutations in the TP53 gene were found in three HL cell lines and a few primary cases.²⁶ Mutations in the CD95 gene were found in less than 10% of cases, and no mutations were found in the CD95 signaling components CASP8, CASP10, and FADD.²⁶ Moreover, no mutations were detected in the proapoptotic gene BAD; mutations in ATM are also very rare.²⁶

Chromosomal translocations, usually involving one of the Ig loci and an oncogene, are a hallmark of most B cell lymphomas. Also in classical HL, chromosomal breaks involving the Ig loci were detected by fluorescence in situ hybridization in about 20% of cases. However, the translocation partners are in most cases unknown. In a few instances, BCL2, BCL3, BCL6, or MYC were identified as partners of the translocations. This also includes composite lymphomas where the clonally related classical HL and the B cell NHL were found to carry the identical translocation—for example, a BCL2-IgH translocation in a composite classical HL/follicular lymphoma.¹⁷ Notably, Ig locus-associated translocations usually function by causing deregulated expression of the translocated oncogene that has been brought under the control of the Ig regulatory elements, which are active in normal B cells and B cell NHL. Because the Ig loci are largely silenced in HRS cells, it is still unclear whether the partner genes of Ig locus-associated translocations in HRS cells are still active and pathogenetically relevant. Perhaps the translocations were important during early stages of HRS cell pathogenesis, when the lymphoma precursor cells still had a B-cell gene expression program, but became less important during later stages of the multistep transformation process. Alternatively, it should also be considered that translocations might function by mechanisms other than Ig enhancer-driven oncogene overexpression (e.g., promoter replacement or tumor suppressor gene inactivation).

HRS cells show a heterogeneous pattern of major histocompatibility complex (MHC) class I and II expression. Recurrent translocations involving the MHC class II transactivator gene CIITA were found in about 15% of classical HL.²⁷ These translocations involved heterogeneous partner genes and seemed to function by impairing CIITA function and hence dampening MHC class II expression. The MHC class I component β-2-microglobulin (B2M) is mutated in more than half of classical HL according to a recent study.²⁸ Downmodulation of MHC class I is often a strategy of cancer cells to evade attack by cytotoxic T cells.

Fig. 74.3 MECHANISM OF NF κ B ACTIVATION IN HODGKIN AND REED-STERNBERG CELLS. A classical and an alternative NF κ B signaling pathway are distinguished. In the classical NF κ B pathway stimulation of numerous receptors (e.g., RANK, CD30, and CD40) leads via TNF receptor-associated factors (TRAFs) and other associated factors, such as the receptor-interacting protein (RIP), to activation of the IKK complex. The IKK complex is composed of IKK α , IKK β , and NEMO. The activated IKK complex phosphorylates the NF κ B inhibitors I κ B α and I κ B ϵ that are encoded by the NFKBIA and NFKBIE genes, respectively. The phosphorylation marks the I κ B factors for ubiquitinylation and subsequent proteasomal degradation. Thus the NF κ B transcription factors (e.g., p50/p65 or p50/REL heterodimers) are no longer retained in the cytoplasm and translocate into the nucleus where they activate multiple genes. The signal transduction from TRAFs/RIP to the IKK complex can be inhibited by A20/TNFAIP3, which removes activating ubiquitins from RIP and TRAFs and additionally links ubiquitins to these molecules to mark them for proteasomal degradation. In the alternative NF κ B pathway, activation of receptors such as BCMA, CD40, and TAC1 causes stimulation of the kinase NIK (encoded by the MAP3K4 gene), which then activates an IKK α complex. Activated IKK α processes p100 precursors to p52 molecules that translocate as active p52/REL NF κ B heterodimers into the nucleus. HRS cells show constitutive activity of the classical and alternative NF κ B signaling pathways. This activity is mediated by diverse mechanisms, including receptor signaling through CD40, RANK, BCMA, and TAC1; genomic REL and MAP3K4 amplifications; destructive mutations in the TNFAIP3, NFKBIA, and NFKBIE genes; and signaling through the EBV-encoded latent membrane protein 1. HRS cells may also harbor nuclear BCL3/(p50)₂ complexes, and in a few cases the strong BCL3 expression appears to be mediated by genomic gains or chromosomal translocations of this gene. In rare instances, inactivating mutations in the inhibitory factors TRAF3 and CYLD have been found. (Modified and updated from Küppers R: *The biology of Hodgkin's lymphoma*. Nat Rev Cancer 9:15, 2009.)

For LP cells of NLPHL, few genetic lesions are known. SOCS1 mutations occur frequently in LP cells, and translocations involving the BCL6 gene are often found in these cells.^{29,30} BCL6 encodes a transcription factor that orchestrates the GC B-cell differentiation program and that has an oncogenic function when constitutively expressed in B cells. A study published in 2016 identified highly recurrent mutations in the serine/threonine kinase SGK1, the phosphatase DUSP2, and the AP-1 transcription factor JUNB in LP cells.²⁹

FUTURE DIRECTIONS

It is now firmly established that HRS and LP cells stem from mature B cells. A few cases with features of classical HL and a T-cell origin of the HRS cells exist. HRS cells in classical HL appear to derive

from crippled GC B cells, whereas LP cells likely originate from antigen-selected GC B cells. HRS cells show deregulated activation of multiple signaling pathways, and numerous genetic lesions have been identified that contribute to the deregulated activation of the NF κ B and JAK/STAT pathways. HRS cells show a nearly complete loss of the B-cell gene expression program.³ As normal GC B cells are stringently selected to express a functional, high affinity BCR, the lost B-cell phenotype may be related to the origin of HRS cells from preapoptotic GC B cells: by losing the B cell–typical gene expression program, the HRS cell precursors may escape from the pressure to undergo apoptosis as “failed B cells.” It has been speculated that transient hypoxic conditions in the GC may contribute to the initial “dedifferentiation” of the HRS precursor cells, because exposing human B cells to hypoxia induces several phenotypic changes in these cells toward an HRS cell phenotype. It should, however, be noted that further distinct subpopulations of GC B cells are currently being

recognized (e.g., CD30⁺ GC B cells), and it will be important to take these novel findings into consideration for a refinement of the cellular origin of HRS and LP cells.

The recent molecular biologic findings about HRS cells also offer some explanations for the typical and rather unique immunophenotypic heterogeneity of the HRS cells between cases and also among HRS cells of a given clone. The heterogeneity is likely due in part to different combinations of transforming events between HL cases. Moreover, the coexpression of multiple master regulators of different hematopoietic cell lineages (e.g., PAX5, ID2, NOTCH1) within one HRS cell clone may cause major fluctuations in gene expression between clone members by fluctuation of the competing transcription factors. Finally, because HRS cells are intimately interacting with multiple types of cells in their microenvironment, both by cellular interactions and through cytokines and chemokines, variations in the direct surrounding of HRS cells may cause differences in gene expression in these cells.

Further work is needed to fully understand the transforming events that lead to the generation of malignant HRS and LP cell clones, but with the availability of new methods, such as massive parallel sequencing of tumor genomes, it can be expected that major progresses will be made in the near future.

Finally, the recent detection of cell-free DNA presumably derived from HRS cells in the blood plasma of patients with HL³⁰ offers exciting novel possibilities to monitor the disease, and this tumor-specific DNA may become a useful biomarker.

HODGKIN LYMPHOMA: CLINICAL MANIFESTATIONS, STAGING, AND THERAPY

Katy Smith, April Chiu, Rahul Parikh, Joachim Yahalom, and Anas Younes

Hodgkin lymphoma (HL) is an uncommon lymphoproliferative malignancy arising from B cells. It can affect all age groups but is most common in young adults. HL is the first adult malignancy to demonstrate the curative potential of combination chemotherapy. Today more than 80% of patients with newly diagnosed HL can now expect to be cured of their disease.

The challenge now, particularly since many affected patients are young, is not only to improve cure rates further, but also to minimize the risk of long-term complications of treatment, which can impact quality of life and survival. Accordingly HL provides a very important clinical model for ongoing cancer research involving both the development of novel targeted agents and the study of late effects of cancer therapy.

Traditionally the choice of frontline therapy for HL has been determined by clinical stage and prognostic factors. A combined modality approach with chemotherapy and radiotherapy remains the standard of care for those with early-stage disease, whereas chemotherapy alone is routinely used for those presenting with more advanced clinical features. The availability of highly effective chemotherapy combinations and sensitive imaging tests has allowed the development of less toxic therapeutic strategies for those with limited disease. This includes the implementation of involved-field radiotherapy (IFRT), and more recently involved-site radiotherapy (ISRT), and a reduction in the number of chemotherapy cycles. This more focused treatment delivery has allowed efficacy to be preserved while exposure to unnecessary toxicity is reduced.

The management of HL continues to evolve. Positron emission tomography (PET) imaging has emerged as a useful tool for assessing response and to guide further therapy that may allow radiation therapy (RT)-free regimens. This, coupled with ongoing research to identify better biologic prognostic factors, is likely to allow for a more accurate risk-adapted approach to management, with the future treatment of patients with HL being tailored to the needs of the individual. In addition, improved understanding of the molecular mechanisms underlying HL has hastened the development of more effective, and often less toxic, targeted therapies for use either as monotherapy or in combination with traditional chemotherapy to augment efficacy and decrease overall toxicity.

EPIDEMIOLOGY AND ETIOLOGY

Incidence and Age of Onset

HL is a rare B-cell malignancy accounting for less than 1% of all cancers with approximately 9200 new cases diagnosed in the United States and approximately 5500 new cases diagnosed in Europe each year. The incidence of HL varies with economic status and geographic location. In developed countries it is associated with a bimodal age of onset distribution, with an early, larger, peak occurring in young adults aged between 20 and 40 years and a second, smaller, peak occurring in those over 55 years. In contrast, in developing countries, the disease predominantly occurs in childhood, with the incidence decreasing with age. Overall, men are affected slightly more frequently than women (1.3:1).

Etiology

The exact cause of HL remains unknown and clearly defined risk factors for the development of the disease are lacking. However, certain associations with its development have been identified. Although a clear genetic cause has not been established, familial susceptibility has been suggested by both an apparent increased risk among siblings of patients with HL, as well as concordance for HL observed in monozygotic twins. Increased maternal education, early birth order, low number of siblings and single-family dwellings in childhood have all also been positively associated with the occurrence of HL in younger patients.

Epstein-Barr virus (EBV)-positive Reed-Sternberg (RS) cells are found in approximately 40% of patients with HL using modern molecular techniques, mostly in cases of mixed cellularity classic HL (MCCHL) and lymphocyte-depleted classic HL (LDCHL), with reduced frequency observed in nodular sclerosis classic HL (NSCHL) and lymphocyte-rich classic Hodgkin Lymphoma (LRCHL). The incidence of HL among those with a past history of EBV infection appears to be higher than those without previous exposure. EBV may play a role in promoting RS survival and has been associated with the increased production of molecules that are involved in mechanisms of immune escape, in turn influencing the microenvironment that supports HL development.

The incidence of HL is higher in patients with human immunodeficiency virus (HIV) infection, suggesting a potential contributory role for immune suppression and reinforcing the likelihood of there being an important immune component underlying HL pathogenesis (see [Special Considerations: Hodgkin Lymphoma in Patients with HIV Infection](#) section, later).

PATHOBIOLOGY OF HODGKIN LYMPHOMA

The World Health Organization (WHO) classifies HL into two distinct disease types: classic HL (cHL), representing 95% of all cases, and nodular lymphocyte-predominant HL (NLPHL), accounting for only 5%. Both cHL and NLPHL are neoplasms composed of a minor component of atypical large neoplastic cells, usually accounting for <10% of all cells that are present in a reactive nonneoplastic background. However, based on their distinct clinical and molecular genetic features, it is now evident that cHL and NLPHL are two biologically distinct entities. Within cHL, four histologic subtypes are recognized based on the morphology of the neoplastic cells, composition of the nonneoplastic infiltrate, and overall nodal architecture: nodular sclerosing (NSCHL), mixed cellularity (MCCHL), lymphocyte-depleted (LDCHL) and lymphocyte-rich (LRCHL). Of these, NSCHL predominates, accounting for 70% of cases of cHL in Europe and the United States ([Table 75.1](#)). The rate of NSCHL, however, varies with geographic location and socioeconomic status and is much lower in developing countries, where MCCHL predominates. Furthermore, NSCHL occurs less frequently in patients infected with HIV, among whom the more common presenting subtype, again, is MCCHL (see [Special Considerations: Hodgkin Lymphoma in Patients with HIV Infection](#) section, later).

Nodular Lymphocyte-Predominant Hodgkin Lymphoma

Typical cases of NLPHL show partial or complete nodal architectural effacement by a macronodular proliferation (Fig. 75.1A), where the nodules are composed of scattered neoplastic cells termed *lymphocyte-predominant (LP) cells*, formerly known as L&H cells. LP cells are large with single folded or multilobulated nucleus with distinct but smaller nucleoli than RS cells. Because of their highly complex nuclear lobation, they have also been widely referred to as “popcorn cells” (see Fig. 75.1B). The background nonneoplastic infiltrate is composed of predominantly small B cells and a variable number of histiocytes. Mixed inflammatory cells such as eosinophils and neutrophils are rare to absent.

LP cells typically express B-cell markers including CD20 (see Fig. 75.1C), PAX-5, and CD79a. In addition, LP cells consistently express CD45, and the B-cell transcriptional factors OCT-2 and BOB.1, that are usually not expressed by RS cells. In contrast to RS cells, LP cells typically lack CD15 and CD30 expression. In keeping with their germinal center B-cell origin, LP cells are consistently positive for BCL6, although CD10 is usually not expressed. They express EMA (epithelial membrane antigen) in approximately 50% of the cases,

and variably express IRF4/MUM1. EBV-encoded RNA (EBER) and latent membrane protein-1 (LMP1) are consistently negative.

The nodules in NLPHL are typically supported by an expanded meshwork of follicular dendritic cells that can be highlighted by CD21 and CD35, and populated by small B cells that are positive for immunoglobulin (Ig) M and IgD. There are a variable number of T cells, a significant proportion of which is positive for CD4, CD57, and programmed cell death protein 1 (PD-1) which frequently form rosettes around the LP cells (see Fig. 75.1D).

Genetic studies performed on microdissected LP cells show clonally rearranged Ig genes with high load of somatic mutations in the variable region, indicating the presence of ongoing mutations and consistent with germinal center B-cell derivation of NLPHL. In contrast to cHL, the Ig rearrangement is functional with detectable Ig mRNA transcripts.

Classic Hodgkin Lymphoma

cHL is characterized by the presence of RS cells and their morphologic variants in a reactive background composed of mixed inflammatory cells (except in lymphocyte-rich variant). *Classic (diagnostic) RS cells* are large binucleated or multinucleated cells with pale chromatin, distinct nuclear membrane, single prominent eosinophilic, inclusion-like nucleolus in each nuclear lobe, and abundant amphophilic cytoplasm (Fig. 75.2A). Mononuclear variants with otherwise similar cytonuclear features are termed *Hodgkin cells* (see Fig. 75.2B). *Mummified cells* are degenerated RS and Hodgkin cells with pyknotic nuclei and condensed cytoplasm (see Fig. 75.2C). These variants are usually seen in various proportions in all four subtypes of cHL. In addition, *lacunar cells* are characteristic of nodular sclerosis cHL but usually not other subtypes, which have abundant pale cytoplasm that frequently retracts in formalin fixed tissue, creating an empty space (lacunae) around the cells (see Fig. 75.2D).

NSCHL is characterized by sclerotic nodal capsule and presence of collagenous bands traversing through the nodal parenchyma,

TABLE 75.1 Frequency of Histologic Subtypes of Hodgkin Lymphoma According to the 2008 WHO Classification

Classic Hodgkin Lymphoma (cHL)	95%
• Nodular sclerosis classic Hodgkin lymphoma (NSCHL)	70%
• Mixed cellularity classic Hodgkin lymphoma (MCCHL)	20–25%
• Lymphocyte-rich classic Hodgkin lymphoma (LRCHL)	5%
• Lymphocyte-depleted classic Hodgkin lymphoma (LDCHL)	<1%
Nodular Lymphocyte Predominant Hodgkin Lymphoma (NLPHL)	5%

Fig. 75.1 A CASE OF NODULAR LYMPHOCYTE-PREDOMINANT HODGKIN LYMPHOMA. The lymph node architecture is effaced by multiple expansile nodules with mottled appearance (A). Within the nodules there are scattered atypical large cells (lymphocyte-predominant [LP] cells) with single folded or multilobulated nucleus with distinct but relatively small nucleoli (B). The LP cells are positive for CD20 (arrows) with similar strong expression intensity as background small reactive B cells (C). The background infiltrate is composed of numerous programmed cell death protein 1 (PD-1)-positive T cells that frequently form rosettes (arrows) around the LP cells (D).

Fig. 75.2 MORPHOLOGIC VARIATIONS OF REED-STERNBERG (RS) CELLS IN CLASSIC HODGKIN LYMPHOMA (cHL). The diagnostic RS cells (A) are large binucleated (*arrow*) or multinucleated cells (*arrowhead*) with distinct nuclear membrane, prominent nucleolus in each nuclear lobe, and abundant amphophilic cytoplasm. Hodgkin cells are mononuclear variants of RS cells with similar cytonuclear features (B); numerous eosinophils and granulocytes are noted in the background. Mummified cells are degenerated RS and Hodgkin cells with pyknotic nuclei and condensed cytoplasm (C). Lacunar cells, characteristic of nodular sclerosis cHL, have abundant pale cytoplasm which frequently retracts in formalin fixed tissue (D).

imparting a prominent nodular pattern (Fig. 75.3A). Within the nodules there are a variable number of RS cells and variants, especially lacunar cells, with a background of mixed inflammatory cells composed of a variable proportion of small lymphocytes, histiocytes, plasma cells, eosinophils, and neutrophils. The RS cells and variants may be singly dispersed or form confluent aggregates/sheets.

In *MCCHL* the lymph node architecture is usually diffusely obliterated, although an interfollicular pattern may be seen in early involvement. In contrast to *NSCHL*, the nodal capsule is not thickened and there are no collagenous bands of fibrosis (see Fig. 75.3B). RS cells and variants are usually easily identified and dispersed throughout the nodal tissue in a mixed inflammatory background. In comparison to *NSCHL*, *MCCHL* is more often associated with higher stage disease and EBV positivity, and is more likely seen in the HIV-infected patient population.

LRCHL is a relatively recently defined subtype of cHL characterized by the presence of RS cells in a background of almost exclusively small lymphocytes, with a paucity or absence of eosinophils and neutrophils. The vast majority of the cases exhibit nodular growth pattern, although a rare diffuse variant has also been described. In the vast majority of the cases the affected lymph node is obliterated by multiple expansile nodules with expanded mantle zones and regressed, eccentrically located residual germinal centers (see Fig. 75.3C).

LDCHL is exceedingly rare (<1% of cHL) with a highly variable histologic appearance, but in all cases characterized by a relative predominance of RS cells in comparison to the background lymphocytes. Some cases are characterized by scattered RS cells in a diffusely fibrotic background containing histiocytes, fibroblasts, and few lymphocytes. In others, sheets of bizarre, pleomorphic, or anaplastic-appearing RS cells are present, imparting a sarcomatous appearance (see Fig. 75.3D).

The immunophenotypic profile of RS cells in all cHL subtypes is similar. RS cells are strongly positive for CD30 with membranous and Golgi pattern in nearly all cases (Fig. 75.4A), and CD15 with variable staining intensity in approximately 80% of the cases (see Fig.

75.4B). Consistent with their B-cell derivation, RS cells express PAX-5 in almost all cases (95%) but with weaker intensity when compared with the surrounding nonneoplastic small B cells (see Fig. 75.4C). However, in keeping with their defective B-cell program, RS cells lack Ig production as evidenced by absence of J chain, and are negative for most other B cell-associated antigens: CD20 (expressed in only 20%–30% of cases; often only in a subset of RS cells with weak/variable intensity), CD19, and CD79a; as well as B-cell transcriptional factors OCT-2 and BOB.1 (each expressed in 10% of cases; coexpression is rare). RS cells are almost always positive for IRF4/MUM1 and negative for CD45 and EMA, features that may help distinguish cHL from NLPHL. Expression of other hematopoietic lineage-associated markers, such as T cells (CD4, granzyme B), dendritic cells (fascin, CCL17), and myeloid cells (colony stimulating factor 1 receptor and α_1 -antitrypsin) is also often present. EBV LMP1 and/or EBV expression (see Fig. 75.4D) by RS cells is seen in approximately 40% of cHL cases overall in Western countries, but mostly in *MCCHL* and *LDCHL* and less frequently in *NSCHL* and *LRCHL*. However, an association with EBV is seen in up to 90% of cHL cases in developing countries and nearly all cases in the HIV patient population.

The nonneoplastic background lymphocytes, with the exception of *LRCHL*, are composed of predominantly T cells with marked predominance of CD4-positive cells that coexpress CD25 and FOXP3, consistent with immunosuppressive regulatory T-cells (TReg). In addition there is a significant population of TH2 cells. TReg and TH2 cells are attracted by cytokines (CCL5, CCL17, and CCL22) secreted by RS cells. In HIV-infected patients there is often a predominance of CD8-positive T cells. In contrast to NLPHL, CD57-positive T cells are not increased in number in cHL.

Polymerase chain reaction studies performed on RS cells procured by microdissection demonstrated that in the vast majority of cHL cases (>98%), the RS cells harbor clonal IgH gene rearrangement. The rearranged IgH shows a high load of somatic hypermutation in the variable region without evidence of ongoing mutation, consistent with germinal center or postgerminal center B-cell derivation. Rare

Fig. 75.3 HISTOLOGIC PATTERNS OF CLASSIC HODGKIN LYMPHOMA (cHL) SUBTYPES. Nodular sclerosis cHL characteristically shows multinodular pattern on low magnification, where the nodules are surrounded by broad collagenous bands. The nodal capsule is markedly sclerotic (A). In mixed cellularity cHL, the lymph node architecture is diffusely obliterated by the neoplastic infiltrate. The nodal capsule is not sclerotic and there are no collagenous bands of fibrosis (B). A case of lymphocyte-rich cHL where the affected lymph node is obliterated by multiple expansile nodules, with strikingly similar morphologic appearance to nodular lymphocyte predominant Hodgkin lymphoma (C). A case of lymphocyte-depleted cHL with presence of numerous pleomorphic/anaplastic appearing Reed-Sternberg (RS) cells (D).

Fig. 75.4 IMMUNOPHENOTYPIC PROFILE OF REED-STERNBERG (RS) CELLS IN CLASSIC HODGKIN LYMPHOMA. The RS cells and variants are positive for CD15 (A) and CD30 (B), with characteristic membranous staining and Golgi accentuation. These cells are positive for PAX-5, but with weaker intensity in comparison to background small reactive B cells (C). The RS cells are positive for Epstein-Barr virus (EBV) as demonstrated by in situ hybridization for EBV-encoded RNA/EBV-encoded RNA (EBER) (D).

Fig. 75.5 IMMUNOHISTOCHEMICAL ANALYSIS OF PDL-1 EXPRESSION IN CLASSIC HODGKIN LYMPHOMA (cHL) AND NODULAR LYMPHOCYTE-PREDOMINANT HODGKIN LYMPHOMA (NLPHL). (A) A case of nodular sclerosis cHL showing distinct membranous expression for PDL-1 by Reed-Sternberg (RS) cells (arrows). PDL-1 also highlights cell processes of tumor-infiltrating histiocytes (arrowheads) with granular staining pattern. (B) A case of nodular lymphocyte predominant Hodgkin lymphoma showing lymphocyte predominant (LP) cells (arrows) are negative for PDL-1, whereas the background tumor-infiltrating histiocytes (arrowheads) are highlighted by PDL-1 with granular pattern of staining by their cell processes.

cases harboring T-cell receptor gene rearrangements have also been documented. Genetic structural alterations that modulate the tumor microenvironment have also been observed. For example, 9p24.1 amplification leads to enhanced PDL-1 expression by RS cells, which inhibit T-cell effector functions by binding to PD-1 on T cells, enhancing survival of the RS cells (Fig. 75.5).¹

DIAGNOSIS AND STAGING

Diagnosis

The definitive diagnosis of HL must be made pathologically via excision biopsy of an affected lymph node or other suspected organ. Core needle biopsy is deemed inferior to excision biopsy because of the unique architecture of the lymph node in HL that comprises a relatively dilute population of malignant cells. The presence of RS cells in cHL, and LP cells in NLPHL in tissue biopsy, provides the basis for discriminating between these two major diagnostic subtypes, with immunophenotypic profiling representing a crucial adjunct for all new cases of HL (see [Pathobiology of HL](#) section, earlier).

Staging

Stage of disease is the major determinant of prognosis for patients with newly diagnosed HL, and accurate assessment is paramount when deciding upon optimal therapy. The current staging system used for patients with HL is the Cotswold-modified Ann Arbor classification system (Table 75.2).

More recently, in 2014, the Lugano classification proposed further modifications to the evaluation, staging, and response assessment of patients with HL: as well as further defining the criteria for and significance of extranodal disease involvement, the group heralded integrated PET/computed tomography (CT) as the “gold standard” for the staging of ¹⁸F-2-deoxyglucose (FDG)-avid lymphomas and reinforced its recommendation as an effective response assessment tool both early on during treatment and at the end of treatment to establish remission status.² CT (neck, chest, abdomen, pelvis) alone

TABLE 75.2 Cotswold-Modified Ann Arbor Staging System for Hodgkin Lymphoma

Stage	Criteria
I	Disease affecting a single lymph node region or lymphoid structure (e.g., spleen, thymus, Waldeyer ring).
II	Disease affecting two or more discrete lymph node regions confined to the same side of the diaphragm.
III	Disease affecting two or more discrete lymph node regions or lymphoid structures on both sides of the diaphragm.
IV	Disease that has spread to one or more extranodal site (that does not meet the criteria for E) or extralymphatic structure including involvement of the bone marrow, liver, or lungs.
Designation	Criteria
A	Absence of B symptoms ^a
B	Presence of B symptoms ^a
S	Involvement of the spleen
E	Single extranodal site or involvement of an extranodal site that is contiguous to an involved nodal region.
X	Bulky disease as defined as >1/3 mediastinum at its widest part or a nodal mass >10 cm at its greatest diameter.

^aB symptoms: constitutional symptoms including night sweats, fevers, or weight loss (>10% over 6 months).

should only be performed if integrated PET/CT is unavailable. In selected cases with mediastinal involvement, chest x-ray (CXR) may still be indicated at staging, to determine whether or not criteria for bulky disease are met.

Bone marrow involvement occurs in <5% of patients with HL at diagnosis. Until recently, following pathologic diagnosis with excisional node biopsy, a bone marrow biopsy was also required as part

of routine staging for all patients with newly diagnosed HL. However, because of the high sensitivity of PET/CT for bone marrow involvement, bone marrow biopsy is no longer mandated for the routine staging of patients with newly diagnosed HL, unless PET/CT imaging is unavailable.²

In addition to excisional node biopsy and staging with PET/CT, assessment of the peripheral blood represents an important part of the diagnostic workup for patients with newly diagnosed HL with particular respect to risk stratification and treatment choice. Complete blood count, erythrocyte sedimentation rate (ESR), and serum biochemistry including C-reactive protein, alkaline phosphatase, lactate dehydrogenase, liver function tests, renal function tests, and albumin are required as part of standard care, and screening for HIV and hepatitis is strongly advised. In addition, given the potentially damaging effects of chemotherapy and RT, certain pretreatment investigations including cardiac and pulmonary function tests, thyroid function tests, reproductive counseling, and serum pregnancy testing, may also be warranted in selected patients.

As advances continue to be made with regards to imaging modality, molecular profiling, and improved disease characterization, further modifications to the current staging approach for patients with HL are expected. However, at present, the principles of the Cotswold-modified Ann Arbor staging system still apply and provide the backbone for management decisions and clinical trial design worldwide.

CLINICAL FEATURES

The importance of an accurate clinical history in facilitating the management of patients with HL should not be underestimated. Certain symptoms may provide clues as to the likely stage of disease or lead to further investigations that might identify additional sites of disease. This may result in important treatment modifications. An accurate past medical history, particularly with regards to lung, heart, and kidney function, is also crucial in highlighting those organs that might benefit from further investigation before commencing therapy, to ensure that treatment choices are both effective and safe for the individual.

Systemic symptoms that are known to influence prognosis in patients with HL include night sweats, fever, and weight loss. These constitutional symptoms have come to be known as “B symptoms” and their importance in HL is reflected by their inclusion as key components of the Cotswold-modified Ann Arbor staging system (see [Staging](#) section, earlier). B symptoms are a presenting feature in approximately 30% of patients with HL and may predate lymphadenopathy in some cases. Fever in HL may take any form, from continuous low-grade pyrexia to intermittent spikes exceeding 38°C (101°F), whereas night sweats are typically drenching. A particular type of fever that is considered characteristic of HL historically, is the Pel-Ebstein fever, which typically follows a swinging pattern, occurring on a daily basis for many weeks, with intermittent afebrile periods occurring between episodes. In reality, however, this phenomenon features rarely in the modern clinical setting. B symptoms may occur in isolation or simultaneously, and incidence tends to increase with more advanced disease.

Other well-described clinical features associated with HL include fatigue, chronic pruritus, which may be an early sign of disease in up to 15% of patients, and the presence of a pain localized to the site of involved lymphadenopathy that is precipitated by the consumption of alcohol.

PROGNOSTIC FACTORS, RISK STRATIFICATION, AND TREATMENT GROUPS

Prognostic factors have helped to predict the likely outcome for individual patients with HL at diagnosis. Clinical stage, presence of systemic symptoms, and tumor burden continue to be important prognostic factors in HL, and, in addition to disease histology and

anatomic stage, are widely used for risk stratification and subsequent selection of appropriate initial therapy.

HL patients have traditionally been divided into two distinct prognostic groups according to clinical stage at diagnosis: early-stage disease, accounting for 45% of newly diagnosed patients, and advanced-stage disease, accounting for 55% of newly diagnosed patients.

Early Stage Disease

The category of early-stage HL includes patients with stages I or II. Early-stage disease may also include patients with B symptoms, bulky disease, or extension to adjacent sites. Limited stage disease is usually confined to nodes above the diaphragm nodes and less frequently presents in only subdiaphragmatic sites.

Data from large clinical studies in which HL patients with variable disease characteristics were treated uniformly and closely followed have allowed additional prognostic factors to be identified. These additional prognostic factors have led to the more accurate stratification of early-stage disease into early “favorable” and early “unfavorable” disease subgroups, with regards to outcome. Early stage I or II HL is considered “favorable” if it is limited to an area above the diaphragm and is not associated with other risk factors. Early stage I or II HL is considered “unfavorable” in the presence of other risk factors related to age, tumor burden, ESR, and number of involved nodal areas ([Table 75.3](#)).

The criteria for early-unfavorable stage HL vary slightly according to international cooperative group. Since 1982 the European Organization for Research and Treatment of Cancer (EORTC) has defined early-unfavorable HL as clinical stage I–IIA disease with one or more of the following: age greater than 50 years; ESR >50 mm/h in the absence of symptoms; ESR >30 mm/h in the presence of B symptoms; large mediastinal mass. The German Hodgkin Study Group (GHSG), however, refined these criteria in 1988 to include clinical stage I–IIA patients with any of the following risk factors: mediastinal mass greater than one-third of the maximum thoracic diameter; greater than three affected nodal areas; elevated ESR and localized extranodal disease infiltration. Early-unfavorable disease is often also referred to as Intermediate stage disease and these terms may be used interchangeably (see [Table 75.3](#)). Thus, early-stage HL is a heterogeneous group and treatment algorithms have been developed for different subgroups based on these prognostic factors and response criteria (see [Treatment of Early-Stage Hodgkin Lymphoma](#) section, later).

Advanced-Stage Disease

The criteria for advanced-stage HL again vary slightly according to international cooperative group. Whereas the EORTC defines advanced stage as those patients with clinical stage III–IV disease only, the GHSG also includes those patients with clinical stage IIB disease and a large mediastinal mass and/or extranodal disease involvement in their definition (see [Table 75.3](#)).

Following the identification of more specific and more widely applicable prognostic factors, the International Prognostic Score (IPS) was developed as an internationally accepted means of distinguishing those patients with newly diagnosed advanced HL who might be cured by standard treatment, and therefore avoid overtreatment, from those in whom standard treatment might fail. In 1998 based on a multivariate analysis of survival data from 5141 patients with newly diagnosed advanced HL treated between 1983 and 1992, seven adverse prognostic factors were identified as being statistically meaningful when predicting 5-year freedom from progression (FFP) and overall survival (OS): age ≥45 years, male sex, albumin <40 g/L, hemoglobin <10.5 g/dL, Ann Arbor stage IV, leucocytosis ≥15 × 10⁹/L, and lymphocyte count <0.6 × 10⁹/L. Five-year FFP was 84% for those patients with no adverse prognostic factors, and each additional factor reduced FFP by 7%, with four to seven factors

TABLE 75.3 Prognostic Factors in Early and Advanced-Stage Hodgkin Lymphoma

Prognostic Group	EORTC	GHSG	NCCN
Early-favorable	CS I-II without risk factors (supra-diaphragmatic)	CS I-II without risk factors	CS IA-IIA without risk factors
Early-unfavorable (Intermediate)	CS I-II with ≥ 1 risk factor (supra-diaphragmatic)	CS I-IIA with ≥ 1 risk factor C/D but not A/B	CS I-II with ≥ 1 risk factor
Advanced	CS III-IV	CS IIB with risk factors A/B CS III/IV	CS III-IV
Prognostic factors	(A) Bulky mediastinal mass ^a (B) Age ≥ 50 years (C) Elevated ESR (>50 mm/h without B symptoms; >30 mm/h with B symptoms ^b) (D) ≥ 4 nodal areas (out of 5 supra-diaphragmatic EORTC areas)	(A) Bulky mediastinal mass ^a (B) Extranodal disease (>1 lesion) (C) Elevated ESR (>50 mm/h without B symptoms; >30 mm/h with B symptoms ^b) (D) ≥ 3 nodal areas (out of 11 GHSG areas)	(A) Bulky mediastinal mass ^a (B) Bulk >10 cm (C) Elevated ESR (>50 mm/h without B symptoms) (D) B symptoms (E) ≥ 4 nodal areas (out of 17 Ann Arbor regions)

^aBulky mediastinal mass: ratio ≥ 0.035 of the maximum horizontal chest diameter (EORTC); ratio $\geq 1/3$ of the maximum horizontal chest diameter (GHSG); ratio $>1/3$ of the maximum horizontal chest diameter (NCCN).

^bB symptoms: night-sweats, fever, weight loss (unexplained, $>10\%$ over 6 months).

CS, Clinical stage; EORTC, European Organization for Research and Treatment of Cancer; ESR, estimated sedimentation rate; GHSG, German Hodgkin Study Group; NCCN, National Comprehensive Cancer Network.

TABLE 75.4 International Prognostic Score (IPS) for Advanced Hodgkin Lymphoma

No of Prognostic Factors	% of patients	5-year FFP (%)	5-year OS (%)
0–1 (low-risk)	29	79	90
2–3 (intermediate-risk)	52	64	80
4–7 (high-risk)	19	47	59

FFP, Freedom from progression; OS, overall survival.

representing an FFP of 40%.³ Three risk groups were established as a result, allowing therapy to be chosen according to these specific clinical characteristics, with the consensus being that higher risk patients should receive more intensive therapy (Table 75.4).

Treatment According to Prognostic Group

The stratification of patients with newly diagnosed HL into early-favorable, early-unfavorable, or advanced prognostic groups, has allowed initial treatment of these individuals to be risk-adapted. The treatment approach for those with early-favorable disease typically involves combined modality therapy, with two to four cycles of chemotherapy followed by IFRT. For early-unfavorable disease the treatment approach is similar, but with four to six cycles of chemotherapy usually being administered before RT. For advanced disease a more aggressive approach is adopted with six to eight cycles of combination chemotherapy alone, followed by consolidative localized RT in selected cases (Table 75.5).

The importance of clinical prognostic factors in predicting outcome and directing treatment for individuals with newly diagnosed HL is well established, and has undoubtedly contributed to the huge advances observed in HL over the past two decades. However, despite high cure rates, up to 30% of patients will still relapse. Furthermore, a significant proportion of those who are cured of their disease will go on to develop serious complications of treatment later on in life. Therefore the identification of additional, and more specific, biologic markers is needed to better discriminate these individuals according to their unique risk profiles, with the subsequent delivery of therapy that is personalized. Response-adapted tailoring of treatment with PET (discussed later) and gene expression profiling of primary tumor tissue are two approaches currently being investigated for this role.

TABLE 75.5 Standard Treatment Approach According to Prognostic Group

Early-favorable HL	Combined modality therapy • 2–4 cycles of chemotherapy followed by involved-field radiotherapy
Early-unfavorable HL (intermediate-stage)	Combined modality therapy • 4–6 cycles of chemotherapy followed by involved-field radiotherapy
Advanced HL	Extensive chemotherapy • 6–8 cycles of chemotherapy $\pm$ consolidation with localized radiotherapy

TREATMENT OF EARLY-STAGE HODGKIN LYMPHOMA

Early-Stage Nodular Lymphocyte-Predominant Hodgkin Lymphoma

Traditionally, patients with NLPHL present with localized, early-stage peripheral lymphadenopathy, and are less likely to present with B symptoms, bulky disease, or mediastinal involvement. The behavior of this disease entity contrasts favorably to cHL, and its clinical behavior is more comparable to that of an indolent non-HL. A retrospective matched-pair analysis from the GHSG of 394 patients with NLPHL (compared with 7904 patients with cHL) confirmed these findings and validated the improved prognosis (tumor control and OS) of this disease entity. In addition, the European Task Force on Lymphoma (ETFL) conducted an analysis comprising 219 patients with histologically confirmed NLPHL. Both analyses revealed that B symptoms, bulky/extranodal disease, increased ESR and lactate dehydrogenase, and involvement of three or more nodal areas were less frequently found in NLPHL than in cHL.

For localized asymptomatic nonbulky NLPHL, ISRT alone is the preferred treatment. For the rare patient with localized NLPHL who presents with B symptoms or bulky disease, ISRT remains a consolidation treatment after initial rituximab and/or chemotherapy.

Early-Stage Classic Hodgkin Lymphoma

Recent strategies for the management of early-stage cHL have continued to focus on optimizing treatment by minimizing the extent of

both chemotherapy and RT while maintaining the excellent cure rate and still reducing short- and long-term risk of complications. These approaches are based on the distinction between the amounts of treatment required in early-favorable patients compared with that required for optimal outcome in early-unfavorable patients. The risk factors that are used by different study groups to define early-stage HL subgroups are listed in [Table 75.4](#). All criteria include the presence of a large mediastinal mass and B symptoms and use the principal that favorable disease should not have any of the risk factors listed (see [Prognostic Factors, Risk Stratification, and Treatment Groups: Early-Stage Disease](#) section, earlier).

The most comprehensive and powerful studies attempting reduction of treatment for early stage HL were published by the GHSG. In the HD10 randomized trial of 1370 patients with favorable disease, as few as two cycles of ABVD (adriamycin, bleomycin, vinblastine, and dacarbazine) followed by 20 Gy IFRT resulted in OS of 96.6% and freedom from treatment failure (FFTF) of 91.2% at 5 years. The minimal combined modality approach has become the standard of care for patients with early-stage favorable HL. HD10 was one of the first large studies to show that reduction of treatment intensity of both chemotherapy and RT did not reduce efficacy, but toxicity was decreased and side-effects of treatment were fewer. The next step of the GHSG to reduce treatment was by testing the possible elimination of either bleomycin or dacarbazine or both from ABVD $\times 2$ followed by IFRT (HD13 trial), but was not successful and data suggested that if using only two cycles of ABVD, both bleomycin and dacarbazine should remain part of the regimen.

In unfavorable early-stage patients the GHSG HD11 trial randomized 1397 patients between four cycles of ABVD and four cycles of baseline BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisolone), and each chemotherapy arm was followed by either 30 Gy or 20 Gy IFRT. Four cycles of ABVD followed by IFRT of 30 Gy resulted in a 5-year FFTF of 85.3% and OS of 94.3% and was less toxic than baseline BEACOPP. Most groups recommend this approach of ABVD $\times 4$ followed by IFRT of 30 Gy as the standard of care. It should be noted, however, that patients with a combination of bulky disease and B symptoms were not included in GHSG unfavorable early-stage programs and were referred to advanced-stage disease studies.

Another approach studied by the GHSG for patients ≤ 60 years who are eligible for a more intensive treatment involved using two cycles of escalated BEACOPP followed by two cycles of ABVD and 30 Gy IFRT (HD14 trial). After a median follow-up of 43 months, FFTF with this protocol was superior in comparison with four cycles of ABVD followed by 30 Gy IFRT, but an advantage in OS could not be shown.

Ultimately the standard practice for patients with unfavorable-risk early-stage HL is four cycles of chemotherapy followed by IFRT (30 Gy). Some current clinical trials are exploring new combinations of new chemotherapy combinations that include brentuximab vedotin (BV) and reduced radiation doses to explore even more effective therapies.

Response-Adapted Treatment Approach

In the era of FDG-PET imaging for assessment of metabolic response to induction chemotherapy, the need for consolidation RT has been challenged in two important recent trials.

The EORTC H10 trial, which used modern-involved node RT (INRT) techniques, randomized (both favorable and unfavorable risk) patients to chemotherapy alone versus combined modality treatment (CMT) for those with a negative FDG-PET after two cycles of ABVD. The outcomes appeared to be excellent (in terms of OS) in both arms of patients who received chemotherapy alone or CMT.⁴ This study enrolled 1137 patients and after 34 events, an interim analysis found an unacceptably high rate of treatment failures in the chemotherapy alone group, subsequently mandating its closure.⁴ The most favorable subgroup of patients in this study, who had a negative early PET scan after two cycles of ABVD only, experienced an inferior

1-year progression-free survival (PFS) of 94.5% (versus 100% in CMT arm). As per the statistical analysis plan for this noninferiority study, the primary endpoint will take place approximately 6.5 years after recruitment, with additional long-term analyses of OS, to be carried out after a median follow-up of 10 and 20 years.

Also, emerging data from the UK National Cancer Research Institute (NCRI) RAPID trial shows that early-stage HL patients with a favorable PET-based response after three cycles of chemotherapy may have an excellent prognosis without consolidation RT.⁵ This study randomized 420 PET-negative patients (after three cycles of ABVD) to receive IFRT versus no further treatment. After a median follow-up of 45 months, this noninferiority trial revealed no difference in OS, but slightly, although not statistically significant, higher 3-year PFS (intention to treat analysis) in patients receiving IFRT (93.8% versus 90.7%), where a margin of $\leq 7\%$ PFS difference was deemed acceptable.⁵ Because 26 of 211 patients randomized to receive consolidation RT died from unrelated causes, but were scored as events within the RT arm, this raised the observation arm under the margin of noninferiority. When an “as-treated” analysis was performed, the 3-year PFS was 97% for CMT versus 90.7% for chemotherapy alone (hazard ratio [HR] = 2.39, $p = .03$).⁵

More recently, in 2015, the Cochrane Hematological Malignancies Group conducted a systematic review of randomized controlled trials that addressed the issue of whether PET-adapted therapy in individuals with HL results in better PFS (OS was not available in these very recent studies). In 1480 patients analyzed, PFS was shorter in participants with PET-adapted therapy (without RT) than in those receiving standard treatment with RT (HR 2.38; 95% confidence interval [CI] 1.62 to 3.50; $p < .0001$). This difference was also apparent in comparisons of participants receiving no additional RT (PET-adapted therapy) versus RT (standard therapy) (HR 1.86; 95% CI 1.07 to 3.23; $p = .03$) and in those receiving chemotherapy but no RT (PET-adapted therapy) versus standard RT (HR 3.00; 95% CI 1.75 to 5.14; $p < .0001$). Based on the data, the authors could assume that of 1000 individuals receiving PET-adapted treatment over 4 years, 222 individuals would experience disease progression or death compared with 100 of 1000 individuals receiving standard treatment.

TREATMENT OF ADVANCED-STAGE HODGKIN LYMPHOMA

The improved outlook for patients with advanced-stage HL (stages IIB–IV) over recent decades is largely attributed to the global drive to develop front-line chemotherapy regimens in which improved efficacy is coupled with reduced treatment-associated toxicity. The identification of adverse prognostic factors at diagnosis has been instrumental to this cause, in allowing more appropriate stratification of patients at baseline into groups in which therapy is risk-adapted. In addition, the use of the IPS over the years to further subdivide patients with advanced HL into more specific prognostic groups, each with significantly different FFP rates, has paved the way for a more preferable treatment approach that aims to achieve cure without exposing the individual to the unnecessary risks associated with overtreatment (see [Prognostic Factors, Risk Stratification, and Treatment Groups](#) section, earlier). In the 1960s the development of the drug combination MOPP (nitrogen mustard, vincristine [oncovin], procarbazine and prednisolone) was a pioneering step in the effective treatment of patients with advanced HL. With a complete remission (CR) rate of up to 80% and cure in more than 50% of patients, this regimen was heralded as revolutionary at the time not only within the field of lymphoma, in which patients with advanced HL had previously been considered incurable, but also for oncology as a whole; it was the first chemotherapy combination to be associated with cancer cure.⁶

Today, the most widely used regimens are ABVD (adriamycin, bleomycin, vinblastine, and dacarbazine) and BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisolone) ([Table 75.6](#)).

TABLE 75.6 Standard Chemotherapy Regimens for the Treatment of Advanced Hodgkin Lymphoma

Regimen	Drugs	Route	Schedule
ABVD	Adriamycin 25 mg/m ²	IV	Day 1 and 15
	Bleomycin 10 mg/m ²	IV	Day 1 and 15
	Vinblastine 6 mg/m ²	IV	Day 1 and 15
	Dacarbazine 375 mg/m ²	IV	Day 1 and 15 Every 28 days
BEACOPP (escalated)	Bleomycin 10 mg/m ²	IV	Day 8
	Etoposide 200 mg/m ²	IV	Day 1–3
	Adriamycin 35 mg/m ²	IV	Day 1
	Cyclophosphamide 1250 mg/m ²	IV	Day 1
	Vincristine 1.4 mg/m ²	IV	Day 8
	Procarbazine 100 mg/m ²	PO	Days 1–7
	Prednisolone 40 mg/m ²	PO	Days 1–14
	G-CSF	SC	From day 8 Every 21 days

G-CSF, Granulocyte colony-stimulating factor.

ABVD

Despite the initial success of MOPP chemotherapy, failure to achieve initial remission continued to be a problem in up to 20% of patients with advanced HL and of those patients who were successfully treated with MOPP, a third still relapsed. Furthermore, as a result of prolonged exposure to alkylating agents, significant toxicities including secondary leukemias, myelodysplasia, and sterility had emerged with this regimen.

In 1975, in an initial attempt to treat patients with relapsed HL, the ABVD drug combination was developed by Bonadonna and colleagues.^{6a} An early randomized control study directly comparing MOPP with ABVD for patients with advanced HL showed comparable CR rates between the two groups (76% versus 75%) and crossover carried out for progressive disease or for relapse after initial remission successfully demonstrated an absence of cross-resistance between the two regimens. As a result, ABVD was highlighted as an appropriate second-line option for those in whom initial MOPP therapy had failed.

In 1986, because of this success, the same group went on to investigate the potential role for ABVD in the first-line setting by comparing standard MOPP therapy with an alternating regimen of MOPP and ABVD in patients with stage IV HL who were chemotherapy-naïve. The alternating MOPP/ABVD regimen was found to be superior to MOPP alone with regards to CR rate (88.9% vs. 74.4%), FFP (64.6% vs. 35.9% at 8 years, $p < .005$), relapse-free survival (72.6% vs. 45.1%), OS (83.9% vs. 63.9%, $p < .06$), and survival of complete responders (94.8% vs. 77.1%). Furthermore, in this landmark study there was no observed increase in associated major toxicity in the MOPP/ABVD arm.

A number of randomized trials were subsequently carried out to further investigate the role of ABVD for the upfront treatment of patients with advanced HL either by itself, or in combination with MOPP. In 1992 results from a pivotal multicenter trial conducted by the Cancer and Leukemia Group (CALGB), comparing six to eight cycles of MOPP alone, six to eight cycles of ABVD alone, and 12 alternating cycles of MOPP and ABVD, showed superior complete response rates (MOPP 67%, ABVD 82%, MOPP/ABVD 83%, $p = .006$) and 5-year failure-free survival rates (MOPP 50%, ABVD 61%, MOPP/ABVD 65%, $p = .02$) in both the ABVD and ABVD/MOPP arms compared with MOPP alone. Although subsequent analysis showed no significant difference between either of the ABVD-containing regimens and MOPP with regards to OS, the ABVD-alone arm was consistently shown to be significantly less myelotoxic than either of the regimens containing MOPP.⁷

Additional studies comparing hybrid regimens of MOPP and ABVD (given concurrently) with alternating cycles of MOPP and ABVD also demonstrated equivalent survival with either approach.^{8,9}

Furthermore, in one study comparing a modified hybrid of MOPP/ABV with ABVD alone, not only were similar OS rates seen (OS ABVD 82% versus MOPP/ABV 81%), but pulmonary toxicity, hematologic toxicity, treatment-related death, and secondary malignancies were also shown to be significantly less in the ABVD-alone arm.¹⁰ The conclusion was that ABVD was not only at least as effective as the standard of care at that time, but also easier to administer and safer. These data subsequently led to the international approval of six to eight cycles of ABVD as the new standard of care for the frontline treatment of patients with newly diagnosed advanced HL (see Table 75.6).

Although one of the main attractions of ABVD is its ability to maintain excellent OS without unnecessarily exposing the patient to the toxicity associated with alkylating agents, bleomycin-induced pulmonary toxicity remains an important problem for some individuals. For this reason, alternative drug combinations utilizing agents that have previously shown promise in the setting of relapsed HL have also been developed for the frontline treatment of patients with advanced HL and of these, etoposide-based regimens have emerged as acceptable substitutes.

BEACOPP

The relationship between chemotherapy dose and tumor response is well established. In 1992 the GHSG conducted a pilot study investigating whether treatment response and outcome could be improved by dose intensification in patients with newly diagnosed advanced HL. Dose intensification was achieved by reducing the duration over which the same treatment was administered and adding etoposide. As a result, the BEACOPP regimen (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisolone) was developed with encouraging results in preliminary studies.¹¹ The subsequent randomized HD9 trial, in 2009, comparing COPP/ABVD with standard-dose BEACOPP and escalated BEACOPP in patients aged 15–65 years with stage IIB, III, and IV HL, showed significantly improved FTF and OS rates with BEACOPP compared with COPP/ABVD, with the best results observed with escalated BEACOPP (OS 91% escalated BEACOPP vs. 88% standard BEACOPP vs. 83% COPP/ABVD, $p < .002$). The rate of early progression was also significantly lower in the escalated BEACOPP arm (2% escalated BEACOPP vs. 8% standard BEACOPP vs. 10% COPP/ABVD, $p < .001$). Because of the superior outcomes observed with both BEACOPP regimens, the COPP/ABVD arm in this study was closed at interim analysis. The improved outcome seen with escalated BEACOPP in the HD9 study was substantiated by long-term follow-up analysis at 10 years.¹²

Despite the success demonstrated by escalated BEACOPP in the HD9 trial, longer-term complications including the development of myelodysplastic syndrome and secondary acute myeloid leukemia (AML) occurred more frequently when compared with standard BEACOPP and COPP/ABVD. In addition, acute hematologic toxicity, including anemia and thrombocytopenia, was also greater in the escalated BEACOPP arm, with blood product support being required more frequently. The increased toxicity observed with escalated BEACOPP provided the rationale for the GHSG to investigate the efficacy and toxicity of a time-intensified, rather than dose-intensified, variant of BEACOPP for patients with advanced HL. In their pilot study, standard dose BEACOPP (i.e., nonescalated) was administered over a reduced cycle duration of 14 days, as opposed to 21 days, along with granulocyte colony-stimulating factor (G-CSF) support. Results showed that although acute leukopenia, thrombocytopenia, and anemia were moderate with BEACOPP-14, the severity appeared to be less than that observed previously with escalated BEACOPP, while efficacy was maintained. This led to a multicenter, noninferiority randomized study (HD15 trial) in which 2182 patients with newly diagnosed advanced HL, aged between 18 and 60 years, were assigned to receive either eight cycles of escalated BEACOPP, six cycles of escalated BEACOPP, or eight cycles of BEACOPP-14, followed by PET-directed RT. The aim of the study was to establish the optimal

number of cycles required to sustain efficacy while reducing toxicity to an acceptable level. FFTF at 5 years was sequentially superior with six cycles of escalated BEACOPP (89.9%) and eight cycles of BEACOPP-14 (85.4%) when compared with eight cycles of escalated BEACOPP (84.4%), as was OS (95.3% for 6× escBEACOPP vs. 94.5% for 8× BEACOPP-14 and 91.9% for 8× escBEACOPP). Furthermore, eight cycles of escalated BEACOPP was associated with a higher mortality rate when compared with either six cycles of escalated BEACOPP or eight cycles of BEACOPP-14 (7.5% vs. 4.6% and 5.2%, respectively), as well as an increased frequency of secondary malignancies (1.8% vs. 0.7% and 1.1%, respectively). It was concluded that overall, in patients younger than 60 years, six cycles of escalated BEACOPP followed by PET-directed RT was more effective and less toxic. This regimen was subsequently adopted as standard of care for patients with newly diagnosed advanced HL in Europe.

ABVD Versus Escalated BEACOPP

ABVD and escalated BEACOPP are internationally accepted as appropriate first-line treatments for patients with newly diagnosed advanced HL, but which of these approaches is optimal remains under debate. Although ABVD is more widely used in the United States, escalated BEACOPP tends to be the more favored approach in Europe.

A number of studies have directly compared these two strategies, not only in an attempt to establish superiority of one over the other in terms of OS, but also to identify specific subgroups of patients with advanced HL who might benefit more from a more intensive, or indeed less intensive, treatment approach.

A randomized study carried out by the EORTC in 2012 investigated whether patients with high-risk advanced disease (IPS ≥ 3) were likely to achieve greater benefit with a more intensive upfront regimen comprising four cycles of escalated BEACOPP followed by four cycles of standard BEACOPP or eight cycles of ABVD. Initial results of this study showed no significant difference in event-free survival (EFS) or OS between the two treatment groups at a median follow-up of 3.9 years.¹³ Relapse rates were higher with ABVD, but the frequency of early discontinuations was greater with escalated BEACOPP. More recently, in 2014, Mounier and colleagues^{13a} published results from the LYSA H34 trial, a parallel study investigating the same two regimens but in patients with advanced HL deemed to be at lower-risk (IPS 0–2). At a median follow-up of 5.5 years, PFS was significantly better in the BEACOPP arm (93% vs. 75%, $p = .007$), but OS was comparable (99% vs. 92%, $p = .06$). Again, fewer relapses were observed with BEACOPP.

Although greater response rates and improved PFS have been well demonstrated with escalated BEACOPP across a number of studies, making it an attractive option for many, its toxicity profile is not insignificant and should be carefully considered. Whether the treatment-related risks associated with this regimen can be justified in all patients remains controversial, particularly when effective salvage strategies with stem cell transplantation exist for patients who subsequently relapse. It is this argument that has led others to favor the use of the less aggressive ABVD approach first for patients with advanced HL.

In 2011 Viviani and colleagues reported results from a trial directly comparing frontline ABVD with escalated BEACOPP in patients with unfavorable or advanced HL (stage IIB, III, or IV, or IPI score ≥ 3). Following this, patients with residual or progressive disease went on to receive high-dose chemotherapy (HDCT) and autologous stem cell transplant (ASCT). Escalated BEACOPP (eBEACOPP) was found to be superior to ABVD with respect to duration of first remission (PFS at 7 years 85% vs. 73%, respectively, $p = .004$). Interestingly however, after completion of treatment overall, it emerged that salvage HDCT was sufficient to achieve comparable 7-year EFS and OS rates between the two groups, regardless of which initial chemotherapy regimen was administered (EFS 78% eBEACOPP vs. 71% ABVD, $p = .15$; OS eBEACOPP 89% vs.

84% ABVD, $p = .39$).¹⁴ Thus, although treatment with BEACOPP resulted in better initial tumor control, the long-term outcome of the two regimens appeared to be the same, suggesting that neither was superior overall. It is important to note, however, that in this study initial ABVD was associated with significantly less treatment-related toxicity, including infertility and secondary malignancy, compared with escalated BEACOPP. Overall then, if the aim of treatment in this patient population is to achieve cure with minimal toxic risk, then a less aggressive frontline approach of ABVD seems reasonable, reserving more intense treatment with HDCT and ASCT for those with refractory or relapsed disease. For those with more adverse prognostic risk, however, more intense treatment with escalated BEACOPP may be warranted upfront. One potential strategy, which is currently being explored in clinical studies, includes reducing the total number of cycles of escalated BEACOPP and using interim-PET assessment to guide ongoing risk-adapted treatment. The overall goal is to maintain optimal disease control while limiting toxicity by restricting exposure to only those with high-risk disease in whom it may be better justified from a risk-benefit perspective. The role of interim-PET in this setting is discussed in more detail later (see [New Directions in the Treatment of Advanced HL](#)).

At present, ABVD and escalated BEACOPP are both considered acceptable strategies for the initial treatment of patients with advanced HL and are each currently recommended as standard of care.

Consolidation Approaches in Advanced Hodgkin Lymphoma

Consolidative Radiotherapy

Consolidation is frequently adopted following initial chemotherapy to augment response and to prevent progression of disease at residual sites. The role of consolidative RT for patients with advanced HL who achieve complete response or partial response (PR) following initial chemotherapy has been widely investigated in clinical trials, but a clear survival benefit has not been demonstrated. Some have pointed to small sample sizes in randomized studies as a reason for this. In an attempt to draw valid conclusions from the available data, Loeffler et al conducted a large metaanalysis of all studies comparing chemotherapy alone versus combined modality treatment ($n = 1740$). Combined modality treatment did not reduce rate of relapse in patients with stage IV disease and was, overall, associated with significantly inferior long-term survival compared with chemotherapy alone.

In 2003 an important prospective randomized study investigating the use of IFRT after chemotherapy for patients with previously untreated advanced HL was published by the EORTC. In this study of 739 patients, those achieving CR after initial treatment with MOPP-ABV ($n = 421$) were randomized to receive either IFRT to all originally involved nodal and extranodal sites or no further treatment. At a median follow-up of 79 months, IFRT was not shown to improve 5-year EFS or OS in those already achieving a CR after initial chemotherapy compared with observation alone (EFS 79% vs. 84%, respectively, $p = .35$; OS 85% vs. 91%, respectively, $p = .07$). However, benefit with consolidative IFRT was observed in those only achieving a PR after initial chemotherapy and interestingly, the overall outcome of these patients matched that of the group who achieved a CR (5-year EFS 79% and OS 87%). This observation suggests a potential role for consolidative RT in this subgroup of patients. Further evaluation is needed, however, and at present the exact subgroups of patients who are likely to consistently benefit from this modality have still not been fully established.

The use of more intensive first-line chemotherapy has led to more durable responses, and as such, the need for consolidation RT has come into question for patients with advanced HL. The increasing use of PET to assess early response and potentially direct ongoing treatment may further question its role. However, importantly, PET-directed management may also clarify those patients with localized

bulky disease who may benefit from irradiation. In the GHSG HD15 trial, following six to eight cycles of standard BEACOPP chemotherapy, patients with residual PET-positive disease received IFRT. PFS at 1 year was 96% for the PET-negative patients who did not receive IFRT and 85% for the PET-positive group who did receive IFRT ($p = .011$), suggesting a possible role for consolidative RT in this subgroup.

Before any sound conclusions can be made, however, long-term follow-up data from these prospective randomized trials are needed to better evaluate the risks and benefits of adjuvant RT after initial chemotherapy in this patient population, particularly when considering the late toxicities that are associated with its use, including secondary malignancy within the treated field and cardiovascular disease (see [Long-Term Complications of Treatment in Hodgkin Lymphoma](#) section, later).

Consolidative Autologous Transplant

The function of ASCT to enhance outcome in patients with advanced HL immediately following standard chemotherapy has been investigated in a number of clinical studies. However, no survival benefit with this approach has been demonstrated. Instead, current practice is to reserve high-dose chemotherapy and ASCT for those patients who have either progressed through, or relapsed after, first-line therapy (see [Relapsed and Refractory Hodgkin Lymphoma](#) section, later).

New Directions in the Treatment of Advanced Hodgkin Lymphoma

Interim PET

The identification of reliable and consistent risk factors is crucial for the future development of more specific, and therefore more successful, treatment approaches for patients with advanced HL, in which therapy is tailored to the needs of the individual. Interim PET analysis early on during first-line chemotherapy is being widely investigated as a potential means of enhancing this risk-directed approach by allowing initial therapy to be modified according to response.

The significance of residual FDG-avid disease during treatment for patients with advanced HL has been well described: In an early prospective study of patients with newly diagnosed advanced HL, a positive PET following two cycles of standard ABVD was associated with a 2-year PFS of 12.8% compared with 95% for those achieving a PET-negative response ($p < .0001$). Furthermore, in multivariate analyses interim PET was found to be more predictive of outcome than IPS score ($p < .0001$).¹⁵ These early observations have been reproduced in parallel studies using escalated BEACOPP.

Clinical studies have since explored the role of interim PET as a tool for directing early, response-based, treatment modifications and have attempted to investigate the effect of this on patient outcome. In a retrospective analysis by Gallamini et al in 2011,^{15a} the outcome of patients remaining PET-positive following two cycles of standard ABVD, who went on to receive treatment intensification with BEACOPP, was better than that of ABVD-treated historic controls. In a contrasting study by Avigdor et al in 2010,^{15b} patients achieving a PET-negative remission following two cycles of escalated BEACOPP underwent deescalation of treatment to ABVD and in this group, despite attenuation of treatment, the 4-year PFS was maintained at 87%, implying that in this PET-negative population similar efficacy can be achieved with a less toxic approach.

At present two large randomized control trials are underway to further determine the role of PET-directed therapy in the future management of patients with advanced HL. The RATHL trial (Response Adapted Therapy using FDG-PET Imaging in Advanced Hodgkin Lymphoma), conducted by the UK NCRI, is evaluating intensification of therapy with BEACOPP in patients who remain

TABLE 75.7

Deauville 5-Point Scale for the Interpretation of Interim and End of Treatment FDG-PET Imaging in Patients with Hodgkin Lymphoma

FDG-PET Uptake	Deauville Score
No uptake above background	1
Uptake equal to or below mediastinum	2
Uptake higher than mediastinum but equal to or lower than liver	3
Uptake moderately higher than liver	4
Uptake significantly higher than liver and/or presence of new lesions	5
New areas of uptake/New FDG-PET avid lesions	X

FDG, ¹⁸F-2-deoxyglucose; PET, positron emission tomography.

PET-positive after two cycles of initial ABVD, while the GHSG's HD18 trial is evaluating the effect of reducing therapy from eight cycles of escalated BEACOPP to four cycles of escalated BEACOPP in patients who are interim PET-negative. Results of both of these trials are eagerly awaited.

Collectively, these data have indicated that early interim PET is a powerful predictor of treatment failure for patients with advanced HL and may effectively discriminate individuals with different risk profiles and therefore different treatment needs. The recent Lugano Classification recommends PET/CT as standard practice for response assessment in all patients with FDG-avid HL both at the end of treatment and early on during treatment using the highly reproducible Deauville 5-point scale² (Table 75.7). At interim analysis, a score of 1 or 2 represents complete metabolic response, whereas a score of 4 or 5 represents partial metabolic response. A score of 3 may or may not reflect a favorable prognosis depending on the timing of assessment, clinical background, and treatment used. At the end of treatment, residual disease denoted by a score of 4 or 5 represents treatment failure.

The strategy of subsequently utilizing PET response to deescalate ongoing treatment in the best responders to avoid late toxicity, or to intensify treatment in patients with suboptimal response, holds great potential for the future management of patients with advanced HL; however, at present this approach still remains investigational. Long-term prospective data from randomized clinical trials are crucial to evaluate the impact of PET-directed alteration of therapy on OS, before it is considered standard of care for this patient population.

Novel Therapies in Advanced Hodgkin Lymphoma

Although effective, the intensification of chemotherapy based on improved risk-stratification techniques may not be appropriate for all patients with HL. The development of novel targeted therapies has recently led to important advances in cancer care by allowing the provision of effective specific biologic agents which are not associated with the same toxic complications as traditional chemotherapy. This approach may be particularly beneficial for those with less favorable performance scores in whom traditional doses of intensive chemotherapy are deemed intolerable. One approach, which is currently being evaluated to further improve outcomes in patients with advanced HL, is the incorporation of novel targeted agents into less intense frontline chemotherapy regimens.

The recent success of BV in the treatment of relapsed/refractory HL (see [Relapsed and Refractory Hodgkin Lymphoma](#) section, later) has prompted efforts to explore its role when combined with standard chemotherapy in the upfront treatment of newly diagnosed advanced HL. In a phase I safety study including patients with newly diagnosed, treatment-naïve advanced HL, escalating doses of Brentuximab Vedotin were added to either an ABVD or modified-AVD backbone (without bleomycin) for up to six cycles. The maximum tolerated dose (MTD) of brentuximab when combined with ABVD or AVD was 1.2 mg/kg. In this study CR was achieved in 95% of those

receiving brentuximab plus ABVD and 96% of those receiving brentuximab plus AVD. Although a manageable toxicity profile was observed with brentuximab and AVD, an unacceptable level of pulmonary toxicity was associated with brentuximab and ABVD, exceeding that of ABVD alone, and, as a result, this combination was contraindicated. In contrast, no toxic pulmonary effects were observed with the brentuximab and AVD regimen.¹⁶ A randomized phase III trial comparing BV and AVD with standard ABVD alone is currently ongoing (ECHELON-1). Similar studies investigating the combination of BV with BEACOPP-like regimens are also underway. Furthermore, the incorporation of other novel agents including rituximab and lenalidomide into frontline chemotherapy for patients with advanced HL is also being explored.

In summary, the current standard of care for the upfront treatment of patients with advanced HL includes initial chemotherapy, generally with ABVD or escalated BEACOPP. A clear role for consolidative RT has not been established. The future standard of care for patients with advanced HL is likely to be shaped by both PET-directed therapy, in which treatment is modified according to risk, and the incorporation of novel targeted agents into frontline chemotherapy regimens, with the overall aim of achieving cure while limiting exposure to unnecessary treatment-related toxicity. As a result, it is anticipated that the overall outcome for patients with advanced HL will continue to improve.

RELAPSED AND REFRACTORY HODGKIN LYMPHOMA

Although the vast majority of patients with newly diagnosed HL achieve a remission after first-line therapy, around 10% will have refractory disease (defined as progression or nonresponse during initial treatment or within 90 days of completing treatment). In addition, of those achieving initial cure, approximately 30% will relapse. Further remissions can be achieved for these patients with salvage therapy, for which the optimal choice depends on a combination of factors including the patient's stage of disease at relapse, their prior therapies, and their risk factor profile.

Prognostic Factors in Relapsed or Refractory Hodgkin Lymphoma

A number of risk factors for refractory disease or relapse following initial therapy have been identified for patients with HL. In two large retrospective analyses conducted by the GHSG, poor performance score at the time of progression, age greater than 50 years, and failure to achieve a temporary remission on first-line treatment were highlighted as significant predictors of adverse outcome for patients with primary refractory HL: in addition, time to first relapse, clinical stage III or IV disease at relapse, and anemia (hemoglobin <12 g/L males or <10.5 females) were considered significant predictors of adverse outcome for patients with relapsed HL.^{17,18} Of these prognostic factors, performance status at relapse, advanced stage at relapse, and time to relapse appear to be consistently associated with poor risk across studies, but prospective confirmation of these is still needed.

Treatment of Relapsed or Refractory Hodgkin Lymphoma

For a select group of patients with favorable criteria who experience localized relapse at previously nonirradiated sites, treatment with salvage RT alone may be effective. More commonly, however, the role for radiation in the management of relapsed HL is limited to the treatment of either localized residual disease following salvage chemotherapy or localized late recurrence (>12 months) as part of planned consolidation. For a subset of other patients who relapse after primary chemotherapy, salvage chemotherapy alone with various, more intensive, second-line regimens can achieve further responses, although these responses are often suboptimal and the long-term

disease-free survival in these patients is often bleak, particularly for those with unfavorable prognostic factors.

The treatment of choice for the majority of patients with relapsed HL, or with refractory disease that has not responded to initial chemotherapy, is cytoreduction with salvage chemotherapy followed by high-dose salvage chemotherapy (HDCT) and ASCT. With modern-day transplant techniques and improved peritransplant management, the rate of early transplant-related mortality with ASCT has fallen from as high as 20% previously to <5% and, as such, ASCT is considered a safer and more accessible treatment option for a wider group of patients. As described later, favorable remissions and improved outcomes have been observed with HDCT followed by ASCT, compared with conventional salvage strategies and, as a result, this approach remains the standard of care for the initial treatment of patients with relapsed or refractory HL.

Salvage Chemotherapy and HDCT Before ASCT

The goal of cytoreduction with salvage chemotherapy and preparative HDCT conditioning before ASCT is to achieve high response rates and a minimal disease state, while maintaining an acceptable toxicity profile, without compromising subsequent stem cell mobilization. A number of second-line salvage chemotherapy combinations are currently in use, but because of a lack of randomized data comparing these regimens, there is no consensus as to which is optimal. Common regimens include DHAP (dexamethasone, cisplatin, cytarabine), ICE (ifosfamide, carboplatin, etoposide), GVD (gemcitabine, vinorelbine, liposomal doxorubicin), ESHAP (etoposide, methylprednisolone, cytarabine, cisplatin), mini-BEAM (carmustine, etoposide, cytarabine, melphalan) and dexa-BEAM (dexamethasone, carmustine, etoposide, cytarabine, melphalan), with patients typically receiving two to three cycles of therapy before proceeding to ASCT. Of these regimens, the greatest experience has been reported with DHAP, mini-BEAM, and dexa-BEAM in the context of randomized control trials assessing ASCT, with similarly high response rates being observed with each combination.^{19–21} Although there is no evidence to suggest superiority of one salvage regimen over another with regards to efficacy, greater toxicity and impaired peripheral blood stem cell mobilization have been reported with melphalan-containing combinations.

HDCT and ASCT

The advantage of HDCT followed by ASCT over standard chemotherapy alone has been demonstrated in a number of studies. In 1997 Yuen and colleagues compared the outcome of patients receiving high-dose etoposide, cyclophosphamide, and total body irradiation (TBI) or carmustine followed by ASCT, with a matched conventional salvage group who received chemotherapy alone. At 4 years of follow-up a clear improvement was seen in those who underwent transplant with regards to OS, EFS, and FFP over chemotherapy alone (OS 54% vs. 47%, $p = .25$; EFS 53% vs. 27%, $p < .01$, FFP 62% vs. 32%, $p < .01$).

Two key randomized control trials (RCTs) have supported the superior role of HDCT followed by ASCT over conventional salvage therapy and have been integral to establishing this approach as the standard of care for patients with relapsed or refractory HL: In a comparison of high-dose BEAM chemotherapy plus autologous transplant versus standard-dose mini-BEAM chemotherapy alone, the British National Lymphoma Investigation (BNLI) group demonstrated significant differences in EFS and PFS in favor of BEAM followed by autologous transplant (53% vs. 10%).¹⁹ In a larger trial conducted by the GHSG/EBMT, 161 patients with relapsed or refractory HL were randomized to receive either four cycles of dexa-BEAM or two cycles of dexa-BEAM followed by two further cycles of high-dose BEAM and ASCT. In chemosensitive patients, FFTR at 3 years was significantly better for those proceeding to HDCT and ASCT (55%) compared with standard chemotherapy alone (34%,

$p = .019$), although there was no significant difference in OS between the two groups.²⁰

Intensification of HDCT

Although HDCT followed by ASCT has become standard practice for the management of patients with relapsed or refractory HL, the intensity of treatment that is required has not been fully determined. Following cytoreduction with salvage chemotherapy, high-dose chemotherapy can be intensified by delivering an additional course of treatment over a shorter period of time, before proceeding to a standard myeloablative regimen and ASCT, so-called sequential HDCT. Whether or not this approach improves outcome, particularly for those patients who achieve less than a complete response (CR) post-salvage therapy, is unclear. In a randomized control trial performed by the GHSG, EORTC, and EBMT intergroup, the impact of sequential HDCT was evaluated. Patients with relapsed HL who had responded to two cycles of DHAP were randomly assigned either standard HDCT with BEAM followed by ASCT or sequential high-dose cyclophosphamide, methotrexate, and etoposide before BEAM and ASCT. There was no significant difference between the two arms with regards to FTF or OS, but sequential HDCT was associated with greater toxicity.²¹ Sequential HDCT has therefore not replaced standard HDCT before ASCT in the treatment of patients with relapsed or refractory HL, although further work evaluating its role is ongoing.

Another intensification approach being investigated for patients with refractory HL or with unfavorable risk is tandem autologous transplantation, in which two courses of HDCT are each followed by a transplant of the patient's own peripheral blood stem cells. In the large multicenter H96 trial led by the GELA, patients were risk-stratified as follows: high-risk patients with primary refractory disease or at least two risk factors (time to relapse <12 months, stage III–IV disease at relapse or relapse in previously irradiated sites) underwent tandem ASCT whereas intermediate-risk patients with one risk factor underwent single ASCT only. Five-year OS was 85% in the intermediate-risk group and 57% in the high-risk tandem transplant group, an improvement on 30% previously reported in this poor-risk population. Randomized control trials are needed to establish the true value of tandem autologous transplant for patients with relapsed or refractory HL.

Despite the intensity of salvage chemotherapy before ASCT, up to 40% of patients will not attain a response.^{19–21} Whether subsequent ASCT is of benefit to these chemoresistant individuals remains unclear because of a lack of randomized data in the literature. Second attempts to achieve responses that are good enough to support subsequent ASCT have been made using other non-cross-resistant agents, but this appears to be effective in only a proportion of patients and the overall outcome of these individuals tends to be unfavorable compared with those who respond to salvage chemotherapy initially.

Role of PET Post-Salvage Therapy and Before ASCT

Emerging data on the role of PET imaging as a means of assessing response post-salvage chemotherapy have reinforced the importance of achieving a second complete response before transplantation and may be of particular benefit for these refractory patients in guiding more appropriate ongoing treatment.

The prognostic value of PET before HSCT and ASCT has been investigated in clinical studies. In a large prospective analysis from Memorial Sloan Kettering Cancer Center (MSKCC) identifying prognostic factors for patients with relapsed or refractory HL undergoing transplant, 153 patients with chemosensitive disease to ICE salvage therapy received HDCT and ASCT. Response was assessed by CT and functional imaging (gallium or FDG-PET) both before and after salvage therapy. Normalization of functional imaging (FI) after salvage therapy was identified as being strongly predictive of outcome: 5-year EFS was 75% in FI-negative patients versus 31% in FI-positive patients ($p < .0001$).²²

In a phase II trial from the same institution, the importance of achieving PET-negativity before ASCT was reinforced further and the potential of this to guide ongoing treatment was suggested: Patients achieving a negative PET following initial salvage therapy with ICE proceeded to ASCT, whereas those remaining PET-positive (38%) went on to receive a second course of salvage therapy with non-cross-resistant gemcitabine, vinorelbine, and liposomal doxorubicin (GVD). Those responding to GVD (26/33) then also proceeded to HDCT and ASCT. At a median follow-up of 51 months, patients with negative PET scans before ASCT (either after one or two lines of salvage therapy) had an improved EFS of >80% compared with 28.6% in those who were PET-positive ($p < .001$). Furthermore, of those patients undergoing a second salvage attempt with GVD, 52% achieved a negative PET scan and the outcome of these patients was comparable to those who were PET-negative post-initial ICE.²³

In summary, these data demonstrate the benefit of achieving PET negativity before ASCT. As such, despite still being investigational, there is mounting evidence to support a formal role for PET post-salvage chemotherapy as a predictive biomarker for directing further treatment in this relapsed/refractory population of patients: For those with a negative PET following salvage therapy, in whom a complete response is confirmed, HDCT followed by ASCT remains standard of care. However, for those with suboptimal response or evidence of disease progression by PET criteria following initial salvage therapy, it may be more appropriate to attempt further salvage approaches first, with ASCT being reserved for those in whom a successful second response is achieved. Validation of this approach, however, is required before it can be considered standard and, at present, the use of interim PET-guided treatment should be restricted to clinical trials.

Treatment Options for Patients Who Relapse Following ASCT

Although durable remissions have been reported following ASCT, approximately 40% of these individuals will experience further recurrence of their disease. Patients who experience relapse after ASCT often have a poor prognosis with mean survival estimated at just over 2 years. For these individuals, the treatment options are limited, with focus typically on achieving palliative control of disease and keeping treatment-related toxicity to a minimum, rather than on cure.

Further responses can be observed with single-agent chemotherapy including gemcitabine, vinorelbine, or bendamustine, but remissions are often not durable. IFRT may be of benefit for patients with localized relapse at previously uninvolved sites, particularly for those in whom further HDCT and ASCT is not deemed appropriate. The aim of RT in this setting is to extend disease control to delay the need for palliative chemotherapy. A more common role for RT in the peritransplant setting, however, is as adjuvant therapy, either directly before or after ASCT, to consolidate the responses achieved with HDCT and ASCT.

In a highly selected group of patients who relapse after first ASCT, a second autologous transplant may also be considered. This approach tends to be restricted to those relapsing more than 1 year after first ASCT, although data defining a clear role for second autograft are lacking. Another approach is to consider a reduced-intensity allogeneic stem cell transplant.

Allogeneic Transplant

Allogeneic stem cell transplantation (aSCT) may be offered as a means of salvage therapy for a specific group of patients with relapsed or progressive disease following ASCT. The benefits of aSCT over autologous include the advantage of using a disease-free graft and the ability to exploit a "graft versus lymphoma" effect as a direct result of acquisition of a new immune system from a healthy donor.

The challenge of aSCT is to generate sufficient immunosuppression to permit donor engraftment, while reducing treatment-related

toxicity to a minimum. Early attempts with myeloablative conditioning regimens in this patient population were associated with unacceptable rates of treatment-related mortality. As such, reduced-intensity, nonmyeloablative conditioning before aSCT, has been adopted as a more appropriate alternative.

In 2012 results of the largest prospective phase II study to date (HDR-ALLO study) were published by the EBMT and the Grupo Espanol de Linfomas/Trasplante de Medula Osea (GEL/TAMO). In this study the role of reduced-intensity aSCT was investigated in 92 patients with relapsed or refractory HL. Fourteen patients died as a result of refractory, and subsequently progressive, disease, with 78 proceeding to reduced-intensity aSCT. The PFS of these patients was 48% at 1 year and 24% at 4 years, with an OS of 71% at 1 year and 43% at 4 years. A nonrelapse mortality (NRM) rate of 8% at 100 days and 15% at 1 year was observed. Interestingly, chronic graft-versus-host disease (GVHD) was associated with lower rates of relapse and improved PFS.

For those who relapse after aSCT, donor-lymphocyte infusion (DLI) has been attempted as a salvage strategy to enhance the graft-versus-lymphoma effect with the aim of preventing relapse. In the HDR-ALLO study described earlier, DLI was administered to half of the patients who relapsed following aSCT. This was associated with an overall response rate (ORR) of 40% and a median time to progression of 7 months. Evidence for the use of DLI in this setting, however, remains limited.

These data suggest that aSCT has the potential to achieve relatively long-term remissions in selected, heavily pretreated, patients with HL who relapse following ASCT and that with a reduced-intensity approach NRM is substantially reduced. In this sense its use may be extended to greater number of patients than previously assumed. The prognosis of these individuals, however, remains extremely poor. A key concern with this approach is the relatively high risk of relapse, which continues to be the main cause of failure and represents the major on-going therapeutic hurdle.

Robust evidence to support a clear role for these potential strategies in the treatment of those with multiply relapsed HL is lacking and the absence of randomized studies has prevented a standard of care from being identified. Patients with relapsed or refractory disease following ASCT have unaddressed clinical needs and, as such, enrollment into well-designed clinical trials evaluating novel agents should be encouraged for all these individuals where possible. One such agent that has shown striking success over recent years and which, at present, remains the only drug approved by the US Food and Drug Administration (FDA) for this indication is BV.

Brentuximab Vedotin

The cell surface antigen CD30 is highly expressed on Hodgkin and Reed-Sternberg (HRS) cells. The efficacy of agents targeting CD30 has been extensively investigated for patients with relapsed and refractory HL. Brentuximab vedotin (SGN-35) is an antibody-drug conjugate (ADC) comprising an anti-CD30 monoclonal antibody conjugated to antitubulin monomethyl auristatin E (MMAE). The impressive activity demonstrated by BV in the preclinical setting has been matched by its marked efficacy in phase I and II clinical trials.

An initial phase I dose-escalation study in patients with relapsed or refractory CD30-positive hematologic cancers showed that BV is associated with a favorable safety profile and established 1.8 mg/kg every 3 weeks as the MTD. Significant efficacy was also observed in this study: tumor regression was demonstrated in 86% of patients, with a median durable response of 9.7 months.²⁴

In a pivotal phase II trial of 102 patients with CD30-positive relapsed or refractory HL who had failed ASCT the safety and efficacy of BV was evaluated further.²⁵ ORR was 75%, with 34% of patients achieving a complete response. The median duration of response was 20.5 months. Peripheral neuropathy, nausea, fatigue, neutropenia, and diarrhea were the most common treatment-related toxicities. As a result of this study, in 2011 BV was the first drug to be approved

by the US FDA for the treatment of patients with relapsed or refractory HL following ASCT.

More recently, a potential role for BV as maintenance therapy following ASCT has also been suggested: Initial data from the international randomized AETHERA trial, presented in abstract form at the 2014 American Society of Hematology (ASH) Annual Meeting, show significantly improved PFS following the administration of BV every 3 weeks for up to 12 months after ASCT versus placebo in patients with high-risk relapsed or refractory HL.

On the back of its success in the relapsed/refractory setting, BV is now being evaluated in the frontline setting in combination with standard chemotherapy and results so far are promising, particularly in the advanced disease setting¹⁶ (see [New Directions in the Treatment of Advanced Hodgkin Lymphoma: Novel Therapies](#) section, earlier).

NOVEL AGENTS

The approval of BV as standard of care for patients with relapsed HL following autologous transplantation has improved the survival in this challenging patient population. The success of BV has paved the way for the development of a number of other novel therapeutics for the treatment of relapsed or refractory HL, including immune checkpoint inhibitors, epigenetic therapeutics, and other small molecules, with promising clinical activity being demonstrated so far ([Fig. 75.6](#)).

PD-1/PDL-1 Checkpoint Inhibitors

PD-1 (programmed cell death protein 1) is a cell surface receptor that is expressed on T regulatory and activated T cells (CD4 and CD8), activated B cells and NK cells. PD-1 binds PDL-1 and PDL-2, two ligands that are expressed by antigen-presenting cells and several cancer cells, including RS cells in HL (see [Fig. 75.5](#)). The PD-1/PDL-1/2 interaction inhibits kinases that are normally involved in T-cell activation. In this way the PD-1 pathway serves as a checkpoint to restrict T-cell-mediated immune responses, enabling tumor cells to evade immune detection. Inhibitors of PD-1, which block PD-1/PDL-1/2 engagement, may enhance T-cell immunity and prevent immune evasion by tumor cells, leading to effective cancer cell death.

Remarkable single-agent activity in patients with relapsed HL has been demonstrated with nivolumab, a specific monoclonal antibody directed against PD-1. Preliminary data from an ongoing trial evaluating the safety and efficacy of this agent in heavily pretreated patients with HL were recently published. Of 23 enrolled patients, 78% had failed prior ASCT and 78% had failed prior treatment with BV. Overall response rate following nivolumab therapy was 87% (95% CI, 66–97), with 17% achieving a CR and 70% achieving a PR. PFS survival at 24 weeks was 86% (95% CI, 62–95). Drug-related adverse events were reported in 78% of patients and none of these were greater than grade 3 toxicity (22%).²⁶

PD-1 blockade with another monoclonal antibody, pembrolizumab, is also under clinical development for patients with relapsed HL after BV failure and preliminary results from a phase Ib study, which were recently presented at the 2014 ASH Annual Meeting, are encouraging.

The striking therapeutic activity and tolerability of PD-1 inhibitors suggests real potential for their inclusion in the future standard of care treatment of patients with relapsed or refractory HL, either as single-agent therapy or in combination with other agents. Long-term data, however, are awaited.

Histone Deacetylase Inhibitors

Histone deacetylase (HDAC) inhibitors are a class of agents that bring about tumor response in two distinct ways: by directly inhibiting tumor cell proliferation as a result of inducing cell cycle arrest

Fig. 75.6 RESPONSE RATES OF CURRENT NOVEL AGENTS UNDER INVESTIGATION FOR THE TREATMENT OF PATIENTS WITH RELAPSED OR REFRACTORY HODGKIN LYMPHOMA. CR, Complete response; PR, partial response.

and apoptosis via epigenetic effects on gene expression, and by interfering with T-cell chemotaxis in the tumor microenvironment and, in turn, indirectly generating a favorable antitumor immune response. As such, HDAC inhibitors have attracted much interest as potential agents for the treatment of patients with relapsed/refractory HL and, based on promising preclinical data, several, including panobinostat, mocetinostat, vorinostat, and entinostat are currently under clinical investigation.

In the largest phase II prospective international study of 129 heavily pretreated patients with HL who failed prior ASCT, the activity and safety of panobinostat (LBH 589) was explored. ORR was 27% ($n = 35$), of which 23% ($n = 30$) were partial responses and 4% ($n = 5$) were complete responses. Tumor reduction was observed in 74% of patients, and the median duration of response (DOR) was 6.9 months. Median PFS was 6.1 months, with an estimated 1-year OS of 78%. Common grade 1 and 2 toxicities included diarrhea, nausea, vomiting, and fatigue, and common grade 3 and 4 toxicities included thrombocytopenia, anemia, and neutropenia, which were all manageable.²⁷ In a similar population of 51 patients with relapsed or refractory HL, mocetinostat (MGCD0103), an oral isotype-selective HDAC inhibitor has also demonstrated single-agent activity (ORR 27%) with acceptable toxicity.²⁸

PI3K/mTOR Pathway Inhibitors

The PI3K/AKT/mTOR intracellular signaling pathway plays an integral role in cell cycle regulation of metabolism, survival, and immunity and its aberrant activation, leading to increased proliferation and reduced apoptosis, has been implicated in a number of malignancies, including HL. Components of this pathway have therefore become attractive targets for anticancer therapeutic intervention.

Idelalisib (GS-1101 or CAL1011), an oral selective PI3K- δ inhibitor, has been shown, via the inhibition of AKT phosphorylation, to attenuate pathway signaling and induce apoptosis in cellular models of relapsed HL. Furthermore, in the clinical setting, promising efficacy and manageable toxicity have been demonstrated by targeting the downstream mTOR kinase: in a phase II study everolimus, an oral mTOR inhibitor, was associated with an ORR of 42% in 57 patients with heavily pretreated HL, with a median PFS of 9 months.²⁹

More recently, the synergistic effect of combining an mTOR inhibitor with an HDAC inhibitor has been explored in the clinical

setting, following compelling preclinical data. In 2013 Oki et al^{29a} published results from a phase I study evaluating the safety and efficacy of panobinostat plus everolimus in patients with relapsed or refractory HL and non-HL. Of the 14 patients with HL the ORR was 43% with a CR of 15%; however, in this study, thrombocytopenia was highlighted as a significant dose-limiting toxicity, suggesting that although this combination is effective, future studies are needed to explore how the tolerability of this approach may be improved.

Immunomodulators

A phase II multicenter study evaluating the efficacy of lenalidomide has provided preliminary evidence supporting the activity of this known, small molecule, immunomodulatory agent in patients with relapsed and refractory HL. In this study of 36 evaluable patients with a median of four prior therapies, the ORR was 19% and treatment was well tolerated.³⁰ The combination of lenalidomide with conventional chemotherapy or with other novel agents might also be considered a viable treatment approach in the future.

In summary, drug development continues to be an attractive and exciting area of clinical research in HL and future directions are likely to focus on how best to incorporate these agents into current treatment approaches. The effect of combining already established novel agents, such as BV, with first- and second-line chemotherapy is already being evaluated and the investigation of other biologics, either as mono or dual therapy, is also expected to continue. As a result, new treatment strategies are anticipated with the overall aim being to improve the survival of patients with HL even further, in the most tolerable way possible.

SPECIAL CONSIDERATIONS

Hodgkin Lymphoma in the Elderly

The number of patients living with cancer over the age of 60 years is increasing. The outcome of elderly patients with HL may differ significantly because of the heterogeneity of this population with regards to life expectancy, premorbid performance status, and comorbidity. Establishing optimal treatment is therefore challenging, particularly because older patients do not tend to be well represented in large clinical trials caused by tight exclusion criteria that often render

them ineligible for enrollment. Data therefore are not necessarily representative of the general elderly population.

In 2005 Engert and colleagues^{30a} from the GHSG published the results of a comprehensive retrospective analysis of 4251 patients with HL showing that acute treatment-related toxicity was higher in older patients compared with those under the age of 60 years. In addition, elderly patients with HL had a worse outcome with respect to FFTF (60% vs. 80%) and OS (65% vs. 90%), which was attributed to both increased mortality during treatment as well as the fact that significantly fewer elderly patients were able to tolerate the intended full dose of therapy (75% vs. 91%).

It is recommended that elderly patients without significant comorbidity and with a good performance status should be treated according to the current standard of care for younger individuals, on a risk-adapted basis, according to stage, with curative intent. Treatment-related toxicity and mortality may, however, occur more frequently. In 2005 a prospective randomized trial (H9-elderly), again conducted by the GHSG, compared standard-dose BEACOPP with COPP-ABVD in patients with newly diagnosed advanced HL. Disease-specific FFTF at 5 years was superior with standard-dose BEACOPP (74% vs. 55%, $p = .13$), but survival was not significantly different between the two treatment groups because of a higher rate of treatment-related mortality in the more intensive BEACOPP regimen compared with COPP-ABVD (21% vs. 8%). BEACOPP is therefore not recommended for elderly patients. More recently, in 2013, the North American intergroup reported results from the E2496 randomized trial investigating the efficacy and tolerability of ABVD and another combination, Stanford V (adriamycin, vinblastine, vincristine, bleomycin, nitrogen mustard, etoposide, prednisolone), in advanced-stage HL patients aged ≥ 60 years. Toxicities were comparable between the two age groups except for bleomycin lung toxicity which occurred more frequently in the elderly population receiving ABVD. Overall treatment-related mortality was 9% among older HL patients versus 0.3% in those less than 60 years old ($p < .001$). Outcome was significantly poorer in the elderly population with respect to 5-year failure-free survival and 5-year OS (5-year FFS 48% vs. 74%, $p < .002$; OS 58% vs. 90%, $p < .0001$), although there was no significant difference in time-to-progression (TTP) (5-year TTP 68% vs. 78%).

For elderly patients with poorer performance status, either caused by frailty or the presence of significant comorbidity, standard chemotherapy is not usually considered appropriate. Alternative, reduced intensity regimens such as VEPEMB (vinblastine, cyclophosphamide, procarbazine, prednisone, etoposide, mitoxantrone, and bleomycin) and, more recently, PVAG (prednisone, vinblastine, doxorubicin, gemcitabine) may be considered, although clear recommendations have not been established because of a lack of randomized data in this patient population. For relapsed disease, oral-based palliative chemotherapy with lomustine (CCNU) has been shown to prolong disease control in some cases. The potential role of less-toxic novel targeted therapies, such as BV, is also under current evaluation for the treatment of elderly patients with HL.

Hodgkin Lymphoma During Pregnancy

Given that the early incidence peak of HL coincides with childbearing age its management during pregnancy should assume special consideration. Lymphoma is the fourth commonest malignancy presenting in pregnancy and, of these, HL occurs most frequently. The diagnosis of HL during pregnancy matches that of the background population; lymph node biopsy can be performed safely either under local or general anesthetic. Clearly, however, traditional staging methods for patients with newly diagnosed HL who are pregnant need to be adapted. To avoid the risks associated with radiation exposure to the fetus, radiologic evaluation via chest x-ray with abdominal shielding, abdominal ultrasound, or magnetic resonance imaging, is recommended rather than CT or PET. Routine blood work and bone marrow biopsy are also indicated, as per standard practice. This modified approach to staging during pregnancy is

considered sufficient to allow appropriate ongoing management decisions, at least until more comprehensive imaging can be completed following delivery.

Consensus regarding the optimal treatment for pregnant patients with HL varies. The risk of spontaneous abortion and congenital malformations secondary to cytotoxic treatments and/or RT is known to be highest in the first trimester. Although risk decreases as pregnancy continues, the exact extent of risk during this period has not been clearly established and long-term complications are unknown. This is largely caused by the lack of data that exists as a result of small patient numbers. Thus whether chemotherapy should be started or not during pregnancy requires cautious evaluation of the risks to the unborn fetus versus the risks to maternal survival as a result of postponing treatment. Low-risk, asymptomatic patients may be monitored closely, with treatment being delayed until either the end of the first trimester or until delivery if diagnosis occurs later on during the pregnancy. For patients with bulky or symptomatic disease that requires treatment, however, single agent anthracyclines or vinca-alkaloids are deemed acceptable first choices, escalating to combined chemotherapy, usually with ABVD, following delivery or during the second or third trimester if there is evidence of progressive disease. In this latter subgroup of patients, however, the option of therapeutic abortion should be discussed with the patient and family to ensure all decisions made are informed. Traditionally, RT has not been advised during pregnancy; however, advancing techniques in this area have led to reduced fetal risk and, as such, it may be considered for selected individuals.

Hodgkin Lymphoma in Patients With HIV Infection

The incidence of HL is approximately 10-fold higher among HIV-positive individuals compared with those who are HIV-negative, and HL remains the most common non-AIDS defining malignancy. The vast majority of cases are associated with concurrent EBV infection, implicating a causative role for EBV in the pathogenesis HL in HIV-positive patients.

HL occurring in HIV-infected patients typically presents with more advanced disease, often with extranodal involvement and the presence of B symptoms. In contrast to HL presenting in HIV-negative patients, the mixed cellularity histologic subtype tends to predominate in this group.

In the past, before the arrival of highly active antiretroviral therapy (HAART), the treatment of HIV-associated HL was challenging, particularly in view of the immunosuppressed state. Less intense combination chemotherapy regimens were attempted, but response was often suboptimal and overall prognosis was poor.

Since the widespread use of HAART, however, the treatment of patients with HIV-associated HL has evolved and the outcome of these patients has significantly improved. Interestingly, despite improved outcome, the incidence of HL in HIV-positive patients has increased in the post-HAART era when compared with the start of the HIV epidemic. It has been postulated that improved CD4 counts, as a direct result of antiretroviral therapy, have allowed the restoration of a more competent immune microenvironment in which newly-populating CD4⁺ T cells are able to support underlying mechanisms of tumor development. To reinforce this, a pathologic shift has also been observed following the advent of HAART therapy, with the nodular-sclerosing subtype of HL now appearing more frequently among HIV-positive patients, mirroring the histologic distribution of cHL usually seen among the HIV-negative background population.

This concept has important implications when considering effective treatment for these patients. The enhanced immune environment following HAART has allowed more intensive regimens to be tested, and to good effect. As such, the current recommendation is to treat newly diagnosed cases of HL in HIV-infected patients with curative intent, using the same treatment approaches that have been adopted as standard of care for those without HIV infection. With modern HIV management, the OS of patients with HIV-associated HL is similar to that of the background, HIV-negative, population.

LONG-TERM COMPLICATIONS OF TREATMENT IN HODGKIN LYMPHOMA

The high cure rate associated with HL translates to a significant proportion of patients who are at increased risk for a range of long-term sequelae of treatment. Data on the cumulative incidence of cause-specific mortality in HL survivors show that although the rate of lymphoma-related deaths plateaus after the first 10–15 years following therapy, the rate of death because of late complications continues to rise.

The management of late toxicities associated with chemotherapy and/or RT is often more challenging than acute, with effects in some cases being irreversible and life threatening. Long-term treatment-related complications in patients previously treated for HL include hypothyroidism, peripheral neuropathy, gonadal dysfunction, secondary malignancy, and cardiovascular disease. Of these, secondary malignancy and cardiovascular complications occur most frequently, with risk continuing even beyond 25 years from diagnosis, and represent the two most common entities determining quality of life, long-term morbidity, and mortality in this patient population.

Secondary Malignancy

It is well described that intensive RT with extended field size and certain chemotherapy agents, such as cyclophosphamide, nitrogen mustard, procarbazine, and etoposide may increase the risk of developing secondary malignancies. Solid tumors appear to account for the majority of cases of secondary malignancy, with breast cancer, lung cancer, and gastrointestinal cancer occurring most frequently. This risk has been shown to be significantly greater among patients treated for HL during childhood or during teenage years. Among the female population, secondary breast cancer predominates, with extended radiation field size and the administration of RT to those under the age of 30 years representing the two most significant risk factors. Time to development of breast cancer is usually about 10–15 years. Therefore for all female patients receiving radiation to the mediastinum or axillae, annual breast screening with mammography is recommended 8–10 years after treatment or from the age of 40 years, whichever occurs first.

The risk of secondary hematologic malignancy, including leukemia and myelodysplasia, has been particularly associated with prior exposure to alkylating chemotherapy, especially when delivered in combination with large-field RT. Although this risk has fallen with the use of more modern chemotherapy, the exact choice of regimen still appears to be significant, with the incidence of AML or myelodysplasia being significantly greater among those treated with more intensive chemotherapy, such as BEACOPP, than with ABVD.^{12,14} Time to development of treatment-related leukemia after HL is about 3–5 years, and the prognosis of these patients is poor, with an estimated OS of 7.2 months.

Cardiovascular Disease

The risk of cardiovascular disease may be three- to fivefold increased in survivors of HL compared with the general population. Cardiac complications tend to present approximately 10–15 years after exposure, although actual disease onset may in fact be well before this, given the lack of early symptoms in many cases. The association between anthracycline-based chemotherapy and cardiac toxicity is well established and is particularly relevant to the setting of HL given the chemotherapy combinations currently used in standard practice. Anthracycline-induced cardiac toxicity typically manifests as arrhythmias or congestive cardiac failure as a result of ventricular dysfunction secondary to direct myocardial damage. The severity of cardiac toxicity is directly correlated to the cumulative dose that is delivered and, as such, both individual dosage and the number of cycles are significant considerations when planning treatment. Radiation exposure has

also been implicated in the development of late cardiac diseases including coronary artery disease, valvular dysfunction, myocardial dysfunction, pericarditis, and conduction defects, and radiation-related cardiac toxicity remains a major factor compromising overall outcome in HL survivors. Optimal screening methods for cardiovascular disease are not clearly established and therefore close monitoring of these patients is warranted, including strict control of cardiac risk factors (including hypertension, diabetes, hypercholesterolemia, and smoking).

Gonadal Dysfunction

A number of agents used in the treatment of HL can result in gonadal dysfunction, which is of particular relevance given the young age of this patient population. Pelvic RT and intensive alkylating-based frontline chemotherapy regimens such as MOPP and escalated BEACOPP have been shown to induce male and female sterility whereas the risk is reduced with baseline BEACOPP and reduced further still with less aggressive combinations such as ABVD where it is usually only transient. Unsurprisingly, however, the risk rises significantly among patients with relapsed or refractory disease following high-dose salvage chemotherapy. It is therefore recommended that all patients with newly diagnosed HL, who are of reproductive age, should be offered fertility preservation before commencing therapy.

The significance of long-term sequelae following treatment for HL has become more apparent over recent years given the growing number of young survivors. However, it is important to remember that a significant proportion of the data surrounding late effects relate to patients who were treated with chemotherapy and RT approaches that no longer feature in current practice. Increased awareness of long-term complications can account for many of the important treatment modifications which have been made over the past two decades, and provides the current rationale for ongoing development with regards to novel agents as well as RT technique. Current and future follow-up approaches for these individuals requires vigilance, focusing on strategies that enable both early detection and primary prevention wherever possible for the impact of these sequelae to be reduced. Guidelines for the optimal monitoring of adult HL survivors 5 years out of treatment have been issued by the National Comprehensive Cancer Network (NCCN).

CONCLUSION

The treatment of HL over the last 50 years has been one of the great success stories in oncology. Developments in combination chemotherapy and its use in association with RT have resulted in cure rates of greater than 80%, for a disease that was once usually fatal. For some patients, however, cure is still unachievable, and for others, survival is limited by late complications of cancer therapy. At present, the key objective in the ongoing management of HL is to increase efficacy without increasing the risk of unnecessary toxicity. Future approaches to management, not only in the relapsed and refractory setting, but also at earlier stages of disease are going to involve the use of targeted therapies. The best example so far is brentuximab vedotin, the first FDA-approved drug for HL since 1977, and its success is likely to revolutionize treatment. As more specific targets emerge based on advances in molecular tumor biology, further antibody and small molecule targeting, including for example PD-1 inhibitors, are likely to be developed. In addition, PET-directed approaches and the identification of more specific predictive biomarkers should help define which patients need more, or less, intensive treatments. The future management of HL is therefore likely to shift toward an approach that is no longer according to prognostic group, but rather according to the specific needs of the individual. This marks a pivotal moment in the treatment of a disease for which the development of new drugs had, until recently, remained static for more than 30 years.

ORIGIN OF NON-HODGKIN LYMPHOMA

Matthew S. McKinney and Sandeep S. Dave

Over the past two decades, discoveries in basic immunology and the pathogenesis of malignancies have significantly advanced our understanding of the origin of lymphoid neoplasms. These diseases have been reexamined and grouped based on recurrent chromosomal rearrangements, histologic patterns, and gene expression profiles. The multiple revisions to the World Health Organization's classification schemes for lymphomas reflect this progress. As with other cancers, lymphoma development is dependent upon acquisition of mutations, DNA copy number changes, recurrent cytogenetic rearrangements, and epigenetic dysregulation of gene expression involving oncogenic and tumor suppressor pathways. Many of these derangements occur as a result of disordered genetic recombination and somatic hypermutation (SHM) events intended to support adaptive immunity. Also, analysis of molecular features of lymphomas compared with normal lymphocyte compartments provides clues to the events driving their pathogenesis.

An evolving understanding of the steps involved in lymphoid development has provided further insights into the development of this diverse group of malignancies because most non-Hodgkin lymphomas (NHLs) reflect stages of lymphoid development. The application of gene expression profiling (GEP) and massively parallel high-throughput sequencing, as well as a better appreciation of the contribution of microRNAs (miRNAs) and epigenetic alterations to lymphoma pathogenesis, have shed new light on the mechanisms underlying lymphomagenesis. Correlation of these findings with the clinical outcomes has further refined prediction of outcome, and has suggested targets for novel therapies.

This chapter reviews the most common NHL subtypes, focusing on common B cell lymphoma subtypes, with regard to classification using prevailing views regarding genetic or genomic classification of these disorders. Additionally, insights regarding pathogenesis, prognosis, and possible therapeutic targets gleaned from genomic approaches are discussed.

OVERVIEW OF B-CELL LYMPHOMAS

Greater than 85% of NHL cases have a B-cell phenotype. With rare exception, B-cell lymphomas represent immortalized, “frozen” stages of B-cell development and the underlying molecular features of B-cell tumors reflect biologic features found in analogous normal B-cell compartments. Understanding factors governing regulation of B-cell compartments that mirror B-cell NHL subtypes is thus crucial to comprehending the driving forces behind lymphoma development (Fig. 76.1).

The goal of early B-cell development is to produce mature B cells expressing surface immunoglobulin M (IgM) that can efficiently recognize cognate antigen. After this is accomplished, B cells develop along pathways involving germinal center (GC), mantle, and marginal zones in lymphoid organs where they encounter antigens in association with activated antigen-presenting cells (APCs). Differentiation of mature B cells into plasma cells after SHM is the final step in B-cell development and is critical to the development of effective humoral immunity. Antibody diversity is accomplished through the process of somatic V(D)J recombination at the pro-B cell stage via recombinase activating genes (*RAG1* and *RAG2*) followed by trafficking to GCs where they proliferate rapidly with dividing times of 6 to 8 hours. High-affinity B-cell clones produced in part via

activation-induced cytidine deaminase (AID) expression and SHM are favored because of protection from apoptosis. Through this mechanism, protective antibodies are produced at the risk of exposing antigen-stimulated B cells to genetic lesions caused by the molecular machinery utilized to create V(D)J recombination and SHM. Many NHLs exhibit translocations of driver oncogenes to highly active Ig loci, implying that recombination events intended to produce high-affinity antibodies are misdirected and instead produce immortalized B cells representing stages of B-cell development. Furthermore, mutations in oncogenes or tumor suppressors frequently occur in a pattern consistent with SHM at these loci. When considered together with the recurrent chromosomal rearrangements noted in NHL, this confirms the notion that these neoplasms stem from mature B cells that have entered (or are poised to enter) GCs.

Subsets of NHL recapitulate this pattern of normal B-cell differentiation at the histologic, molecular, and genomic levels and serve as a template for the classification of these diseases. This template can be applied to the entire spectrum of B-cell neoplasms, suggesting that NHLs form as a result of genetic alterations developed along this process. B-cell differentiation must be carefully choreographed at the molecular and genomic level because the expression of the *RAG* genes and AID cause DNA strand breaks and put the nascent lymphocyte at risk of oncogene overexpression and tumor suppressor deletion. Moreover, a coordinated regulation of gene expression is required to allow such genomic revision without triggering reflexive, protective apoptotic pathways and to allow appropriate B-cell differentiation. GC B cells highly express *BCL6*, and its functions are critically important to regulation of cell survival and differentiation. Targets of *BCL6* also include cell cycle regulators (p21, p27) and TP53, which may overall work to facilitate cell cycle progression in the face of ongoing AID-mediated DNA strand breaks. *BCL6* also represses *PRDM1/Blimp1* and serves to prevent plasmacytic differentiation. Plasma cell differentiation is mediated by upregulation of *IRF4* and nuclear factor kappa-B (NFκB), which establish characteristic regulatory programs.

Genetic lesions altering these pathways are found recurrently in NHL. *BCL6* rearrangements occur in diffuse large B-cell lymphoma (DLBCL) and other lymphomas, and constitutively active NFκB signaling is associated specifically with aggressive phenotypes of DLBCL. Translocations and/or mutations of *BCL2*, which is expressed at very low levels in GCs, occur in almost all follicular lymphomas (FLs) and illustrate the dangers of aberrant recombination events in the GCs because *BCL2* translocation appears to be a primary event in the formation of these tumors. Recent analyses of whole genome/exome/transcriptome sequencing data have confirmed the frequent presence of these genetic lesions and have illuminated other pathways driving lymphomagenesis. In GC-derived B cell lymphomas, mutations in *EZH2*, a member of the polycomb group (PcG), occur frequently. In these tumors, *EZH2* mutations result in aberrant histone methylation with resultant dysregulated control of gene expression and result in GC hyperplasia in mouse models. This process appears to enhance lymphomagenesis due to an acquired inability of GC B cells to differentiate and appropriately complete maturation and thus become transformed in a state of reflecting GC B cells (Fig. 76.2). A similar role for GC regulation has been defined for genes in the sphingosine-1-phosphate receptor2 (S1PR-2) signaling pathway. Genes encoding mediators of this pathway such as *S1PR2*, *P2RY8* and *GNAI3* are frequently mutated in GC B-derived lymphomas and

Fig. 76.1 CLASSIFICATION OF COMMON NON-HODGKIN LYMPHOMAS (NHLs) IN RELATION TO B-CELL DEVELOPMENT IN GERMINAL CENTERS (GCs). Hematopoiesis results in B cell precursors that ultimately produce immunoglobulin M (IgM) that recognize cognate antigen via activation of recombinase activating genes (*RAG1* and *RAG2*) and a GC reaction occurs. A regulatory program relying on *BCL6* regulation of cell proliferation and apoptosis occurs at this point, and rearrangements presumed to occur along this course result in post-GC lymphomas, including follicular lymphoma, Burkitt lymphoma, and diffuse large B-cell lymphoma (DLBCL). The underlying molecular biology of NHL subsets (and other lymphoid neoplasms) reflects the GC step and other stages of B-cell development. For example, gene profiling of DLBCL reveals that whereas activated B cell-like (ABC) DLBCL reflects the plasmablast stage along normal B-cell development, multiple myeloma expression profiles more consistent with differentiated plasma cell origin.

result in dissemination of GC cells within lymph nodes. Thus, derangements in several different genes can result in abnormal GC homeostasis and drive lymphoma formation; thus is a novel paradigm whereby dysregulation of B cell differentiation leads to transformation and lymphoma.

Regulation of antigen stimulation of the B-cell receptor (BCR) is also important in both B-cell maturation and the development of NHL. The BCR consists of a multimeric signaling complex, including CD79A and CD79B, which acts through the immunoreceptor tyrosine activation motif on CD79B and leads to a cascade of molecular events involving SYK and BTK signaling. The end-result of this cascade is an increase in cellular proliferation through activation of NFkB target genes and other cellular machinery. Almost all NHLs express surface Ig, suggesting that functional BCR signaling is important at some point in the process of lymphoma formation. Analysis of Ig SHM patterns in lymphoma samples further suggests that antigen-induced selective pressure is important in the pathogenesis of NHL. The antigen(s) involved in this process are unknown, and it is also unclear whether ongoing antigen stimulation is important in subsets of NHL.

Epidemiologic studies have bolstered the argument that chronic immune activation and inflammation are connected with NHL development; these data also suggest that immune surveillance also plays a role in the origin of NHL. DLBCL and Burkitt lymphoma (BL) occur more frequently in immunocompromised hosts and are often Epstein-Barr virus (EBV)-positive. HIV/AIDS is a significant risk factor for post-GC neoplasms, and this risk is attenuated with the use of highly active antiretroviral therapy. For example, the risk of central nervous system lymphomas is increased more than 1000-fold in patients with AIDS. NHL also occurs more frequently in acquired or inherited immunodeficiencies such as common variable immunodeficiency and severe combined immunodeficiency and with solid organ and hemopoietic transplantation. Other clinical situations in which chronic infection or inflammation occurs have also been linked to NHL. Gastric MALT (*Helicobacter pylori*), hepatosplenic T-cell lymphoma (associated with infliximab use), and thyroid NHL (Hashimoto thyroiditis) are specific instances in which the development of lymphoid malignancy can be traced to chronic inflammation, either of microbial or autoimmune etiology. Finally, a

critical association with EBV has been noted for posttransplant lymphoproliferative disorder, a disease that occurs in the setting of organ transplantation and immunosuppression targeting cellular immunity.

Beyond these factors, the contributions of other modifiable risk factors and heredity appear to play only a small role in NHL development. Several environmental factors (pesticides, Agent Orange, radiation exposure) have been implicated in NHL, but the associations between these agents and lymphomagenesis are difficult to prove and the effect size of these factors appears to be relatively small. Pesticide exposure does appear to have a dose-effect relationship with regard to NHL pathogenesis and has been linked to recurrent t(14;18) cytogenetic rearrangements that are noted in DLBCL and FL, but the percentage of cases linked to pesticide exposure in these entities is very low. Likewise, several genetic linkage studies have found associations between several genes and the development of various lymphoma subtypes, but the role of variations in these pathways in lymphomagenesis has not been validated. Thus, there does appear to be inherited or modifiable risk factors that likely conspire with other acquired genetic/molecular lesions in the origin of lymphoma.

And so, factors related to abnormal immune surveillance, chronic inflammation, external exposures and host factors conspire to produce genetic/molecular lesions involved in lymphoma formation and progression. The remainder of this review will focus on current knowledge of biologic features of individual NHL subtypes.

DIFFUSE LARGE B-CELL LYMPHOMA

Diffuse large B-cell lymphoma is the most common subtype of NHL (~25% of all NHL) and is responsible for more patient deaths than any other form of lymphoma. This entity often presents at an advanced stage, and around 50% of all patients fail to respond long-term to standard chemotherapy programs; the vast majority of those patients will eventually succumb to their disease. Even prior to the availability of gene expression profiling technology, it was clear clinically (based on tumor morphology, immunohistochemical staining, and patient outcomes) that DLBCL is a heterogeneous disease.

Fig. 76.2 EXPANSION OF GERMINAL CENTERS WITH EZH2 MUTATION CONFERRING INCREASE HISTONE 3 LYSINE 36 TRIMETHYLATION (H3K36ME3). *Upper* color panels depict histologic staining as indicated by row (PNA, EZH2, Ki67, B220) of murine mouse model bearing wild type versus mutant (Y641N) EZH2 with or without exposure to EZH2 inhibitor GSK503. Panels at *bottom* depict H3K36me3 levels according to EZH2 mutational status. (See Beguelin, W: EZH2 is required for germinal center formation and somatic EZH2 mutations promote lymphoid transformation. *Cancer Cell* 23: 677, 2013.)

Advances in molecular biology and genomic technologies have clarified the basis for some of this observed heterogeneity, and it has become clear that DLBCL comprises a diverse group of lymphomas that have distinct cellular origins, recurrent gene mutations, and chromosomal rearrangements that dictate their behavior. It is also clear that the stromal environment appears to play a key role in the development and progression of DLBCL, as with other cancers.

GENE EXPRESSION PROFILES DEFINE DIFFUSE LARGE B-CELL LYMPHOMA SUBTYPES

GEP has identified GC B cell-like (GCB) and activated B cell-like (ABC) DLBCL subsets that express gene signatures that mimic GCs and activated B cells (Fig. 76.3; Table 76.1). Roughly 30%

Fig. 76.3 GENES CHARACTERISTICALLY EXPRESSED BY SUBGROUPS OF DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL). Activated B-cell-like (ABC) DLBCL, germinal center B cell-like (GCB) DLBCL, and primary mediastinal B-cell lymphoma (PMBL). Each column represents gene expression data from a single DLBCL biopsy sample, and each row represents expression of a single gene. Relative gene expression is indicated according to the color scale shown. (From Alizadeh, AA: *Distinct types of diffuse large B-cell lymphoma identified by gene expression profiling*. *Nature* 403:503, 2000.)

TABLE 76.1

Frequency of Recurrent Genetic Aberrations in Diffuse Large B-Cell Lymphoma Subtypes

Genetic Feature	ABC DLBCL	GCB DLBCL	PMBL	Notes
BCL2 translocation t(14;18)	0%	40%–50%	20%	Alternatively translocated to light chain loci 5–10% of time
BCL2 amplification	34%	10%	16%	
BCL6 translocation t(3;V) (q27;V)	25%	10%	20%	Variable translocation partners (14q32, 2p11, 22q11, 4p11, 6p21, 11q23)
3q amplification	25%	0%	<5%	
9q24 amplification	5%	0%	45%	
PRDM1/PRDM1 deletion/mutation	25%	0%	Unknown	
REL amplification	0	15%	25%	
Recurrent mutation	CARD11, MYD88, CD79B	EZH2, GNA13, BCL2	PTPN1, SOCS1, STAT6	
MYC rearrangement t(8;14) (q24;q32)	5%–10% of all DLBCLs	25%–30% occur with t(14;18)(q32;q21)		

ABC, Activated B cell-like; DLBCL, diffuse large B-cell lymphoma; GCB, germinal center B cell-like; mPMBL, primary mediastinal B-cell lymphoma. Compiled from Iqbal J: Distinctive patterns of BCL6 molecular alterations and their functional consequences in different subgroups of diffuse large B-cell lymphoma. *Leukemia* 21:2332, 2007; Iqbal J, Neppalli VT, Wright G, et al: BCL2 expression is a prognostic marker for the activated B cell-like type of diffuse large B-cell lymphoma. *J Clin Oncol* 24:961, 2006; Iqbal J, Weisenburger DD, Greiner TC, et al: Molecular signatures to improve diagnosis in peripheral T-cell lymphoma and prognostication in angioimmunoblastic T-cell lymphoma. *Blood* 115:1026, 2010; Pasqualucci L: Inactivation of the PRDM1/BLIMP1 gene in diffuse large B cell lymphoma. *J Exp Med* 203:311, 2006; and Tam W: Mutational analysis of PRDM1 indicates a tumor-suppressor role in diffuse large B-cell lymphomas. *Blood* 107:4090, 2006.

of DLBCLs cannot be classified using this system and have been deemed unclassified DLBCL. There are thousands of genes that differ between these subtypes at the GEP level, which is a magnitude similar to that seen between acute myeloid and lymphoblastic leukemias that have profoundly different mechanisms of origin and natural histories.

GC B DLBCLs express a characteristic spectrum of genes and exhibit evidence of ongoing AID-mediated SHM as well as a histologic phenotype consistent with GC origin. *BCL6* and *LMO2* are both important to the transcriptional program of GCs and are commensurately overexpressed in GCB DLBCLs. Conversely, *PRDM1* is downregulated by *BCL6*, which results in decreased *PRDM1* activity in GCs, and GCB DLBCLs display a similar pattern. Histologically, GCB DLBCLs are characterized by CD10 expression and lack of IRF4 expression. Evaluation of Ig loci within GCB DLBCLs has also revealed evidence of ongoing SHM, which is further evidence that GCB DLBCLs reflect the biology of normal GC B cells and that dysregulation of pathways involved in GC formation might lead to this subset of DLBCL.

Alternatively, the ABC subtype of DLBCL expresses a post-GC phenotype but appears trapped just before differentiation into plasma cells. ABC DLBCLs are characterized by downregulation of many GC genes, including *BCL6* and *LMO2*, and by expression of genes associated with activated B cells and plasma cells. One of the hallmarks of the ABC DLBCL phenotype is upregulation of NFκB. NFκB is a transcription factor that targets a number of gene programs governing cell proliferation, immortality, and angiogenesis within NHLs. The effectors of NFκB signaling exist in inactive form in the cytosol and require signaling either through MAPK/ERK (mitogen-activated protein kinase/extracellular signal-regulated kinase) signaling (the canonical NFκB pathway) or through ligation of CD40–LTβR–BAFF-R (B-cell activating factor receptor), which results in phosphorylation of the inactive complex and translocation of either the p50–RelA or p52–Rel B complexes to the nucleus and subsequent transcription of target genes. In ABC DLBCL cell lines, a signaling complex involving CARD11, BCL10, and MALT1 (the CBM complex) constitutively activates NFκB signaling and selective knock-down of any of the components of this complex using RNAi or small molecule inhibitors is lethal to ABC cell lines. Interestingly, a few GCB cell lines also demonstrate activation of NFκB and mutations in the NFκB pathway, which might confer sensitivity to inhibition of this pathway in those tumors. The mechanisms by which DLBCLs acquire and maintain constitutive NFκB activity are still being elucidated and may provide insights into the origin and into possible treatments for this entity.

Primary mediastinal B-cell lymphoma (PMBL) represents a distinct subset of patients that have sometimes been classified as DLBCL. PMBL was originally identified based on the clinical characteristics of the disease. Patients with PMBL are generally young (third or fourth decades of life), predominantly women, and present with a large mediastinal mass; outcomes with chemoimmunotherapy for PMBL are generally superior to those with other subtypes of DLBCL. GEP studies revealed that PMBL can be clearly delineated from ABC and GCB, subtypes. Indeed, by gene expression, PMBL appears similar to Hodgkin lymphoma with many shared features in both diseases, including the expression of CD30 (Fig. 76.4). Both diseases also express genes associated with JAK (Janus-activated kinase)–STAT (signal transducer and activator of transcription) signaling as well as targets of the NFκB pathway.

Molecular Pathogenesis of Diffuse Large B-Cell Lymphoma

Investigation of the molecular landscape of DLBCL has revealed a set of recurrent cytogenetic and molecular abnormalities associated with pathogenesis. Chromosomal translocations involving *BCL6*, *BCL2*, and *MYC* (*v-myc* myelocytomatosis viral oncogene homolog) occur frequently in DLBCL, and these translocations appear to be specific to cell-of-origin phenotype. 3q27 rearrangement with Ig gene partners is

the most common rearrangement seen in DLBCL and occurs in about 30% of both the ABC and GCB subtypes. An oncogenic phenotype results from this genetic rearrangement through upregulation of the *BCL6* gene. Additional mutations in the transcriptional regulatory program of *BCL6* may also occur with alternative translocation. Notably, *BCL6* translocations appear to not be sufficient for lymphoma formation as evidenced by mice bearing t(3;14) translocations that develop NHL at a low rate. *BCL2* translocations occur in a minority of GCB DLBCLs but are not seen in the ABC phenotype; this mirrors the situation in FL, in which *BCL2* overexpression is associated with disordered GC transit. *MYC* rearrangements additionally occur in DLBCL (~10% to 15% of cases), sometimes with rearrangements of *BCL2*, *BCL6*, or both. These tumors, sometimes termed *double-hit lymphomas*, display an aggressive phenotype seemingly intermediate between BL and DLBCL.

Oncogenic mutations and areas of chromosomal amplification or deletion also appear important in the pathogenesis of DLBCL. Upregulation of c-REL occurs in about 20% of GCB tumors through amplification of the 2p locus. Amplification of *MYC* and *BCL2* may also occur through this mechanism. *TP53* mutations and SHM of other loci, including *PIM1*, *BCL6*, and *MYC*, also appear to contribute to lymphoma formation and progression. Mutations in *CARD11* causing constitutive NFκB activation have been described in a subset of both ABC and GCB DLBCLs and appear to drive oncogenesis in these tumors. Overall, the patterns of gene mutation and recurrent cytogenetic abnormalities add further complexity to the classification of DLBCLs.

The genetic mutational landscapes of genes involved in DLBCL pathogenesis have also been reported. Most recently, several groups have reported analyses of whole-genome, exome, or transcriptome data from the application of massively parallel sequencing in DLBCLs. These studies have identified hundreds of novel mutations in DLBCL and have further defined patterns of mutational overlap through studies of mutual exclusivity (Fig. 76.5). Interestingly, some of the molecular features of lymphoma subtypes such as activation of the NFκB signaling pathway identified through gene expression profiling have been shown to correlate with specific mutations in DLBCL cancer genes. Inactivating mutations of *PRDM1* and mutation in genes regulating NFκB signaling (*TNFAIP3*, *MYD88*, *CARD11*) have been noted in ABC DLBCL subtypes. *CD79B* and *BCL2* have also been found to harbor mutations in DLBCL and other NHLs. A series that performed RNA sequencing on 127 NHL samples (including 83 DLBCL tumors) found 651 coding single nucleotide variants (cSNVs), many of which were not previously documented in malignancies. Truncating deletions in tumor suppression genes (*TP53*, *TNFRSF14*, *CREBBP*) were among the most significantly mutated genes and other heavily mutated genes not previously known to be involved in DLBCL pathogenesis (including *MLL2*, *BTG1*, *EZH2* and *GNA13*). *MLL2* contained cSNVs in 26% of tumors and most often occurred as a heterozygous defect, and sometimes multiple mutations occurred in trans fashion. *MLL2* functions as a H3K4-specific methyltransferase responsible for regulation of transcription of developmental genes. Ostensibly, *MLL2* might serve to deregulate genes involved in differentiation or development and act in conjunction with other oncogenes to facilitate NHL. Other groups have confirmed mutations in *MLL2* and other genes (*CREBBP/EP300*) that coordinate chromatin acetylation, leading to the hypothesis that mutations in histone-modifying genes lead to DLBCL and other NHLs. Further work is needed to dissect the mechanism(s) by which the various molecular lesions in individual tumors cause lymphoma formation and this will perhaps also improve our understanding of normal lymphocyte biology while providing new tools for lymphoma diagnosis and treatment.

The Tumor Microenvironment and Diffuse Large B-Cell Lymphoma

The complexities of antigen presentation and recognition and regulation of B-cell proliferation that occur in GCs suggest that the

Fig. 76.4 THREE TYPES OF DIFFUSE LARGE B-CELL LYMPHOMA DELINEATED BY HISTOLOGIC PATTERNS. Germinal center B cell-like (GCB), activated B-cell-type, and primary mediastinal B-cell lymphoma (PMBCL) type. GCB, or germinal center (GC)-derived large B-cell lymphomas usually have a centroblastic morphology (A), are CD20⁺, and express the GC markers CD10 (B) and BCL6 (C). In this case, the patient's staging bone marrow (D) showed paratrabecular involvement by small cleaved cells (centrocytes), indicating that the large B-cell lymphoma likely arose from a lower grade follicular lymphoma. Activated B cell-like large B-cell lymphoma can sometime have an immunoblastic morphology (E) and can typically express MUM1 (F) and CD138 (G). These post-GC cell types of lymphomas can also have a plasmablastic morphology (H), as sometimes seen in HIV-related cases. PMBCLs are frequently composed of multilobated centroblasts (I). They are typically CD45⁺, CD20⁺, and usually CD30⁺ (J) but CD15-negative. Surface immunoglobulin may be negative on such cases. PMBL is commonly associated with fibrosis, which is present in broad bands (K) or surrounding individual cells (as in I).

microenvironment may play a role in the origin and progression of DLBCL. Tumor-infiltrating T cells have been correlated with longer survival in patients with DLBCL, and failure of immune editing is likely responsible for the increase in NHL in HIV-positive and immunosuppressed persons. Gene expression profiling has been used to define stromal elements related to DLBCL progression. In one series, hierarchical clustering was used to define three groups among DLBCL samples by GEP. Clusters identifying gene signature termed *oxidative phosphorylation*, *BCR proliferation*, and *host response* were identified; notably, the host response group exhibited gene expression profiles associated with T and natural killer cells, dendritic cells, and macrophages. This work illustrates that patterns of stromal involvement in DLBCL could play a key role in pathogenesis. In another series involving biopsy specimens from 414 patients treated with chemotherapy and immunochemotherapy, two gene signatures characterizing patterns of tumor stroma best predicted survival. Improved survival was noted with a pattern that included genes associated with the extracellular matrix and histiocytic infiltration. The converse was true for gene profiles correlating to angiogenesis because these were associated with far worse overall survival.

Although it is not known what roles distinct lymph node subsets play in the pathogenesis of lymphoma, it is clear from these studies that the tumor microenvironment plays a role in the origin of NHL.

Conclusions

Diffuse large B-cell lymphoma represents a heterogeneous group of B-cell neoplasms with a distinct underlying biology, prognosis, and response to therapy. Recent genomic approaches to studying DLBCL have identified a number of interesting potential targets for better prognostic stratification and treatment of patients afflicted with this disease. More work is needed to this end and to better understand the origin of DLBCL and the role of stromal factors in disease progression.

BURKITT LYMPHOMA

Burkitt lymphoma (BL) is a highly aggressive lymphoma entity characterized by a high mitotic rate, extranodal spread, and early death, but it is frequently curable with high-intensity multi-agent chemotherapy. It was first described more than 50 years ago as a disease in young Africans in association with EBV infection. Since then, sporadic and immunodeficiency-related forms of the disease have been described. Subsequent work has shown that translocation of the *MYC* gene on chromosome 8q24 to the Ig locus occurs in virtually all cases of BL (see Figs. 76.6 and 76.7 for an overview of BL). Given the high prevalence of *MYC* rearrangements and the high

Fig. 76.5 GENOMIC EVENTS IN DIFFUSE LARGE B CELL LYMPHOMA AND FOLLICULAR LYMPHOMA. CIRCOS plot of coding single nucleotide variant (cSNVs), copy number variation (CNV) and loss of heterozygosity (LOH) in DLBCL and FL cases plotted by gene (chromosomal) annotation. (From Morin: *Nature* 476:298, 2011.)

Fig. 76.6 BURKITT LYMPHOMA (BL). (A) A case of BL illustrated at low power showing the “starry sky” appearance. This appearance is attributable to the dense proliferating cells producing the “dark sky,” and the scattered lighter-staining tingible body macrophages (“stars”) phagocytizing dying cells. (B) Higher magnification image illustrating the syncytia of intermediate-sized cells with coarse chromatin and multiple nucleoli. Note the tingible body macrophage with abundant light cytoplasm and ingested debris (center bottom). (C) Burkitt cells as seen on a Wright-stained bone marrow aspirate in a patient with BL. Notice deep blue cytoplasm with numerous vacuoles. (D) Fluorescence in situ hybridization with probes to MYC and immunoglobulin h (IgH) illustrate the IgH–MYC fusion. (Courtesy Dr. Yanming Zhang, University of Chicago.)

cure rates observed with chemotherapy, many have studied BL as a model for other B-cell lymphomas.

BL tumors typically display the immunophenotypic characteristics of GC B cells, and genetic and genomic studies have reinforced this notion of GC origin. Additionally, in virtually all cases, rearrangements are found between the MYC locus and one of the Ig genes, most commonly with the IgH locus at 14q32.33 in more than 80% of cases. Alternative rearrangements involving MYC and the κ or λ

light chain regions are also noted in a minority of cases. Two different patterns of rearrangement and SHM have been noted among the three types of BL. In endemic BL, chromosome 14 breakpoints can be mapped to J_H regions, indicating RAG1- or RAG2-mediated rearrangement occurring at the pro-B cell stage. In contrast, sporadic and immunodeficiency-related BL often demonstrate SHM and rearrangement at chromosome 14 breakpoints related in Ig switch regions; this is consistent with GC or memory B-cell origin.

Fig. 76.7 Relative expression of genes that distinguish Burkitt lymphoma (BL) from subgroups of diffuse large B-cell lymphoma (DLBCL)—activated B cell–like (ABC) DLBCL, germinal center B (GCB) DLBCL, and primary mediastinal B-cell lymphoma (PMBL)—is categorized into gene expression signatures: *c-myc* and its target genes (A); genes that are expressed in normal germinal center (GC) B cells (B) and are expressed more highly (BL-high), less highly (BL-low), or equivalently (BL-GCB) in BL than in GCB DLBCL; major histocompatibility class I genes (C); and genes targeted by the nuclear factor kappa-B (NFκB) signaling pathway (D). GC B-cell signature genes are those that were overexpressed in normal GC B cells, compared with blood B cells. The “BL-high” genes were expressed at levels twice as high in BL as in GCB DLBCL ($p < .001$). The “BL-low” genes were expressed at levels twice as high in GCB DLBCL as in BL ($p < .001$). The expression levels of the “BL-GCB” genes did not differ significantly between the two lymphoma subtypes. (From Dave SS, Fu K, Wright GW, et al: *Lymphoma/Leukemia Molecular Profiling Project: Molecular diagnosis of Burkitt's lymphoma*. *N Engl J Med* 354:2431, 2006.)

Translocations placing MYC downstream of Ig genes result in massive gene upregulation and oncogenesis by dysregulation of multiple pathways. In normal B cells, MYC regulates B-cell proliferation and differentiation and is tightly regulated by multiple mechanisms, including posttranslational modifications and transcriptional autoregulation and by other factors, including a careful balance of interactions with regulatory proteins. Under normal circumstances, MYC also induces a number of proapoptotic cellular mechanisms, which are then perturbed when MYC is overexpressed by the robust Ig gene promoters existing in GC B cells. Constitutive induction of MYC expression in GCs via the upstream Ig gene promoter then confers a neoplastic phenotype. Highlighting the complexities of MYC in this setting, even brief reversal of MYC overexpression may induce a reversion of tumors to a benign phenotype; this implies that

c-MYC–Ig rearrangements might serve as the “switch” that drives BL formation in the context of GCs.

Recently, GEP has further examined the role of MYC in BL and revealed insights into the similarities and differences between BL and other GCB-origin NHLs. This work has further defined the differences between BL and DLBCLs carrying MYC rearrangements because these entities can be difficult to distinguish on histopathologic grounds alone. Although BL is characterized by gene expression profiles consistent with GC origin, a group of genes found in GCB DLBCL, including *LMO2*, *BCL2*, *CD80*, and *CD86*, are expressed only weakly in BL. BLs also express low amounts of NFκB and major histocompatibility class I molecules compared with DLBCL. These data also serve to allow the diagnostic distinction of BLs on molecular grounds. In two large studies, a fraction of DLBCLs were classified as BL in instances when

there was DLBCL–BL overlap, causing disagreement among pathologists. The outcome with CHOP-like chemotherapy in these instances was associated with poorer survival. Furthermore, classic MYC t(8;14) rearrangements and intermediate molecular phenotypes were also associated with worse overall survival.

The development of a molecular diagnosis for BL aids in distinguishing BL from DLBCL and further illustrates the complexity of MYC rearrangements in NHL. Lymphoma entities containing MYC rearrangement in addition to rearrangements in *BCL2* or *BCL6* (double hit lymphomas) exhibit clinical behavior distant from BL and is often associated with progressive disease, a high International Prognostic Index score, and poor response to intensive chemotherapy regimens. More work regarding this subtype of NHL is needed to understand its pathogenesis.

Aside from gene expression patterns related to GC origin, further genomic alterations may contribute to BL pathogenesis. As in DLBCL, whole genome/exome/transcriptome approaches have deepened our understanding of the importance of genetic lesions beyond MYC rearrangement in BL pathogenesis. While MYC mutation (occurring in addition to MYC rearrangement) appears to be the most frequent mutation in BL, mutations in the transcription factor *TCF3* or its negative regulator *ID3* occur in the majority of cases of BL and appear to lead to phosphoinositide-3-kinase activation and other complex transcriptional changes with BL cells. *ID3* mutations may also serve as a regulator of MYC and directly influence cell cycle progression, thus fostering BL development. *TP53* is frequently also mutated or deleted in a subset of BL tumors. High throughput genomic techniques have revealed many other novel BL cancer mutations in genes such as *SMARCA2* and *CCND3* and recurrent copy number abnormalities including gains of 1q and 18q and deletion of 19p13. Thus these studies have revealed molecular complexity beyond the dysregulation of MYC through cytogenetic rearrangement.

EBV infection is also thought to play a role in the development of BL because virtually 100% of cases of endemic BL and 30% to 50% of all other BLs are associated with EBV positivity. The exact role of EBV in BL is unclear. Endemic BL is frequently associated with endemic malaria, which further suggests a complex interaction of the host immune response with microorganisms and other factors. Other host factors or genomic changes may further contribute to the development of BL.

Further work is needed to define what other genomic changes and host–environmental interactions contribute to the pathogenesis of BL. Ongoing studies seeking to define the entire spectrum of molecular, immunologic, genomic, and epigenetic changes associated with BL pathogenesis may further elucidate this process.

FOLLICULAR LYMPHOMA

Follicular lymphoma is a low-grade B-cell neoplasm that is also characterized by recurrent chromosomal rearrangements involving the IgH locus. It is the most common indolent NHL with more

than 16,000 adults diagnosed yearly in the United States. It is characterized by significant heterogeneity with regards to histologic grade and overall survival, with more than 10% of patients surviving at least 15 years after diagnosis. A spectrum of histologic grading based on the density of centroblasts is also characteristic of this disorder, with higher FL grades resembling DLBCL. There is no clear association between grade and clinical outcome in the disease. Some patients with FL experience an aggressive clinical course and transformation to aggressive lymphomas, but others may experience disease progression only after many years with the disease. This review focuses on the classic rearrangements of *BCL2* and the additional molecular changes associated with FL development and with histologic transformation of FL to more aggressive subtypes.

BCL2 Rearrangements and Other Genomic Alterations in Follicular Lymphoma

Follicular lymphoma arises from GC B cells that have been immortalized at this stage of B-cell differentiation (see E-Slide VM03961). Cytogenetic studies performed in the early 1970s defined a recurrent translocation involving the long arms of chromosomes 14 and 18 in more than 90% of FL cases. Further investigation revealed that this places the gene encoding the important antiapoptotic gene *BCL2* downstream of the Ig heavy chain transcriptional regulators. The *BCL2* protein inhibits the release of cytochrome c from mitochondria in the process of apoptosis. In normal GCs, *BCL2* is essentially absent because selection of B-cell clones via apoptosis is an important step in the production of high-affinity Ig idiotypes. The t(14;18) (q32;q21.3) appears to be mediated by *RAG1/RAG2* in pre-GC B cells because *BCL2* is most often found juxtaposed to J chain exons. Isolated t(14;18) is not sufficient to induce FL because transgenic mice bearing this translocation develop lymphoid hyperplasia but require other genetic lesions to develop FL. Additionally, B cells with t(14;18) can be isolated from apparently normal individuals who never develop lymphoma, and in situ follicular hyperplasia with *BCL2* overexpression has been noted on examination of otherwise normal lymph nodes. This suggests that other lesions must be acquired for development of FL; a preponderance of evidence suggests this occurs in GCs. Histologically, FL is characterized by an abnormal follicular architecture containing neoplastic cells. The follicles loosely resemble GCs but usually lack an appreciable mantle zone. The follicles generally occur in close proximity to follicular T-helper cells expressing CD3, CD4, CD57, PD1, and CXCL13. FL usually exhibits a CD10+BCL6+IRF8+ GC-like phenotype in association with ongoing SHM, confirming GC or post-GC origin (Fig. 76.8). One obvious hypothesis is that *BCL2* overexpression dysregulates apoptosis such that GC transition and SHM result in further genomic and epigenomic changes that result in FL. This framework might need to be reexamined in the small proportion of FL cases that do not express *BCL2*.

Fig. 76.8 FOLLICULAR LYMPHOMA (FL). Details from a case of FL, grade 1 of 3 associated with t(14;18) (q32;q21). Malignant follicle (A) with immunohistochemical stains for the germinal center marker, BCL6 (B), and BCL2 (C). Note the overexpression of BCL2 compared with a reactive follicle (D).

Although BCL2 is thought to have a critical role in development of FL, nearly 30% of grade 3A and a majority of grade 3B FLs are t(14;18) negative. Alternative rearrangements involving the κ or λ light chains and BCL2 may occur, but many t(14;18) FLs do not express BCL2. These entities express a post-GC CD10-IRF4-phenotype with 3q27/BCL6 rearrangements and are associated with lower chemotherapy response rates as well as worse overall survival compared with t(14;18)-positive FLs. It is not clear how this subset of FL evolves from normal B cells, but this immunophenotype suggests a late- or post-GC origin. GEP and analysis of miRNA profiles of FL confirm this association. Leich et al analyzed gene expression profiles of 184 grade I-3A FLs, of which 17 were t(14;18) negative (six of these rearrangement-negative FLs still overexpressed BCL2). Analysis of this data showed enrichment of signatures associated with activated B cells, including NF κ B signaling, and those associated with cell cycle, proliferation, and the tumor microenvironment. A study involving a similar cohort showed that a pattern of 17 miRNAs was differentially expressed between translocation positive and negative phenotypes. A group of five miRNAs was found to be downregulated in the t(14;18) group, and this correlated with overexpression of genes related to proliferation, apoptosis, and differentiation. Thus evidence for a post-GCB origin of t(14;18) translocation-negative FLs exists at the gene expression level. Further work is needed to fully understand how BCL2-negative FL develops.

Similar work with BCL2-positive FL has revealed the additional steps required for FL development after t(14;18). Conventional cytogenetic studies in FL reveal recurrent duplications of 1p36 and 6q and gains of chromosomes 2, 8, 17, 21, and X. Additionally, SHM appears to affect glycosylation status of surface Ig, implicating BCR signaling in FL pathogenesis. As in DLBCL, FL is characterized by frequent mutations in genes involved in epigenetic regulation of gene expression including ARID1A, MLL3, CREBBP as well as other genes involved in cellular proliferation and avoidance of apoptosis such as TP53, MCL1 and TNFRSF14.

Further genomic changes and host factors have also been delineated for DLBCL arising from FL. Histologic transformation is associated with further mutations or deletions in TP53 and p16 and appears to occur by distinct mechanisms involving either clonal

evolution or transformation of a putative progenitor FL stem cell. Acquired rearrangement of the MYC oncogene can also occur and has been associated with an aggressive plasmablastic phenotype. Stromal factors with FL tumors also likely play a key role in FL propagation and have been studied as having prognostic consequence in FL as well.

Tumor Microenvironment and Survival in Follicular Lymphoma

Just as the lymphoid microenvironment is integral to the formation and function of GCs and immune factors predict survival in DLBCL, FL development appears to depend on stromal factors and the host immune response. In the largest study examining this relationship Dave et al performed gene expression analysis using whole-genome microarrays on 191 FL specimens with the goal of determining genomic predictors of survival. Genes identified were stratified into two groups based on correlation of expression with patient outcome (gene sets associated with good prognosis or poor prognosis). Hierarchical clustering then identified five survival gene sets within each of these groups; analysis revealed that a combination of two gene sets (immune response-1 and immune response-2) formed the best model for prediction of survival. Interestingly, immune response-1 consists of genes (*CD7*, *CD8B1*, *ITK*, *LEF1*, *STAT4*) associated with specific T-cell populations and macrophages. Conversely, immune response-2 consisted of genes found in dendritic cells and macrophages and was devoid of genes expressed by T-cell subsets (Fig. 76.9). Comparison with T-cell genes suggested a complex relationship with immune response-1 rather than a simple preponderance of T cells in the tumor biopsy.

Several hypotheses can be generated regarding the implication of these findings in FL biology. Given the relationship of genes involved in the immune response to survival, a direct impact of T-cell effector subsets in FL tumors could be one conclusion. Conversely, poor-risk tumors may be those that have become independent of FL follicles and therefore are more aggressive; this may be reflected in the variability of the immune response gene signatures seen across FLs. The

Fig. 76.9 SURVIVAL IN FOLLICULAR LYMPHOMA (FL) CAN BE PREDICTED USING FEATURES OF THE TUMOR MICROENVIRONMENT. (A) Two sets of coordinately expressed genes, termed the *immune response-1* and *immune response-2* signatures, are associated with survival in FL. The expression pattern of each gene in these two signatures is shown for FL biopsy samples. Expression of the immune response-1 signature is associated with favorable survival after diagnosis, and expression of the immune response-2 signature is associated with adverse survival. These signatures are combined into a multivariate model of survival that generates a survival predictor score for each patient. Patients are ranked according to this survival predictor and divided into four equal quartiles as shown. (B) Kaplan-Meier plot of overall survival of patients in the four quartiles of the survival predictor. (A, see Dave SS, Wright G, Tan B, et al: Prediction of survival in follicular lymphoma based on molecular features of tumor-infiltrating immune cells. N Engl J Med 351:2159, 2004.)

Fig. 76.10 MANTLE CELL LYMPHOMA (MCL). (A) A case of MCL presenting as lymphomatoid polypoid. (B) The lymphoma cells are small to intermediate in size and have irregular nuclear contours and condensed nuclear chromatin. The cells were CD19⁺, monoclonal B cells with λ light chain restriction, coexpression of CD5, FMC-7, and lack of CD23. C, The cells showed cyclin D1 expression by immunohistochemical staining. The t(11;14)(q13;q32) was detected by conventional cytogenetic analysis. (D) In comparison, the blastoid variant of MCL has larger cells with a high mitotic rate and fine chromatin. (E) These cases frequently overexpress p53 and are associated with a complex karyotype, including t(11;14).

impact of immune factors has been seen in other studies as well because survival may depend on FoxP3⁺ regulatory T-cell subsets, infiltration of macrophages, and the peripheral total monocyte count. Further work is needed to more clearly identify how the FL micro-environment impacts FL development and progression and to clarify whether manipulation of the immune compartment may be used therapeutically.

MANTLE CELL LYMPHOMA

Mantle cell lymphoma (MCL) is characterized by the chromosomal translocation t(11;14)q13;q32, which places cyclin D1 under the transcriptional control of the IgH promoter. MCL is predominantly a disease of elderly men and is characterized by a rather short median survival of 5 to 7 years. Histologic evaluation divides MCL into classic and blastoid variants, with the blastoid subtype having worse survival. Subgroups can also be defined on the basis of somatic mutations in the IgH loci because Ig-mutated tumors tend to have a more indolent disease as is the case with chronic lymphocytic leukemia (CLL), another CD5⁺ neoplasm. This suggests two disparate origins for MCL with one subtype arising from pre-GC B lymphocytes and another stemming from cells that have encountered antigens and consequently have undergone SHM. Genomic approaches have also identified molecular profiles delineating MCL from histologically similar neoplasms and identified factors associated with survival. Notably, a minority of patients with MCL are cyclin D1-negative, and GEP has been useful in identifying this entity; further work in this area has identified numerous genomic lesions and molecular pathways involved in MCL. Herein the pathogenesis of MCL is reviewed focusing on the genomic and molecular basis of this disease.

Cyclin D1 and Mantle Cell Lymphoma

The genetic hallmark of MCL, the t(11;14) (q13; q32) translocation, juxtaposes the *CCND1* gene to the IgH locus, leading to overexpression of the cell cycle regulator cyclin D1. The three D-type cyclins (D1, D2, and D3) play an important role in cellular proliferation by propelling cells from G₁ to S phase of the cell cycle. Each forms heterodimers with the cyclin-dependent kinases CDK4 and CDK6, thus forming active kinase complexes. These complexes inactivate retinoblastoma protein (Rb) and bind to p27kip1, which functions

to facilitate cell entry into the S phase of the cell cycle and consequent proliferation.

Cyclin D1 is not expressed in normal lymphocytes, and t(11;14) thus represents a pathogenic event in the origin of MCL. The gene encoding cyclin D1 (*CCND1*) consists of five exons that are alternatively spliced into two isoforms, cyclin D1a and D1b. Cyclin D1b does not appear to play a role in MCL. The proliferative capacity of MCL tumors appears closely tied to the degree of cyclin D1a overexpression. MCLs carry mutations in the 3' untranslated region of *CCND1* that serve to stabilize cyclinD1a transcripts by removing miRNA (miR15/16) binding sites and deleting mRNA destabilizing elements. These sequences usually result in cyclin D1a being an unstable entity, with a half-life of less than 1 hour, but in MCL these deletions or mutations result in cyclin D1a accumulation and increased cellular proliferation. Additional mutations in the translated regions of cyclinD1 result in protein stabilization through the blockade of GSK3 β -mediated nuclear export of cyclin D1.

A minority of patients with MCL are cyclin D1-negative and are alternatively characterized by overexpression of cyclin D2 or D3 and cyclin D2. These derangements serve to deregulate the G₁-S transition in a manner similar to t(11;14) and highlight the theme that MCL is a disease created by cyclin complex-mediated cell cycle progression aided by upregulation of several molecular pathways associated with cellular proliferation and genomic instability.

Secondary Genomic Alterations in Mantle Cell Lymphoma

Beyond t(11;14), MCL is characterized by extensive genomic instability relative to other NHLs, and a variety of genetic lesions appears to drive proliferation of these tumors. Recurrent chromosomal losses, gains, and amplifications are seen in MCL, and many of these affect a large proportion of cases. Secondary genetic instability may occur as a result of aberrant DNA replication in the setting of deregulated S phase transition mediated by cyclinD1-CD4-complexes. Acquired lesions in genes mediating cellular response to DNA damage and microtubule dynamics may contribute to the accumulation of these alterations as well.

Many (30%–50%) of MCL cases are characterized by mutations or deletions in the DNA damage response pathway mediated by ATM and TP53 or modifiers of this pathway such as MDM2 and p14/ARF. *ATM* is often mutated with loss of the other chromosomal allele. TP53 may also be downregulated in these tumors via similar

mechanisms, and overexpression of TP53-negative regulators MDM2 and MDM4 also occurs via copy number amplification (examples of MCL histology with cyclin D1 and p53 staining are shown in Fig. 76.10). These overall serve to deregulate important cellular machinery involved in DNA damage repair, apoptosis, and cell cycle arrest, leading to increased cell cycle progression and proliferation in MCL. Further deletions at 9p21 occur frequently in MCL and serve to enhance cell cycle progression and block apoptosis. The 9p21 locus encodes p16(INK4a) and p14(ARF), which function as tumor suppressors. p16(INK4a) inhibits CDK 4/6 complex binding to cyclin D1, which results in decreased cell cycle progression. Deletion of p16(INK4a) in the setting of t(11;14) enhances proliferation in MCL and has been associated with worse overall survival. The function of p14(ARF) in MCL pathogenesis is less clear, but p14(ARF) blocks MDM2-mediated TP53 ubiquitination; p14(ARF) has other effects on cellular proliferation that usually work in a homeostatic pattern. Interestingly, cyclin D1 levels and INK4a/ARF deletions both correlate to a MCL proliferation signature created using GEP. Using a similar strategy, cyclin D1 expression levels and the presence of INK4a/ARF deletion have been used to create a predictor of overall survival using a cohort of patients with MCL. Survival among groups stratified by this approach varies widely (from 6–7 years to <10 months), which confirms the importance of involvement of genes involved with the cell cycle and proliferation in MCL. This parallels the experience noted with histologic markers of tumor proliferation because Ki-67 (a marker of actively dividing cells) and the presence of blastoid features have previously been shown to correlate with worse outcomes.

When considered together, the recurrent deletions and mutations noted in MCL illustrate the importance of unchecked cell cycle progression in this disorder. DNA instability is another hallmark of MCL that appears to result from the blockade of cell cycle checkpoints in the setting of ongoing DNA damage. These factors are intertwined in a complicated fashion in MCL and further work to upregulate several diverse molecular pathways involved in cellular proliferation and survival.

Molecular Pathways and Profiles in Mantle Cell Lymphoma

A variety of molecular pathways have recently been described as being active in MCL. These include signaling pathways facilitating cellular proliferation, avoidance of apoptosis, evasion of immune editing, and cellular microenvironment interactions. As in other NHLs, GEP has been used to define a molecular diagnosis of MCL and identify genes and molecular pathways involved in its pathogenesis.

Genomic approaches identify a subset of MCL that is cyclin D1-negative and has features similar to other CD5+ B-cell neoplasms such as CLL. Although such cases are indistinguishable by histologic analysis, GEP demonstrates that these tumors express gene signatures that are otherwise nearly identical to cyclin D1+ MCL but lack the classic t(11;14) rearrangement. Overexpression of other D cyclins (cyclin D2 or D3) via rearrangement, amplification, or other mechanisms is found in many of these cases; this is consistent with the underlying theme that MCL is a disease of disordered cell cycle progression. Using a similar approach, *SOX11* has been identified as a sensitive and specific marker of MCL regardless of cyclin D1 expression status. *SOX11* encodes an HMG-box transcription factor that regulates embryogenesis and is important in neural development. Because greater than 90% of MCL specimens overexpress *SOX11* and this finding is rare in histologically similar NHLs, *SOX11* is a potentially useful marker for improving the diagnosis of MCL. *SOX11* has also been incorporated into prognostic models of MCL using histologic, clinical, and GEP data. Reports regarding the clinical significance of *SOX11* have been conflicting. Thus further work is needed to understand the molecular mechanisms underlying *SOX11* expression in MCL and the implications in this disease.

Mantle cell lymphoma has also been characterized by expression of several molecular pathways that enhance cellular proliferation and

metabolism and are tightly intertwined with abnormalities in cell cycle regulation (Fig. 76.11). *Wnt 3* is a consistently overexpressed gene in MCL, and abnormal Wnt signaling may be one way that MCLs bypass negative feedback loops controlling differentiation. Proliferation in MCLs may also depend on Wnt-B-catenin signaling, but the impact of this pathway on patient survival or as a therapeutic target in MCL is unknown. Similar to ABC DLBCLs, the NFκB pathway is also active in MCL, and crosstalk between proliferation signaling between this pathway PI3K/AKT/mTOR and cell cycle signaling also appears to be important. Importantly, phosphatase and tensin homologue (PTEN), a molecule that has important roles in providing negative feedback to the mTOR pathway is also commonly deleted or acquires loss of function mutations in MCL. Taken together, these facts reinforce that abnormalities in several diverse signaling pathways are required beyond t(11;14) for MCL to form. Further work is needed to define how to use these findings to build better prognostic models in this disease, and studies investigating the therapeutic utility of targeting these pathways are beginning.

OTHER NON-HODGKIN LYMPHOMAS

Gene expression profiling and high-throughput sequencing have been applied to other lymphomas in manners similar to the subtypes already described. Important discoveries regarding other NHLs such as marginal zone lymphomas, lymphoplasmacytic lymphoma, and peripheral T-cell lymphomas (PTCLs) have refined our understanding of how these diseases develop. Recurrent mutations in genes and involvement of molecular pathways governing control of apoptosis, cellular proliferation, and metabolism are recurrent themes in these NHL subtypes as well as those described earlier. In addition to being found in DLBCLs, *MYD88* L265P mutations have been reported in virtually all cases of lymphoplasmacytic lymphoma (Waldenström macroglobulinemia) and may serve (along with *CXCR4* mutations) as a marker to differentiate this disease from other indolent lymphomas. *NOTCH2* mutations have been noted in a subset of marginal zone lymphomas and have been found in DLBCLs and other NHLs. Gene clusters have also been developed for T-cell lymphomas and identify PTCL subtypes such as angioimmunoblastic T-cell lymphoma (AITL) and hepatosplenic T cell lymphoma as distinct molecular entities as compared with other PTCLs; this work also has shown upregulation of genes involved in NFκB signaling in AITL. A subset of PTCL is characterized by t(2;5) (p23;q35), which joins the anaplastic lymphoma kinase-1 gene (*ALK*) next to *NPM-1* at 5q35. This creates an aberrant tyrosine kinase that appears to have a number of downstream transforming effects. ALK positivity is generally associated with response to cytotoxic chemotherapy in PTCL; however, better molecular predictors of response are needed. Whereas NFκB gene signature expression also correlates to improved survival in PTCL, tumors that exhibit increased markers of proliferation are associated with poor outcomes, as in other NHLs. High throughput genomic sequencing approaches have also revealed distinct patterns of somatic tumor mutations in PTCL subsets compared with B cell lymphomas. A recurrent mutation in *RHOA* (*RHOA* G17V), a small GTPase involved in regulation of actin polymerization and stress fiber formation occurs in both PTCL subtypes and AITL and appears to correlate with gene signatures of NFκB and MAP kinase activation, although the exact oncogenic role of *RHOA* in these tumors is unknown. Additionally, activating mutations in mediators of T cell receptor (TCR) signaling including *FYN* kinase have been reported and point toward an oncogenic role for constitutively active TCR signaling in these lymphomas. Further studies are needed to define the roles of these mutations in T cell lymphogenesis.

FUTURE DIRECTIONS

Non-Hodgkin lymphoma represents a complex group of related neoplasms that have quite disparate molecular characteristics. Given

Fig. 76.11 HIERARCHICAL CLUSTERING OF EXPRESSION MEASUREMENTS FROM 42 MANTLE CELL LYMPHOMA (MCL) SIGNATURE GENES THAT ARE MORE HIGHLY EXPRESSED IN MCL SAMPLES COMPARED WITH SMALL LYMPHOCYTIC LYMPHOMA (SLL), ACTIVATED B CELL-LIKE (ABC) DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL), AND GERMINAL CENTER B (GCB) DLBCL SAMPLES. Each column represents a single lymphoma specimen, and each row represents expression of a single gene. Red squares indicate increased expression, and green squares indicate decreased expression relative to the median expression level according to the color scale shown. the lack of modifiable risk factors and varied prognosis with standard treatment (chemoimmunotherapy), a better understanding of the processes driving NHL is needed. Advances in technology have recently allowed whole-genomic surveys to identify the role of altered genetics, transcription, and epigenetic regulation as contributors to the observed lymphoma phenotypes. This work will serve as the starting point for the unraveling of new diagnostic and prognostic markers, as well as therapeutic targets in a group of diseases in which such options are urgently needed.

CHRONIC LYMPHOCYTIC LEUKEMIA

Farrukh T. Awan and John C. Byrd

Over the past several decades, major advances have been realized in terms of improved understanding of the pathophysiology and therapeutic options for chronic lymphocytic leukemia (CLL). The plethora of information about CLL has increased dramatically and made management of what was a relatively straightforward disease quite complex but more rewarding. The authors herein provide a reference source focused on critical issues in routine clinical management of CLL.

EPIDEMIOLOGY

CLL is one of the most common types of leukemia in the Western Hemisphere. Surveillance, Epidemiology, and End Results (program and database) (SEER) estimates for 2015 indicate that approximately 14,620 patients (9940 men and 4678 women) were diagnosed in the United States and that 4650 patients died from CLL. The median age at diagnosis for CLL was 71 years from 2008–2012, according to the SEER database. The incidence of CLL increases proportionately by decade, as shown in Fig. 77.1. This figure illustrates that CLL is a very uncommon diagnosis before 45 years of age and infrequent (30% of total patients diagnosed) in patients before 65 years of age. The age-adjusted incidence rate was 4.5 per 100,000 men and women per year; 0.6% of men and women born from 2010–2012 are expected to be diagnosed with CLL during their lifetime. The estimated survival after diagnosis at 5 years is 81.7%, which explains the estimated prevalence of 126,299 patients currently living with CLL in the United States. Similar to other types of leukemia, the risk of dying from disease-specific causes increases proportionately with increasing age. Another analysis of the SEER database comparing outcome of elderly patients with CLL with age- and sex-matched healthy control participants demonstrated that CLL has the greatest impact on survival in the most elderly group of patients. However, even for patients diagnosed with CLL before the age of 50 years, Montserrat and colleagues demonstrated that the median expected life span is only 12.3 years compared with 31.2 years in age-matched control participants. Thus, CLL is a significant health problem affecting all ages of patients with this disease.

CLL is more common in men than women. Women diagnosed with CLL have 5- and 10-year overall survival (OS) rates that exceed those of men. CLL is most common in whites and decreases in frequency in a descending order among Blacks, Hispanics, American Indians and Native Alaskans, and Asians and Pacific Islanders, respectively. While adverse outcome based upon race has been reported, this has not been uniformly confirmed in other studies. The rarity of CLL among Asians and Pacific Islanders persists even in immigrants from these areas who have migrated to the Western Hemisphere. This implicates a possible genetic predisposition to the development of CLL. The relationship of environmental factors such as exposure to benzene and other chemicals to the development of CLL is not clearly defined. However, CLL is recognized as a service-connected illness among Vietnam War veterans who were exposed to Agent Orange. Occupational or environmental exposure to radiation does not appear to predispose patients to a higher risk of developing CLL. For example, although the frequency of acute myeloid leukemia (AML), chronic myeloid leukemia (CML), and acute lymphoblastic leukemia (ALL) were increased among survivors of the atomic bomb at Hiroshima, an increase in CLL was not appreciated. The recently

reported large International Lymphoma Epidemiology Consortium non-Hodgkin lymphoma Subtypes Project (InterLymph Study), identified multiple factors that were associated with the presence of CLL; including 1) family history of a first degree relative with hematologic malignancy including lymphomas, leukemias, and myeloma; 2) a history of working or living on a farm; 3) hairdressers, and 4) a history of hepatitis C infection. Protective factors included a history of allergies, blood transfusions, sun exposure, and smoking.

FAMILIAL CHRONIC LYMPHOCYTIC LEUKEMIA

Up to 10% of CLL patients have a first- or second-degree relative with CLL, making CLL one of the most common types of malignancy with familial predisposition. Newer studies identifying an even higher frequency of monoclonal B-cell lymphocytosis (MBL) in these families provides further evidence of inheritance in a subset of patients. Unlike other types of familial cancer, it is very uncommon for CLL patients to have large pedigrees with many affected distant relatives throughout an extensive family tree. Rather, the more common finding is for most patients to have one or two first- or second-degree relatives with this diagnosis. Large case-control studies concluded that the risk ratio (RR) for first-degree relatives of CLL probands to also have CLL was higher than that for most other cancers. Although the average RR for all cancers in a U.S. study was approximately 2.1, CLL showed an RR of 5.0, the fourth highest of all cancers. Relatives of patients with CLL also appear to have a higher frequency of other lymphoproliferative disorders and autoimmune diseases. Unlike a variety of other cancers that have known predisposing genes, identification of divergent genes in CLL has been generally unsuccessful. Multiple association studies have identified numerous putative genes, polymorphisms and genetic factors including death-associated protein kinase (DAPK) and LEU7 (CD57), IRF4, BAK, CD38, CD5, TNF- α and others, but weak evidence for linkage and conclusive studies demonstrating a strong mechanistic contribution to pathogenesis are lacking. The role of anticipation in identifying other family members has been reported by several groups; patients with such a family history are generally diagnosed a median of 10 years earlier than other patients. However, other clinical features of CLL at diagnosis do not appear to be different. Thus, patients with familial CLL do not appear to be genetically or clinically different from individuals with sporadic CLL.

PATHOBIOLOGY

The complexity of the biology of CLL has become increasingly apparent, as insight into these processes has expanded. Despite these advances, many questions remain unsolved, including (1) the cell of origin from which CLL is derived, (2) the existence of a CLL stem cell as occurs in other leukemias, (3) the biologic etiology of the divergent natural histories of immunoglobulin heavy chain variable regions (IGHV)-mutated versus unmutated CLL, and (4) the existence and identification of infectious or other naturally occurring antigens that may drive the appearance of B-cell clone. Nonetheless, significant advances in our understanding of the roles of cytogenetics, immunology, and other relevant biologic markers in predicting the natural history, disease progression and response to therapy in CLL

Fig. 77.1 GRAPH SHOWING THAT CHRONIC LYMPHOCYTIC LEUKEMIA IS A VERY UNCOMMON DIAGNOSIS BEFORE AGE 45 YEARS AND INFREQUENT (<30% OF TOTAL PATIENTS DIAGNOSED) BEFORE AGE 65 YEARS.

make an understanding of the basic biology of CLL increasingly relevant and important to clinicians caring for CLL patients.

For many years, CLL was believed to represent a single disease that had a varied natural history. Basic research focused on understanding (1) the normal cell of origin from which CLL is derived; (2) the function of the B-cell receptor (BCR) in CLL; (3) the maturational point in B-cell development at which CLL occurs; (4) the relevance and contribution of a self- or acquired-antigen to driving the disease; and (5) the role of the microenvironment in disease development and progression. All of these observations are important scientific areas of active, ongoing study, and readers are referred to several recent definitive reviews for further information on the basic biology of CLL. The biology and genetics covered within this chapter focus predominantly on areas relevant to clinicians who care for patients with CLL.

B-CELL RECEPTOR PATHWAY AND ITS ROLE IN PATHOGENESIS

Modulation of the BCR plays an integral part in the development and maturation of B cells. Its constitutive activation through antigen dependent or independent signaling provides an important survival signal for the propagation of CLL B cells. Signal transduction occurs through a variety of kinases including LYN, PI3K, SYK and Bruton tyrosine kinase (BTK) with resultant phosphorylation of phospholipase C (PLC)- γ 2 and induction of downstream second messengers that further modulate cell survival regulators. These kinases can now be effectively pharmacologically targeted, which results in abrogation of the survival signal leading to B-cell apoptosis. Combinations of these inhibitors with existing and novel therapeutic agents have the potential to change the natural history of the disease.

X-linked agammaglobulinemia is a disease characterized by a severe immunodeficient state that results from deficient BTK. Characterization of this defect and its resultant impact on causing severe impairments in B-cell development and humoral immunity has been critical to our understanding of CLL disease biology. Activating mutations of BTK have not been identified in CLL or other cancers but CLL B cells tend to have higher levels of BTK that can be induced through the BCR signaling pathway. Ibrutinib is the first in class BTK inhibitor that efficiently targets BTK and results in significant abrogation of downstream survival signaling transduced through this pathway and results in the inhibition of cell survival and proliferation. Similarly, both SYK and PI3K can be induced by activation of BCR pathway. The PI3-kinase isoform delta

inhibitor idelalisib and syk inhibitors have been shown to antagonize these survival signals and result in clinically meaningful disease responses.

IGHV Mutational Status

Two seminal manuscripts in 1999 demonstrated that the IGHV gene had undergone somatic mutation, indicating that the patient's CLL arose after this point in B-cell maturation, in 60% of CLL patients at diagnosis. Detailed epigenetic studies examining the methylation changes occurring in normal B cells during development have subsequently suggested that immunoglobulin mutational analysis may indicate simply where in normal B-cell development transformation occurred. In an attempt to identify surrogate genes associated with IGHV-unmutated disease, ZAP-70 overexpression was identified. The majority of IGHV-unmutated CLL cells have ZAP-70 expression and demonstrate evidence of syk activation and other essential BCR downstream activation signals after ligation of surface immunoglobulin M (sIgM) that is related to overexpression of this protein. In contrast, virtually all IGHV-mutated patients lack significant ZAP-70 expression and do not signal after ligation by sIgM, but can often weakly signal through other alternative BCRs. Thus, although gene expression profiling demonstrates all CLL cells to be most closely related to memory B cells, IGHV-unmutated and IGHV-mutated CLL cells differ significantly with respect to their ability to transduce intracellular signals after sIgM ligation. A common repertoire of mutational changes among CLL patients has also been documented that differs significantly from that found in the normal adult B-cell repertoire. These studies have prompted the hypothesis that CLL may represent an antigen-driven disease. Targeting BCR signaling based on this has already resulted in the development of several therapeutic agents directed against signaling pathways downstream of the BCR.

Defective Apoptosis

Since its initial description and early characterization, CLL has been considered a disease of slow accumulation of tumor cells caused by disrupted or defective apoptosis. Multiple studies have demonstrated that CLL cells overexpress several antiapoptotic proteins, including BCL2, MCL1, Bak, and X-linked inactivator of apoptosis protein, and have diminished expression of compensatory proapoptotic proteins such as Bax. Overexpression of BCL2 and MCL1 and an increase of the ratio of these proteins to Bax have correlated not only with disrupted apoptosis but also shortened OS and poor response to therapy. Studies have demonstrated that CLL cells are characterized by constitutive activation of several antiapoptotic transcription factors, including nuclear factor kappa-B (NF κ B), nuclear factor of activated T cells, and signal transducer and activator of transcription 3. Each of these transcription factors can influence one or more of the antiapoptotic proteins that promote survival in vivo. The source of activation of these different transcription factors is not completely defined but may be partly attributable to autocrine and paracrine networks involving B-cell activation factor (BAFF), a proliferation inducing ligand vascular endothelial growth factor, interleukin-4 (IL-4), and CD40. CLL cells are also maintained through contact with stromal cells (bone marrow [BM] and dendritic) and similar nurse cells through a complex interface of adhesion molecules and stromal survival factors such as stromal cell-derived factor. The importance of the in vivo environment to CLL survival is supported by the increase in apoptosis when CLL cells are cultured in vitro.

Genetic Abnormalities

Detailed study of the genetics of CLL has been hindered by the inability to effectively induce proliferation of tumor cells for standard

TABLE 77.1**Summary of Important Prognostic Markers and Their Role in Disease Biology**

Prognostic Markers	Frequency (%)	Putative Role in Disease Biology
Del17p/loss of Tp53	~7–10	Loss of p53 protein and decreased levels of miR34a results in cell cycle dysfunction. Predicts for poor response to treatment and worse survival
Del11q	~18–20	Results in ATM gene deletion in the majority of patients and subsequently a lack of repair of double-stranded DNA breaks. Predicts for shorter time to treatment failure and survival. Impact may be overcome with the use of alkylator based chemoimmunotherapy.
Trisomy 12	~16–20	Impact maybe through a gene dosage effect especially of genes encoding CDK4 and MDM2. Predicts for intermediate risk disease
Del13q	~55–60	Results in the loss of miR-15a and miR-16-1 along with DLEU7 that results in loss of tumor suppressor activity. Generally associated with favorable outcomes including response to chemoimmunotherapy and survival
NOTCH1 mutation	~10	Constitutive activation of NOTCH1 results in increased cell survival and resistance to apoptosis and predicts for inferior response to rituximab and shorter treatment-free interval
SF3B1 mutation	~9–18	Mutually exclusive with NOTCH1 mutations. May cause abnormal transcription and splicing events. Associated with rapid disease progression
BIRC3 mutation	~5	Associated with unmutated IGHV, a shorter treatment-free interval and del11q. mutually exclusive with Tp53 mutations
MYD88 mutation	~3–13	Important adapter of the IL-1 and toll-like receptor pathway. Gain of function mutations result in increased cytokine production and activation of the NFκB pathway. Associated with improved survival

ATM, Ataxia-telangiectasia–mutations; IGHV, immunoglobulin heavy chain variable region; IL, interleukin; MYD88, myeloid differentiation primary response 88; SF3B1, NA splicing factor 3B, subunit 1

metaphase cytogenetic analysis and the poor response of CLL cells to B-cell mitogens. Nonetheless, several cytogenetic studies identified a variety of deletions, including del(11q22.3), del(17p13.1), del(13q14), and del(6q21-q23), as well as trisomy 12, as common abnormalities in CLL. The frequency of these abnormalities has been further refined through the use of fluorescence in situ hybridization (FISH) of interphase cells, which does not require isolation of dividing cells. These studies have demonstrated that del(13q14) is by far the most common cytogenetic abnormality in CLL followed by trisomy 12, del(11q22.3), del(17p13.1), and del(6q22.3). Stimulation of CLL cells with CpG oligonucleotides plus IL-4 or CD40 confirmed the prevalence of these abnormalities and identified unbalanced translocations not generally observed with traditional metaphase cytogenetics. The prognostic implications of these unbalanced translocations appear to be significant. Similarly, the complexity of karyotype appears to be a poor prognostic factor in CLL. Interestingly, balanced translocations, which are more frequently observed in ALL and AML, are generally not observed in CLL.

The presence of recurrent deletions in CLL suggests the possibility of unique tumor suppressor genes in these different regions. This was confirmed by the discovery of miR15 and miR16, two noncoding microRNAs, in the deleted region of 13q14. Noncoding RNAs range in size from 21–25 nucleotides and represent a newly recognized class of gene products whose function is to silence genes through binding to the 3'-untranslated region of specific genes to inhibit translation. It was later shown that miR16 regulates expression of BCL2, which is overexpressed in CLL and other B-cell lymphoproliferative disorders. Multiple different studies have associated specific miR expression with rapid disease progression, fludarabine resistance, and poor prognosis. In addition, miR34a has been directly related to the adverse outcome associated with p53 dysfunction. Further study of miRs in CLL is under way to elucidate their role in the pathogenesis and progression of CLL.

Recurring Mutations in Chronic Lymphocytic Leukemia

Until the advent of whole-exon and whole-genomic sequencing, CLL was not typically associated with recurring mutations early in the

pathogenesis of the disease. Probably best characterized are p53 mutations, which occur in up to 10% of patients at diagnosis, often in conjunction with deletion of the alternative allele (at 17p13.1 loci) that is associated with rapid disease progression and poor survival. With treatment and subsequent relapse, the frequency of p53 mutations continues to increase proportionately and is most common in patients with Richter transformation. Thus, p53 mutations are considered by most to be a secondary abnormality in CLL associated with progression. Nonetheless, p53 mutations or deletions have significant impact on consideration of treatment of CLL, and the 2008 International Workshop on CLL (IWCLL) criteria recommended that patients with p53 mutations with deletions be treated in a different manner than other CLL patients. Although detailed studies of ataxia-telangiectasia–mutations (ATM) have been performed, the impact of this abnormality is less well defined, in particular as it relates to treatment response. Other recurring mutations in CLL, including SF3B1, NOTCH1, MYD88, XPO1, and ERK1 have been described with varying clinical significance. With continued sequencing studies, more abnormalities will likely be appreciated. A summary of important genetic abnormalities and their impact is provided in Table 77.1.

Immune and Microenvironmental Features

The importance of progressive immune suppression with progression of CLL has become appreciated in both human forms of CLL and murine models of this disease. The absolute number of T cells and natural killer (NK) cells in CLL patients at diagnosis has been shown to predict OS. In particular, expansion of suppressive T-regulatory cells has been documented as patients approach the time when they require therapy. Similarly, the importance of microenvironmental compartments of CLL such as lymph nodes and BM, where stromal cells provide proliferative signals as well as survival signals to protect CLL cells from apoptosis, has been recognized. Based on this work, biomarkers involving measurable chemokines which are responsible for T-cell recruitment to the microenvironment have been identified. Given the link of these stimuli to BCR signaling, inhibitory molecules directed at kinases involved in this interaction can now target these pathways.

CLINICAL MANIFESTATIONS

At diagnosis, most CLL patients do not have clinical manifestations associated with their disease. For early stage CLL patients, the diagnosis is often identified as part of routine blood tests for evaluation of an unrelated problem such as an infection, kidney stones, or during a preoperative assessment in which an elevated leukocyte count is noted with increased mature lymphocytes observed. For a much smaller subset of patients with CLL, presentation of disease occurs as a consequence of fatigue, weight loss, early satiety (from spleen enlargement), petechiae (from low platelets), or new palpable lymph nodes. Patients with symptomatic CLL at diagnosis represent only 15% of those seen, corresponding to the more indolent nature of this disease at diagnosis. With additional follow-up, the majority of CLL patients will eventually manifest symptoms of the disease that ultimately lead to the need for treatment. The most common symptoms associated with progression include increasing fatigue (as a consequence of anemia and cytokines elaborated by the involved tissues), increasing lymph node and spleen size, worsening hematologic parameters (anemia and thrombocytopenia), and rarely infiltration of other organs (kidney, lung, pleural space, skin) that necessitates initiation of treatment to palliate symptoms. Symptoms generally associated with CLL progression are night sweats, fevers, and weight loss. These are generally suggestive of Richter transformation.

Separate from direct CLL progression, the disease is also immunosuppressive, and with more advanced disease, an increase in infections is generally observed. This represents a major morbidity of CLL and is a leading contribution to mortality associated with this disease. Other manifestations of immune suppression, including higher rate of secondary malignancies and autoimmune complications.

DIAGNOSIS AND LABORATORY MANIFESTATIONS

The diagnosis of CLL, as defined by the IWCLL 2008 criteria, requires an absolute malignant B-cell lymphocyte count of greater than 5000/ μ L that coexpress CD5 and CD23 on immunophenotyping. Morphologically, the lymphocytes appear mature with fewer than 55% prolymphocytes (Fig. 77.2A–E). The BM aspirate smear if done, should show greater than 30% of all nucleated cells to be lymphoid, or the BM core biopsy shows lymphoid infiltrates consistent with CLL (Fig. 77.2F–G). The overall cellularity is normocellular or hypercellular. Immunophenotyping reveals a predominant B-cell monoclonal population coexpressing the B-cell markers CD19, CD20, and CD23 and the T-cell antigen CD5 in the absence of other pan-T cell markers (see later section). In some cases, a hypocellular marrow can be present as an artifact of marrow aspiration.

Patients may present with tumor cells immunophenotypically consistent with CLL but have predominantly lymph node disease without a peripheral B-cell lymphocyte count of 5000/ μ L despite BM involvement. Although these patients are considered to have small lymphocytic lymphoma (SLL) and not true CLL by the National Cancer Institute criteria, the most recent World Health Organization classification considers such SLL patients to have CLL, given the similar immunophenotypic features, genetic findings, natural history, and complications of these two diseases. The clinical management of SLL patients should be similar to CLL with respect to diagnostic testing and treatment.

The recent increase in diagnostic blood testing for other B-cell lymphoid cancers has led to recognition of a clinical precursor to CLL called MBL. Patients with MBL have circulating peripheral B cells immunophenotypically consistent with CLL but do not have enlarged lymph nodes, a malignant lymphocyte count greater than 5000/ μ L, or cytopenias. The frequency of MBL increases with age; 0.3% of patients younger than the age of 40 years have MBL compared with 2.1% of 40- to 60-year-old patients and 5.2% of 60- to 90-year-old patients. The frequency of MBL in family members of patients with a first-degree relative with CLL is significantly higher in both young and older patients. With the new IWCLL 2008 definition of CLL requiring 5000/ μ L malignant B lymphocytes, more cases of MBL

Initial Evaluation of Young Patients With Chronic Lymphocytic Leukemia

Only 10% of patients diagnosed with CLL are younger than 50 years of age, and these patients often present a diagnostic and therapeutic dilemma to hematologists initially evaluating them. The great majority of patients diagnosed before the age of 50 years will have early-stage CLL with a slightly higher predisposition to a prior first-generation relative with this disease. In addition, these patients are generally of a higher economic status or have chronic fatigue or medical illnesses for which they have been undergoing routine blood testing, leading to diagnosis of CLL. When the diagnosis of CLL is made, these younger patients have a more challenging time understanding how the disease will impact them. For patients with no symptoms referable to CLL, we generally discuss complications of the disease during the first visit and have a detailed discussion regarding assessment of genetic risk factors predisposing to early disease progression, including select interphase chromosomal abnormalities (del[17p13.1] and del[11q22.3]) and IGHV mutational status (unmutated). During this time, it is important to counsel patients that identification of high-risk genomic features can actually increase anxiety because no treatment intervention is indicated in the absence of symptoms, regardless of genomic profile, outside of a clinical trial. In our experience, the great majority of patients desire this testing. Despite the potential benefit of allogeneic stem cell transplantation in younger patients with CLL, we generally mention this only as one treatment option used in this disease and do not pursue consultation or tissue typing of patients or siblings until patients are truly symptomatic from their disease. We provide considerable discussion about the promising but early data with kinase inhibitors currently approved and other promising novel molecules and therapies available in clinical trials. During the second visit 4 to 6 weeks later, we review the results of these prognostic factors and answer additional questions that have arisen. Ultimately, the majority of patients have low-risk disease, and knowing this allows patients to take partial control of their disease and move on with their lives. Serial assessment of the psychologic well-being of patients with CLL during this first year is incredibly important. At no place during the evaluation do we refer to CLL as being a good or favorable leukemia. In our experience, the most common reason for dissatisfaction toward the initial hematology evaluation is lack of explanation of the disease process or the minimization of CLL as a “good leukemia to have.”

For young patients presenting with other chronic medical problems who are asymptomatic from their CLL, we follow the approach outlined earlier. More commonly, these patients have fatigue, mild anemia, or other symptoms that could be attributable to the CLL. In addition, this group is more commonly overweight or obese. In either setting, it is important to first think like an internist and pursue other causes for symptoms potentially attributable to CLL. In particular, encouragement of both weight loss and a fixed exercise plan should be encouraged for fatigue and often improve quality of life and in other medical comorbidities. In some cases here, methylphenidate can be effective for the management of CLL related fatigue. It is very important to note that younger patients with CLL can often go a decade or more without therapy and early treatment of this patient group in the absence of symptoms still offers no proven long-term advantage. For this reason, our group remains very conservative on starting therapy for young patients with CLL unless they have high-risk disease and are treated on a clinical trial.

have been recognized than in the past with many patients being downstaged from early CLL to MBL. Similar to the relationship of monoclonal gammopathy of undetermined significance and multiple myeloma, it appears that only a small proportion of patients with MBL develop overt CLL over time. Whereas genetic features such as IGHV mutational status and cytogenetic abnormalities may predict progression of CLL, it is unclear if these tests bear any relevance to predicting MBL progression to CLL. For this reason, we generally do not perform these tests in MBL patients. Interestingly, these patients have many of the long-term complications of CLL related to immune suppression including a higher frequency of infections and also secondary malignancies. We therefore approach the initial counseling of these patients similar to newly diagnosed CLL patients with respect to interventions (vaccines and education) to minimize these

Fig. 77.2 CHRONIC LYMPHOCYTIC LEUKEMIA (CLL). The peripheral blood smear (A) typically shows lymphocytosis and increased smudge cells as a result of the fragility of the CLL cells (see also smudge cell in C, *right side*). These can be avoided by making a preparation of blood and bovine serum albumin (22%) at a ratio of 11 drops of blood and 1 drop of albumin before preparing the slide (B). Cytologic features of CLL cells differ. Classic cells have a small nucleus with a “soccer ball” chromatin pattern (C). Some cases have increased large cells, or prolymphocytes, with more open chromatin and prominent “punched-out” nucleoli (D; prolymphocyte, *right side*). Other cases, sometimes referred to as “atypical,” have clefted cells and large cells (E). The bone marrow can show nodular infiltrates of CLL cells (F), an interstitial infiltrate, or a diffuse infiltrate (G).

Fig. 77.3 FLOW IMMUNOPHENOTYPING IN CHRONIC LYMPHOCYTIC LEUKEMIA (CLL). Flow data in a typical case of CLL. The clonal B cells are CD19⁺ with κ light chain restriction (weak to moderately intense), with coexpression of CD5 and CD23, but lack of FMC-7. The cells were CD38-negative.

TABLE 77.2 Diseases That Can Mimic Chronic Lymphocytic Leukemia

- Mantle cell lymphoma
- Marginal zone lymphoma
- Hairy cell leukemia
- Acute lymphoblastic leukemia
- T-cell prolymphocytic leukemia
- Large granular natural killer or T-cell leukemia

complications. We also continue to follow these patients with yearly blood counts and exams.

LABORATORY MANIFESTATIONS

For many years, the diagnosis of CLL was made based on morphologic examination of the peripheral blood smear, which demonstrated mature lymphocytes with an abundance of smudge cells. Despite rigorous morphology, many diseases can mimic CLL in both appearance and clinical presentation, as summarized in Table 77.2, resulting in incorrect diagnoses. With the advent of new, more effective tar-

geted therapies for CLL and other related diseases listed in Table 77.2, determining the correct diagnosis is of great importance. Flow cytometry, or immunophenotyping is now the standard approach to establish the diagnosis of CLL (Fig. 77.3, for example). The diagnosis of CLL relies on immunophenotypic confirmation, and flow cytometry should therefore be performed on all CLL patients at diagnosis. CLL cells have a relatively consistent immunophenotype, which differentiates CLL from mantle cell lymphoma, hairy cell leukemia, follicular lymphoma, marginal zone lymphoma, and other indolent B-cell malignancies. Specifically, CLL cells express a variety of B-cell markers, including dim sIg, CD19, dim CD20, CD200, and CD23, as well as the pan T-cell marker CD5. Kappa or λ restriction is always present, establishing the presence of a clonal B-cell population, although sIg expression may be so dim that light chain restriction may be difficult to determine. In contrast, the presence of CD10, FMC7, or CD79b (all typically absent on CLL cells) or bright expression of CD11c, CD20, or CD25 (all typically dim on CLL cells) suggests an alternative low-grade B-cell lymphoproliferative malignancy. Expression of CD5 without CD200 or CD23 suggests mantle cell lymphoma, and FISH for t(11;14) should be performed to exclude mantle cell lymphoma. Some genetic subsets of CLL are predisposed to variant antigen expression, particularly patients with trisomy 12. Repeating immunophenotyping after the initial diagnosis is not required unless there is a suspicion of transformation to a more aggressive histology or there is a need to assess

Fig. 77.4 TRANSFORMATION IN CHRONIC LYMPHOCYTIC LEUKEMIA (CLL). Some patients with CLL develop increasing numbers of prolymphocytes (A) and a “prolymphocytic transformation.” A Richter transformation indicates evolution to a large-cell lymphoma (B; large cells, *upper left*, residual CLL, *lower right*). Occasionally, cases can transform to Hodgkin lymphoma (i.e., the Hodgkin variant of Richter syndrome) (C). With the use of fludarabine and other immunosuppressants, patient can also develop Epstein-Barr virus–related lymphadenopathies or lymphadenopathies with large areas of necrosis caused by herpes simplex virus (HSV). The case illustrated in (D) and (E) had both (E; *upper panel* shows an immunostain of HSV-1/2, and lower is *Epstein-Barr virus*—encoded small RNAs in situ hybridization).

BM response or antigen expression for an antibody directed therapeutic agent. Transformation of CLL (Fig. 77.4A–C) to either prolymphocytic leukemia (PLL) or large cell lymphoma (Richter transformation) is often associated with immunophenotypic drift, where CD5 is lost and FMC7 expression is acquired. In addition, expression of CD20 and surface immunoglobulins typically become brighter in PLL or Richter transformation. Although the morphologic appearance of prolymphocytes or large lymphoid cells in blood, BM, or lymph nodes is typically adequate to make the diagnosis of transformation, flow cytometry may be useful in cases when morphologic findings are less clear.

Patients with CLL often present with no symptoms, with the diagnosis being made as a consequence of asymptomatic enlarged lymph nodes or splenomegaly detected on physical examination or routine blood work done for another cause. Other patients present with symptoms of BM replacement (fatigue, dyspnea, or petechiae secondary to anemia and thrombocytopenia), symptomatic lymphadenopathy or hepatosplenomegaly, autoimmune complications (hemolytic anemia or idiopathic thrombocytopenic purpura), or B symptoms (fevers, night sweats, and weight loss). A small proportion of CLL patients will have pulmonary infiltrates at diagnosis that are representative of CLL involvement in some cases and active infection in others.

In addition to blood and BM lymphocytosis, a few abnormal laboratory findings are commonly observed in CLL. Neutropenia, anemia, and thrombocytopenia can develop as a consequence of BM infiltration or myelosuppressive therapy administered to eliminate the leukemia. A positive direct antibody, or Coombs, test result is observed in approximately 10% to 25% of CLL patients at some time during the course of the disease. Similarly, autoimmune thrombocytopenia or neutropenia may be present, although other causes such as BM replacement or chemotherapy effect are much more common and should be excluded. Pure red blood cell (RBC) aplasia can sometimes be observed with isolated anemia and absence of RBC precursor cells. Hypogammaglobulinemia is common in CLL and becomes more frequent and marked as the disease progresses. In contrast, hypercalcemia and markedly elevated lactate dehydrogenase (LDH) are not common in CLL and suggest Richter transformation. Clearly, a wide spectrum of presentations exists for patients with CLL.

When Do We Consider a Transplant Evaluation in Chronic Lymphocytic Leukemia?

With the introduction of nonmyeloablative stem cell transplantation, the morbidity and mortality associated with this therapy in CLL has decreased, and this option thereby was extended to young and older patients alike. In addition, extended follow up at several transplant series suggested that prolonged remissions could occur with this treatment approach, potentially providing the only curative therapeutic option for this disease. However, with the availability of newer and more effective therapeutic options such as the kinase inhibitors and soon to be approved BCL2 inhibitor, the indications for transplant have declined tremendously over the past few years. In general, we do not consider detailed discussion of transplant or referral for asymptomatic patients. When patients become symptomatic and require therapy for their CLL, we briefly discuss the role of stem cell transplantation (SCT) as a potentially curative option. Approximately 50% of patients with CLL are 75 years of age or younger, have acceptable end-organ function, and lack comorbidities when symptomatic disease develops. This CLL patient group may benefit from an allogeneic transplant consultation. However, this group can potentially attain a long-term disease control state with the administration of kinase inhibitors. Moreover, the use of kinase inhibitors does not result in a significant number of complete responses and SCT in patients with residual disease generally results in a higher incidence of relapses. Autologous transplant in CLL offers no opportunity for cure and is associated with treatment-related myelodysplastic syndrome (MDS)/AML. For patients without del(17p13.1) who attain a complete remission (CR) with initial chemotherapy, we do not consider a consolidative SCT. For patients treated with ibrutinib, SCT can be considered, although it is not our preference for young healthy patients with del17p and complex karyotype in complete or good partial response since these patients typically have the worst outcomes even in the era of kinase inhibitor therapy. However, we do not consider this approach until the patient is 1 to 2 years into treatment with kinase inhibitors. The impressive and sustained disease control afforded by kinase inhibitors and the possibility of more effective and potentially curative and less toxic therapeutic alternatives like chimeric antigen T cell (CAR-T cells) have significantly limited the role of SCT for the routine management of patients with CLL.

TABLE 77.3 Rai Staging System

Rai Stage at Diagnosis	Percent of Patients Never Requiring Chronic Lymphocytic Leukemia Therapy	Expected Survival in Months From Initial Diagnosis
0 - Lymphocytosis $>5 \times 10^9/L$ only	59	150
1 - Lymph node enlargement	21	101
2 - Spleen or liver enlargement	23	71
3 - Anemia with hemoglobin <11 g/dL	5	19
4 - Thrombocytopenia $<100 \times 10^{12}/L$	0	19

Adapted from Rai KR, Sawitsky A, Cronkite EP, et al. Clinical staging of chronic lymphocytic leukemia, *Blood* 46:219, 1975.

PROGNOSIS

Historically, patients with CLL have been staged using either the Rai (Table 77.3) or Binet system. Both of these discriminate CLL by the sites of disease and degree of cytopenias induced by BM replacement by the leukemia. Patients can be categorized into three groups on the basis of these features. According to the modified Rai criteria, patients in the low-risk group (stage 0) have lymphocytosis without any other abnormality; patients in the intermediate-risk group (stages I and II) have, in addition to their lymphocytosis, enlarged lymph nodes, spleen, or liver; and patients in the high-risk group (stages III and IV) have anemia (hemoglobin <11.0 g/dL) or thrombocytopenia (platelets $<100 \times 10^9/L$). The median survival times for the Rai low-, intermediate-, and high-risk groups are similar to those of Binet stages A, B, and C: 12+, 8, and 2 years (see Table 77.2). For early-stage patients with CLL (Rai low- and intermediate-stage and Binet stages A and B), a significant range of time to developing symptoms of CLL exists. The lack of survival advantage with early treatment, the observation that a subset of CLL patients will never require therapy, and the varied natural history of the disease have driven research efforts in CLL to identify specific biologic or clinical prognostic factors that predict time to progression.

Although lymphadenopathy is a common clinical feature of CLL and is incorporated into both major clinical staging systems, computed tomography (CT) scans are not commonly used to determine staging or to evaluate response to therapy outside of clinical trials. However, several studies have examined whether the incorporation of CT scans in initial staging or response evaluation may affect the ability to predict disease progression at diagnosis and assessment of clinical response to therapy. Although a few reports have suggested that such studies may help predict disease progression, studies done serially at the time of treatment and for response show that CT scans generally do not impact assessment of response, progression-free survival (PFS), or OS. In addition, CT scan identification of new nodal areas do not impact decisions for retreatment. Thus, routine CT scans should not be performed for staging and response evaluation in CLL. Similarly, positron emission tomography (PET) scans appear to be sensitive for Richter transformation, with a high negative predictive value, but specificity is poor. We generally use these studies to identify patients who warrant biopsy for Richter transformation and to localize where to biopsy.

With recent advances in the molecular biology of CLL, some prognostic factors such as BM infiltration pattern, which requires an invasive procedure at diagnosis, have not maintained their usefulness in predicting disease progression. Prognostic features outside of the traditional staging systems outlined earlier relative to daily practice are summarized later (Table 77.4).

TABLE 77.4 Evaluation of Chronic Lymphocytic Leukemia Patients at Diagnosis

History

- B symptom and fatigue assessment
- Infectious history assessment
- Occupational assessment for chemical exposure
- Familial history of CLL and lymphoproliferative disorders
- Preventive interventions for infections and secondary cancers

Physical Examination

Laboratory Assessment

- CBC with differential
- Morphology assessment of lymphocytes
- Chemistry, LFT enzymes, LDH
- Flow cytometry assessment to confirm immunophenotype of CLL
- Serum immunoglobulins
- Serum β_2M levels
- Interphase cytogenetics for del(17p13.1), del(11q22.3), del(13q14), del(6q21), and trisomy 12
- IGHV mutational analysis
- Stimulated metaphase karyotype (if available)

Selected Tests Under Certain Circumstances

- DAT, haptoglobin, reticulocyte count if anemia present
- CT scan if unexplained abdominal pain or enlargement present
- PET scan or biopsy (or both) if large nodal mass present
- BM aspirate and biopsy if cytopenias present
- Familial counseling if first-degree relative with CLL

Teaching

- Varicella zoster identification instruction
- Skin cancer identification
- Disease education (Leukemia and Lymphoma Society)

BM, Bone marrow; CBC, complete blood count; CLL, chronic lymphocytic leukemia; CT, computed tomography; DAT, direct antiglobulin test; IGHV, immunoglobulin heavy chain variable region; LDH, lactate dehydrogenase; LFT, liver function test; PET, positron emission tomography.

Thymidine Kinase Activity and β_2 -Microglobulin

Thymidine kinase is an enzyme involved in the salvage pathway of DNA synthesis and its levels correlate with proliferative activity. Elevated thymidine kinase activity (TKA) has been observed to be predictive of early progression in a subgroup of untreated patients with smoldering CLL. β_2 -Microglobulin (β_2M) is an extracellular protein component of the human leukocyte antigen (HLA) class I complex. β_2M has been shown to have significant prognostic relevance in lymphoma and multiple myeloma patients and correlates with disease burden in CLL patients. Hallek and colleagues examined 113 CLL and immunocytoma patients for β_2M levels and TKA and demonstrated that elevated TKA and β_2M both were independent predictors of shortened PFS. Keating et al confirmed the prognostic value of β_2M in CLL patients, reporting that an elevated level was associated with a significantly shorter survival time for both untreated and previously treated patients. In their studies, elevated β_2M levels were observed in patients with high tumor burden and extensive BM infiltration. In addition to disease progression, both β_2M and TKA have been associated with short duration of remission and inferior survival after treatment.

IGHV Mutational Status

Although the malignant CLL cell morphologically resembles a mature lymphocyte, genetic, immunologic, and phenotypic studies suggest that this cell is better designated as either a pregerminal or postgerminal B cell. Somatic mutations in the first and second complementarity-determining regions (CDR1 and CDR2) of the IGHV genes are thought to occur in the germinal centers. Examination of IGHV genes in patient cells suggests that there may be two

subsets of CLL: leukemias whose cell of origin has successfully traversed the germinal center, resulting in the mutated IGHV phenotype, and leukemias that are derived from naive B cells with the unmutated (germline) IGHV sequence. Whereas approximately 60% of CLL patients have cells with mutated IGHV genes (<98% identity to germline), the remaining patients have cells exhibiting unmutated IGHV ($\geq 98\%$ sequence identity with germline), typical of pregerminal B cells. The prognostic significance of the absence of IGHV gene mutations is substantial, with studies uniformly noting an inferior survival and high tendency to require early treatment in this patient subset. A CLL Research Consortium study examined the impact of IGHV mutation in 307 untreated CLL patients enrolled in a prospective tissue collection study. A total of 53% of these patients exhibited unmutated IGHV genes, and this population had a significantly shorter median time to initial therapy (3.5 years) than those with mutated IGHV (9.2 years; $p < .001$).

Because of the difficulties in determining IGHV gene mutational status, researchers have sought surrogate markers for this parameter. Correlation between the absence of IGHV gene mutations and elevated expression of the cell surface molecule CD38 on CLL cells has been noted. In another report, ZAP-70 expression was shown to correlate with IGHV gene mutational status. ZAP-70 is a T-cell receptor–associated tyrosine kinase that is aberrantly expressed in CLL cells, and ZAP-70 expression is generally found in patients with unmutated IGHV but not in patients with mutated IGHV. These two associated biomarkers appear to be linked directly to the difference in the behavior between these two genetic subtypes of CLL and are discussed independently. Other surrogate markers for the mutational status of the IGHV gene have been reported, including methylation and subsequent silencing of TWIST2, a transcription factor that negatively regulates p53. TWIST2 methylation and silencing are preferentially observed in IGHV-mutated CLL cases. Elevated levels of lipoprotein lipase and related genes have been noted in patients with IGHV-unmutated disease. In addition, it has been reported that IGHV-mutated CLL cells have long telomeres with low telomerase activity, but IGHV-unmutated patients have short telomeres with high telomerase activity. The extreme shortening of telomeres and elevated telomerase activity are associated with both genetic instability and disrupted apoptosis in other diseases, suggesting that a similar process occurs in IGHV-unmutated CLL cells. Finally, distinct gene and microRNA (miRNA) expression profiles have also been correlated with IGHV gene mutational status.

CD38 Expression

Retrospective studies have shown that CD38 is an independent prognostic marker in CLL, demonstrating that high CD38 expression is associated with both a shorter time from diagnosis to treatment and inferior survival. CD38 functional studies using CD31 and plexin B1 transfected fibroblasts have provided a biologic explanation for this observation. CD38 interaction with its ligand, CD31, in the presence of IL-2 results in upregulation of the survival receptor CD100 exclusively on proliferating CLL cells. This occurs with concomitant downmodulation of CD72, a negative regulator of immune response. The interaction between CD38 and CD100 on CLL cells and CD31 and plexin B1, respectively, on transfected fibroblasts results in enhanced survival and growth of CLL cells. Furthermore, the presence of nurse-like cells in CLL patients expressing high levels of CD31 and plexin B1 corroborates the interplay of CD38 and CD31 and provides further evidence of activation of circulating CD38-positive CLL cells by the microenvironment. This finding provides an explanation for the aggressive nature of these CLL clones.

ZAP-70

ZAP-70 expression was identified as another surrogate marker for IGHV gene mutational status by a cDNA microarray analysis of

untreated CLL patients. Functional studies in ZAP-70–positive cases have shown that BCR ligation leads to increased phosphorylation of cytosolic proteins (Syk, BLNK, PLC γ), calcium mobilization, degradation of I κ B, and ultimately NF κ B target gene activation. Despite clear data showing that ZAP-70 is a prognostic marker, the reproducibility of this assay across laboratories has been problematic. Inconsistent measurement of ZAP-70 may be the cause of this lack of reproducibility because ZAP-70 is a labile protein, and laboratories have used different methods and reagents. Given the challenges of measuring ZAP-70 protein accurately, others have attempted to identify alternative markers or more stable readouts of ZAP-70 expression. For example, methylation of select regions in the proximal 5' region of the ZAP-70 gene has been shown to correlate closely with expression of ZAP-70 and to be correlated with treatment outcome. Overall, despite the apparent usefulness of ZAP-70 in research laboratories for discriminating CLL patients at high risk for progression, this test is of limited utility for routine clinical practice.

CD49d Expression

CD49d is a surface subunit of the integrin heterodimer that is involved in promoting survival of the CLL cells through microenvironment derived growth signals. CD49d can be used as a reliable predictive marker of aggressive disease course and inferior survival is associated with $\geq 30\%$ cells expressing CD49d by flow cytometry.

Other Prognostic Markers

Various other markers have been used for predicting the disease course of CLL patients. Elevated serum LDH levels are associated with aggressive disease and with the development of Richter syndrome and prolymphocytic lymphoma. Similarly, patients with a lymphocyte doubling time of 12 months or less have been shown to have a worse overall and treatment-free survival. Other markers include soluble factors including CD23, CD44, VCAM-1, CD27, and MMP-9, IL-6 and IL-8, etc. However, none of these biomarkers are routinely used in clinical practice.

MicroRNAs (miR) are noncoding RNAs that are 19–25 nucleotides in length and modulate mRNA translation and synthesis of various proteins. Various microRNAs have been validated as useful CLL prognostic markers, especially miR-15a and miR-16-1 which were the first to be identified as being underexpressed in CLL B-cells. Deletion of chromosome 13q14 decreases their transcription and increases the expression of the antiapoptotic BCL2 protein. Similarly, miR-34c is affected by del11q23 and regulates the expression of ZAP-70 and other proteins involved in the Tp53 pathway. MiR mass array profiles have also been found to be predictive of disease progression, fludarabine resistance and clinical outcomes.

Chromosomal Aberrations

Conventional metaphase karyotype analysis can identify chromosomal aberrations in only 20% to 50% of CLL cases because of the low in vitro mitotic activity of CLL cells. Abnormalities noted in descending frequency of occurrence include trisomy 12; deletions at 13q14; structural aberrations of 14q32; and deletions of 11q, 17p, and 6q. In addition, a complex karyotype (three or more abnormalities) occurs in approximately 15% of patients and is predictive of rapid disease progression, Richter transformation, and inferior survival. The use of CD40L or the combination of IL-2 and CpG for B-cell stimulation has revealed translocations in 33 of 96 patients (34%). These translocations were both balanced and unbalanced, occurring at 13q14, 11(q21q25), 14q32, or regions also seen in lymphomas such as 1(p32p36), 1(q21q25), 2(p11p13), 6(p11p12), 6(p21p25), and 18q21. The presence of such translocations defines a prognostic subgroup of patients with a significantly shorter median time from diagnosis to requiring therapy (24 vs. 106 months) and

OS (94 vs. 346 months) as compared with those without translocations. The frequency of such translocations in untreated patients is less common, suggesting that such transactions accumulate with disease progression.

Given the limitation of standard or stimulated karyotype analysis, interphase FISH has become the state-of-the-art technique for accurately distinguishing genetic subtypes of CLL. The largest study of interphase FISH resulted in improved sensitivity to detect partial trisomies (12q12, 3q27, 8q24), deletions (13q14, 11q22-23, 6q21, 6q27, 17p13), and translocations (band 14q32) in more than 80% of all cases. In a large study of 325 patients by Dohner and colleagues, a hierarchical model consisting of five cytogenetic subgroups was constructed on the basis of regression analysis of CLL patients with chromosomal aberrations. Patients with a 17p deletion had the shortest median survival time (32 months) and the shortest treatment-free interval (TFI, months); patients with an 11q deletion followed closely with 79 months and 13 months, respectively. Whereas the favorable 13q14 deletion group had a long TFI of 92 months and a median survival of 133 months, the group without detectable chromosomal anomalies and those with trisomy 12 fell into the intermediate group with median survival of 111 and 114 months, respectively, and TFI of 33 and 49 months, respectively. According to this pivotal study, CLL patients are prioritized in a hierarchical order (deletion 17p13 > deletion 11q22-q23 > trisomy 12 > no aberration > deletion 13q14). The hierarchical model of cytogenetic abnormalities in predicting disease progression by FISH has been further confirmed by other studies. Of interest, patients with high-risk interphase cytogenetic abnormalities or other complex abnormalities are almost always found to have IGHV-unmutated CLL.

Mutational Analysis

Numerous recurrent mutations and or deletions have been described in CLL that are often associated with IGHV mutational status. While the majority of these mutations do not impact the clinical outcome of CLL patients, several including p53, ATM, NOTCH1, SF3B1, XPO1, and BIRC3 have been shown to predict time to initiation of treatment and also overall survival. Outside of p53 mutations, the frequency of these mutations are often low and therefore prevent definitive independent determination of their impact on outcome with respect to other features. The presence of several other mutations including ERK1, BRAF, and MYD88 have served as a rationale for therapeutic targeting with novel agents that are U.S Food and Drug Administration (FDA) approved or are being evaluated in clinical trials. However, none of these drugs have been shown to be effective in CLL. Despite routine mutational tests being available, it is not our practice to examine these broadly at diagnosis or at time of treatment. The exception to this is p53 mutations for which there may be value although their independence of del(17)(p13.1) as a negative biomarker has only rarely been demonstrated because of the common association of these two aberrations.

TREATMENT

Initiation of Treatment of Newly Diagnosed or Previously Untreated Patients

Many patients are incidentally diagnosed with CLL on routine complete blood count examination and are asymptomatic with a normal hemoglobin and platelet count at the time of initial diagnosis. Expectant observation without therapy is the standard practice for such asymptomatic patients, and patients receive treatment only when their disease progresses. This practice is based on several studies that failed to show an improvement in OS when early therapeutic intervention with chlorambucil was administered to asymptomatic patients. A metaanalysis of 2048 patients participating in six trials demonstrated no difference in death rate between patients who were randomized to early therapy (42.6%) and those with treatment

How Should Staging and Biomarkers Be Used for Treatment Decisions in Chronic Lymphocytic Leukemia Patients?

Our understanding of the biology of CLL has improved dramatically, and many relevant biomarkers are now available for predicting when CLL patients will clinically progress. However, no study to date has demonstrated that earlier treatment will alter the natural history of the patient in even the higher risk groups with high progression rates. Therefore, at the present time, the use of staging and predictive biomarkers should be used only to provide patients with information relative to the expected course of their disease. Outside of a clinical trial, these results should never be used to initiate therapy in patients with asymptomatic disease or as an indication for treatment. Before performing predictive tests, a detailed discussion with the patient of how these tests will be used should occur and the option of not performing them should be provided. In a subset of patients, significant anxiety can be produced by identifying high-risk features for which observation, without therapeutic intervention, remains the standard of care. [Table 77.4](#) provides an example of the initial evaluation provided by our group when seeing a newly diagnosed patient. Because lymphocyte-doubling time is a prognostic feature in the progression of CLL, our approach is to follow patients every 3 months during the first year following diagnosis; if little change in clinical or laboratory parameters occurs at this point, we extend this time period to every 6 months in the absence of new complaints.

deferred (41.6%). Thus, patients with asymptomatic or early-stage disease derive no therapeutic benefit from early alkylating agent therapy. However, in these studies, chlorambucil was administered as initial therapy, and chlorambucil achieves complete response (CR) in few patients. Similarly, fludarabine when used early for patients who do not meet the conventional criteria for treatment resulted in higher response rate but failed to demonstrate a survival advantage. A recently completed trial from the German CLL study group of high risk CLL patients did not demonstrate an advantage of even more aggressive chemoimmunotherapy with fludarabine, cyclophosphamide, and rituximab in improving overall survival. It is now well-established that CLL undergoes genetic clonal evolution over time with greater frequency in IGHV-unmutated CLL, resulting in increasing resistance to therapy. Thus, the issue of early treatment needs to be reconsidered, particularly in patients with high-risk biological or molecular markers predicting a poor long-term prognosis, such as IGHV-unmutated disease and especially with the advent of kinase inhibitors that may be associated with limited toxicities.

To establish uniform clinical practice standards and ensure reproducible eligibility criteria for entrance into clinical studies, the IWCLL established guidelines for initiation of treatment. Indications to begin therapy included nonautoimmune cytopenias (Rai stage III and IV), bulky or symptomatic lymphadenopathy or hepatosplenomegaly, disease-related B symptoms or fatigue, extreme lymphocytosis ($>300 \times 10^9/L$) or a rapid lymphocyte-doubling time, and autoimmune hemolytic anemia (AIHA) or thrombocytopenia not controlled with steroids. A rapidly rising lymphocyte doubling time was recently removed from the National Comprehensive Cancer Network (NCCN) criteria as an indication to treat as it commits many patients to earlier intervention, which may not be necessary in the absence of other symptoms. It is imperative to determine if a patient's symptoms are attributable to CLL or a comorbid medical condition because constitutional symptoms such as fatigue are nonspecific and can be attributed to many causes in elderly patients with comorbid illnesses. In addition to the official IWCLL 2008 criteria for therapy, an increasing frequency of infections and slowly progressive anemia are other indications that can aid the practicing physician in deciding when to initiate therapy in patients with CLL. A summary of the IWCLL 2008 guidelines for treatment is provided in [Table 77.5](#) with some minimal modifications used by our group.

A useful paradigm for clinical practice is to institute treatment in CLL only for cytopenias or directly referable symptoms. When treatment is necessary, a variety of agents have been examined in clinical trials (outlined below). Previously identified biomarkers are used in

TABLE 77.5 Modified Indications for Treatment of Chronic Lymphocytic Leukemia

- Grade 2 or greater fatigue limiting life activities
- B symptoms persisting for ≥ 2 weeks
- Lymph nodes >10 cm or progressively enlarging lymph nodes causing symptoms
- Spleen or liver with progressive enlargement or causing symptoms
- Anemia (hemoglobin <11 g/dL) referable to CLL
- Thrombocytopenia (platelets $<100 \times 10^{12}/L$) referable to CLL or ITP poorly responsive to traditional therapy
- Severe paraneoplastic (e.g., insect hypersensitivity, vasculitis, myositis) process related to CLL not responsive to traditional therapies

CLL, chronic lymphocytic leukemia; ITP, idiopathic thrombocytopenic purpura.

selecting the initial treatment for CLL. In addition, several studies have shown that CLL patients older than 70 years of age or who have multiple comorbid illnesses do not benefit from fludarabine-containing regimens, which should be factored into treatment algorithms. Below, we summarize the findings of clinical studies of different treatments for CLL; where such data exist, we integrate genomic biomarkers as well as clinical features, including age and comorbid illnesses. Different therapies are outlined below with attention to details related to their initial use in previously untreated CLL. Because many of these regimens were also developed in relapsed CLL patients, these data will be reviewed and later referred to in the section [Treatment of Patients With Relapsed Chronic Lymphocytic Leukemia](#).

Cytotoxic Chemotherapy

Alkylating Agents

Chlorambucil and other alkylating agents have served as first-line therapy for CLL for many decades, and chlorambucil is still given as first-line therapy for some patients, particularly older patients and patients who cannot tolerate purine analog therapy. Chlorambucil is generally administered as a single pulse dose 40 mg/m² orally (PO) every 28 days with or without concomitant steroid therapy, although alternative dosing schedules are used, particularly in Europe. Chlorambucil is typically given without steroid therapy because the addition of steroids to alkylating agent therapy has not been shown to improve survival. Although a high-dose continuous dosing schedule of 15 mg/day PO has been evaluated in several large European studies and led to results superior to those of pulse therapy, high-dose therapy is associated with greater myelosuppression and frequently requires dose reduction, particularly in older or more fragile patients in whom chlorambucil is typically considered. Although high-dose therapy may be more effective if maximal cytoreduction is desired, the less intensive pulse dosing schedule should generally be used outside the setting of a clinical trial. Because most studies of alkylating agent therapy predated widespread use of cytogenetic and biologic risk factors, data on the effect of biomarkers on predicting response to chlorambucil are limited. However, the existing data indicate that patients with del(11q22.3) or del(17p13.1) have a lower response rate and a shorter duration of remission to chlorambucil compared with patients without these abnormalities. The primary advantages of chlorambucil are its well-established toxicity profile and its low cost; its primary disadvantages are its low CR rate, even in previously untreated patients, and the small possibility of developing myelodysplasia with extended therapy. Although not typically given as a single agent to younger patients, its use should be considered in older patients and other patients who may not tolerate more intensive chemotherapy based regimens. Given the benefit of the chimeric monoclonal anti-CD20 antibody rituximab as part of chemoimmunotherapy regimens with fludarabine, several studies have been performed combining chlorambucil with rituximab, ofatumumab and

the novel type II monoclonal anti-CD20 antibody obinutuzumab. (Both obinutuzumab and ofatumumab are discussed later in this chapter.)

Bendamustine

Although typically classified as a bifunctional alkylator, bendamustine has an uncertain mechanism of action. Although the drug predominantly promotes cytotoxicity by inducing DNA damage and the generation of reactive oxygen species, bendamustine displays a distinct pattern of activity unrelated to other DNA-alkylating agents but closest to melphalan. Unlike other alkylating agents, bendamustine activates a base excision DNA repair pathway rather than an alkyl-transferase DNA repair mechanism. Studies of bendamustine in a variety of solid tumors, non-Hodgkin lymphoma (NHL), multiple myeloma, Hodgkin disease, and CLL have shown single agent activity. Bendamustine has been widely used in East Germany and several European countries for decades and was approved by the U.S. Food and Drug Administration (FDA) for treatment of CLL in 2008. This was based on a well-controlled, randomized phase III study comparing bendamustine 100 mg/m² intravenous (IV) on days 1 and 2 with chlorambucil 0.8 mg/kg PO on days 1 and 15 every 4 weeks for six cycles. A total of 319 patients were enrolled with an overall response rate (ORR) of 68% and 31% CR with bendamustine versus 31% ORR and 2% CR with chlorambucil treatment ($p < .0001$). The median PFS was significantly better ($p < .0001$) with bendamustine (21.6 vs. 8.3 months) than chlorambucil. Grade 3/4 hematologic toxicity and severe infections (grades 3–4) occurred more commonly with bendamustine. Overall, this study and others that have followed showed that bendamustine is well tolerated in young and old CLL patients. This agent has been effectively combined with rituximab and will be discussed later in this chapter.

Combination Chemotherapy With Alkylating Agents

A variety of trials combining alkylating agents and other cytotoxic agents have been performed. A phase III Eastern Cooperative Oncology Group (ECOG) study of chlorambucil and prednisone (CP) with or without vincristine (CVP) demonstrated no benefit in PFS for the CVP arm. The French CLL group showed that a modified cyclophosphamide, Adriamycin, vincristine, prednisone (CHOP) regimen was superior to CVP and achieved similar results as fludarabine monotherapy. A metaanalysis compared alkylating agent-based combination regimens with a single-agent regimen based on an alkylating agent and demonstrated no survival benefit. Given that alkylating agent-based combination regimens are associated with more toxicity and show no benefit over fludarabine-based therapy, there is a limited role for combination alkylator-based therapy in the routine management of patients with CLL. In the relapse setting, although salvage lymphoma regimens such as CHOP-R; rituximab, ifosfamide, carboplatin, and etoposide (R-ICE); and etoposide, methylprednisolone, cytarabine, cisplatin, and rituximab (ESHAP-R) are used to treat CLL, clinical studies of these regimens in CLL are lacking, and the utility of these regimens is undefined.

Purine Analogs

The introduction of purine analogs in the 1980s by Grever and later Keating revolutionized CLL therapy, and fludarabine has demonstrated significant clinical efficacy in both relapsed and previously untreated CLL. Pentostatin was the first nucleoside analog that demonstrated clinical activity in CLL and related B-cell lymphoproliferative disorders; however, subsequent phase II studies showed modest activity, limiting further trials of this agent. Given its more favorable myelosuppression profile compared with other nucleoside analogs, pentostatin has been combined with other agents and shown favorable clinical activity and toxicity in selected populations. Two

other nucleoside analogs, fludarabine and cladribine, were subsequently found to be clinically active in CLL. Phase II–III studies of cladribine monotherapy achieved similar clinical responses as alkylating agent–based treatment but were associated with more cytopenias and immune suppression. The FDA approved fludarabine for the treatment of CLL, and thus most studies of purine analog–based therapy in CLL have focused on fludarabine. The remainder of this section focuses predominantly on clinical trials of fludarabine.

Fludarabine was initially approved by the FDA for alkylating agent–resistant CLL in 1991 based on two phase II studies demonstrating a high response rate to fludarabine in this patient subset, prompting several additional trials of fludarabine as monotherapy in relapsed and previously untreated CLL. After the observation of high response rates and a 33% CR rate in previously untreated CLL by Keating and colleagues, several large prospective randomized studies in previously untreated CLL patients compared alkylating agent–based regimens with fludarabine. These studies collectively established fludarabine as an accepted standard first-line therapy for CLL based on improved response rates and PFS. A multicenter European study randomized 196 evaluable patients to fludarabine or cyclophosphamide, doxorubicin, and prednisone (CAP). The ORR favored fludarabine (60% vs. 44%), and this benefit was observed in both relapsed ($n = 96$; 48% vs. 27%) and previously untreated ($n = 100$; 71% vs. 60%) patients, although the difference was not statistically significant in the untreated group. Fludarabine achieved a longer median duration of response than did CAP, with a tendency toward longer OS in previously untreated patients. A randomized, multicenter American study confirmed these findings in 509 previously untreated CLL patients. Patients were randomized to receive fludarabine 25 mg/m² IV daily for 5 days every 28 days, chlorambucil 40 mg/m² PO every 28 days, or fludarabine 20 mg/m² daily for 5 days and chlorambucil 20 mg/m² PO every 28 days, for up to 12 cycles. Patients who failed to respond or relapsed were allowed to cross over to the other arm. The combination arm was closed because of excessive toxicity. Fludarabine achieved a superior CR rate, ORR, median duration of remission, and median duration of PFS (20%, 63%, 25 months, 20 months, respectively) than did chlorambucil (4%, 37%, 14 months, 14 months, respectively). However, there was no statistically significant difference in OS even after 10 years of follow up (66 vs. 56 months), possibly because of the crossover design. A multicenter French study randomized 938 patients with previously untreated Binet stage B and C CLL to fludarabine, CHOP, or CAP. Although fludarabine achieved better response rates than CAP, OS (67–70 months) was identical for all three treatment groups. Thus, single-agent fludarabine achieves superior response rates and duration of PFS than alkylating agent–based regimens. The impact of prognostic factors on response rates and duration of PFS to fludarabine was recently examined; patients with high-risk cytogenetic abnormalities, including del(11q22.3) and del(17p13.1), have significantly shorter PFS in response to fludarabine-based therapy than patients with other cytogenetic abnormalities.

However, the benefit of fludarabine does not apply to patients older than the age of 65 years. A phase III trial by the German CLL Study Group randomized 193 previously untreated CLL patients older than 65 years to fludarabine 25 mg/m² IV for 5 days every 28 days for six cycles or chlorambucil 0.4–0.8 mg/kg PO every 15 days for 12 months. Fludarabine achieved higher OR (72% vs. 51%) and CR rates (7% vs. 0%) and longer time to treatment failure (19 vs. 18 months). However, PFS was similar in both arms (19 months vs. 18 months), and OS was 46 months for fludarabine compared with 64 months for chlorambucil arm ($p = .15$). Thus, the results achieved in younger patients do not necessarily apply to older patients with comorbid diseases or who otherwise cannot tolerate more aggressive therapies.

Combining Fludarabine With Alkylating Agent Therapy

Fludarabine was combined with cyclophosphamide (Flu/Cy) in three randomized phase III studies, based on two promising pilot studies

in previously untreated CLL patients, with the goal of improving response rates and hopefully long-term survival. The German CLL Study Group randomized 375 previously untreated patients (age younger than 65 years) to standard fludarabine or Flu/Cy (fludarabine 30 mg/m² IV and cyclophosphamide 250 mg/m² IV daily for 3 days) every 28 days for six cycles. The ORR (94% vs. 83%), CR rate (24% vs. 7%), median PFS (48 vs. 20 months), and duration of treatment-free survival (37 vs. 25 months) all favored Flu/Cy, although there were more patients with cytopenias in the combination arm. Furthermore, no difference in OS was observed. ECOG randomized 278 patients to single-agent fludarabine or fludarabine 25 mg/m² on days 1–5, cyclophosphamide 600 mg/m² on day 1, and granulocyte colony-stimulating factor (G-CSF) support every 28 days for six cycles. Flu/Cy therapy achieved a superior ORR (74% vs. 59%), rates of CR (23% vs. 5%), and duration of PFS (32 vs. 19 months), although no OS advantage was observed. The United Kingdom LRF CLL4 study randomized 777 patients to oral chlorambucil, fludarabine, or Flu/Cy. Patients randomized to Flu/Cy enjoyed superior ORR, CR rates, and 5-year PFS rates (94%, 39%, and 33%, respectively) as compared with patients who received chlorambucil (72%, 7%, and 9%, respectively) or fludarabine (80%, 15%, and 14%, respectively).

These three large, prospective, randomized, multicenter studies in the United States and Europe have clearly demonstrated that Flu/Cy therapy is associated with better response rates and duration of PFS than single-agent fludarabine. However, no OS advantage for upfront Flu/Cy has been observed to date. Although toxicity has generally been manageable, greater hematologic toxicity has been observed with Flu/Cy. In addition, patients older than 65 or 70 years, who make up the majority of CLL patients receiving therapy in clinical practice, have either been excluded or minimally represented in these trials. Further studies are needed to determine if Flu/Cy is as well tolerated and active in older patients as it is in younger patients. Finally, of these patients, long-term follow up is required to determine the duration of remission, OS, and the incidence of potential late complications such as therapy-related myeloid neoplasia (tr-MN) to fully assess the utility of the Flu/Cy regimen. Indeed, the U.S. Intergroup study of Flu/Cy versus Flu suggested an increased risk of tr-MN in the Flu/Cy arm. Examination of outcome by cytogenetic risk groups showed that patients with high-risk cytogenetic abnormalities, including del(17p13.1), had a significantly shorter remission than patients in the groups with good- or intermediate-risk cytogenetic findings. Therefore, the addition of alkylating agents to fludarabine does not appear to alter the poor prognosis associated with high-risk cytogenetic abnormalities except for patients with del(11q22.3).

Rituximab

Rituximab is a chimeric murine monoclonal antibody that targets the CD20 antigen on the surface of normal and malignant B-lymphocytes, and is the best studied and most widely used monoclonal antibody for the treatment of CLL and B-NHL. CD20, a calcium channel that interacts with the BCR complex, is an ideal target, because CD20 is expressed in 90% to 100% of cases of CLL and B-NHL and is only minimally internalized or shed. Rituximab induces antibody-dependent cellular cytotoxicity (ADCC) and complement-dependent cytotoxicity (CDC), activates caspase 3, and induces apoptosis in CLL and B-NHL cells. These multiple mechanisms of action likely contribute to rituximab's effectiveness in CLL.

In phase I clinical studies in indolent B-NHL rituximab, 375 mg/m² IV was administered weekly for four doses, although the dose and length of treatment were empirically determined. The pivotal phase II trial of rituximab was pursued in 166 patients with relapsed or refractory indolent B-NHL, including SLL. Although an ORR of 60% was achieved in indolent follicle center B-NHL, only four of 30 patients (13%) with SLL/CLL responded. Similarly, disappointing results were obtained in several other small studies. Responses in each of these studies were predominantly in the blood and nodal

compartment with little improvement in BM disease. In contrast, two trials in which higher doses of rituximab weekly (≤ 2250 mg/m² per dose) or in which rituximab was administered thrice weekly (at 375 mg/m²) to relapsed CLL patients showed improved response rates with response duration approaching that achieved in follicular B-NHL. These studies established a role for single-agent rituximab in patients with relapsed CLL and led to combination therapy with other agents.

In contrast to studies in relapsed CLL, weekly single-agent rituximab demonstrated greater clinical efficacy when given to patients with previously untreated SLL/CLL. Forty-four previously untreated patients with SLL/CLL received 4-weekly doses of rituximab 375 mg/m²; the ORR after the first course of rituximab was 51% (CR 4%). Twenty-eight patients with stable or responsive disease received additional 4-week courses of rituximab every 6 months for up to four cycles. However, there was only a modest increase in ORR (58%) and CR rates (9%), and the median duration of PFS of 19 months was shorter than the 36- to 40-month median duration of PFS reported by the same investigators using the same regimen in previously untreated patients with follicle center B-NHL. Nonetheless, this response duration compared favorably with the response duration achieved with fludarabine in the upfront setting, suggesting that rituximab is active and may have a role in the upfront therapy of SLL/CLL.

Rituximab is selective for the B-cell antigen CD20 and therefore has a relatively favorable toxicity profile. Toxicity associated with infusion of this agent commonly occurs with the first infusion of rituximab and may be greater in patients with CLL compared with patients with NHL. These symptoms generally include fever, rigors, transient hypoxemia, dyspnea, and hypotension, which are partly caused by an inflammatory cytokine release syndrome. Although poorly understood, CLL patients with platelet counts less than $50 \times 10^3/\text{L}$ may experience transient, severe thrombocytopenia associated with this infusional toxicity and may require platelet transfusions with the first one or two doses of rituximab. Patients with preexisting thrombocytopenia should therefore have a posttherapy platelet count after the first one or two doses of rituximab. Another uncommon but potentially severe toxicity is a tumor lysis syndrome, which is generally observed in patients with a high circulating peripheral lymphocyte count with CLL variants. Such patients should receive prophylactic allopurinol, hydration, and careful observation, and inpatient monitoring before administration of rituximab can be considered for the highest risk patients. Patients who develop tumor lysis syndrome after the first dose of rituximab can safely receive subsequent doses, especially after the number of circulating CLL cells is reduced. Other rare toxicities with rituximab therapy include delayed neutropenia, hepatitis B reactivation, skin toxicity, interstitial pneumonitis, serum sickness, and progressive multifocal encephalopathy. Patients with prior hepatitis B exposure, as indicated by positive serologies, should receive rituximab only if viral load testing indicates no active disease. Such patients should undergo regular viral load monitoring during and after completion of rituximab therapy, and prophylactic antiviral therapy may be considered to reduce the likelihood of viral reactivation. Patients who develop profound neutropenia, pulmonary, or skin toxicity with rituximab should not be challenged with repeated dosing. In general, rituximab is a very well-tolerated therapy, making it ideal for use in combination with other agents in patients with CLL.

Phase II Studies of Rituximab Chemoimmunotherapy

Given its activity and toxicity profile, rituximab has been combined with cytotoxic chemotherapy in the treatment of CLL, and clinical trials have examined several such chemoimmunotherapy regimens. Studies of chemoimmunotherapy in CLL have focused primarily on fludarabine-based combinations because of the established role of fludarabine therapy in this disease. The approval of bendamustine and potentially its unique mechanism of action has led to combination therapy with bendamustine and rituximab. Finally, given the recent recognition that elderly patients do not benefit from

fludarabine-containing regimens, several trials have also combined rituximab with chlorambucil with promising results. Alternative regimens, including FCR-mitoxantrone (FCR-M) and pentostatin, rituximab, and cyclophosphamide (PCR), have been published and used in CLL but are unlikely to be building blocks for improvement in CLL therapy in the future and are therefore not described later.

Fludarabine and Rituximab

The Cancer and Leukemia Group B (CALGB) 9712 study randomized 104 previously untreated CLL patients to sequential or concurrent fludarabine and rituximab (FR) therapy. Patients received standard fludarabine 25 mg/m² days 1–5 every 4 weeks for six cycles with or without concurrent rituximab 375 mg/m² on day 1 of each cycle with an additional dose on day 4 of cycle 1. Patients in both arms received rituximab 375 mg/m² weekly for four doses beginning 2 months after completion of fludarabine; thus patients in the concurrent arm received 11 total doses of rituximab compared with four in the sequential arm. Patients receiving concurrent FR therapy enjoyed a superior CR rate (47% vs. 28%) and ORR (90% vs. 77%) as compared with patients in the sequential arm. Retrospective comparison to a fludarabine only-containing treatment study performed previously by CALGB demonstrated improved PFS and OS for patients enrolled in the concurrent arm. Analysis of prognostic cytogenetic abnormalities demonstrated that patients with del(11q22.3) and del(17p13.1) have a shorter duration of response to FR. A recent update of this study with a median follow up of 117 months showed that the median OS was 85 months with 71% of patients alive at 5 years. The median PFS was 42 months with 27% progression-free at 5 years. Importantly, an estimated 13% of patients remained free of progression after almost 10 years of follow-up. IGHV-mutated disease status was favorably associated with extended PFS and OS, but not having high-risk cytogenetic abnormality was also associated with a favorable OS. Notably, there were no cases of tr-MN occurring before relapse contrasting with prior studies with fludarabine- and alkylator-containing regimens.

Fludarabine, Cyclophosphamide, and Rituximab

The most favorable phase II results with chemoimmunotherapy have been reported by the MD Anderson group with a combination FCR regimen in both previously treated and untreated CLL. A total of 177 evaluable patients with previously treated CLL received fludarabine 25 mg/m² and cyclophosphamide 250 mg/m² on days 2–4 of cycle 1 and on days 1–3 of cycles 2–6 in addition to rituximab 375 mg/m² on day 1 of cycle 1 and 500 mg/m² on day 1 of cycles 2–6. An ORR of 73% with a 25% CR rate and 16% nodular PR rate was reported, and 12 of 37 patients (32%) in CR achieved molecular remission. The same authors administered FCR to 300 previously untreated CLL patients; the ORR was 95%, with 72% of patients attaining a CR. Six-year PFS was 51%, and OS was 77%. Features associated with poor response included high $\beta_2\text{M}$ levels, del(17p13.1), age older than 70 years, and white blood cell count elevation above $150 \times 10^9/\text{L}$. Late infectious or other complications were uncommon except for tr-MN, which occurred in 9% of patients. The outcome of patients with tr-MN was poor irrespective of treatment. In a multivariate analysis of patients receiving fludarabine-based therapy at MD Anderson, FCR therapy was significantly associated with improved survival, thereby validating the experience with FR, suggesting that rituximab therapy was improving OS. Moreover, patients with mutated IGHV with a low $\beta_2\text{M}$ level did not experience any relapse of their disease after 10 years suggesting that a subset of patients can achieve long-term remissions and potentially cure.

The benefit of adding rituximab to FC was confirmed by the German CLL study group, which randomized 817 physically fit, previously untreated CLL patients, ages 30–81 years, to fludarabine 25 mg/m² on days 1–3 and cyclophosphamide 250 mg/m² IV on days 1–3, with or without rituximab 375 mg/m² day 0 of cycle 1 and 500 mg/m² day 1 of cycles 2–6 every 28 days for six cycles. A total of 761 patients were evaluable for response. FCR induced higher OR (95 vs. 88%) and CR rates (44 vs. 22%) than FC. Median PFS was 32.8 months for FC and 51.8 months for FCR, and the largest benefit

for FCR was observed in Binet stage A and B patients. The OS rate at 37.7 months favored FCR over FC (84% vs. 79%; $p = .01$). FCR resulted in more grade 3 and grade 4 neutropenia (34% vs. 21%) and leukopenia (24% vs. 12%), but there was no difference in the number of severe infections or treatment-related deaths between the two arms. As with other chemoimmunotherapy trials in CLL, neutropenia was more common with FCR than FC. Emerging from this study were numerous biologic correlative studies showing the most predictive test of long-term PFS and OS was attainment of a minimal residual disease (MRD)-negative state using high-sensitivity flow cytometry. In addition, patients with unmutated IGHV disease had a shorter PFS and OS with both FCR and FC, although rituximab appeared to benefit both treatment groups. All groups based upon cytogenetic analysis benefited from rituximab with the exception of the del(17p13.1) and normal karyotype patients, who had similar outcomes to FC or FCR treatment. An update of this study demonstrated that IGHV-mutated CLL have the similar long-term disease free plateau suggestive of potential cure after earlier follow up than the MD Anderson series. Thus, even in the age of new targeted therapy, FCR must be strongly considered as a therapeutic option for the younger patient group with IGHV-mutated disease given the potential for cure with combined chemoimmunotherapy.

Bendamustine and Rituximab

Based on promising single agent activity of bendamustine in previously treated CLL and in vitro studies demonstrating synergy between bendamustine and rituximab, the German CLL Study Group examined the feasibility and safety of this combination in a phase II study in 78 relapsed CLL patients. Bendamustine was administered at a dose of 70 mg/m² days 1 and 2 and rituximab at 375 mg/m² on day 0 of cycle 1 and 500 mg/m² on day 1 of cycles 2–6. Using an intent-to-treat analysis, the ORR was 59% with a CR of 9%. The median PFS was 14.7 months. Response was poor (7%) in the del(17p) patients. Severe infections occurred in 13% of patients. Grade 3 or grade 4 neutropenia, thrombocytopenia, and anemia were documented in 23%, 28%, and 17% of patients, respectively.

A follow-up study (CLL2M) included a total of 117 symptomatic, previously untreated CLL patients who were treated with bendamustine (90 mg/m² on days 1 and 2) and rituximab (375 mg/m² in cycle 1 and 500 mg/m² in cycle 2–6). Treatment was administered every 28 days for up to six cycles. Demographics of the patients included a median age of 64 years with 48% having Binet C disease. The ORR was 91%, and the CR was 33%. After 18 months, 76% of patients were still in remission, and median PFS had not been reached at the time of the report. The treatment was well tolerated with cytopenias and infections being most problematic. Treatment-related mortality (TRM) was 2.6%. Patients with all cytogenetic groups based upon cytogenetic analyses except for del(17p13.1) responded favorably. Based on these encouraging phase II data, the German CLL Study Group conducted a phase III study comparing bendamustine/fludarabine (BR) with FCR (CLL10) in previously untreated, physically fit CLL patients. FCR therapy demonstrated an improved CR (39% vs. 30%) and PFS (median 55 months vs. 41%) as compared with BR but OS was similar after an early follow up. FCR was associated with significantly higher risk of neutropenia, thrombocytopenia, and infections. However, early data in the favorable IGHV-mutated patients has not suggested that a similar disease-free plateau exists with BR as with FCR. Thus, it is our practice in the current era of kinase inhibitor therapy to use FCR when considering chemoimmunotherapy with intent of pursuing extended DFS and potential for patients to be off therapy for an extended period of time.

Chlorambucil and Anti-CD20 Antibodies

Based on the success of chemoimmunotherapy and the potential absence of benefit of nucleoside analogs in elderly CLL patients, Hillmen and colleagues initiated a study in 100 elderly, previously untreated CLL patients combining rituximab (day 1; 375 mg/m² IV cycle 1, 500 mg/m² cycles 2–6) and chlorambucil (days 1–7; 10 mg/

m²/day PO) every 28 days for six cycles. Patients were permitted to receive six additional cycles of chlorambucil if they had evidence of continuing clinical response after six cycles. The median age was 70 years. The OR rate on an intent-to-treat analysis was 82%, with nine patients achieving a CR, 58 patients achieved a partial response (PR), 15 patients achieved a nodular PR (nPR), and 11 patients had stable disease. The median PFS to date is 23.5 months. The response rate in this study was significantly higher than patients receiving chlorambucil alone in the CLL4 study, suggesting a benefit of adding rituximab. A second Italian phase II study using a similar combination of chlorambucil and rituximab together demonstrated a similar favorable response data. Based on these phase II studies, a randomized phase III study comparing chlorambucil (Chl) versus chlorambucil with either rituximab (Chl-R) or the human monoclonal antibody which binds to CD20, obinutuzumab (Chl-O) was conducted by the German CLL Study Group. In this CLL11 trial the Chl-O had higher ORR (78% vs. 65% vs 31%) and CR rates (20% vs. 7% vs. 0%) in Chl-O versus Chl-R versus Chl arms respectively. Similarly, PFS was also improved significantly with Chl-O (median 26 months vs. 16 months vs. 11 months). Importantly, Chl-O was able to induce a higher proportion of MRD-negative responses when compared with Chl-R. Chl-O was associated with higher incidence of infusion reactions and cytopenias but the incidence of infections was similar in all three groups. In a similar study, ofatumumab in combination with chlorambucil was compared with chlorambucil alone in previously untreated patients and demonstrated a significantly prolonged median PFS of 22 months versus 13 months. Based on these results both obinutuzumab and the fully human monoclonal antibody for CD20, ofatumumab were approved in combination with chlorambucil for the treatment of patients with untreated CLL who would not otherwise be candidates for conventional chemotherapy.

Alemtuzumab

Alemtuzumab is a humanized monoclonal antibody against CD52, a cell-surface glycopeptide expressed by virtually all human lymphocytes, monocytes, and macrophages, a small subset of granulocytes, but not erythrocytes, platelets, or hematopoietic stem cells. CD52 is

What Is the Role of Anti-CD20 Antibodies in Chronic Lymphocytic Leukemia?

Studies of rituximab have demonstrated modest single-agent clinical activity in both previously untreated CLL patients using the weekly dosing schedule and in the relapsed state using more intensive dosing regimens. Rituximab does not have activity against CLL with del(17p13.1). For this reason, rituximab monotherapy is generally used in either of these settings only if more definitive therapy cannot be administered because of other comorbid conditions. Rituximab's greatest contribution is to combination therapy both in symptomatic, previously untreated CLL patients and relapsed patients receiving the FR or FCR regimen, particularly in younger patients. Phase III studies have demonstrated the clear benefit of chemoimmunotherapy over traditional chemotherapy alone and have established chemoimmunotherapy as the standard of care for CLL. Several other studies have combined rituximab with other therapies such as bendamustine, chlorambucil, and pentostatin–cyclophosphamide that might be more tolerable to older patients. Inclusion of rituximab in alternative chemoimmunotherapy regimens for patients not appropriate for chemotherapy-containing regimens is reasonable. Multiple other CD20 targeting agents including especially obinutuzumab, however have been reported to have demonstrated superiority over rituximab. Although several studies of maintenance rituximab have been published after completion of chemoimmunotherapy, the benefit of this is uncertain. These studies were performed mostly in patients with low-risk disease who would ordinarily be expected to respond well to conventional therapy. Similar results have also been reported with ofatumumab suggesting a slight benefit in patients relapsing after chemoimmunotherapy. At this time, maintenance rituximab or other CD20 antibody in CLL cannot be justified and should not be used outside of the context of a clinical trial.

expressed on all CLL cells and indolent B-NHL cells. Alemtuzumab has been demonstrated to mediate apoptosis, CDC, and ADCC of CLL cells in vitro. CD52 is not shed, internalized, or modulated and is therefore an ideal antigen for targeted immunotherapy. However, the ubiquitous expression of CD52 on normal lymphocytes and monocytes is predictive of the increased neutropenia, lymphopenia, and infectious complications observed with alemtuzumab therapy. Alemtuzumab has modest efficacy in patients with relapsed disease including patients with del17p disease but not in patients with bulky lymphadenopathy (>5 cm). Responses are better and more durable when it was used in patients with previously untreated disease and comparable with other CD20 antibodies when used in combination with chlorambucil. Similarly, the combination of alemtuzumab with chemotherapy resulted in improved responses but with significantly higher toxicities. Alemtuzumab is not marketed in the U.S. anymore for CLL but is available from the manufacturer on request. Given its infrequent use, the discussion on alemtuzumab has been curtailed and readers are referred to previous editions of this chapter.

What is the Role of Ibrutinib in the Initial Management of Patients With Del(17p13.1)?

Conventional chemotherapy has limited benefit in the initial treatment of patients with del(17p13.1) deletion with the median PFS being in the range of 11–14 months. Limited and early data from the use of ibrutinib has been extremely promising and ibrutinib use has resulted in an ORR of up to 97% in this high-risk group of patients. Responses were rapid and deepened with time and resulted in a PFS at 24-months of 82%. This compares extremely well with historic data with alternative agents used for patients with del(17p13.1) and along with activity observed in patients with relapsed disease, resulted in the approval of ibrutinib for patients with del(17p13.1).

TREATMENT OF PATIENTS WITH RELAPSED CHRONIC LYMPHOCYTIC LEUKEMIA

The approach to reinitiating therapy for CLL patients who have relapsed after initial therapy is similar to that applied to the assessment for initial therapy. Patients need not receive therapy at the first sign of relapse. Rather, patients should have an indication for treatment, as discussed earlier. Patients should have repeat interphase FISH analysis of the peripheral blood or a BM aspirate because patients may acquire additional cytogenetic abnormalities, most notably del(17p13.1), as their CLL becomes more advanced. The incidence of del(17p13.1) increases from 5% in patients at initial diagnosis to nearly half of heavily treated patients with advanced CLL, and acquisition of this abnormality has profound implications on treatment, as will be discussed later. IGHV mutational analysis does not need to be performed if such information has been obtained previously because a patient's IGHV mutational status does not change with time. A BM analysis should be performed if cytopenias are present to confirm that CLL is the cause and to exclude other potential causes of cytopenias such as transformed lymphoma, prolonged BM toxicity from prior therapy, or development of treatment-related myelodysplasia. Patients should be treated according to the indications outlined in Table 77.5. Multiple novel agents have now been approved and more are in the advanced stages of development. The treatment for relapsed disease will continue to evolve with time. In general, therapy is moving away from chemoimmunotherapy to better tolerated targeted oral agents especially for patients older than 70 years of age and those with multiple comorbid conditions.

Agents Targeting B-Cell Receptor Signaling Pathways

BCR signaling and microenvironmental signals are now known to be important in both proliferation and protection of CLL cells in BM

and nodal sites. These findings prompted the introduction of several novel, orally available kinase inhibitors. In particular, agents targeting the δ isoform of PI3-kinase and BTK have shown very promising clinical activity and, importantly, durability of remission over time in refractory CLL patients. Early results from these trials led to the approval of both ibrutinib and idelalisib for the treatment of patients with relapsed CLL. Moreover, ibrutinib was also approved for treatment of patients with del17p disease. The results of these studies are summarized later.

Ibrutinib

Ibrutinib is a potent, irreversible, covalent inhibitor of BTK. BTK is a tyrosine kinase in the Tec family of tyrosine kinases and is an essential element of the BCR signaling pathway. Genetic knockout or inactivation of BTK in mice produces predominantly a B-cell defect with absent B1 lymphocytes, diminished B cells, and disrupted BCR signaling. Mutations in BTK in humans result in a more profound humoral immune defect with absent B cells, immunoglobulins, and an increased incidence of infections. Preclinical work with ibrutinib demonstrated disruption of BCR signaling and in vivo activity in spontaneous canine lymphoma models with documented targeted inhibition of BTK. Preclinical trials demonstrated that ibrutinib promotes apoptosis of CLL cells, inhibits activation of PI3-kinase, ERK1, and NF κ B by external microenvironment signals, and also prevents CLL proliferation.

Collectively, these preclinical studies prompted phase I/II studies with ibrutinib in NHL and CLL. The phase I study of ibrutinib was completed at two dose levels above where BTK inhibition occurred without obtaining a maximum tolerated dose. At the highest dose, toxicity was quite mild, including grade 1/2 nausea, diarrhea, infections, rash, and fatigue. Activity was seen at all doses, including in 9 of 16 CLL/SLL patients. A subsequent trial used the 420 mg daily oral dose of ibrutinib and demonstrated an ORR of 71% with an additional 20% of patients experiencing PR with lymphocytosis (PR+L). The PR+L state observed with ibrutinib does not appear to predict for inferior PFS. Importantly, the responses seen with ibrutinib are sustained and resulted in a PFS of 69% at 30 months. Responses to ibrutinib also tend to improve with time and after a median follow up of 2-years CR rates improved from 2% to 7%. Responses were also seen in patients with del17p who had an ORR of 55.9% with a median duration of response of 25 months. This compares favorably in historical comparison with either cyclin-dependent kinase inhibitors or other conventional therapies used in the past for patients with del17p. Patients with previously untreated CLL also appear to benefit from ibrutinib monotherapy with an ORR of 71% and 13% PR+L. PFS was 96% at 2 years. Ibrutinib was also well tolerated and the most common side effects were diarrhea, nausea, and fatigue. A subsequent randomized study comparing ibrutinib with ofatumumab in relapsed CLL confirmed the benefits of ibrutinib with an improved response rate, PFS and OS. However, these studies also demonstrated a higher incidence of both minor bleeding possibly caused by a collagen-mediated platelet aggregation defect and atrial fibrillation with ibrutinib. Ibrutinib should therefore be used with caution in patients receiving concurrent anticoagulation with warfarin and patients should be taken off treatment for 3–7 days before and after surgical procedures. Patients experience a progressive decline in the incidence of infectious complications with continued use of ibrutinib and do not require routine antimicrobial prophylaxis. There is also subjective improvements in stress, depressive symptoms, fatigue, and quality-of-life in patients.

Since treatment with ibrutinib does not result in CRs in the majority of patients, at this time it is recommended that treatment be continued indefinitely until disease progression or unacceptable toxicity, since ibrutinib discontinuation in heavily pretreated patients often results in rapid disease progression. Development of resistance has been rare but whole-exome sequencing has identified a cysteine-to-serine mutation in BTK at the binding site of ibrutinib and three distinct mutations in PLC γ 2. Functional analysis revealed that the C481S mutation of BTK results in a protein that is only reversibly inhibited by ibrutinib. The R665W and L845F mutations

in PLC γ 2 are both potentially gain-of-function mutations that lead to autonomous B-cell–receptor activity. To improve the depth of response, ibrutinib is being combined with various other agents like rituximab and BR or FCR. This has resulted in higher response rates but improvements in PFS are yet to be demonstrated. The combination of ibrutinib and rituximab in patients with high-risk CLL was generally well-tolerated and resulted in an OR rate of 95% and a PFS of 78% at 18 months in all patients, and 72% in patients with del17p. A randomized phase III trial comparing BR + placebo with BR + ibrutinib in patients with relapsed CLL demonstrated a significant improvement in PFS in the ibrutinib arm. From preliminary reports, PFS at 18 months was 79% for the BR + ibrutinib arm and 24% in the BR + placebo arm. Therapy was generally well tolerated with a slightly higher percentage of patients in the ibrutinib arm discontinuing therapy. These promising results have resulted in the initiation of two pivotal trials for the initial treatment of patients with CLL. The ECOG (ECOG 1912) trial is for patients younger than 70 years of age and is comparing patients treated with either FCR or ibrutinib + rituximab. The Alliance (A041202) trial is for patients ≥ 65 years of age and is comparing BR versus ibrutinib + rituximab versus ibrutinib alone. Participation in these trials is strongly encouraged and they have the potential to change the treatment paradigms for this disease.

Idelalisib

Idelalisib (GS1101, CAL-101) is an orally bioavailable, isoform specific, PI3-kinase- δ inhibitor that, at therapeutic levels obtained in patients, does not inhibit other isoforms of PI3-kinase. Genetic mouse models knocking out PI3-kinase- δ demonstrate predominantly a B-cell defect, absent B1 lymphocytes, and disrupted BCR signaling. Preclinical studies demonstrated that idelalisib promotes the apoptosis of CLL cells via a PI3-kinase- δ pathway and inhibits signals from the microenvironment that protects CLL cells from apoptosis. Based in part on these data, a phase I study in healthy volunteers showed this agent to be well tolerated, and subsequently a large phase I study in NHL, CLL, multiple myeloma, and AML was undertaken. Idelalisib was active at all dose levels tested, with the dose-limiting toxicity being reversible transaminitis that generally occurs during the first 2 months of therapy in approximately 5% to 20% of patients, depending on histology. Although patients with NHL experienced a higher incidence of transaminitis, the cause of which is poorly understood, the incidence of transaminitis was less than 5% in CLL patients. In a phase I trial of 54 patients, with relapsed/refractory high-risk CLL patients, idelalisib resulted in an ORR of 72 percent (including PR+L). The median PFS was 15.8 months. Therapy was generally well-tolerated with the most commonly observed grade ≥ 3 adverse events being pneumonia in 20%, neutropenic fever in 11% and diarrhea in 6% of the patients. Subsequent studies have been undertaken with idelalisib combining it with rituximab, ofatumumab, obinutuzumab and bendamustine/rituximab, showing that combination therapy with idelalisib is feasible. The combination of idelalisib and rituximab was also compared with rituximab and placebo in a phase III trial and resulted in an ORR of 81% versus 13% and PFS at 1 year in excess of 90% versus 5.5 months in the rituximab and placebo arm respectively. Serious toxicities observed with idelalisib were similar to the ones observed with the single agent. Based on these results, idelalisib was approved in combination with rituximab for the treatment of patients with relapsed CLL who would not be considered suitable for conventional chemotherapy.

Ofatumumab in Relapsed Chronic Lymphocytic Leukemia

Ofatumumab is a fully human type I anti-CD20 monoclonal antibody that was initially approved for the treatment of CLL in late 2009. In vitro, it has improved CDC, ADCC, and direct killing (with cross-linking), compared with rituximab. Ofatumumab has a different binding epitope of CD20 than rituximab, binding to both the small and large extracellular loops of CD20, and a slower off rate as well. Ofatumumab is able to kill rituximab-resistant CLL cells caused by its greater induction of CDC and its ability to kill cells with low CD20 expression, which may be relevant given the limited CD20

expression by CLL cells. Based on these promising data, a phase I/II study of ofatumumab, given at doses of 500–2000 weekly for four doses in 33 relapsed or refractory CLL patients, demonstrated that it is generally well tolerated even at higher doses. Ofatumumab was active, with an ORR of 50% in the cohort treated at 2000 mg. Infusion-related adverse events were similar to those reported with rituximab and decreased after the first infusion. Infections were fairly common, occurring in 51% of patients, including one fatal infection. These results prompted a pivotal, single-arm study of ofatumumab administered as eight weekly infusions of ofatumumab followed by 4 monthly infusions. Patients received 300 mg as the first dose to minimize infusion-related reactions, and the dose was increased to 2000 mg for all subsequent infusions. Patients included in this study were required to be fludarabine-refractory and also alemtuzumab-refractory (FA-refractory group; $n = 95$) or to have bulky lymphadenopathy larger than 5 cm (BF-refractory group; $n = 111$). The ORR, as assessed by an independent review committee, was 51% for the FA-refractory group and 44% for the BR-refractory group, with two CRs observed in the BF-refractory group. All other responses were partial. The median duration of response was 5.7 months in the FA-refractory group and 6.0 months in the BF-refractory group with most patients progressing during treatment. The median PFS was 5.5 months in both the FA-refractory and BF-refractory groups. Median OS was 14.2 months and 17.4 months, respectively. For rituximab-treated ($n = 117$), rituximab-refractory ($n = 98$), and rituximab-naïve ($n = 89$) patients, the OR rates were 43%, 44%, and 53%, respectively; median PFS was 5.3, 5.5, and 5.6 months, respectively; and median OS was 15.5, 15.5, and 20.2 months, respectively. Thus, prior exposure to rituximab did not affect the response to ofatumumab.

The presence of del(17p13.1) was associated with a lower response rate and shorter median PFS in both patient groups (37% vs. 56% and 3.3 months vs. 5.5 months in FA-refractory group; 22% vs. 49% and 3.8 vs. 5.6 months in BF-refractory group). Thus, in contrast to rituximab, ofatumumab is active as a single agent in del(17p13.1) CLL but has less activity as compared with alemtuzumab. Toxicity included infusion-related reactions, infections, and cytopenias. This trial led to accelerated approval of ofatumumab for the treatment of patients with fludarabine- and alemtuzumab-refractory CLL, however, a phase III study of ofatumumab versus physician's choice of therapy in bulky, fludarabine-refractory CLL has preliminarily not documented a significant improvement in PFS. Determination of the clinical superiority of ofatumumab over rituximab will require randomized trials comparing equivalent doses and as a result the use of ofatumumab has been limited in CLL. In addition, the approval of BCR signaling inhibitors has further diminished the use of this option in salvage therapy of CLL.

Other Emerging Therapeutic Modalities for Chronic Lymphocytic Leukemia

Several other promising therapeutics are in late phase II/III clinical trials for CLL. Those with documented activity in this disease that have potential to be approved for use in CLL are described here.

BCL2 Inhibitors

The BCL2 antiapoptotic protein is overexpressed in CLL and has been shown to disrupt apoptosis of CLL cells. Although the BCL2 antisense molecule genasense did not meet the bar for regulatory approval in CLL, attempts to target BCL2 with small molecule inhibitors have proceeded. Another potent inhibitor of BCL2, navitoclax (formerly ABT263), demonstrated single agent activity in relapsed CLL with a target specific (BCL-XL) dose-limiting toxicity of profound thrombocytopenia. A second-generation oral BCL2 inhibitor venetoclax (ABT-199) that lacks off-target effects on BCL-XL is currently being evaluated in clinical trials and has shown impressive activity with deep remissions in patients with relapsed and refractory CLL including those who have del17p. Therapy with venetoclax has been complicated by the development of episodes of

fulminant tumor lysis syndrome especially in patients with high burden of disease and mitigation strategies have been developed to improve its safety and reduce the incidence of hyperacute tumor lysis. Early results have demonstrated impressive activity of this agent in patients with relapsed disease with an ORR of 88% with 31% CRs including in patients with del17p. Venetoclax use also resulted in deep MRD-responses that have persisted for sustained periods. It was generally well tolerated and the most common adverse events were cytopenias. Multiple studies are currently ongoing to further establish the role of venetoclax as monotherapy or in combination with other agents for patients with CLL.

Chimeric Antigen Receptor T-Cell Therapy

To date, efforts at directing T-cell immune suppression toward the tumor cells have been relatively limited. A major development has been preclinical and early phase I studies demonstrating that ex vivo transfected T cells with chimeric T-cell receptors bearing both CD3 and also a B-cell-specific antigen (most often CD19) have great potential to eradicate established B-cell tumors after administration into both xenograft models and, recently, patients with refractory CLL. Even though chimeric antigen receptor T cell (CAR-T) therapy has preliminarily shown deep and durable responses, toxicity remains a major concern and it continues to require significant development and optimization before this can be readily administered widely.

Lenalidomide

Lenalidomide (Revlimid), is an immunomodulatory drug that is a more potent analog of thalidomide. Lenalidomide is approved for marketing in multiple myeloma and transfusion-dependent myelodysplasia. Lenalidomide has clinical activity in a variety of other malignancies, including CLL. Two initial studies examining either an intermittent 25 mg PO daily for 21 days or 5 mg with dose escalation to 10 mg PO as tolerated given as continuous therapy were pursued initially in relapsed CLL. The higher dose, intermittent schedule was active with an ORR of 47% and 9% CR. Major side effects of therapy were cytopenias, rash, and tumor flare, which in some cases can be life threatening. The continuous, low-dose regimen had a 32% intent-to-treat ORR with a 7% CR rate. Toxicity was less with this schedule but still included cytopenias in most. On the basis of these promising phase II clinical studies, a large, multicenter trial randomizing patients to low-dose (10 mg) or high-dose (25 mg) lenalidomide was undertaken, which was halted early because of life-threatening adverse events in patients receiving the higher dose of therapy. Subsequent studies have shown that lower doses of lenalidomide administered as continuous treatment in patients with relapsed CLL are feasible. These data have prompted several single agent studies in symptomatic, previously untreated CLL in which the clinical activity has ranged from an ORR of 56% to 65% with up to 10% CR. Most provocative of these studies was the observation that lenalidomide reversed the hypogammaglobulinemia observed in CLL patients. PFS with this treatment is approximately 2 years. Associated toxicity, includes tumor flare, cytopenias, rash, and infection, but these events are manageable. Lenalidomide was subsequently combined with other agents, most notably anti-CD20 antibodies such as rituximab and ofatumumab, or used as consolidation therapy after purine analog or bendamustine-based induction therapy. Antibody combination therapy diminished the tumor flare but was associated with increased cytopenias. Similarly, lenalidomide as consolidation therapy after PCR-based treatment, appeared to potentially extend PFS over that previously seen with PCR alone. Unfortunately, a pivotal trial comparing chlorambucil with lenalidomide was halted because of higher mortality observed in elderly patients on the lenalidomide arm. No obvious cause of the increased mortality has been identified. This has significantly limited the prospects of further development of this agent in CLL. However, lenalidomide has profound immunologic effects in patients

with CLL and the immune modulatory effects could be used as a strategy for earlier control of the disease or as an adjuvant to vaccine-based approaches. Because of its relative modest activity in heavily pretreated patients, other alternatives for first-line therapy, and the potential for life-threatening tumor flare and other toxicities associated with lenalidomide, this agent should only be considered as part of a well-designed clinical trial despite its FDA approval for other indications (MDS and multiple myeloma).

Other Agents

Therapeutic antibodies or small modular immune pharmaceuticals targeting surface antigens, including CD19 (Xm5574), CD37 (odertuzumab, IMG529, and MAB 37.1), and BAFF-R (VAY736), are under development. In addition, therapeutic agents targeting signal transduction pathways (HSP-90 inhibitors, Syk inhibitors, AKT inhibitors, ILK inhibitors, NFκB inhibitors, and PP2A activating agents) are in early clinical development. Finally, agents targeting epigenetic events or innate immune activation (CpG oligonucleotides or IL-21) have promising data to support their ongoing early clinical investigation.

Stem Cell Transplantation

For many years, autologous and allogeneic SCT was extensively used for treatment of CLL late in the course of the disease. However, trials of SCT have indicated that patients with multiply relapsed and chemotherapy-resistant disease are at highest risk for both relapse and TRM. In addition, many patients with heavily treated CLL cannot be adequately cytoreduced or disease control cannot be maintained for a sufficient period of time to obtain insurance approval and find a suitable allogeneic donor, producing a selection bias that often excludes patients with the most refractory or aggressive disease from actually receiving a SCT. The recognition that patients with poor prognostic features such as del(11q22.3) and del(17p13.1) and patients who fail to achieve CR after receiving regimens such as FCR have a short remission duration, had prompted many transplant centers to consider earlier application of allogeneic SCT as therapy for CLL, including its use as consolidation treatment after induction therapy for the highest risk patients. The timing of SCT has been thrown into a bigger conundrum with long-term disease control seen in patients with relapsed disease including patients with high risk disease receiving ibrutinib. Recent data has identified a subgroup of patients with a complex karyotype that have a shorter PFS despite kinase inhibitor therapy. Referral of such high-risk CLL patients at the time of treatment to an experienced transplant center for evaluation, potential tissue typing of the patient and his or her siblings, and initiation of an unrelated donor search (if needed) should be considered. Although autologous SCT has been used historically as a treatment for CLL, nonmyeloablative allogeneic SCT is the preferred modality for most patients requiring a transplant unless a suitable allogeneic donor is not available. Autologous SCT is no longer used in CLL because of a lack of a survival advantage, only modest benefit in PFS, and a high risk of tr-MN with this modality. Therefore, autologous SCT is not reviewed in this chapter.

Myeloablative Allogeneic Stem Cell Transplantation

The use of an allogeneic donor provides an immunologic graft-versus-leukemia (GVL) effect for patients with CLL. Limited data suggest that total body irradiation (TBI)-containing conditioning regimens are superior to chemotherapy-only regimens in CLL transplant patients. A small study of 25 patients demonstrated a 100-day TRM of 57% in patients who received busulfan and cyclophosphamide (Bu/Cy; $n = 7$), compared with 17% for patients who received a TBI-containing regimen ($n = 18$). Five-year actuarial survival was 56% for 14 patients transplanted with TBI regimens during

1992–1999. A study of Cy/TBI in 28 CLL patients observed a 100-day TRM of 11%. Five-year PFS and OS were 78% and 78% for chemosensitive patients compared with 26% and 31% for refractory patients.

A retrospective European Society for Blood and Marrow Transplantation (EBMT) study of 135 patients showed 54% 3-year OS and 40% 100-day TRM. The International Bone Marrow Transplant Registry Database (IBMTR) reported similar findings, with 45% 3-year OS and 30% 100-day TRM in 242 patients. The high TRM may be explained in part by the late stage of the disease in many of these patients. Median time from diagnosis to SCT was 41 and 46 months in these two studies, and 37% of patients in the EBMT study were chemorefractory before transplant. In a Canadian study of allogeneic SCT in 30 CLL patients, the 5-year EFS and OS were both 39%, with 48% for patients with sibling donors. The role of unrelated donor allogeneic SCT was examined by a multicenter study of 38 patients, 92% of whom received TBI. Five-year PFS and OS were 30% and 33%, and TRM was 38%. Although there are no prospective randomized studies, a retrospective comparison showed a 3-year DFS of 57% for allogeneic SCT versus 24% for purged autologous SCT. Finally, allogeneic SCT appears to overcome the adverse prognosis associated with an unmutated IGHV; an analysis of 34 CLL patients who underwent SCT found that only two of 14 patients who received allogeneic SCT relapsed, compared with 13 of 20 patients who underwent autologous SCT. Thus, myeloablative allogeneic SCT may provide superior DFS to patients with CLL compared with autologous SCT. Although the 3-year DFS after allogeneic SCT is approximately 50%, longer follow up is needed to determine if the disease remissions are durable. However, this DFS advantage is offset by significantly higher TRM, thus limiting the use of allogeneic SCT in CLL. Limited data indicate that Bu/Cy may be particularly toxic in this population; by contrast, TBI regimens have acceptable TRM. To preserve the immunologic GVL effect while reducing TRM, the focus of clinical SCT practice in CLL has turned to nonmyeloablative or reduced-intensity allogeneic SCT.

Nonmyeloablative Allogeneic Stem Cell Therapy

Ideally, the goal is to harness the GVL effect of allogeneic SCT for patients with CLL while reducing TRM from acute graft-versus-host-disease (GVHD), acute infection, and organ toxicity associated with myeloablative conditioning. Fludarabine, busulfan, and ATG were administered to 30 German CLL patients; the stem cell source was a matched related ($n = 15$) or unrelated ($n = 15$) donor. Grade 2–4 acute GVHD was observed in 56% of patients and 75% developed chronic GVHD. Responses were seen in 93% of patients, with 40% achieving CR. Of note, it took up to 2 years for patients to achieve CR, suggesting a GVL effect. All patients achieved a molecular CR by PCR, but only six patients were in continued molecular CR after a median follow up of 2 years. Two-year TRM, PFS, and OS were 15%, 67%, and 72%, respectively. The EBMT retrospectively examined 77 CLL patients who received a variety of nonmyeloablative conditioning regimens, followed by allogeneic SCT. The 1-year TRM was 18%, and the 2-year probability of relapse was 31%. Two-year DFS and OS were 56% and 72%, respectively. Nineteen patients received donor lymphocyte infusions (DLIs) for relapse or incomplete donor chimerism, but only seven responded to DLI (37%). Unfortunately, this study was complicated by the heterogeneity of conditioning regimens and the use of ATG or Campath-1H for T-cell depletion of the grafts in 40% of patients. A retrospective analysis of 73 CLL patients who underwent nonmyeloablative SCT and 82 patients who underwent myeloablative allogeneic SCT showed that the TRM was significantly reduced in the former group, with a hazard ratio of 0.4; however, there was no difference in EFS or OS between the two groups.

Sixty-four patients received 200 cGy of TBI, with ($n = 53$) or without ($n = 11$) fludarabine followed by an allogeneic SCT from a related ($n = 44$) or unrelated ($n = 20$) donor. The 2-year DFS and OS were 52% and 60%, respectively, and the 2-year TRM was 22%. The incidence of relapse at 2 years was 26%, and the mortality

because of relapse was 18%. Finally, a British study of 41 CLL patients who received fludarabine, melphalan, and alemtuzumab followed by an allogeneic SCT from a related ($n = 24$) or unrelated ($n = 17$) donor observed a 2-year OS and TRM of 51% and 26%. Eleven patients (27%) relapsed and received escalated DLIs, but only three patients had a sustained response to DLI. Five patients (12%) died of relapsed disease.

Given the approval and outstanding results observed with agents that target BCR signaling, the actual timing of transplantation in CLL has been questioned. Our own practice is to not consider reduced intensity allogeneic transplant for CLL in patients unless they have relapsed after ibrutinib. An exception to this is the younger patient with a complex karyotype receiving ibrutinib where transplant might be considered as part of consolidation therapy given the high risk of eventual relapse. Further follow up on outcome of the kinase inhibitors will be required before definitive recommendations can be made to where transplant should be considered in CLL.

Management of Chronic Lymphocytic Leukemia in Specialized Centers

Given the recent advent of prognostic markers and treatment options in CLL, a recent study that examined the impact of physician expertise on patient outcomes in CLL has shown that disease-specific expertise made significant differences in outcomes across all aspects of patient care from prognostic evaluation to choice of therapy. These findings suggest that the expertise of the physician caring for the patient with CLL/SLL is an independent prognostic variable that may not be related to the number of patients he or she manages. We therefore recommend that all patients with newly diagnosed CLL/SLL should be managed in consultation with a CLL expert at a tertiary care center with access to the most recent molecular diagnostic tools.

SPECIAL CLINICAL SCENARIOS IN CHRONIC LYMPHOCYTIC LEUKEMIA

Young Patients (Younger Than 50 Years of Age) With Chronic Lymphocytic Leukemia

As mentioned previously, CLL is a disease of elderly adults, with only 10% of patients being younger than the age of 50 years at diagnosis. Although CLL patients live for a prolonged period of time, young patients without comorbid illnesses have a great potential to have their lives significantly shortened by the disease, irrespective of their cytogenetic abnormalities. In addition, stress associated with job performance, insurance coverage maintenance, and disease-related symptoms are most significant in this age group. Special attention to psychosocial issues related to CLL should occur early during the course of the disease to allow patients to maintain or resume their normal lifestyles as soon as possible. In the absence of impending need for therapy, our approach is generally not to empirically pursue HLA typing or examine transplant options before the development of symptomatic disease. When therapy is initiated for this group of patients, aggressive intervention to promote prolonged remission duration is always compared with prolonged disease control state with the use of kinase inhibitors. SCT and/or CAR-T-cell therapy is generally considered for patients in this age group who have high-risk cytogenetic abnormalities in first remission and for all patients who relapse after initial therapy unless high-risk cytogenetic abnormalities are not present and a CR is attained.

Patients With Fludarabine-Refractory Chronic Lymphocytic Leukemia

Fludarabine-refractory CLL is generally considered to exist if a patient has not responded to a fludarabine-based therapy or relapses within

6 months of completing such a regimen. Several retrospective studies have documented a short survival time (9–12 months) and a particularly high frequency of both bacterial and opportunistic infections in this patient population. With the introduction of chemoimmunotherapy as initial therapy, another poor prognostic group includes patients relapsing within 2 years of FCR- or FR-based therapy. These patients have a significantly shorter PFS with subsequent therapies. Other therapeutic agents such as bendamustine, ofatumumab, and alemtuzumab have been evaluated in this setting and have modest activity and produce relatively short remissions. Newer kinase inhibitors have resulted in impressive responses and PFS and are the recommended therapeutic option for the vast majority of patients with relapsed disease. Currently there is no consensus about the management of patients relapsing after kinase inhibitor therapy and these patients should be considered for participation on clinical trials. The complexities of complications, poor therapeutic options, and acute features of this advanced form of CLL can put great strain on the patient, family members, and general hematologist alike. Referral of such patients to tertiary CLL centers for access to clinical trials and treatment of these specialized needs should be considered for patients with fludarabine-refractory, short remission after chemoimmunotherapy and relapsed disease after kinase inhibitors.

Patients Relapsing After Kinase Inhibitors

The use of kinase inhibitors has significantly transformed the management of CLL, and patients are now experiencing prolonged progression-free intervals. Less than 5% of patients with previously untreated disease who have been treated with ibrutinib in the front-line setting have experienced disease progression at 3-years of follow-up. However, a larger proportion of patients have disease progression when they were treated with either ibrutinib or idelalisib in the relapsed setting. The majority of these patients have high-risk disease and have failed prior chemoimmunotherapy based treatments. Moreover, patients also experience transient disease flares if they have to temporarily hold therapy for routine surgical or unrelated medical procedures. There is limited data to guide management of these patients and multiple trials are currently underway to address these issues. Early experience with these patients indicate that switching kinase inhibitors for progressive disease is a feasible option in a subset of these patients. Similarly, there is no direct comparative data comparing the efficacy of these agents and a formal recommendation cannot be made regarding the choice for initial kinase inhibitor therapy. Therapy should be tailored to patient needs and comorbid conditions and special consideration should be made for patients who require long-term anticoagulation in which idelalisib might be a better option, and for patients with lung, liver, or gastrointestinal issues in whom ibrutinib might be more suitable.

Richter Syndrome

Richter syndrome (RS), the development of high-grade lymphoma in patients with CLL, was described by Maurice Richter in 1928. Over the years, the classification of RS has expanded to include lymphoid malignancies such as Hodgkin disease, lymphoblastic lymphoma, PLL, and hairy cell leukemia (see Fig. 77.4A–C). Incidence estimates range from 2.8% to 10.7%. Recent studies have suggested that the development of RS may be related to the evolution of an abnormal clone unrelated to the underlying CLL clone. Clearly identifiable risk factors for the development of RS are lacking, and its development has been shown to be independent of disease stage, duration of disease, type of therapy, or response to therapy. However, the presence of diffuse lymphomatous involvement, advanced Rai stage, IGHV-unmutated disease, ZAP-70 expression, high LDH, del(17p13.1), high serum β_2 M levels, and recently NOTCH1 mutations may predict the development of RS. RS is characterized by sudden onset of B symptoms (fever, night sweats, weight loss) and rapidly progressive lymphadenopathy at any anatomic site. Rarely, the lymphomatous

clone may arise from the bone or an extranodal site. Laboratory abnormalities including anemia, neutropenia, and thrombocytopenia which may be caused by large-cell transformation in the BM. A rapid increase in the serum LDH is seen in the majority of patients. The diagnosis is generally made after examining the histology of a rapidly enlarging lymph node, which typically reveals large-cell lymphoma. PET scans can be helpful in these patients to localize the most hypermetabolic node for biopsy. Historically, RS has been treated with regimens similar to those used for the treatment of large-cell lymphomas involving multiple agents such as methotrexate, doxorubicin, cyclophosphamide, vincristine, prednisone, bleomycin, dexamethasone, cytarabine, and cisplatin (e.g., methotrexate with leucovorin rescue, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin [MACOP-B], CHOP-B, dexamethasone, high-dose cytarabine [ara-C], and cisplatin [Platinol] and vincristine, doxorubicin, dexamethasone [VAD]) in combination with rituximab. Other regimens incorporating oxaliplatin have been reported, although their benefit in RS is uncertain over traditional lymphoma regimens. Our institution prefers dose-adjusted infusional therapy (R-EPOCH) for the initial treatment of these patients. The duration of response and the OS rates are dismal, with most patients likely to die within 6 months of their diagnosis despite aggressive therapy. Long-term remissions and survival have been reported in a few patients after allogeneic SCT, but this approach is associated with a high TRM. When Richter transformation occurs, treatment on a clinical trial and consolidation with allogeneic SCT is the preferred treatment.

Similar to RS, prolymphocytic transformation (PT) occurs in fewer than 10% of patients with CLL. PT is characterized by the appearance of large, immature prolymphocytes in the peripheral blood, which make up >55% of the peripheral circulating malignant lymphoid cells. These patients may be older with advanced disease and have more pronounced lymphadenopathy and splenomegaly. PT is associated with a poor outcome, with limited survival beyond 1 year. These patients often have del(17p13.1) but do appear to respond to many of the newer therapies coming forward for treatment of CLL. Allogeneic SCT may also be used as a potentially curative therapeutic option.

Hodgkin lymphoma can also manifest as a form of RS and may have a better outcome provided patients are treated appropriately. Identification of this diagnosis can sometimes be challenging because of its localization to the bone marrow, lower standardized uptake value (SUV) readings on PET scan, and also more insidious onset as compared with the diffuse large B-cell lymphoma (DLBCL) presentation of RS. Hodgkin lymphoma disease in the setting of CLL can be treated as de novo disease with some individuals attaining long-term remissions. Unlike DLBCL transformation of CLL to RS where reduced intensity allogeneic SCT is recommended, we generally do not pursue this in individuals with Hodgkin lymphoma transformation.

Secondary Malignancies in Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia is associated with an increased risk of secondary malignancies. These include not only hematologic malignancies such as MDS and AML associated with the use of chemotherapeutic agents but also solid tumors such as Kaposi sarcoma, malignant melanoma, and laryngeal and lung cancers. The increased incidence of secondary malignancies may be attributable to multiple reasons, including the immune dysfunction associated with CLL, the frequent infectious complications, the carcinogenic side effects of the various chemotherapeutic agents, and the increased and close medical surveillance that patients with CLL receive from trained oncologists.

Hypersensitivity in Chronic Lymphocytic Leukemia to Mosquitoes and Insect Bites and Treatment

Patients with chronic lymphocytic leukemia commonly exhibit an exaggerated cutaneous response to insect bites. This was first reported in 1965 by Robert Weed, who documented a hypersensitivity

reaction to insect bites in 8 of 97 patients with CLL over a 13-year period. The reaction is characterized histologically by the presence of a dermal infiltrate composed of a mixed population of T and B cells, eosinophils, and eosinophilic granule protein. The extent of eosinophilic degranulation may also correlate with the severity of symptoms. Clinically, these patients present with recurrent, painful, bullous eruptions that may be traced to an insect bite in some instances. In limited cases, we have also observed that CLL patients have hypersensitivity to bed bugs, and this should be considered in the differential diagnosis. Identification and avoidance of known triggers may be useful in some cases, but most patients are unable to identify the inciting exposure. Treatment with a short course of steroids is usually effective, but these patients frequently relapse and may require multiple courses of therapy. Dapsone and chlorambucil may also be useful in severe, recurrent cases.

Other cutaneous conditions are also common in CLL patients, with up to 45% reporting some form of skin involvement. These include petechial, purpurial, or ecchymotic lesions related to thrombocytopenia; infectious eruptions such as herpes simplex and zoster; and direct leukemic involvement in fewer than 10% of all patients with advanced disease.

INFECTIONS IN PATIENTS WITH CHRONIC LYMPHOCYTIC LEUKEMIA

Infectious complications remain the leading cause of morbidity and mortality in patients with CLL. The incidence of infectious complications has been estimated to be as high as 80% with a mortality rate of approximately 60%. Various factors contribute to the increased incidence of infectious complications in CLL, the most important being progressive disease affecting host immunity through an impaired antibody response and hypogammaglobulinemia; weakened host cellular immune responses, including impaired macrophage function; a decrease in T-regulatory cells; and, finally, the acquired defects after immunosuppressive chemotherapy.

Recent studies have examined predictors of acquiring severe infections in patients with CLL. In their retrospective analysis of infection-related mortality in 280 patients, advanced age, clinical stage B or C disease, unmutated IGHV, and positive CD38 status have been identified as independent predictors of both shorter time to first infection and infection-related mortality. Other risk factors that may also have an impact on development of infections include type of initial therapy and development of renal insufficiency.

Historically, sinopulmonary infections from encapsulated bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae* have been the most common cause of infectious complications in patients with CLL. With the recent use of more potent cytotoxic chemotherapy and the resultant profound myelosuppression, an increased frequency of severe pulmonary infections, bacteremia, and gram-negative infections has been reported. Infections caused by atypical organisms such as *Listeria monocytogenes*, *Nocardia* spp., *Mycobacterium* spp., and *Neisseria meningitidis* are relatively infrequent in patients who receive conventional chemotherapy. Treatment for presumed infection should be initiated empirically in CLL patients who develop fever because fever in CLL patients usually indicates an active infection. Therapy should be tailored to the particular organ involved and the sensitivity of the organism. Prophylactic antibiotics can be initiated for debilitated patients with high-risk disease and significant immune dysfunction.

Viral infections are also commonly encountered in CLL patients (see Fig. 77.3D–E). Herpesvirus infections are especially common in patients treated with nucleoside analogs and alemtuzumab. Chronic, indolent oropharyngeal and circumoral herpes simplex virus (HSV) outbreaks are more frequent than aggressive, disseminated visceral disease. Reactivation of Epstein-Barr virus (EBV) has been implicated in some cases of Richter transformation. Other viruses may cause severe systemic disease in patients with CLL. Varicella zoster virus can cause herpes zoster, herpetic neuralgia, and rarely meningoencephalitis, parvovirus B19 can cause severe polyarthritides and pure

RBC aplasia, and JC polyoma virus has been implicated in the development of progressive multifocal leukoencephalopathy. Management of these infections depends on early recognition of disseminated viral disease, timely initiation of antiviral therapy in cases of HSV and EBV, and a low threshold for the introduction of prophylactic acyclovir and supportive therapy. All patients should be provided instructions to identify the signs and symptoms of herpes virus infection at the time of diagnosis of CLL.

Fungal infections are not typically observed in CLL in the absence of treatment with corticosteroids or other immunosuppressive therapy for autoimmune complications arising from CLL. Cryptococcal meningitis, pneumonia, and fungemia are well-recognized events in patients with CLL and are associated with significant morbidity and mortality. More cases of *P. carinii* pneumonia, systemic candidiasis, and aspergillosis have been reported since the advent of combination nucleoside analog therapy with steroids. Treatment of the infection is dictated by the identification of the particular organism. Trimethoprim-sulfamethoxazole is routinely used as effective prophylaxis against *P. carinii* infections, especially during and immediately after the use of nucleoside analogs or alemtuzumab. Fungal prophylaxis with posaconazole may also be used during protracted therapy with high-dose steroids to avoid invasive aspergillosis.

Prophylactic Strategies for Infections

Routine use of prophylactic antibiotics is generally not used for CLL despite the higher frequency of infections observed in patients with this disease. Early recognition of signs and symptoms of infection and prompt initiation of empiric broad-spectrum antibiotics is probably a more feasible and cost-effective approach. When chemoimmunotherapy is used that includes a nucleoside analog or alemtuzumab therapy, prophylaxis for herpes simplex and varicella zoster should be used, particularly in older patients. Trimethoprim-sulfamethoxazole (or other alternative *P. carinii* pneumonia prophylaxis) should also be administered in this setting. Fortunately, kinase inhibitors result in continued decline in the incidence of infectious complications with ongoing therapy, primarily as a result of better disease control and routine prophylactic antibiotics are either not required or can be tapered off in the majority of patients.

Hypogammaglobulinemia is virtually always present in advanced CLL, and several studies have examined whether IV immunoglobulin (IVIG) replacement therapy can reduce the incidence and severity of infectious complications. Patients receiving IVIG in a double-blind, placebo-controlled trial experienced significantly fewer bacterial infections than the placebo group. The therapy was well tolerated with few adverse reactions, but there was no observed benefit in terms of preventing viral or fungal infections. However, other studies have shown an almost 50% reduction in the number of serious infections per year with IVIG infusions. Limited data support the use of IVIG at a higher dose of 600 mg/kg every 4 weeks to reduce the number and severity of respiratory infections. However, the prohibitive cost of IVIG therapy and the fact that it has not been shown to prolong survival argues against its empiric use in all patients. IVIG should be used judiciously and reserved for patients with advanced disease and recurrent infections. The usual dose used is 200–400 mg/kg every 4–6 weeks as needed, with the aim of keeping the trough serum IgG concentration greater than 500 mg/dL. Our group routinely uses this strategy for refractory patients or those who have more than two infections requiring hospitalization during 1 year.

Among the strategies for preventing infections in this patient population is immunization. CLL patients, however, typically respond poorly to pneumococcal and influenza vaccines. Advanced age, advanced disease stage, hypogammaglobulinemia, and low levels of soluble CD23 influence the rate of responses to immunizations. Soluble CD23, a degradation product of membrane-bound CD23, is involved in several aspects of B-cell activation and proliferation and has a synergistic effect on histamine release. Histamine has a direct inhibitory effect on immunoglobulin production by B cells in vitro via histamine type-2 (H2) receptors and acts as an immune regulatory

factor that can be modulated by H2 receptor antagonists. Thus, responses to vaccines may be further enhanced by adjuvant treatment with H2 blockers. Studies have shown that response to protein-conjugated vaccines may be enhanced by ranitidine in CLL patients to as much as 90% compared with 43% in the control group. Unfortunately, this response is not seen with polysaccharide vaccines. Other studies have indicated that protein-conjugated vaccines may be more immunogenic, as shown by a more significant immune response to *Haemophilus influenzae* type b conjugate vaccine than to plain polysaccharide antigen. In light of the paucity of data on an appropriate immunization schedule, we suggest a modified immunization plan based on the recommendations of the Advisory Committee on Immunization Practices. This includes use of Prevnar-13 for pneumococcal prophylaxis and avoiding live vaccines, including the varicella zoster virus.

Growth factors such as G-CSF or granulocyte macrophage colony-stimulating factor can be used prophylactically in high-risk, severely neutropenic patients to shorten the duration and severity of neutropenia.

AUTOIMMUNE COMPLICATIONS OF CHRONIC LYMPHOCYTIC LEUKEMIA

Patients with CLL have a greater predisposition to develop autoimmune hematologic complications, including AIHA, idiopathic thrombocytopenia purpura (ITP), and pure RBC aplasia. AIHA occurs in up to 37% of CLL patients at some time during the course of their disease. A small proportion (10–15%) of patients may present with AIHA at diagnosis. AIHA can have a varied presentation, with patients developing signs of anemia, including weakness, lethargy, dyspnea on exertion, and dizziness over a period of months. Examination may reveal pallor, jaundice, hepatosplenomegaly, and lymphadenopathy. Hemolysis can cause mild to moderate indirect hyperbilirubinemia, elevated LDH levels, and hemoglobinuria. The direct antiglobulin Coombs test result is positive in up to 74% of patients with CLL, but not all patients develop hemolysis. Most of the antibodies produced are warm reactive, but patients can occasionally present with cold agglutination syndrome. The antibodies are mostly polyclonal and usually a product of normal B cells rather than the leukemic clone.

In contrast to the high frequency of AIHA in CLL, ITP or ITP and AIHA, or Evans syndrome, occurs less frequently in CLL. These events can occur throughout the entire course of CLL and are much more difficult to diagnose because of the absence of multiple implicating laboratory features as seen with AIHA. Given the small number of patients with AIHA, there are no data from controlled trials to guide the management of AIHA. Glucocorticoids have been used since the 1940s and are considered the first line of therapy. Most patients will respond to prednisone at a dose of 1 mg/kg for 10–14 days followed by a slow taper over 2–3 months, depending on the extent of hemolysis. ORRs of up to 90%, with 65% CRs, have been reported with the use of steroids. Unfortunately, approximately 60% of patients relapse when steroid therapy is stopped. Rituximab 375 mg/m² weekly for 4 weeks is often effective for steroid-resistant AIHA or ITP and if steroid withdrawal is not possible. Because of the long-term morbidity of prolonged steroid administration in CLL and data demonstrating benefit to concurrent steroids and rituximab for rapid withdrawal of corticosteroids in ITP, our group gives these two agents concurrently at diagnosis of ITP or AIHA unless contraindicated (e.g., hepatitis B). IVIG, the next line of treatment, induces responses in 40% of patients for both AIHA and ITP. Thrombopoietin agonists are effective for refractory ITP in CLL and could also be considered at this time. Cyclosporine A (CSA) at 5 mg/kg per day given in divided doses twice daily has been used for refractory AIHA and ITP of CLL. The dose should be adjusted to maintain a serum level of around 100–150 µg/dL. Other treatment modalities include splenectomy or splenic irradiation, alkylating agents, or therapy (FCR or FR directed at the disease if active). Treatment of the underlying CLL is generally required for long-term control of

autoimmune cytopenias. However, our practice is to first control the autoimmune process with steroids or other therapies before considering treatment of the underlying CLL. Supportive therapy with periodic RBC transfusions is also important in the management of AIHA. Ibrutinib has also been shown to reduce the incidence of autoimmune complications in patients who initiate therapy for progressive disease and provides an exciting option for these patients. Unfortunately, ibrutinib has not been shown to be effective when treating active AIHA.

Pure RBC aplasia (PRCA) is a relatively rare T-cell-dependent complication associated with CLL, with an incidence as high as 6% having been reported. PRCA was first described by Dameshek and colleagues in 1967. It is characterized by a hypoproliferative anemia that can be detected even in early-stage CLL patients and is thought to be caused by the cytotoxic effects of suppressor T cells on erythroid progenitor cells. Increased numbers of cells coexpressing CD3, CD8, and CD57 have been shown to gradually accumulate in the BM of patients with PRCA. Abeloff and Waterbury described the first remission of PRCA with cyclophosphamide therapy in 1974, and Chik-kappa and colleagues described the first case of response to CSA. Subsequent larger studies have shown a response rate as high as 63% with 300 mg/day of oral CSA. Mild reversible nephrotoxicity may warrant dose adjustment in some patients. Most patients exhibit a response by having reticulocytosis within the first 10–14 days of the initiation of therapy, but maximal response may occur on average after 10 weeks. Steroid therapy at a dose of 1 mg/kg per day of prednisone remains the first line of treatment. If a response is not obtained in 4 weeks, CSA should be added to the regimen. Other agents that have shown promising activity in treating PRCA include rituximab, IVIG, alemtuzumab, and antithymocyte globulin. Packed RBC transfusions are usually indicated in patients who are clinically symptomatic from severe anemia.

A number of other complications, most of which are autoimmune in nature, have been reported in patients with CLL. These complications include paraneoplastic pemphigus, angioedema caused by acquired C1-inhibitor deficiency, and nephrotic syndrome. As a result of autoimmune involvement of various organs, patients with CLL may have abnormal serum chemistry profiles and liver function tests.

FUTURE DIRECTIONS

Advances in the understanding of molecular events associated with CLL over the past 2 decades has resulted into new diagnostic tests that allow better assessment of initial prognosis and also treatment assignments. In addition, multiple new therapies have been identified, and progress is being made to extend remission duration, clarify mechanisms of resistance, develop stopping rules for therapies and improve the quality of life of CLL patients. In addition, medications and interventions to overcome complications that arise from CLL have also been introduced. Overall, the future for patients with CLL remains brighter based on such efforts and likely will continue to improve with additional laboratory and clinical research. In particular, the use of kinase inhibitors have transformed treatment approaches and the outcome of patients with CLL which will likely alter the natural history of the disease.

HAIRY CELL LEUKEMIA

Farhad Ravandi

INTRODUCTION

Hairy cell leukemia (HCL) is one of the diseases exemplifying the importance of the application of appropriate diagnostic techniques and treatment strategies to obtain the best treatment outcomes for the individual patient.¹ The disease was first described by Bouroncle and colleagues in 1958. The term *hairy cell leukemia* was first used to describe the disorder by Schreck and Donnelly in 1966 and is derived from the observation of hair-like projections from mononuclear cells giving rise to a frayed cell surface appearance.

The evolution of therapeutic strategies in patients with HCL over the past 25 years has led to a significant change in the natural history of the disease. Using the currently available drugs, the majority of patients with this disease achieve complete response (CR), and the published survival curves from several large series are similar to those for appropriate age-matched individuals without the disease. At the same time, recent research efforts have led to a better understanding of the molecular mechanisms responsible for the disease pathogenesis. Several studies, using modern techniques, have demonstrated the persistence of minimal residual disease (MRD) after therapy with nucleoside analogs in the majority of patients without consensus on the significance of such MRD. The role of monoclonal antibodies, naked or conjugated with toxins, in the management of HCL, as well as their ability to eradicate MRD, is under investigation. The possibility of such strategies of chemoimmunotherapy leading to further improvements in the outcome of patients with HCL needs to be further investigated.

EPIDEMIOLOGY

HCL is an uncommon lymphoid malignancy, accounting for only 2% of lymphoid leukemias, with approximately 600 to 800 new patients diagnosed each year in the United States.¹ The disease is more common in whites and occurs more frequently in men than women by a ratio of 4:1.¹ The median age at diagnosis is reported by most studies to be 50 to 59 years. However, it is possible that the disease is underreported in the older population. The Swedish Cancer Registry has maintained records on the incidence of the disease for several decades and has shown a stable incidence since the 1980s. It reports the median age at diagnosis of 62 years, suggesting less rigid diagnostic efforts in older patients.

HCL has been diagnosed in patients aged in their 20s and 30s but is exceptionally rare in children. Using data from the 17 population-based cancer registry areas in the United States, the National Cancer Institute's Surveillance Epidemiology and End Results program reported that the incidence of the disease was stable in the decades between 1978 and 2004 with a rapid rise in age-specific incidence ratios until approximately age 40 years and then at a slower pace beyond that age.

ETIOLOGY AND CELL OF ORIGIN

Several reports have suggested an association between development of HCL and exposure to benzene, organophosphorus insecticides, and other solvents. However, such association has not been confirmed by other reports. Exposure to radiation, wood dust, or agricultural

chemicals, and a previous history of infectious mononucleosis have also been suggested as predisposing factors, but a direct, causal association has not been established with any of these or other factors.

Morphologically and phenotypically, the cells in HCL have no resemblance to any of the normal stages of B-cell development and maturation; past studies have debated the cell of origin. Initially, because of morphologic and functional similarities between hairy cells and cells of the monocyte/macrophage system, HCL tumor cells were thought to be derived from a cell transformed from the reticuloendothelium. Korsmeyer demonstrated the rearrangement of the B-cell receptor (BCR) immunoglobulin genes in HCL, demonstrating for the first time the B-cell origin of the disease. Recently, several studies have increased our understanding of the cell of origin in HCL allowing for a better description of pathogenic mechanisms responsible for its development.²

In lymphoid cells, the analysis of the immunoglobulin variable region genes provides a tool for the delineation of the clonal history of cells at which lymphoid neoplasms originate, identifying whether antigen encountered by a normal mature B cell has resulted in somatic mutation (Fig. 78.1). This process occurs within the germinal centers (GCs) of lymph tissues and may be associated with isotype switching. The enzyme activation-induced cytidine deaminase (AICD) is critical for both processes. Tumor cells from various B-cell malignancies are arrested at a number of stages along normal B-cell differentiation, conserving the immunogenetic characteristics of the stage-specific cell. The analysis of immunoglobulin variable gene regions can provide information about whether the cell of origin has undergone somatic mutation and isotype switching. Several reports have clearly demonstrated that in more than 85% of patients with HCL, the tumor cells express switched immunoglobulin isotypes, and their rearranged variable region genes have undergone somatic mutations.³ Furthermore, HCL cells express AICD, the enzyme that is critical for both processes.³ This suggests that the cell of origin in the majority of HCL cases has transited through the GCs of peripheral lymphoid tissue having undergone the GC reaction.² Of interest, in about 40% of cases of HCL, the leukemia cells express multiple immunoglobulin heavy chain isotypes, with dominance of immunoglobulin G3 (IgG3) but only a single light chain, suggesting that clonally related multiple isotypes coexist in single hairy cells. Therefore, this subset of the disease may be arrested at a point after isotype switching and before exit from the GC. However, other lines of evidence suggest a post-GC origin.²

Arons and colleagues have provided evidence that in the majority of patients with classic HCL (83% of 102 cases), the cell of origin is post-GC with a mutated immunoglobulin heavy chain variable region.⁴ This is contrasted with historic data for patients with chronic lymphocytic leukemia, in which case, about half of the time the cell of origin is unmutated. They also reported higher usage of certain immunoglobulin gene families and a difference in mutational frequency among these genes.⁴ Furthermore, by demonstrating that the mutations fulfilled predefined characteristics of a canonic and non-random event, Arons and colleagues provided further evidence suggestive of an antigen-driven process.

The post-GC origin of HCL is supported by gene expression profiling studies comparing HCL cells with cells from other lymphoid neoplasms, as well as with naive and memory B cells.⁵ HCL patients displayed a homogeneous pattern of gene expression that was clearly distinct from other B-cell lymphomas and was related to post-GC

Fig. 78.1 GERMINAL CENTER REACTION. The process of somatic hypermutation and isotypic switch in the germinal center.

memory B cells.⁵ Other investigators have reported this remarkably stable genome in HCL. Furthermore, when compared with memory B cells, HCL cells had a remarkable conservation of proliferation, apoptosis, and DNA metabolism programs but differed significantly in the expression of genes controlling cell adhesion and response to chemokines.⁵ Against the hypothesis of a memory B-cell origin is the lack of expression by hairy cells of the memory B-cell marker, CD27. However, CD27-negative memory B cells have been described in humans, and hairy cells may lose this marker as a result of the neoplastic transformation.

As lymph node involvement in HCL is uncommon, the post-GC cell of origin is likely to originate from the spleen or the bone marrow, sites involved by the disease almost invariably. A number of reports have suggested that HCL may originate from the B cells of the splenic marginal zone (SMZ). Normal SMZ B cells are mainly memory B cells. Vanhentenriik and colleagues, using comparative expressed sequence hybridization studies, demonstrated that hairy cells had an expression profile consistent with a splenic expression signature that most likely reflected the expression profile of spleen-specific components, such as the sinusoidal lining cells from the red pulp and the marginal zone B cells from the white pulp.

Recently, Tiacci and colleagues reported the presence of *BRAF* V600E mutations in each of 47 patients with HCL and no mutations in the cells from patients with 195 peripheral B-cell lymphomas or leukemias.⁶ Using whole-genome sequencing they identified, in an index patient, five missense somatic clonal mutations, including a heterozygous mutation in *BRAF* that resulted in a *BRAF* V600E variant protein.⁶ Since *BRAF* V600F is known to be oncogenic in other tumors, Tiacci and colleagues focused on this mutation and analyzed the subsequent 46 cases as well as the patients with other lymphomas. They also demonstrated expression of phosphorylated MEK and extracellular signal-related kinase (ERK), showing constitutive activation of the RAF-MEK-ERK mitogen-activated protein kinase pathway in HCL.⁶ This discovery has potential significance in the understanding of the pathogenic mechanisms of HCL; its applications in diagnosis and treatment of this disease are likely to increase with further research.

CLINICAL PRESENTATION AND DIAGNOSIS

Typically, the majority of patients present with pancytopenia and splenomegaly with the associated fatigue, left upper quadrant abdominal pain, fever and infections, and/or bleeding problems (Table 78.1). Common presenting features include significant anemia, seen in up to 85% of patients, thrombocytopenia in about 60% to

80%, and leukopenia in 60% of patients; these cytopenias can be severe and life-threatening and are likely multifactorial, with hypersplenism and marrow infiltration being the more important contributors. Monocytopenia is a characteristic finding. Circulating hairy cells are typically scant in most patients and frequently absent. Hairy cells are small- and medium-sized lymphoid cells with an oval or indented (bean-shaped) nucleus with homogeneous chromatin that is less clumped than normal B cells (Fig. 78.2).¹ Nucleoli are typically absent or inconspicuous and the cytoplasm abundant and pale blue in color with circumferential “hairy” projections. Electron micrographs of hairy cells clearly demonstrate their distinctive and complex surface features with multiple surface folds and clusters of short microvilli, creating an appearance unique to hairy cells (Fig. 78.3).

Bone marrow involvement can be interstitial or patchy with the infiltrate characterized by widely spaced nuclei because of the abundant cytoplasm, giving rise to the commonly described “fried egg” appearance (Fig. 78.4).¹ Occasionally, an increase in the bone marrow reticulin fibrosis, as well as significant loss of the hematopoietic elements, leads to a “dry tap.” Bone marrow fibrosis is caused by the production and assembly of a fibronectin matrix by hairy cells and the deposition of fine reticulin fibers (mainly composed of type III collagen fibrils) by fibroblasts.² Hairy cells express isoenzyme 5 of acid phosphatase, which imparts resistance to treatment with tartaric acid, with virtually all cases being positive for tartrate-resistant acid phosphatase (TRAP) (Fig. 78.5). Combined expression of DBA44 and TRAP by immunohistochemical analysis is highly specific and useful for arriving at the diagnosis. More recently, immunostaining for annexin A1 (ANAX1) has been reported to be very specific for HCL.⁷ ANAX1 can be used to distinguish HCL from its variant form and from other lymphoid neoplasms such as SMZ lymphoma

(SMZL).^{1,7} Cyclin D1 (encoded by *CCND1* gene) is frequently expressed, but this is not secondary to translocation involving *CCND1*, unlike mantle cell lymphoma. In a proportion of patients, the bone marrow is hypocellular with the loss of hematopoietic elements, which can result in an erroneous diagnosis of aplastic anemia. Immunostaining for antigens such as CD20 may be helpful to detect the abnormal B-cell infiltrate, hence prompting more specific stains for HCL.¹

HCL cells have a characteristic immunophenotype with flow cytometry being an important element of diagnostic evaluation in this disease (see Table 78.1). Hairy cells strongly express CD45 and gate within the monocytic region when analyzed by CD45 versus side scatter, which is typically devoid of monocytes. They exhibit a mature B-cell phenotype and commonly express one or more heavy chains and monotypic light chains (κ and λ light chains in equal numbers of patients). They express B-cell associated antigens CD19, CD20, CD22, FMC7, and CD79b but typically lack CD5, CD10 (positive in about 10%), and CD23 (positive in about 20%) expression. No single marker is specific for distinguishing HCL from other B-cell neoplasms; however, the antigens CD11c, CD103, CD123, as well as the interleukin (IL)-2 receptor α -subunit (CD25), are typically expressed in HCL. Bright expression of CD22 and CD20 is also seen, which can be important therapeutically. Among the patients evaluated in one study, CD52 was also universally expressed.

Fig. 78.5 BONE MARROW ASPIRATE SMEAR (TRAP STAIN $\times 1000$). (Courtesy Jeffrey Jorgensen, Department of Hematopathology, UTMDACC.)

Splenic enlargement is present in the majority of patients and can be massive in about 20% of cases. Splenic involvement is characterized by diffuse infiltration of the red pulp cords and sinuses, with atrophy and replacement of white pulp. Blood-filled sinuses lined by hairy cells (often referred to as *pseudosinuses* or *red blood lakes*) are often a prominent but not pathognomonic finding (Fig. 78.6).¹ Significant lymphadenopathy is uncommon and present only in the advanced stages of the disease. When involved, the lymph node enlargement is largely confined to the abdominal and retroperitoneal nodes. The infiltrates are distributed in the interfollicular and paracortical areas of the nodes and may extend through the capsule to the surrounding adipose tissue. Hepatomegaly is much less frequent, occurring in up to a third of patients. However, the liver is almost always involved with a mononuclear cell infiltrate in the sinusoids, portal areas, or both. Unusual sites of disease involvement have been reported, including mediastinal and paravertebral masses, skeletal lytic lesions, pleural effusions and ascites, as well as involvement of skin, eye, the central nervous system, and the gastrointestinal tract. Other notable clinical features include a predisposition to infections and an uncommon association with autoimmune disorders such as polyarteritis nodosa, vasculitis, and rheumatoid arthritis.

Several cytogenetic abnormalities have been reported in HCL but no single abnormality is present consistently. Few cytogenetic studies have been reported because of the rarity of the disease, difficulty in obtaining marrow samples, and low responsiveness of hairy cells to common mitogens. In the reported series, chromosomes 1, 2, 5, 6, 11, 14, 19, and 20 are most frequently involved, with chromosome 5 and 14 abnormalities predominating. Deletions and mutations of p53, as well as overexpression of cyclin D1, have been reported. Lack of reciprocal chromosomal translocations in HCL is consistent with a memory B-cell origin of the disease, because these translocations are thought to arise from mistakes in the immunoglobulin remodeling mechanisms, which are believed to be turned off in memory B cells.²

DIFFERENTIAL DIAGNOSIS

HCL must be distinguished from other indolent lymphoid neoplasms, such as B-prolymphocytic leukemia and SMZL, and most notably, from HCLv, the variant form of the disease. HCLv is a rare disorder accounting for approximately 10% of cases and occurring in an older population, with the median age being 71 years.⁸ There are no reports of an association with exposure to carcinogens, radiation, or viral infections, and no specific underlying cause has been described. Patients often have an elevated WBC count ($>10 \times 10^9/L$) including atypical hairy cells with prolymphocytic features and lack

monocytopenia. Splenomegaly and cytopenias are present in the majority of patients, and the pattern of bone marrow and splenic involvement is similar to HCL and different from prolymphocytic leukemia and SMZL. The immunophenotypic expression of various lymphoid markers is also different in these disorders, with HCLv lacking CD25 expression, further assisting diagnosis (Table 78.2). Another aid in distinguishing HCL from HCLv is CD123 expression, which is positive in the former and negative in the latter. A number of chromosomal abnormalities, including translocations, have been reported in a few cases. Although HCLv has some similarities to HCL, the two conditions differ in a number of features, most notably being HCLv's lack of responsiveness to classic HCL therapies. As such, it is important to distinguish the two and consider them as separate diseases. HCL and HCLv have different immunoglobulin heavy (IGH) chain gene repertoires and somatic hypermutation patterns.⁴ A recent report also suggested that high expression levels of AICD can distinguish HCL from HCLv, as well as from SMZL. However, the same group was unable to find distinct cytogenetic events to distinguish HCL from its variant, using high-resolution genomic profiling. Most recently, *BRAF*V600F mutations have been shown to occur exclusively in HCL samples and not in those from patients with HCLv and SMZL.

SMZL (previously referred to as *splenic lymphoma with villous lymphocytes [SLVL]*) exhibits some of the clinical and morphologic features of HCL but typically has a more prominent peripheral blood involvement, lacks TRAP expression, and has a different immunophenotype, including absence of expression of CD25 and CD103. HCL should be distinguished from other indolent lymphoid neoplasms such as chronic lymphocytic leukemia, prolymphocytic leukemia, and follicular lymphomas, but this distinction is typically easily made using the characteristic morphologic and immunotypic findings characteristic of these disorders (see Table 78.2). Other disorders that should be included in the differential diagnosis include aplastic anemia, primary myelofibrosis, and systemic mast cell disorders.

TREATMENT

Indications for Therapy

HCL has an indolent course, with some patients surviving many years without receiving therapy and others not requiring further therapy despite persistence of residual morphologic evidence of the disease after the initial treatment.⁹ Therefore a watch-and-wait strategy may be appropriate in the initial management of patients with limited or no manifestations of the disease. Disease progression that necessitates therapy is commonly evident by the development of progressive cytopenias and their associated complications, such as infections, bleeding, and progressive fatigue. No specific criteria for therapy have been established, but generally treatment is indicated when the patient has significant cytopenias, symptomatic organomegaly or adenopathy, infections, or constitutional symptoms such as fever, night sweats, or fatigue. Typical blood counts warranting therapy

include an absolute neutrophil count $<1.0 \times 10^9/L$, a platelet count $<100 \times 10^9/L$, and/or a hemoglobin <12.0 g/dL.

Historic Aspects of Therapy

Progress in the treatment of patients with HCL over the last 25 years has been significant, with survival curves now approaching those of age-matched cohorts without the disease. Before the introduction of interferon (IFN)- α , splenectomy was used effectively to treat patients with HCL. Although splenectomy does not result in morphologic remissions in the bone marrow, the peripheral blood counts are normalized in up to 70% of patients. Progression of disease can be expected in about 45% within 5 years. Furthermore, there is an associated morbidity and mortality with the procedure. As such, splenectomy is no longer performed in this disease except in rare, selected patients.

The first report of effective treatment of HCL with IFN- α described several patients with progressive disease who received daily doses of 3 million units. Three patients achieved CR with the other four having partial responses (PR). The activity of IFN- α in HCL was further confirmed by several large trials reporting CR rates of 4% to 30% and PR rates of 43% to 86%. Even in patients achieving a CR, careful morphologic examination of the bone marrow revealed residual hairy cells. With further follow up of patients treated with IFN- α , it is clear that a significant proportion will relapse and require further therapy. However, the same authors reported that a number of patients remaining alive after a 10-year follow up had not required further therapy with interferon. The median failure-free survival reported by these and other investigators ranges from 6 to 25 months. A number of predictors of outcome have been evaluated, with expression of CD5 reported as a predictor of poor response.

The precise mechanism of action of IFN- α in HCL is unknown and may be related to the reduced production of a number of cytokines such as granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor, IL-3, and IL-6. Others have demonstrated that IFN- α can mediate apoptosis of hairy cells through the effects of tumor necrosis factor- α .

Treatment with IFN- α is associated with significant toxicity including flu-like symptoms, anorexia, fatigue, nausea and vomiting, diarrhea, skin rash, peripheral neuropathy, and central nervous system dysfunction (such as depression and memory loss). This and the introduction of nucleoside analogs that are generally more effective in achieving responses has led to the use of interferon being limited to rare cases and special circumstances.

Purine Nucleoside Analogs

Although there are no specific guidelines for the treatment of HCL, monotherapy with cladribine or pentostatin is the current established standard. Furthermore, despite the lack of a comparative study, a substantial number of data suggest that both drugs are equally effective in terms of response rate and durability.¹⁰ The use of nucleoside

analogs in treating lymphoid neoplasms can be traced back to the observation that children with the deficiency of the enzyme adenine deaminase (ADA) developed severe combined immunodeficiency. The accumulation of the triphosphorylated form of deoxyadenosine (dependent on the action of the enzyme deoxycytidine kinase [DCK]) is thought to be responsible for the lack of lymphocyte development. Similarly, after treatment with purine nucleoside analogs, the accumulation of deoxyadenosine triphosphate results in DNA strand breaks, inhibition of DNA repair, and apoptosis preferentially in lymphoid cells, rich in DCK and low in 5' nucleotidase (the enzyme responsible for degrading deoxyadenosine monophosphate).

Cladribine is a purine nucleoside analog resistant to deamination by ADA. It accumulates in lymphocytes rich in DCK and inhibits ribonucleotide reductase, impairing DNA synthesis and repair. Cladribine has been very effective for the initial therapy of HCL, with overall response rates ranging from 75% to 100% after a single course of the drug (Table 78.3). Piro and colleagues first reported 12 patients with HCL who received cladribine 0.1 mg/kg per day by intravenous continuous infusion for 7 days.¹¹ Eleven patients achieved CR, and one had PR.¹¹ Since then, other dose, routes of administration, and schedules of the drug have been used effectively (see Table 78.3 and Table 78.4). Weekly administration was evaluated in severely neutropenic patients in a pilot study in an effort to produce a less toxic strategy.¹² The authors reported a 73% CR rate, with an overall response rate of 100%. However, only 16% developed severe neutropenia and 8% infections.¹² In a more recent report, 132 patients with untreated HCL were randomized to receive cladribine either on 5 consecutive days or a novel schedule of six weekly doses.¹³ The response rates, overall response rates, progression-free, overall survival, and incidence of grade 3 and 4 infections were the same in the two arms.¹³ The subcutaneous route was also evaluated after the initial demonstration that similar plasma levels to those seen with the intravenous route can be achieved subcutaneously. Juliusson and colleagues treated 73 patients with cladribine administered as a subcutaneous daily injection for 7 days and reported a CR rate of 75% after one course and 81% after two courses.¹⁴

TABLE 78.4 Alternative Dose and Schedules of Cladribine Therapy Reported in the Literature

Study	Dosing	Route of Administration	Responses
Saven ¹⁵	0.1 mg/kg/day × 7 days	Continuous IV infusion	CR: 91%; PR: 7%

CR, Complete response; IV, intravenous; PR, partial response.

Fig. 78.7 LONG-TERM FOLLOW UP OF PATIENTS TREATED WITH NUCLEOSIDE ANALOG MONOTHERAPY. Excellent outcome for the majority, and significantly better relapse-free survival for patients achieving complete (CR) versus partial response (PR) with initial therapy. (Else M, Dearden CE, Marutes E, et al: Long-term follow-up of 233 patients with hairy cell leukaemia, treated initially with pentostatin or cladribine, at a median of 16 years from diagnosis. Br J Haematol 145:733, 2009.)

Despite the very high response rate to cladribine, responses are not universal and a significant proportion of patients relapse. Saven and colleagues reported the long-term outcome of 358 patients with HCL who were followed for a median of 52 months.¹⁵ Of these patients, 26% relapsed after a median of 29 months.¹⁵ The same group reported on 209 patients treated with cladribine with a follow-up period of at least 7 years.¹⁶ Although the overall response rate was 100%, 76 (37%) patients relapsed after their first course of cladribine with a median time to relapse of 42 months.¹⁶ Notably, the time to treatment failure curve did not show a plateau, indicating that the treatment is probably not “curative.”¹⁶ Outcome of patients achieving CR with their initial therapy is better than those achieving PR (Fig. 78.7). More recent publications have confirmed the high response rate of patients with HCL treated with cladribine and have provided long-term follow-up data.¹⁷ Jehn and colleagues described a 12-year follow up of 44 patients (including 11 with prior therapy before receiving cladribine) who received cladribine at the originally

reported dose and schedule. The CR rate was 98%, and with a median follow up of 8.5 years (range 0.1–12.2), 17 patients had relapsed. Eight of nine patients retreated with cladribine responded again. The overall survival at 12 years was 79%. Zinzani and colleagues reported the long-term outcome of 37 patients treated with one of two regimens of cladribine. Twenty-one patients received cladribine by a 2-hour infusion for 5 days, whereas 16 patients were treated with a once-weekly schedule for 5 weeks. A CR rate of 81% with an overall response rate of 100% was reported, with no difference between the two schedules. After a median follow up of 122 months (range 54–156), the overall relapse rate was about 30% for both groups. The projected 13-year overall and relapse-free survival rates were 96% and 52%, respectively. Investigators at Northwestern University treated 86 consecutive patients with cladribine and reported a CR rate of 79%, as well as a PR rate of 21%.¹⁷ The progression-free survival after 12 years was 54%. After a median follow up of 9.7 years (range 0.3–13.8), 31 patients (36%) relapsed.¹⁷ Of these, 23 were treated with a second course of cladribine; 12 (52%) achieved CR, and 7 (30%) achieved PR. The overall survival after 12 years was 87%.¹⁷ The authors suggested that the lower CR rate in this study was caused by their more stringent criteria for response, which included a requirement for resolution of splenomegaly and lymphadenopathy by computed tomography scan as criteria for CR.¹⁷

Similar excellent responses have been achieved using pentostatin (Table 78.5). Overall CR rates of 44% to 89% have been reported with pentostatin administered intravenously at a dose of 2–4 mg/m² every 2 weeks. Spiers and colleagues were the first to report that a nucleoside analog (pentostatin) was capable of producing CRs in patients with HCL. The activity of pentostatin in HCL was confirmed in a number of larger studies by several investigators. Grever and colleagues conducted a large, randomized clinical trial comparing pentostatin with IFN- α in patients with previously untreated HCL.²⁰ Patients were randomized to receive either IFN- α 3 million units subcutaneously three times per week or pentostatin 4 mg/m² intravenously every 2 weeks.²⁰ Patients who did not respond to initial treatment were crossed over. Confirmed complete and overall response rates were reported for 76% and 79% of patients treated with pentostatin, respectively, as compared with 11% and 38% of those treated with IFN- α .²⁰ Response rates were significantly higher ($p < .0001$), and relapse-free survival was significantly longer with pentostatin than with interferon ($p < .0001$).²⁰ Furthermore, patients who were initially assigned to receive interferon were frequently crossed over to pentostatin therapy, achieving a CR rate of 66%. In a follow-up report, Flinn and colleagues described the long-term outcome of 241 patients who were treated with pentostatin either as initial therapy or after failure of IFN- α .²¹ The 5- and 10-year event-free survival rates were 85% and 67% respectively (Fig. 78.8). Other investigators have reported long-term follow-up data on patients treated with pentostatin. Maloisel and colleagues reported outcome of 230 evaluable patients with HCL treated with pentostatin, including 84 with pentostatin as the initial agent. They reported a CR rate of

79%, with an overall response rate of 96%. With a median follow up of 63.5 months, 34 (15%) of 220 responding patients had relapsed. The estimated 5- and 10-year disease-free survival was 88% and 69%, respectively, and the estimated 5-year overall survival was 89%.

There are no prospective trials comparing the efficacy and durability of response between cladribine and pentostatin. Dearden and colleagues examined the outcome of the patients with the two agents at their institution and reported that 82% of 165 patients treated with pentostatin achieved a CR compared with 84% of 45 patients treated with cladribine. Relapse rates were 24% with pentostatin and 29% with cladribine after median follow up of 71 and 45 months, respectively. These relapse rates suggest a longer remission duration with pentostatin. However, with further follow up, there appears to be no difference between the two agents with regard to disease-free survival (Fig. 78.9A). Further follow-up data of these cohorts of patients have been reported.¹⁰ With a median follow up of 16 years, there was no significant difference in the outcome of the patients treated with the two drugs. After relapse or nonresponse, patients could be successfully retreated with pentostatin or cladribine but

achieved lower response rates, with a decline in the proportion of patients achieving CR with second- and third-line therapy (see Fig. 78.9A).¹⁰ However, CRs were equally durable after first, second, or third line of treatment. Complete responders and those with pretreatment hemoglobin >10.0 g/dL and platelet count $>100 \times 10^9/L$ had the longest relapse-free survival ($p < .0001$) (Fig. 78.10).¹⁰ Patients who were in CR after 5 years had only a 25% risk for relapsing by 15 years.¹⁰ These data suggest that both pentostatin and cladribine are highly effective in treating patients with HCL but not curative in all patients. Few predictors of response and long-term outcome have been reported, but the recent demonstration by two groups that patients with unmutated IGH chain variable (IGHV) region gene were less likely to respond to cladribine suggests that further insight into the biology of the disease may potentially clarify mechanisms of resistance (Fig. 78.11).^{19,22}

Monoclonal Antibodies

Several therapeutic options are now available for patients with relapsed HCL. The efficacy of the monoclonal antibody rituximab in treating these patients has been suggested by a number of studies (Table 78.6). Rituximab is a monoclonal antibody directed against the pan-B-cell antigen (CD20), which is heavily expressed on the surface of hairy cells. Nieva and colleagues reported their experience with 4 weekly doses of rituximab in 24 patients with HCL who

Fig. 78.10 (A) Relapse-free survival after initial therapy with nucleoside analogs by initial response and blood counts. (B) Relapse-free survival analyzed by line of therapy and response to treatment. Complete responses (CR) were equally durable, whether achieved at first-, second-, or third-line single-agent treatment. PR, Partial response. (Else MA, Ruchlemer R, Osuji N, et al: Long remissions in hairy cell leukemia with purine analogs. *Cancer* 104:2442, 2005; and Else M, Dearden CE, Matutes E, et al: Long-term follow-up of 233 patients with hairy cell leukaemia, treated initially with pentostatin or cladribine, at a median of 16 years from diagnosis. *Br J Haematol* 145:733, 2009.)

had failed prior treatment with cladribine. The overall response rate was 26%, with 13% CR and 13% PR. No unusual toxicity was reported. Lauria and colleagues treated 10 patients with relapsed/progressed HCL with 4 weekly doses of rituximab and reported one CR and four PR (overall response rate of 50%). Hagberg and colleagues treated 11 patients with HCL (including three previously untreated patients) with the same regimen of rituximab for 4 weeks. The response rate was 64%, with six CRs and one PR (including one CR in an untreated patient). The Swiss Group for Clinical Cancer Research reported their study of 4 weekly doses of rituximab in 26 patients with relapsed/progressed HCL, showing an 80% response rate, with 32% achieving CR. Thomas and colleagues used an extended regimen of rituximab 375 mg/m² weekly for eight doses to treat 15 patients with relapsed/refractory HCL and reported a response rate of 80%, including eight (52%) CR, two (13%) CR with residual marrow disease, and two (13%) PR.²³

Rituximab has been evaluated in a sequential strategy to improve responses in patients with HCL after treatment with cladribine.²⁴ Rituximab has also been used concomitantly to treat patients with refractory disease with reported excellent responses suggesting a

possible synergy. The investigators from the Royal Marsden NHS Trust treated 18 patients with either pentostatin ($n = 12$) or cladribine ($n = 6$) in combination with rituximab after a median of two (range, 1–6) prior treatments and reported a CR rate of 89%. Toxicity with the combination was minimal, and with a median follow up of 36 months, all 16 patients who had achieved CR remained in CR.

Other monoclonal antibody-based therapies have developed and are under investigation. BL22 is a recombinant immunotoxin containing the variable domains of the anti-CD22 monoclonal antibody RFB4 fused to a truncated pseudomonas endotoxin A.²⁵ In a dose-escalation study, 16 patients who were resistant to cladribine were treated with BL22 by intravenous infusion every other day for a total of three doses.²⁵ Response included 11 CR and 2 PR. The three nonresponders either had preexisting neutralizing antibodies or received low doses of the immunotoxin.²⁵ Toxicity included a cytokine-release syndrome and development of a reversible hemolytic-uremic syndrome in two patients.²⁵ In a larger phase I follow-up study of 46 patients with previously treated CD22+ lymphoid malignancies, including 31 with HCL, 61% achieved a CR and 19% experienced a PR, further demonstrating the activity of this agent in HCL. Neutralizing antibodies occurred in 11 (24%) of 46 patients (all HCL), and a reversible hemolytic uremic syndrome requiring plasmapheresis was observed in 1 patient with NHL during cycle 1 and in 4 patients with HCL during cycle 2 or 3. The median duration for CR was 36 months (range, 5–66 months). The maximum tolerated dose (MTD) was established at 40 $\mu\text{g/kg}$ every other day $\times$ three doses. More recently, the results of a phase 2 study of the same drug in 36 patients with relapsed or refractory HCL was published.²⁶ Patients received BL22 at the MTD on cycle 1. Those achieving hematologic remission were observed while the others were retreated at 30 $\mu\text{g/kg}$ every other day for three doses every 4 weeks beginning at least 8 weeks after cycle 1. The response after one cycle (CR, 25%; PR, 25%) improved when 56% were retreated (CR, 47%; PR, 25%).²⁶ A modified version of this agent, moxetumomab pasudotox (or HA22), has a superior affinity for CD22 and is under clinical development.

CD52 is also expressed on the surface of hairy cells, and an anecdotal report of a response to alemtuzumab has recently been published.

Minimal Residual Disease and Its Significance

Despite excellent responses, there is a definite relapse rate associated with therapy of HCL with both cladribine and pentostatin, and the relapse-free survival does not appear to plateau.¹⁰ Wheaton and colleagues were the first to note that detection of MRD by immunohistochemistry (using anti-CD45RO, anti-CD20, and DBA.44) in paraffin-embedded bone marrow sections of 39 patients with HCL in CR after receiving cladribine was predictive of relapse.²⁷ More sensitive methods of MRD detection such as immunophenotyping using multiparameter flow cytometry, as well as analysis of antigen receptor genes by polymerase chain reaction (PCR) using consensus or clone-specific primers, have been evaluated recently and can be used to monitor the disease course (Fig. 78.12).^{24,28,29} Other

Fig. 78.12 MONITORING MINIMAL RESIDUAL DISEASE IN HAIRY CELL LEUKEMIA. (A) Total nucleated cells in a hemodilute bone marrow aspirate (*a* and *b*); total lymphocytes (*c* to *e*). Hairy cells (*red*, about 6% of total cellularity and 12% of lymphocytes) show increased side scatter (SSC) because of their high cytoplasmic complexity, compared with normal B cells (*blue*). Hairy cells often show increased expression of CD20 (*a*). On CD45 versus SSC gating plots (*b*), they may be mistaken for monocytes. Hairy cells usually show bright expression of CD11c and CD22 (*c*) and CD25 (*d*) and are positive for CD103 (*e*). (B) Total lymphocytes from a posttherapy bone marrow aspirate, positive for minimal residual hairy cell leukemia, accounting for about 0.6% of total cellularity. Hairy cells (*red*) can be easily distinguished from normal B cells (*blue*), particularly on the basis of their bright expression of CD11c (*a*) and CD25 (*b*) and positivity for CD103 (*c*). In *a*, 30,000 total cells were collected; in *b* and *c*, 100,000. (Courtesy Jeffrey Jorgensen, Department of Hematopathology, UTMDACC.)

markers of the disease, such as serum-soluble CD25, CD22, and CD307, have been evaluated and shown to be reliable for disease monitoring.³⁰

Rituximab has been evaluated for eradication of MRD assessed by flow cytometry and consensus primer PCR; whether such elimination of MRD can translate to a longer relapse-free survival is unclear.^{9,24} Sigal and colleagues reported that patients with HCL may harbor MRD and even morphologically evident disease many years after initial therapy without experiencing overt relapse, raising the question of whether eradication of MRD should be the goal of therapy in HCL.⁹ However, several studies have suggested that patients who achieve a morphologic CR have a better outcome than those with lesser responses. Whether this can be extrapolated to complete eradication of detectable disease remains to be established.

Treatment of Disease Relapse

Despite the success of the nucleoside analogs in achieving generally durable responses in the majority of patients, they are not considered to be curative, with about 40% of patients relapsing by 10 years after treatment.¹⁰ Second and third courses of nucleoside analogs have been used, either with the same or the alternate agent used to treat relapsing disease. However, CRs are less frequent with subsequent courses. Because a single course of cladribine or pentostatin can suppress CD4⁺ lymphocytes for a substantial period of time, concerns about the use of multiple courses of these agents have been raised.¹⁸

Rituximab has the advantage of sparing T-lymphocytes and has shown significant activity in patients with relapsed disease (see Table 78.6). However, the overall response rate is relatively low, particularly in studies using only 4 weekly doses of rituximab. Recent studies of combination therapy with rituximab and nucleoside analogs have reported high response rates, improved activity in variant HCL, and second CR durations longer than the first CR achieved with nucleoside analogs alone.^{31,32} Immunotoxins such as BL22 and HA22 have been studied in cases of relapsed disease, produce high responses, and have limited toxicity; however, they are not, as yet, widely available. Bendamustine, a novel molecule with structural features of both an alkylating agent and a purine nucleoside analog, has been used by one group for the treatment of relapsed and refractory disease. Anecdotal reports have circulated about the use of other agents such as alemtuzumab. BCRs signaling kinase inhibitors such as ibrutinib have shown significant promise in the treatment of a number of lymphoid neoplasms and are being investigated in patients with relapsed disease and HCLv.³³ The identification of *BRAF* V600F as a universal aberration in patients with HCL and the availability of *BRAF* inhibitors for the treatment of solid tumors such as melanoma led to the investigation of this agent in patients with relapsed HCL with promising early reports.³⁴ The *BRAF* mutation, BRAFV600E constitutively activates the mitogen activated kinase pathway in virtually all patients with HCL. Two phase II trials of the *BRAF* inhibitor, vemurafenib, have been reported.³⁵ The treated patients had relapsed or were refractory to treatment with purine analogs. The drug was administered orally at a dose of 960 mgms orally twice a day for 16 to 18 weeks. The overall response rate was 96% to 100% with a CR rate of 35% to 42%. All patients had evidence of MRD at the end of treatment. The progression-free survival rate was 73% and the overall survival was 91%. Myelosuppression was minimal and the most common adverse effects were rash, arthralgias or arthritis. These studies suggest that *BRAF* inhibitors are promising agents for HCL patients that are unresponsive or refractory to purine analogs. The role of these agents in treating patients with HCL will need further studies and longer follow up.

Incidence of Second Malignancies

Early studies suggested an association between HCL and development of second malignancies, but this link is controversial and

has been refuted by other reports. The reported second cancers include melanoma, prostate cancer, gastrointestinal cancers, and non-Hodgkin lymphomas. Whether these second malignancies are related to the primary disease itself or to its treatment has also been debated. A number of long-term studies of patients treated with pentostatin or cladribine have not shown a statistically significant increased risk for second malignancies. It remains unclear whether the immunosuppressive effects of nucleoside analogs play a role in such susceptibility to developing a second malignancy or whether disease-related factors or perhaps increased monitoring of these patients are important.

FUTURE DIRECTIONS

Over the past decade, success in the treatment of HCL has led to diminished interest in developing new therapeutic strategies for treating this uncommon leukemia, with research confined to a few specialized centers interested in the biology and pathogenesis of this disease. Recent reports unraveling the biologic and molecular aspects of the disease have kindled a significant resurgence of interest.² Further studies into other aspects of the disease, such as the role of microenvironment, BCR signaling, and the complex interaction of various signaling pathways will likely provide better therapeutic tools and strategies.

MARGINAL ZONE LYMPHOMAS (EXTRANODAL/ MALT, SPLENIC, AND NODAL)

Carlos A. Ramos

The term *marginal zone* refers to a histologic compartment located at the periphery of lymphoid follicles immediately outside their mantle zone.¹ The marginal zone is especially evident in the spleen, although identical areas have been observed in other lymphoid structures, including mesenteric lymph nodes and mucosa-associated lymphoid tissue (MALT) (Fig. 79.1).² Ordinarily, it is composed predominantly of B cells that are slightly larger than mantle zone lymphocytes and strongly positive for surface immunoglobulin (Ig) M, but weakly positive for IgD (in contrast to mantle zone cells, which are strongly positive for IgD).³ Marginal zone B lymphocytes are thought to be involved in fast protective responses against pathogenic encapsulated bacteria that do not trigger classical T-cell-dependent humoral immunity.⁴ They are also assumed to be the physiologic counterpart of a group of non-Hodgkin lymphomas (NHL) that are currently referred to as *marginal zone lymphomas* (MZLs).

Although MZLs share a common denomination, arising from histologic similarities, new genetic findings and longer follow-up studies have established that the currently recognized subtypes of MZLs, initially described in the Revised European-American Lymphoma (REAL) classification, are different diseases.⁵ In the most recent WHO classification of tumors of the hematopoietic and lymphoid tissues,⁶ these disorders comprise three distinct entities: extranodal MZL of MALT type (ENMZL), splenic MZL (SMZL) and nodal MZL (NMZL). Immunoproliferative small intestinal disease (IPSID), formerly known as alpha heavy chain (or Seligmann) disease, has been recently recognized as a variant of ENMZL.⁷ In aggregate, MZLs represent approximately 10% of all NHL.⁸ Clinically, they behave indolently and have a prolonged course. Therefore, management strategies share similarity with other low-grade lymphomas,⁹ although specific biologic characteristics and particular pathophysiologic mechanisms determine unique therapeutic approaches in some of the subtypes. This chapter will summarize the clinical characteristics and current management strategies for the different types of MZL.

INITIAL EVALUATION OF MARGINAL ZONE LYMPHOMA

As for other lymphomas, biopsy of an adequate amount of tissue with review by a hematopathologist with expertise in the field is essential to establish the diagnosis. Excisional or incisional biopsies of a lymph node or suspicious mass, obtained by endoscopic or conventional means, are preferred. In patients without easily accessible nodes or masses, computed tomography (CT) or ultrasound-guided core needle biopsy is usually well tolerated and may be adequate for diagnosis. Fine-needle aspiration is not appropriate for diagnosis; sufficient material must be obtained for proper histologic examination and required immunophenotypic and genetic studies.

Physical examination with special attention to peripheral lymph nodes and the abdomen should be performed. Initial laboratory evaluation should include a complete blood count (cytopenias may be evidence of marrow infiltration or of autoimmunity) with evaluation of a peripheral blood smear (to exclude leukemic involvement) and basic biochemical studies, including lactate dehydrogenase (LDH) level, which is an important prognostic factor and a potential indicator of transformation from indolent to aggressive lymphoma.

Antiglobulin tests and reticulocyte count may be useful to rule out autoimmune hemolytic anemia. Serum protein electrophoresis and immunofixation may demonstrate a monoclonal immunoglobulin. β_2 -microglobulin levels may have prognostic value¹⁰ as in other indolent lymphomas. Viral hepatitis (B and C) and HIV studies to exclude coexisting infections that affect therapeutic approaches should be obtained.

Depending on the primary site of disease, specific procedures may be indicated. Gastrointestinal MZLs may require repeat staging endoscopies, during which an adequate number of biopsies should be obtained. For gastric ENMZL, the European Gastro-Intestinal Lymphoma Study (EGILS) group recommends a mapping procedure with a minimum of 10 biopsies taken from visible lesions and additional ones from macroscopically normal mucosa; the same procedure should be repeated to assess treatment response.^{11–17} Because endoscopic biopsies are not transmural, endoscopic ultrasound (EUS) is a useful way to assess the depth of involvement, which has prognostic implications.^{12–17} For head primaries, such as ocular adnexal ENMZL, appropriate directed examination and imaging studies (CT or magnetic resonance) are indicated.

STAGING OF MARGINAL ZONE LYMPHOMA

Imaging studies of the chest, abdomen, and pelvis, usually CT scans, should be obtained to adequately stage the disease. Positron emission tomography (PET) scan has been increasingly used for staging and evaluation of response to therapy in NHL, but it may be less useful in MZL because up to 60% of these lymphomas may be PET-negative, especially in early-stage gastric ENMZL.¹⁸ Some MZL series, however, document a PET-positivity rate of up to 80%,^{19–23} with better detection rates seen for head and neck and bronchial versus gastric or ocular MZL.²⁴ Also for staging and, occasionally, for diagnostic purposes, bone marrow biopsy and aspirate are usually advocated, even in cases in which the likelihood of systemic disease is low, because any positive result has important implications for therapy.

Staging of MZL is similar to that of other lymphomas; the Ann Arbor system, or an adapted version,²⁵ is used most frequently (Table 79.1). Nonetheless, specific staging systems have been adopted for particular sites. Gastrointestinal MZL is often staged according to a modified Ann Arbor scheme, commonly known as the Lugano staging system,²⁶ which incorporates indices corresponding to depth of mucosal invasion and proximity of affected lymph nodes to the primary lesion (see Table 79.1). Of note, the Lugano system has no stage III, and its stage IIE may refer to lesions that extend by contiguity to adjacent organs and not necessarily to secondary involvement of lymph nodes. Recently, arguing that the dissemination patterns of extranodal lymphomas are essentially different from those of primary nodal lymphomas, the EGILS group has proposed a new staging system (the Paris staging system)²⁷ that is based on the TNM scheme used for solid tumors (see Table 79.1). The International Society for Cutaneous Lymphomas (ISCL) and the cutaneous lymphoma task force of the European Organization of Research and Treatment of Cancer (EORTC) have also recently suggested a new, TNM-based staging system for cutaneous lymphomas other than mycosis

Fig. 79.1 NORMAL MARGINAL ZONE CELLS. (A) Marginal zone cells are seen most readily in sections from the normal spleen. The splenic white pulp typically has three distinctive layers: the germinal center, the mantle zone, and external to this, the marginal zone (see *asterisk*). (B) Marginal zone cells are not usually seen in lymph nodes, but for some reason are sometimes present in mesenteric lymph nodes (see *asterisk*). They have a similar appearance to those in the spleen. (C) In the gastrointestinal tract, the lymphoid tissue in Peyer's patches is believed to have a marginal zone equivalent (see *asterisk*). The cells are again external to the mantle zone and are believed to traffic between the epithelium and the lymphoid follicle.

^aIn case of more than one visible lesion synchronously originating in the gastrointestinal tract, select the characteristics of the more advanced lesion.
^bAnatomic designation of lymph nodes as *regional* according to site: (a) stomach: perigastric nodes and those located along the ramifications of the celiac artery (i.e., left gastric artery, common hepatic artery, splenic artery); (b) duodenum: pancreaticoduodenal, pyloric, hepatic, and superior mesenteric nodes; (c) jejunum/ileum: mesenteric nodes and, for the terminal ileum only, the ileocolic as well as the posterior cecal nodes; (d) colorectum: pericolic and perirectal nodes and those located along the ileocolic, right, middle, and left colic, inferior mesenteric, superior rectal, and internal iliac arteries.

fungoides and Sézary syndrome,²⁸ which may be used for the cutaneous forms of ENMZL.

EXTRANODAL MARGINAL ZONE LYMPHOMA OF MALT TYPE

Epidemiology and Manifestations

ENMZL is the most frequent of the MZL subtypes, accounting for approximately 8% of all NHL.⁸ A recent analysis of Surveillance, Epidemiology, and End Results (SEER) data quotes a yearly incidence rate of 1.59 per 100,000 adults in the United States.²⁹ The median age of presentation is around 60, with a wide range spanning from

the third to the ninth decades, and there is a slight female predominance (55%).³⁰ In contrast to most other indolent lymphomas, ENMZL frequently presents at a localized stage ($\approx 40\%$ stage I and $\approx 30\%$ stage II), and the risk for systemic dissemination is low (albeit variable depending on primary location), which has important implications for the choice of therapy.

The most commonly affected primary site is the mucosa of the gastrointestinal tract, in particular the stomach (approximately 44% of all ENMZL cases) followed by the small intestine ($\approx 7\%$). Ocular structures are also frequently involved ($\approx 12\%$), namely, the orbit ($\approx 40\%$ of all ocular adnexal ENMZL), the conjunctiva (35%–40%), the lacrimal glands (10%–15%), and the eyelids ($\approx 10\%$).³¹ Other commonly affected sites include the bronchial mucosa ($\approx 11\%$ of all ENMZL cases), the skin ($\approx 9\%$), the salivary glands ($\approx 6\%$), and the thyroid gland ($\approx 6\%$). More rarely reported sites are Waldeyer pharyngeal lymphoid ring, breast, liver, pancreas, urogenital tract, and central nervous system.^{32–35} Findings at presentation depend on the specific organ affected. Gastric ENMZL may lead to dyspepsia, epigastric pain, nausea, anorexia, and manifestations of gastrointestinal bleeding.³⁶ Conjunctival ENMZL often forms a painless nodule or plaque that has a “salmon-pink patch” appearance and can be associated with erythema, chemosis, and foreign-body sensation.³⁷ Primary cutaneous ENMZL frequently presents as multiple red to violaceous papules, plaques, or nodules, most often on the trunk or extremities, in particular the arms, which very uncommonly ulcerate.³⁸ Salivary and lacrimal gland ENMZL are often preceded by sicca syndrome, with xerostomia or xerophthalmia. B symptoms are uncommon ($\approx 15\%$ of cases).³²

IPSID usually affects young adults, with no gender predominance, and is seen most commonly in the Middle East and Northern Africa, usually in low socioeconomic status populations.³⁹ The disease affects the proximal small bowel diffusely and generally presents with a malabsorption syndrome, with steatorrhea, hypocalcemia, weight loss, abdominal pain, and fever. Cases involving the stomach, the colon, and very rarely, the respiratory tract have been described.⁷

Pathobiology and Differential Diagnosis

Etiology

ENMZL is strongly associated with chronic antigenic stimulation, including that deriving from chronic bacterial infections^{15,17,40–59} or

autoimmune disorders^{60–64} (Table 79.2), although the strength of this correlation for some primary sites of disease is discordant among studies, suggesting a possible geographic variation. The common assumption about this association is that continual immune stimulation by bacterial or self-antigens leads to expansion of lymphoid elements in the connective tissue adjacent to the epithelium involved, initially leading to a process of reactive lymphoid hyperplasia. Persistent lymphocytic activation and proliferation predisposes to the accumulation of genetic errors that ultimately may result in antigen-independent growth and, consequently, lymphoma emergence.^{55,66} The histologic distinction between the reactive inflammatory process associated with chronic infection (or autoimmunity) and lymphoma proper may be difficult, in which case demonstration of immunoglobulin gene monoclonality by molecular studies may aid in establishing the diagnosis of lymphoma.⁶⁷

Histology

ENMZL is composed predominantly of morphologically heterogeneous small B cells.⁶⁷ These resemble a spectrum spanning from small lymphocytes with scant cytoplasm to slightly larger cells with nuclei

similar to those of centrocytes and having relatively abundant pale cytoplasm (leading possibly to a monocytoid appearance). These cells are located in the outer zone of reactive lymphoid follicles, extend into the interfollicular region, and may sometimes colonize the germinal centers. Larger, immunoblast- or centroblast-like cells may be present in small numbers, but an abundance of these should raise suspicion for diffuse large B-cell lymphoma (DLBCL), which requires different management. According to the newest WHO classification, the term *high-grade MALT lymphoma*, denoting the presence of sheets of transformed cells, should not be used and instead these tumors should be diagnosed as DLBCL.

Often there are lymphoid infiltrates invading and destroying glandular structures, with eosinophilic degeneration of epithelial cells (so-called lymphoepithelioid lesions), which are strongly suggestive, albeit not pathognomonic, of progression to lymphoma in cases where the differential diagnosis with reactive lymphoid hyperplasia is in doubt (Fig. 79.2). Plasmacytic differentiation is frequent, especially in association with cutaneous, thyroid, and intestinal (IPSID) ENMZL and may pose differential diagnosis problems with lymphoplasmacytic lymphoma. These plasmacytoid cells often contain periodic acid–Schiff (PAS)–positive inclusions, known as Dutcher or Russell bodies, depending on whether they are located over the nucleus or in the cytoplasm, respectively.⁶⁸

In gastric ENMZL, histology also plays an important role in establishing the diagnosis of *Helicobacter pylori* infection. All biopsy samples should have sections appropriately stained for its detection (see Fig. 79.2D). Because proton pump inhibitors (PPIs) may decrease the sensitivity of detection, patients should stop taking these medications for at least 2 weeks before biopsies are obtained.^{69,70}

TABLE 79.2 Chronic Antigenic Stimulation and Extranodal Marginal Zone Lymphoma

Bacterial Infections		
Organism	Site	Prevalence (%)
<i>Helicobacter pylori</i> ^{15,17,41,42,43}	Stomach	72–100
<i>Campylobacter jejuni</i> ⁴⁴	Intestine (IPSID)	≈70
<i>Chlamydomphila psittaci</i> ^{45,46,47,48,49,50,51,52,53,54,55}	Conjunctiva	0–89
<i>Borrelia burgdorferi</i> ^{56,57,58,59}	Skin	0–42
Autoimmune Disorders		
Disease	Site	Relative Risk
Hashimoto thyroiditis ^{61,62}	Thyroid	67–80
Sjögren syndrome ^{60,63,64}	Salivary and lacrimal glands	6.6–30.6

^aEstimated by assuming cases of thyroid histiocytic lymphoma were ENMZL because these were published before the REAL classification.

Immunophenotype

ENMZL cells display common pan-B-cell markers, such as CD19 and CD20. They are also usually positive for the complement receptors CD21 and CD35, antigens that are shared with follicular dendritic cells, and also for CD79a. Plasmacytoid cells can be CD138-positive. Helpful in the differential diagnosis with other indolent lymphomas, ENMZL are usually CD5-negative (in contrast to chronic lymphocytic leukemia/small lymphocytic lymphoma [CLL/SLL] and mantle cell lymphoma [MCL]), CD23-negative (in contrast to CLL/SLL), CD10-negative (in contrast to follicular lymphoma [FL]), and cyclin D1-negative (in contrast to MCL). They

Fig. 79.2 EXTRANODAL MARGINAL ZONE LYMPHOMAS OF MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT LYMPHOMAS). A–C, An example of a MALT lymphoma in the parotid gland is illustrated with various stains. The glandular tissue is overrun by lymphoid cells, which disrupt and destroy the gland. The resulting structure is referred to as a *lymphoepithelial lesion* (A). These can be more clearly identified with a keratin stain (B) and with a B-cell stain such as CD20 (C), which illustrate the glandular remnant and the B-cell proliferation. (D) MALT lymphoma of the stomach is commonly associated with *H. pylori* infection, which can be identified by special stains (*top*).

TABLE
79.3

Frequency of Common Genetic Aberrations in Extranodal Marginal Zone Lymphoma According to Primary Site of Disease

Primary Site	Genetic Abnormality ^{33,34,71} Genes Involved ⁷⁷					
	t(11;18)(q21;q21) <i>BIRC3/MALT1</i>	t(14;18)(q32;q21) <i>IGH@/MALT1</i>	t(1;14)(p22;q32) <i>IGH@/BCL10</i>	t(3;14)(p14.1;q32) <i>IGH@/FOXP1</i>	+3 ^a <i>NFKB1Z, BCL6, FOXP1, ...</i>	+18 ^a <i>BCL2, NFATC1, ...</i>
Lung	36–53	6–10	2–7	0	13–20	7
Intestine (non-IPSID)	13–56	0	0–13	0	75	13–25

Thyroid	0–17	0	0	0–50	11–17	0–22

All values expressed as percentages of cases.

^aMostly partial trisomies. Data summarized based on references noted.

are also negative for BCL6, which may be helpful to exclude transformation to DLBCL. Except for IPSID, in which tumor cells express a truncated alpha heavy chain without any light chain, most ENMZL are typically positive for IgM or, less commonly, IgA or IgG, with light chain restriction. IgD expression is usually negative or very weak. These immunoglobulins may be secreted, especially when there is significant plasmacytic differentiation, and can give rise to a monoclonal band in the serum protein electrophoresis. The truncated heavy chains of IPSID usually do not appear as a monoclonal band because they comigrate with other serum proteins but can be detected with anti-alpha heavy chain antibodies on immunofixation.

Genetics

Specific chromosomal aberrations have been associated with ENMZL, the frequency of which depends strongly on the primary site of disease (Table 79.3).^{33,34,71} These abnormalities can be detected by conventional cytogenetics in metaphase plates or through fluorescent in situ hybridization (FISH) of interphase nuclei using specific probes. The most commonly observed abnormality is the t(11;18)(q21;q21), which fuses the *BIRC3* (baculoviral inhibitor of apoptosis repeat containing 3, also known as API2, or apoptosis inhibitor-2 protein) and *MALT1* (MALT lymphoma translocation-1 protein) genes in chromosomes 11 and 18, respectively, leading to expression of a *BIRC3-MALT1* chimeric protein.⁷² The native *MALT1* is part of a protein complex that includes the *BCL10* protein (B-cell lymphoma protein 10) and that indirectly leads to nuclear factor kappa-B (NFκB) activation, a process under strict control by several upstream factors. Expression of the fusion protein leads to constitutive activation of NFκB via canonic⁷³ and noncanonic⁷⁴ pathways, which in turn leads to resistance to apoptosis and uncontrolled proliferation. The t(11;18) has a special prognostic significance in gastric ENMZL, because its presence is associated with worse response to antibiotherapy,⁷⁵ which is at least partly because of its higher prevalence in *H. pylori*-negative gastric ENMZL.⁷⁶

Another, less frequently observed, abnormality is the t(14;18)(q32;q21). This translocation is different from that observed in follicular lymphoma, which involves the *BCL2* gene, and instead brings the *MALT1* gene under the influence of the immunoglobulin heavy chain gene promoter (IGH@), leading to overexpression of *MALT1* and, through mechanisms akin to those of t(11;18), constitutive activation of NFκB. The t(1;14)(p22;q32) is seen even more rarely and causes overexpression of the *BCL10* gene, which is placed under control of the IGH@ promoter, and, in turn, activation of the same pathways affected by *MALT1*. A fourth translocation, t(3;14)(p14.1;q32), described mostly in ocular, cutaneous, and thyroid ENMZL, involves the *FOXP1* (forkhead box protein P1) transcription factor and the

heavy chain promoter.⁷⁸ Although *FOXP1* is overexpressed in these tumors, its exact significance in their biology is unknown.

Apart from the translocations described, all believed to be mutually exclusive, ENMZL has also been associated with gains of genetic material, in particular partial trisomies of chromosomes 3 (including regions affecting *FOXP1*, *NFKB1Z* [NFκB inhibitor zeta], and *BCL6*) and 18 (affecting *NFATC1* [nuclear factor of activated T cells, cytoplasmic, calcineurin-dependent 1], and *BCL2*). Gains at 6p25 and losses at 6q (affecting *TNFAIP3* [tumor necrosis factor, α-induced protein 3])^{79,80} and 1p have also been reported.⁷⁷

Consistent with a postgerminal center B-cell origin, ENMZL have rearranged immunoglobulin genes that display somatic hypermutation of their variable regions.⁸¹ In the case of IPSID, there are deletions of the alpha heavy chain gene in the VH and CH1 regions, which result in the production of an abnormal heavy chain that cannot bind light chains to form a complete immunoglobulin molecule.⁸²

Therapy for Early-Stage (I/II) Disease

Given its rarity, there are no randomized controlled trials defining the optimal treatment for ENMZL. Most recommendations arise from consensus panels based on data from retrospective or uncontrolled prospective trials. The most extensive body of data has been gathered on gastric ENMZL.

Gastric Extranodal Marginal Zone Lymphoma

This form of ENMZL has a strong association with active *H. pylori* infection. If histologic analysis of the gastric biopsies obtained during staging endoscopy fails to demonstrate *H. pylori*, noninvasive methods, such as breath tests, stool antigen test, or serology, should be used to exclude the infection. Although not necessarily a marker of active infection, the presence of antibodies against *H. pylori* in an individual not previously treated for this bacterium implicates it in the pathogenesis of the lymphoma.

The focus of therapy for *H. pylori*-positive disease is on eradication of the infection with one of the currently recommended regimens for this purpose. These commonly combine a PPI and clarithromycin with a second antibiotic, usually amoxicillin or metronidazole (triple therapy), but this is an issue in flux as resistance to clarithromycin is increasing in several regions.⁸³ Alternatively, quadruple therapy with a PPI, bismuth, tetracycline, and metronidazole can be used. Most authors recommend 10–14 days of treatment because of data suggesting better results than with 7-day courses. According to some authorities, eradication of *H. pylori* should be confirmed

with an appropriate test, such as the urea breath test, at least 4 weeks after finishing antibiotherapy and 2 weeks after discontinuing PPI.⁸³ Pooled data from several prospective and retrospective studies suggest more than 90% eradication rates after initial antibiotherapy.⁸⁴ Persistent infection should be treated with a different course of antibiotics, preferably guided by sensitivity tests, because the same data suggest an eradication rate close to 100% after second- or third-line treatments. Repeat endoscopy with biopsies should be obtained 3 months after completion of antibacterial therapy to assess tumor response and also to allow histologic confirmation of *H. pylori* eradication. If *H. pylori* is still detected, a different antibiotic combination should be tried and the patient reassessed as mentioned previously.^{9,11}

Responses to therapy are classified according to biopsy findings on endoscopy. Complete histologic response (complete remission [CR]) should be confirmed by a second endoscopy 3 months later and is managed by observation and regular follow up thereafter as clinically indicated. The presence of small residual lymphoid aggregates early after *H. pylori* eradication, corresponding to a category of *probable minimal residual disease* in the French Study Group of Adult Lymphomas (GELA) grading system for posttreatment evaluation, should also be managed as CR.⁸⁵ In some cases, these lymphoid aggregates have been shown to harbor cells with the same monoclonal rearrangements of the original tumor.⁸⁶ Nevertheless, these patients do not seem to have an increased risk for relapse and most will have evidence of complete response in a subsequent evaluation.⁸⁷

Patients with overt residual (partial remission [PR]) or stable disease, as long as asymptomatic, can also be managed conservatively, with observation or antibiotherapy as appropriate, for several months. Of interest, responses may occur as late as more than 18 months after completion of antibiotic therapy.^{43,87} Progressive or symptomatic disease should be managed with local therapy, with radiotherapy being preferred. Despite its established efficacy in disease control, gastrectomy, because of its immediate morbidity and long-term metabolic complications, is currently reserved for management of rare complications such as perforation or bleeding that cannot be controlled endoscopically.^{9,11}

A recent meta-analysis of 1436 patients with early stage (IE-IIIE1) *H. pylori*-positive disease on prospective or retrospective studies estimates an overall CR rate of 78% after eradication of *H. pylori*,⁸⁸ but with individual study remission rates anywhere from 47% to 100%.^{15,17,41–43,86,89–113} On univariate analysis of available data from the same studies, adverse risk factors for achieving remission included the presence of t(11;18), stage greater than IE1, proximal (body or fundus) location of lesions, and Western (versus Asian) residence. No good evidence is available to support adjuvant chemotherapy after anti-*H. pylori* treatment as a means to prevent recurrence in localized gastric MALT lymphomas, although this has only been formally addressed with an additional single agent (chlorambucil).¹¹⁴

The management of early-stage *H. pylori*-negative disease is controversial, with some groups suggesting involved field radiation therapy or, if radiation therapy is contraindicated, systemic therapy with rituximab as initial treatment,⁹ whereas others propose a trial of anti-*Helicobacter* therapy.¹¹ The rationale for the latter derives from anecdotal reports of CR in *H. pylori*-negative gastric ENMZL patients who were treated exclusively with antibacterials,¹¹⁵ with a metaanalysis suggesting a response rate of up to 19%.¹¹⁶ These patients are assumed to have been infected with *H. pylori* that was missed by diagnostic tests or with a different species of *Helicobacter*, several of which have been recently recognized.^{117,118}

Responses to radiation therapy are excellent, with some series reporting CR rates of up to 100% with total doses as low as 30 Gy.^{119,120} Recurrence rate is very low in these patients, but follow up is limited for most series reported.

The optimal follow-up schedule is unknown, although most recommend periodic endoscopies every 3–6 months for the first 5 years and yearly thereafter.^{9,11} Long-term follow-up data in patients with complete remission after *H. pylori* eradication document a 7.2% relapse rate overall (2.2% per year).⁸⁸ Some of these relapses were associated with *H. pylori* recurrence, and responses to retreatment

for *H. pylori* were seen. Whether most complete remissions equate to cures is a question that will require longer follow-up studies. An additional argument in favor of periodic endoscopies is that *H. pylori* may be associated with an increased risk for gastric adenocarcinoma.¹²¹

Molecular studies should not be done routinely in follow-up biopsy samples, outside of a research protocol. Several studies have shown that molecular disease, defined by the presence of residual t(11;18) or monoclonal immunoglobulin as evidenced by PCR methods, may still be detected even with complete pathologic remissions.^{100,122,123} However, this finding is not associated with an increased relapse rate and thus is not currently helpful for clinical management.

Ocular Extranodal Marginal Zone Lymphoma

Localized forms of ocular adnexal ENMZL are most frequently managed with radiation therapy, with treatment specifics dependent on the exact location of the tumor in the orbit. Reported responses are very good, with CR rates of 83%–100%.^{124–133} Local recurrence rates vary between 0% and 17%, and distant recurrences can occur up to 25% over 10 years, although disease-specific survival approaches 100% in most series. The exact site of presentation correlates with the risk for systemic recurrence, the lowest being for conjunctival and the highest for eyelid primaries.³¹ Long-term complications, such as cataract formation and xerophthalmia, occur in approximately half the patients.¹³⁴

Based on the success of antibiotherapy for *H. pylori*-associated ENMZL and reports of the presence of *Chlamydophila psittaci* (by PCR, immunofluorescence, or electron microscopy) in ocular tissues of patients affected by ocular adnexal ENMZL, a course of an anti-chlamydial antibiotic has been evaluated as initial management for these patients.^{45–55} A few of these studies have reported PR or CR in a significant fraction of these patients, with a recent prospective study documenting an overall response rate (CR+PR) of 65% and suggesting improved response rate and progression-free survival in patients in whom *C. psittaci* eradication was documented.⁵⁰ However, the recommendation to treat with a tetracycline at initial diagnosis is still controversial because the reported rates of association with *C. psittaci* are highly variable—some studies suggest prevalences as high as 80%, whereas others are not able to detect the organism in any of the patients. A meta-analysis has suggested that the benefit of antibiotherapy may be restricted to specific geographic areas and, even then, is likely to be limited.¹³⁵

Cutaneous Extranodal Marginal Zone Lymphoma

Results for both surgical excision and radiation therapy for limited disease are comparable, with CR rates approaching 100%. Both approaches have a relapse rate (usually limited to the skin) of around 45%. Encouraging results have also been obtained with intralesional injection of rituximab or α -interferon.³⁸

Studies from Europe have suggested an association between *Borrelia burgdorferi* infection and ENMZL of the skin, although this has not been reproduced in Asian and American studies.^{56–59} In view of this, similar to ocular lymphoma, it has been suggested that a course of a tetracycline may be a reasonable first approach, especially in locations where the association has been documented or when infection by *B. burgdorferi* is detected.

IPSID

Antibiotherapy (varying from single-agent tetracycline to triple-antibiotic therapy with ampicillin, metronidazole, and tetracycline, or an *H. pylori* regimen)^{136–139} has long been recognized as being able to induce CR in early-stage disease. Recently, IPSID has been associated with chronic infection with *Campylobacter jejuni*.⁴⁴ Therefore

treatment of early disease is directed at bacterial eradication. Historic rates of remission vary between 30% and 70%, depending on the study. Maximal responses may take more than 5 months of therapy, and relapses occur in a fraction of patients.

Other Extranodal Marginal Zone Lymphoma

Early-stage ENMZL in other primary sites is managed in a similar way to ocular adnexal or cutaneous forms. When feasible, surgery can be potentially curative and often may be done with primary diagnostic intent. If full resection is achieved, these patients may be observed. Otherwise, for sites not amenable to surgery or if there is residual disease after surgical excision (i.e., positive margins), radiation therapy is the usual preferred approach. If radiation is contraindicated and the patient is asymptomatic, observation is an option. Otherwise, systemic therapy as for advanced stage, preferably one with minimal toxicity, is appropriate.^{9,140}

Therapy for Advanced-Stage (III/IV) Disease

The data regarding management of advanced-stage disease are also limited, because most large treatment series with long-term follow-up aggregate all indolent lymphomas and include only a small fraction of patients with MZL among other more frequent histologies. Thus most treatment approaches have been modeled after those for FL (see Chapter 80), and indeed the most common recommendation is that advanced ENMZL be managed as advanced FL.⁹ In any case, there is some suggestion that responses may be better, possibly because of a usually lower burden of disease. Eligible patients should be included whenever possible in clinical trials.

As in other indolent lymphomas, extensive disease is likely incurable with current approaches, which together with a generally slow pace of progression means that systemic treatment is not always indicated. Because no benefit in survival has been demonstrated with early systemic treatment of asymptomatic disease, unless a treatable etiology has been identified, initial management of asymptomatic patients with expectant observation is acceptable. While on this watch-and-wait approach, patients should be reassessed approximately every 3 months with history, physical examination, complete blood counts, basic chemistry, and LDH. Any new symptoms or findings suggestive of transformation should be investigated with a repeat biopsy to rule it out. Routine repeat imaging studies are controversial but often used.

Indications for initiating systemic treatment include symptomatic disease caused by mass effect or effusion, risk for local compressive disease, bulky lymphadenopathy, symptomatic splenomegaly, B symptoms, cytopenias arising from bone marrow involvement, or rapid disease progression. Although unlikely to contribute to regression of established advanced disease, treatment of an underlying infection associated with the lymphoma (such as *H. pylori* for primary gastric ENMZL and *C. jejuni* for IPSID) is advisable to remove any inciting factor. Otherwise, as already mentioned, the same treatment approaches used for FL (see Chapter 80) are usually followed for ENMZL. Nonetheless, a few studies specifically addressing MZL are worth reviewing here.

Rituximab

Given its low toxicity, single-agent immunotherapy with rituximab has generated a lot of interest in the management of advanced disease. Two series of approximately 30 patients each, pooling early- and advanced-stage ENMZL, have reported overall response rates of around 75%,^{141,142} with up to 48% CR in patients without previous therapy. In one of the series, median time to treatment failure was 22 versus 12 months in chemotherapy-naïve versus non-naïve patients, respectively.¹⁴¹ Rituximab has activity in t(11;18)-positive disease.¹⁴²

Alkylating Agents

Single-agent alkylators have also been used in this setting. A study of 24 patients with gastric ENMZL (stages IE or IV) treated with daily oral chlorambucil or cyclophosphamide for 12–24 months showed a CR rate of 75%, with the remaining patients achieving PR.¹⁴³ Remissions were durable in approximately half of the patients after a median follow-up time of 45 months. Another study of 21 patients (stages I to IV) treated with continuous alkylating drugs documented a CR rate of 42% and 89% in t(11;18)-positive and t(11;18)-negative disease, respectively.¹⁴⁴ After a median follow up of 7.5 years, CR was sustained in all patients with translocation-negative disease, but in only one patient otherwise.

The combination of rituximab and chlorambucil has produced an impressive 100% CR rate in 13 patients with t(11;18)-positive gastric ENMZL (stages I to IV).¹⁴⁵ No relapses were observed after a median follow-up of 24 months in this report but long-term data were not available.

This combination has been studied in a randomized controlled trial versus each single agent in 393 patients not responding or not suitable for local therapy.^{146,147} CR rate, and 5-year event-free and progression-free survival were better with the combination, but 5-year overall survival was 90% in the whole population, without significant differences between the three arms.

Purine Analogues

The purine analogue cladribine has also been used as single-agent therapy in a series of 25 patients (stages I to IV), and CR was obtained in 84% of them. After a median follow-up time of 80 months, seven patients experienced disease relapse.¹⁴⁸ Of note, one of the patients treated developed a myelodysplastic syndrome immediately after the third infusion of the drug.¹⁴⁹ Another purine analogue, fludarabine, has been used in combination with rituximab to treat a series of 22 patients (stages I to IV).¹⁵⁰ At the end of treatment (three cycles, with some patients requiring six), 90% of patients achieved CR. The progression-free survival rate at 2 years in patients with gastric and extragastric ENMZL was 100% and 89%, respectively. Both purine analogues seem to have activity in t(11;18)-positive gastric ENMZL.

Other Single Agents

Other single chemotherapeutic agents whose use has been reported in ENMZL include oxaliplatin, bendamustine, bortezomib, and vorinostat. In a study of 16 patients (stages I to IV) treated with oxaliplatin, a CR rate of 56% with a median time to response of 4 months was observed.¹⁵¹ Responses to bendamustine (with or without rituximab) have been documented in patients with relapsed/refractory indolent lymphomas, a small fraction of which were ENMZL.^{152,153} A retrospective series of 14 ENMZL patients reported 10 CR and three PR with the combination of bendamustine and rituximab.¹⁵⁴ Other studies of patients with relapsed, multiply treated indolent lymphomas report encouraging responses to bortezomib (two cases with PR out of two patients)¹⁵⁵ and vorinostat (one CR and one PR out of nine patients).¹⁵⁶ Long-term follow up is not available; therefore, the role of these agents as first-line therapy has not been established.

Combination Chemotherapy

Combination chemotherapy regimens reported in ENMZL patients include CVP (cyclophosphamide, vincristine, and prednisone) followed by radiation therapy,¹⁵⁷ FM (fludarabine and mitoxantrone),¹⁵⁸ CHOP (cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], and prednisone) followed by CVP,¹⁵⁹ MCP (mitoxantrone, chlorambucil, and prednisone),¹⁶⁰ R-CHOP (rituximab, cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], and

prednisone) and R-CNOP (rituximab, cyclophosphamide, mitoxantrone [Novantrone], vincristine [Oncovin], and prednisone).¹⁶¹ These regimens have mostly been used in patients who were believed to have more aggressive disease. CR rates vary from 61% to 100%, with relapse rates reaching up to 36% on long-term follow-up. Advanced/transformed IPSID has usually been treated with combination chemotherapy, such as CHOP.^{7,162}

Radioimmunotherapy

Radioisotope-conjugated forms of anti-CD20 antibodies (ibritumomab and tositumomab) have also been used both as first-line¹⁶³ therapy (eight CRs and one PR in nine patients with ocular adnexal ENMZL) and for relapsed disease^{164,165} (three CRs and three PRs in six patients with ocular adnexal ENMZL; four CRs and one PR in six patients with a variety of primary sites). The combination of conventional radiation therapy and rituximab has been studied for early-stage follicular lymphoma.¹⁶⁶ There are no published studies of its use on ENMZL.

Therapy for Relapsed Disease

Limited relapses can be retreated, if feasible, with local therapy. Otherwise, treatment considerations are similar to those described for advanced disease. Symptomatic, relapsed extensive disease will usually require an alternative regimen to those previously used.

The role of hematopoietic stem cell transplantation is controversial because most series do not directly address ENMZL and thus most recommendations are again extrapolated from studies of FL.^{167–171} Given that most young patients with relapsed systemic ENMZL are likely to succumb to complications of their disease, considering them for allogeneic stem cell transplantation is reasonable, although this should preferably take place on a clinical trial. Encouraging results have also recently been reported with high-dose therapy and autologous stem cell transplantation specifically for MZL.¹⁷²

Prognosis

Overall, prognosis of limited stage ENMZL is excellent, as mentioned in each of the treatment subsections. Even for advanced disease, the expected lymphoma-specific survival at 5 years is close to 90%, with some series showing survivals similar to those of early disease. A recent retrospective analysis of SEER data lists the best 5-year overall survivals for cutaneous (88%), ocular (83%) and thyroid (85%) forms, and worst for genitourinary (76%), intestinal (69%), and central nervous system (71%) forms.²⁹ As in other indolent lymphomas, transformation to aggressive forms (DLBCL) can occur, but this is thought to be a rare event (less than 10% of cases) associated with acquisition of additional genetic abnormalities.³⁵ Regardless, even patients in CR after first-line therapy can develop DLBCL. For instance, 0.05% of individuals with gastric ENMZL who underwent successful antibiotic treatment had evidence of DLBCL between 6 months and 2 years after achieving remission.⁸⁸ On the other hand, untreated IPSID tends to evolve to large-cell transformation.^{7,162}

As for other lymphomas, the International Prognostic Index (IPI)¹⁷³ (see Chapter 82) predicts outcomes, with reported 5-year overall survivals of >90%, 70%–80%, and 40%–50% for patients with low, low-intermediate/high-intermediate, and high-risk scores, respectively.³⁰ Nonetheless, the utility of the IPI in ENMZL has been disputed.¹⁷⁴ One of the main criticisms to its use in patients with indolent lymphomas is that prognostic subgroups do not have a good discriminating power, because most patients are assigned to the favorable outcome groups and only very few patients are allocated to the adverse prognostic groups.¹⁷⁵ To circumvent this issue, modifications of the original IPI have been proposed in some cases,¹⁷⁶ but none has been universally adopted.

Suggested Treatment Approach to Extranodal Marginal Zone Lymphoma

Stage I/II

Gastric *H. pylori*-Positive

- Antibiotic therapy
- Repeat endoscopy in 3–6 months
- If still *H. Pylori*-positive and no progression, alternative antibiotic therapy
- Repeat endoscopy in 3 months

Nongastric, Gastric *H. pylori*-Negative or Not Responding to Antibiotic Therapy

- Antibiotic trial for stage I gastric, ocular, or cutaneous?
- Involved field radiation therapy (30 Gy)

Stage III/IV or Relapsed After Antibiotic and Radiation Therapy

- Expectant observation until indication to treat
- Rituximab ± single-agent alkylator/purine analogue or combination chemotherapy (CVP/FND)

The recent explosion of genomic analysis of these neoplasms has also led to a plethora of findings that have been shown to have prognostic significance in ENMZL. For instance, the expression of FOXP1 in tumors predicts poor prognosis and transformation to diffuse large B-cell lymphoma.¹⁷⁷ Although these findings are not yet incorporated into clinical practice, as they become more widely available, they may be useful for risk stratification and therapeutic decisions (see box on [Suggested Treatment Approach to Extranodal Marginal Zone Lymphoma](#)).

SPLenic MARGINAL ZONE LYMPHOMA

Epidemiology and Manifestations

SMZL (Fig. 79.3; E-Slide VM03955) is a rare disease, corresponding to <1% of all NHL,⁸ with a yearly incidence rate of 0.25 per 100,000 adults in the United States according to SEER data.²⁹ The median age at diagnosis is around 65, but as with ENMZL, the age range is wide and there may be a slight female predominance. The vast majority of patients present with advanced-stage disease involving the spleen (with splenomegaly in more than 80% of patients), abdominal (mainly splenic hilar) lymph nodes, and in 83%–94% of patients, the bone marrow.^{178–181} Peripheral lymphadenopathy is, however, uncommon. Liver involvement is seen in up to one-fourth of patients, and rarely other nonhematopoietic sites can also be involved. B symptoms occur in approximately 25%–60% of patients, depending on the series.^{179,180}

Circulating villous lymphocytes (with short polar villi) can be seen in approximately two-thirds of patients (see Fig. 79.3B) and frank lymphocytosis in up to one-half. This has led to a prior designation of *splenic lymphoma with villous lymphocytes* being given to a specific presentation of this disorder and explains why the disease was called *SMZL with or without villous lymphocytes* in a previous version of the WHO classification. Anemia is seen in about one-half to two-thirds and thrombocytopenia in one-fifth of cases, which can be the result of bone marrow involvement or an autoimmune process (seen in approximately 15% of patients). Between 25% and 40% of patients have a low-level circulating monoclonal immunoglobulin (mostly IgM),¹⁸⁰ and in a few patients, especially in those with active hepatitis C virus (HCV) infection, mixed cryoglobulins can be demonstrated, which can be associated with vasculitis.^{182,183}

Pathobiology and Differential Diagnosis

Etiology

Approximately 10%–20% of SMZL patients from European series have evidence of HCV infection,^{178,181} and a significant fraction of

Fig. 79.3 SPLENIC MARGINAL ZONE LYMPHOMA, VILLOUS LYMPHOCYTES, AND PRIMARY NODAL MARGINAL ZONE LYMPHOMA. (A) Splenic marginal zone lymphoma is characterized by an expansion of the marginal zone cells (*left*) and their spilling into the red pulp (*right*). (B) These cells can also become leukemic and can be recognized on the peripheral blood smear. Note the polar distribution of the cytoplasmic projections. (C) Primary nodal marginal zone lymphoma is rare, and involvement of a node by extranodal disease must always be ruled out. NMZL is histologically characterized by an expansion of marginal zone cells (formerly referred to as monocytoid B cells) in between reactive germinal centers.

these patients can achieve CR after successful treatment of the infection.^{183,184} This raises the possibility that, like ENMZL, this disease is associated with chronic antigenic stimulation. However, no other infections have been described in clear connection to SMZL, despite a suggested association with *Plasmodium*,¹⁸⁵ and thus the etiology of most cases is unknown.

Histology

The classic histology of SMZL includes a population of small lymphocytes that surrounds or replaces the germinal centers of the lymphoid follicles of the white pulp, effacing their mantle zone, and progressively merging peripherally with larger, marginal zone–like cells.¹⁸⁶ These cells expand to the interfollicular zones and invariably invade the red pulp (see Fig. 79.3A). A few scattered lymphoblasts are usually present, and as in ENMZL, plasmacytic differentiation can occur. Bone marrow involvement usually gives rise to nodular interstitial lymphoid infiltrates that resemble the histology of the spleen, although the cell types are usually admixed, without distinct zones. Peripheral blood involvement is typically associated with lymphocytes that have short polar villi (see Fig. 79.3B), as mentioned earlier, although the villi may be absent.

Immunophenotype

The phenotype of SMZL is similar to that of ENMZL (see earlier), but in contrast to the latter, SMZL is usually IgD-positive. The same differential diagnosis considerations apply; additionally, because this disease behaves as a chronic B-cell leukemia, it is of interest that SMZL is negative for annexin A1 and CD25 and usually negative for CD103 (in contrast to hairy cell leukemia).¹⁸⁶ Rare cases may be CD5-positive.¹⁸⁷

Genetics

A substantial amount of genetic data on SMZL has been accumulated during the last decade. A recent review of 330 patients with SMZL documented del(7q) (affecting different loci in regions q21 to q36) as the most frequent cytogenetic abnormality (≈40% of patients).¹⁸¹ Gains of genetic material from chromosomes 3 (≈25%), 8 (≈10%), and 12 (≈8%) were also seen frequently. Translocations involving

14q32, different from those seen in ENMZL, occurred in 12% of patients. The translocation t(11;18) was not seen in SMZL. More than 50% of cases had three or more cytogenetic aberrations. Deletions of 8p and 17p (TP53) have been seen in approximately 15% of cases analyzed with DNA microarrays.⁷⁷ The biologic significance of these chromosomal abnormalities is unclear at this point, although there are ongoing efforts at clarifying it.¹⁸⁸

Approximately 50%–60% of SMZL have evidence of somatic hypermutation of the immunoglobulin genes,^{181,188–190} and there is some evidence that, similar to CLL, these cases may have better overall prognosis.¹⁸⁹ Both mutated and unmutated tumors display bias in variable region usage, with predominance of VH1-2 family genes. Intracлонаl variation has also been described, which suggests the presence of ongoing mutational events in these lymphomas.¹⁹¹

In contrast to hairy cell leukemia, the V600E BRAF variant has not been detected in SMZL.¹⁹² In addition, the L265P MYD88 mutation commonly observed in Waldenström macroglobulinemia/lymphoplasmacytic lymphoma is rare in SMZL.¹⁹³ These findings may help distinguish these disorders when the diagnosis is in doubt.

Therapy

Because SMZL behaves indolently, in asymptomatic patients without significant or progressive cytopenias, expectant observation is a reasonable approach. The 5-year overall survival rate of 32 patients with asymptomatic SMZL who never received treatment was 86% in one published series.¹⁹⁴ In another series, 10 out of 14 untreated patients were alive between 1 and 6 years after diagnosis.¹⁹⁵

Indications for lymphoma treatment are similar to those for advanced-stage ENMZL, including symptomatic splenomegaly. As for other forms of MZL, there are no data from randomized trials guiding selection of therapy, and most recommendations come from consensus opinions of experts in the field.⁹

Anti-HCV Therapy

In patients with evidence of active HCV infection, anti-HCV therapy is recommended. A study of the effects of interferon- α (IFN- α) in SMZL showed eight complete and one partial hematologic responses in nine HCV-positive patients after clearance of HCV (with two of them requiring addition of ribavirin), versus no responses in six HCV-negative individuals.¹⁸⁴ One patient in CR treated initially only

with IFN- α had a relapse of the lymphoma with detectable levels of HCV RNA; treatment with IFN- α and ribavirin resulted in second complete virologic and hematologic responses. Given that newer anti-HCV drugs are less toxic and more effective than IFN- α , these may become first choice for these patients. Of note, evidence of monoclonal immunoglobulin gene rearrangement may persist after successful treatment of HCV and SMZL.¹⁸³

Rituximab

Rituximab has been used as single agent or in combination with chemotherapeutic drugs in symptomatic HCV-negative patients or in those whose disease did not respond to anti-HCV treatment. The response rate to single-agent rituximab in a retrospective subseries of 25 patients with splenic and nonsplenic MZL was 88%, which compared favorably with that of 11 patients who received chemotherapy alone (55%).¹⁹⁶ In two other retrospective studies, rituximab was found to be an effective therapy in 90%–95% patients with SMZL, with reduction in splenomegaly and improvement in blood counts.^{197,198} Because of its low toxicity, single agent rituximab is often proposed as initial therapy for symptomatic SMZL.

Splenectomy

Before rituximab was widely available and studied in SMZL, splenectomy was frequently used as first-line therapy. A benefit of this procedure, which may be done for diagnostic purposes in patients with localized disease, is the usual improvement of cytopenias occurring as a result of hypersplenism. Precise response rates to splenectomy are difficult to ascertain. All of 25 patients in a series treated with splenectomy alone had responses, including two CRs.¹⁰ Most responses were durable: only eight of these 25 patients experienced disease progression on long-term follow up, with a median time to progression of 32 months (with a range of 4–137 months).¹⁹⁹ Moreover, all of 16 patients treated with first-line splenectomy in an earlier series had good responses, most likely partial (complete responses could not be assessed because of a lack of bone marrow assessment after treatment); two patients progressed subsequently.¹⁹⁵ Finally, another series of 28 patients documented a 5-year overall survival of 71% after splenectomy; no CRs were reported.¹⁹⁴ Although an effective procedure with very low operative mortality, splenectomy is associated with a long-term increased risk of infection and sepsis, and possibly a hypercoagulable state with potential cardiovascular complications.²⁰⁰ On the other hand, retrospective analysis of SEER data showed no advantage of splenectomy over other treatment approaches for SMZL.²⁰¹ Given these considerations, the role of therapeutic splenectomy in SMZL has been questioned.^{202,203}

Chemotherapy

Single alkylating agents (chlorambucil or cyclophosphamide) have also been used for treatment of SMZL. Most series are very small, but all report a significant fraction of responses, albeit mostly partial. Fludarabine has produced encouraging results also,^{204,205} but the efficacy of cladribine is controversial.^{206,207} The use of combination chemotherapy (including CVP and CHOP) has also been reported, but differences between CHOP (or CHOP-like) therapy and other less-intensive regimens could not be demonstrated.¹⁸⁰ In a subseries of 19 patients treated with chemotherapy alone, the 5-year overall survival rate was 64%.¹⁹⁴

Radiation Therapy

In patients ineligible for any of the aforementioned therapies, radiation therapy to the spleen can be used for symptomatic control. Even

Suggested Treatment Approach to Splenic Marginal Zone Lymphoma

HCV-Positive

- Anti-HCV therapy

HCV-Negative (or Not Responding to Anti-HCV Therapy) or Relapsed

- Expectant observation until indication to treat
- Rituximab
- Splenectomy?
- Rituximab + single-agent alkylator/purine analogue or combination chemotherapy (CVP/FND)
- If contraindication to splenectomy and systemic therapy, low-dose splenic irradiation

low-dose radiation (around 4 Gy) can result in resolution of splenomegaly and correction of cytopenias,²⁰⁸ at least temporarily.

Although it is tempting to compare the results of observation, splenectomy and systemic therapy, this is not prudent. All published series have considerable selection bias, because patients who are believed to have more aggressive disease have been usually offered more-intensive therapies.

Prognosis

Reported 5-year overall survival rates vary from 65%–78%,^{180,194} with a median survival of 10.4 years.¹⁰ The Italian Lymphoma Intergroup (ILI) has proposed a prognostic model using hemoglobin less than 12 g/dL, LDH higher than normal, and albumin less than 3.5 g/dL as risk factors.¹⁷⁸ Low-risk (no factors), intermediate-risk (one factor), and high-risk (two or more factors) patients have 5-year overall survivals of 83%, 72%, and 56%, respectively. Shorter survival has been associated with CD38 expression, unmutated variable region immunoglobulin genes, and expression of a specific set of NF κ B pathway genes (by gene expression array).¹⁸⁸ The presence of both del(8p) and del(17p) involving TP53 is associated with worse prognosis, although isolated deletion 17p is not.⁷⁷ Transformation to aggressive lymphoma may occur in around 10% of cases¹⁰ (see box on [Suggested Treatment Approach to SMZL](#)).

NODAL MARGINAL ZONE LYMPHOMA

Epidemiology and Manifestations

NMZL represents approximately 2% of all NHL, corresponding to a yearly incidence rate of 0.83 per 100,000 adults in the United States according to SEER data. The reported incidence of NMZL has increased significantly over the previous decade,²⁹ but it is unclear whether this is the result of a true increase in the number of cases or of an increased recognition of this entity. The diagnosis requires the absence of extranodal or splenic disease, the presence of which makes ENMZL and SMZL more likely. The median age at presentation is around 60, and in most series there is a slight female predominance. Most patients present with asymptomatic lymphadenopathy, most often in peripheral lymph nodes (especially cervical and inguinal), which is frequently associated with mediastinal or abdominal involvement. The most recent series report the presence of B symptoms in less than 20% of patients.^{32,179,209–213} Except in three of the published series,^{210–212} the majority of patients present with stage III or IV disease (approximately 70%–80% of cases), with bone marrow involvement detected in up to two-thirds of cases. Anemia and thrombocytopenia have been described in up to 30% and 10% of cases, respectively. A monoclonal IgM is seen in approximately 10% of patients. A pediatric form, with excellent prognosis, has been recognized, reported in 2003.²¹⁴

Pathobiology and Differential Diagnosis

Etiology

As with SMZL, some series have reported an association with HCV in up to one-fourth of NMZL cases, but with a strong geographic variation (mostly Italian and Spanish series).^{209,210,212,213} No other clear association has been described.

Histology and Immunophenotype

The histology and immunophenotype of NMZL resembles that of ENMZL or SMZL (see Fig. 79.3C).²¹⁵ The frequent presence of monocytoid B cells explains why this disease has been previously called *monocytoid B-cell lymphoma*²¹⁶ and *NMZL with or without monocytoid B cells*. A primary ENMZL should always be ruled out with appropriate studies (such as endoscopy) because 30%–40% of cases presenting as NMZL may in fact represent nodal dissemination of an ENMZL of MALT type.^{217,218}

Genetics

Complex genetic abnormalities are usually observed in NMZL, with the most frequent being partial trisomies of chromosomes 3 and 18, affecting the same regions as in ENMZL. None of the characteristic translocations of ENMZL are seen in NMZL, however.⁷⁷ Furthermore, del(7q) is also not observed. More than 75% of cases have mutated immunoglobulin genes.^{210,219} Of interest, different VH immunoglobulin gene segments are predominantly involved in HCV-positive and HCV-negative patients, raising the possibility that distinct antigens drive different underlying chronic immune stimulation processes.²²⁰

Therapy

Few data are available to guide treatment of NMZL, and most recommendations are extrapolated from the management of FL.⁹ As in other indolent lymphomas, expectant observation is appropriate for asymptomatic patients. Radiation therapy may be curative for early disease. Symptomatic advanced disease can be managed with the same general approach described for advanced ENMZL, although there is usually a tendency to use combination chemoimmunotherapy identical to that for FL as first-line treatment because of the generally worse outcomes with NMZL as compared with ENMZL.

Prognosis

Most series report worse prognosis for NMZL when compared with the other forms of MZL.³² Overall survival rates at 5 years vary from 55% to 70% in most series, except for those containing a greater proportion of early-stage disease, which report 5-year survivals of up to 80%. Five-year progression-free survival is around 30%. Relapse in extranodal sites is rare. As in other lymphomas, the IPI correlates with outcomes, as does the Follicular Lymphoma International Prognostic Index (FLIPI)²²¹ (see Chapter 80). In a series of 47 patients, those with low-, intermediate-, and poor-risk FLIPI scores had a 5-year overall survival of approximately 90%, 70% and 35%, respectively.²⁰⁹

CLINICAL MANIFESTATIONS, STAGING, AND TREATMENT OF FOLLICULAR LYMPHOMA

John G. Gribben

Non-Hodgkin lymphoma (NHL) refers to all malignancies of the lymphoid system with the exception of Hodgkin lymphoma. Development of the lymphoid system is a highly regulated process, characterized by differential expression of a number of cell-surface and intracytoplasmic proteins and antigen receptor gene rearrangements, somatic hypermutation, and class switching. Dysregulation of this orderly process can result in humoral deficiency, autoimmunity, or malignancy. The indolent B-cell lymphomas are mature peripheral B-cell neoplasms that exclude those diseases associated with an aggressive clinical course. Despite differences in cell of origin, molecular biology, clinical presentation, and clinical course, the indolent lymphomas share common features, including frequent localization to the principal lymphoid organs, a propensity for bone marrow (BM) infiltration and leukemic presentation, and generally an indolent clinical course. The classification of NHLs has been a challenge for pathologists as well as practicing physicians. A number of classifications have been proposed over the years, leading to considerable confusion and difficulty in comparison of outcomes of clinical trials performed using different pathologic classifications. The World Health Organization (WHO) lymphoma classification lists nearly 100 different types of lymphoid neoplasm.¹ This classification uses all available information such as morphology, cytochemistry, immunophenotype, and molecular genetics as well as clinical features. The WHO classification does not include the terminology *indolent lymphoma*. This is a clinical and not a pathologic term and defines those lymphomas that tend to grow and spread slowly and produce few symptoms (<http://www.nih.gov>). Indolent lymphomas represent 35% to 40% of NHLs, and follicular lymphoma (FL) is the most common of the indolent lymphomas.

EPIDEMIOLOGY

It is estimated that in 2016 more than 72,500 cases of NHL will be diagnosed in the United States and more than 20,000 patients will die of their disease, making NHL the seventh most common cancer and the fifth most common cause of death from cancer (<http://seer.cancer.gov/statfacts/html/nhl.html>). NHL is extremely heterogeneous in its molecular pathophysiology, histology, and clinical course, and there are major differences in the incidence of subtypes in different geographic locations and among different racial and ethnic populations. This difference in geographic distribution is particularly striking for FL and in the Western world, FL is the second most common lymphoma, comprising approximately 20% of all NHLs. The incidence of FL in the United States is approximately 3.18 cases per 100,000 persons per year and in Europe is approximately 2.18 cases per 100,000 persons per year.² The incidence of FL and other indolent lymphomas is shown in Table 80.1. The incidence appears stable over time. There is no strong sex preponderance, but the incidence in whites is approximately twice that of black and Asian populations and the disease appears less common in Central and South America. The incidence increases with age and the median age of diagnosis is 65 years. Although most cases are sporadic, there is an increased incidence in family members of affected individuals, with a relative risk of 2.3 for siblings of patients.³ Differentiation of complex environmental factors from true inherited factors remains

difficult. The complexity of the epidemiology of NHL mirrors the complexity of the disease and the complexity of the immune system. Since lymphomas do not constitute a single disease, it should come as no surprise that there is no single etiologic factor. The influence on immune dysregulation of viruses, chemicals, radiation, diet, and aging remains unclear. Immune suppression leads to increased incidence of aggressive lymphomas, but not usually indolent lymphomas. FL typically presents in middle age and in the older adult, and the median age at diagnosis is 60 years. There is a slight female preponderance.²

PATHOGENESIS

FL (Fig. 80.1) is derived from germinal center B cells and maintains the gene expression profile of this stage of differentiation.⁴ FL cells express CD19, CD20, CD22, and surface immunoglobulin and 60% express CD10. A hallmark of the disease is the chromosomal translocation t(14;18) contributing to overexpression of the antiapoptotic protein BCL2. Morphologically the disease is composed of a mixture of centrocytes and centroblasts. The WHO third edition pathologic classification recommended grading in grades 1–3 according to the number of centroblasts (0–5, 6–15, and >15 per high-power field, respectively). Grade 3 was further subdivided into 3A (centrocytes still present) and 3B (sheets of centroblasts). An increased percentage of centroblasts is predictive of poor outcome. A problem with this classification is that it is poorly reproducible among pathologists. It is also clear that there are no major biologic or clinical differences between grades 1 and 2, whereas grade 3B FL is biologically distinct from grades 1–3A, with features suggesting a close relationship to diffuse large B-cell lymphoma (DLBCL).⁵ These considerations led to the recommendation to group together FL grade 1–3A as FL and create a new category called FL3B. However, the gene signature in FL3B is closer to FL than to DLBCL.⁶ The final classification combined FL grades 1 and 2 into one category (FL1–2 of 3) and made the distinction between FL3A and FL3B optional rather than mandatory.⁷ The fourth edition of the WHO classification recognizes some distinctive clinical and genetic subtypes of FL, including primary duodenal FL and the pediatric type of FL that lacks the t(14;18) and usually presents with localized disease. Several variants of FL that lack the t(14;18) have some distinctive features, e.g., predominantly diffuse FL with deletions of 1p36 that presents with localized bulky disease in the inguinal region. The gene expression profiles of FL cases with and without t(14;18) show some differences, with t(14;18)–negative FL resembling activated late-stage germinal center B cells.⁸

Although 85% of patients with FL have the t(14;18), the pathogenesis of FL remains poorly understood. Recent studies have demonstrated frequent secondary genetic alterations including genomic gains, losses, and mutations, particularly inactivating mutations of the *MLL2* gene, which occurred in 89% of FL cases examined,⁹ as well as in the *EPHA7*, *TNFRSF14* and *EZH2* genes. The major mutations seen in FL are shown in Table 80.2. A notable feature of these findings is that many of the mutated genes are involved in transcriptional regulation. It is likely that posttranscriptional modification of histones is of key importance in germinal center B cells and that the deregulated histone modification caused by these mutations

TABLE 80.1	Incidence Rates Per 100,000 of the Indolent Lymphomas (Ref)			
	All	Male	Female	
Non-hodgkin lymphoma	32.2	40.2	25.9	
Follicular lymphoma	3.6	3.9	3.3	
Small B lymphocytic lymphoma/Chronic lymphocytic leukemia/	6.6	7.9	4.6	
Lymphoplasmacytic lymphoma	0.6	0.8	0.5	
Mantle cell lymphoma	0.8	1.3	0.4	
Marginal zone lymphoma	2.0	2.1	1.9

TABLE 80.2	Mutations in Follicular Lymphoma			
Gene Name	Abbreviation	Location	Frequency at Diagnosis	
Myeloid/lymphoid or mixed-lineage leukemia 2	<i>MLL2</i>	12q	89%	
CREB binding protein	<i>CREBBP</i>	16p	33%	
Tumor necrosis factor receptor superfamily member 14	<i>TNFRSF14</i>	1p	25%	
E1A binding protein p300	<i>EP300</i>	22q	15%	
Myocyte enhancer factor 2B	<i>MEF2B</i>	19p	13%	
Enhancer of zeste homolog 2	<i>EZH2</i>	7q	11%	

Fig. 80.1 FOLLICULAR LYMPHOMA: MORPHOLOGIC AND IMMUNOPHENOTYPIC FINDINGS. (A) Low-power photomicrograph illustrates a lymph node involved by follicular lymphoma. The lymphoma cells grow in nodules or follicles that resemble the normal lymphoid follicles of a reactive lymph node. However, in the lymphomatous growth, the follicles are crowded, show back-to-back localization, and lack many of the features of their reactive counterparts. At higher power (B), the neoplastic follicles lack mantle zones, and the normal polarization of small and large germinal center cells (centrocytes and centroblasts, respectively), which occurs because of the cellular response to antigenic stimulation as it sweeps thorough the follicle. (C) The neoplastic follicles stain for the germinal center markers, BCL6 and CD10; however, they overexpress BCL2 (D) caused by the associated translocation t(14;18) involving the *IgH* gene and *BCL2*. BCL2 is not much expressed in normal germinal center B cells (E, control for comparison). Follicular lymphoma is graded by the number of large neoplastic cells (centroblasts) present among the smaller neoplastic cells (centrocytes) (F–I). The grading system is not entirely accurate, but provides some framework for subclassifying cases morphologically. Only 0–5 centroblasts per average field is grade 1 (F); between 6 and 15 is grade 2 (G); and greater than 15 is grade 3A (H). Grades 1 and 2 are now considered together. When most of the cells in the neoplastic follicles are centroblasts without centrocytes the case is considered grade 3B (I) (see text).

is likely to result in reduced acetylation and enhanced methylation, which will act as a driver event in the development of FL. Attention has also been paid recently to the complex interaction between the malignant B cell, the host,¹⁰ and the tumor microenvironment.^{4,11,12}

CLINICAL PRESENTATION

The majority of patients present with lymphadenopathy in one or more sites. Patients with FL often present with a long history of having noted painless increased lymph nodes (LN) over a number of years before presentation. Lymphadenopathy may wax and wane and spontaneous remissions can occur, albeit rarely.¹³ Disease transformation to a more aggressive histologic type is a common terminal event.¹⁴

Extranodal disease is relatively common and can affect any organ. The most common sites of extranodal disease include the BM, skin, gastrointestinal tract, and bone. Symptoms may be nonspecific or related to the site of disease involvement. Many patients are asymptomatic, but some, particularly those with bulky disease may present with B symptoms defined as fever, drenching sweats, or weight loss of more than 10% of body weight. Patients may present with evidence of bowel obstruction from intraabdominal lymphadenopathy, and retroperitoneal disease may manifest as obstructive uropathy. Inguinal disease may cause compression of the venous system with deep venous thrombosis. Central nervous system involvement can occur, but is uncommon in FL.

DIAGNOSIS OF FOLLICULAR LYMPHOMA

Suggested guidelines for the diagnosis of lymphomas have been outlined by the National Comprehensive Cancer Network (guidelines available at <http://www.nccn.org/>) and by the European Society for Medical Oncology.¹⁵ In all cases possible, diagnosis should be confirmed by excisional biopsy of an accessible LN with review by an expert hematopathologist with expertise in lymphoma diagnosis. In patients without easily accessible peripheral nodes, computed tomography (CT) or ultrasound-guided biopsy are typically well tolerated. Fine-needle aspiration is not appropriate for diagnosis in these conditions and sufficient material must be obtained for immunophenotyping and genetic studies as required for diagnosis and assay for prognostic markers. Where possible consent should be obtained for the procurement and storage of use of excess tissue from LN biopsies at the time of presentation and at each subsequent relapse of disease for research purposes to investigate the molecular biology of these diseases as new technologies and findings become available.

Initial essential investigations are shown in Table 80.3. Physical examination should include careful examination of all peripheral LN groups including the cervical, supraclavicular, axillary, and inguinal chains and examination of the Waldeyer ring. Abdominal examination should focus on evaluation of any intraabdominal masses, with particular attention paid to detection of enlargement of the liver or spleen. The skin should be carefully examined. Patients may present with pleural or pericardial effusions, although this is less common than in the aggressive lymphomas. Laboratory investigations should include a complete blood count to evaluate for cytopenias, which may be evidence of BM infiltration or of autoimmunity. A white blood count with differential and examination of the peripheral blood smear may elucidate leukemic involvement with disease. Baseline electrolytes including calcium and phosphate, creatinine, and liver function tests are important to determine organ dysfunction that may be related to direct infiltration by lymphoma. Elevation of lactate dehydrogenase (LDH) is an important prognostic factor and may be a useful indicator of transformation from indolent to aggressive lymphoma. Hepatitis B testing is essential as patients will likely require subsequent treatment with anti-CD20 monoclonal antibody therapy.

Staging workup also includes a CT scan of the chest, abdomen, and pelvis. Particular attention should be paid to sites of bulk disease and to the number of involved sites. BM biopsy provides essential

TABLE 80.4

Ann Arbor Staging

Stage	Criteria
I	Involvement of 1 lymph node (I) or 1 extralymphatic organ or site (IE)
II	Involvement of ≥ 2 lymph nodes on same side of diaphragm (II) or localized extralymphatic organ or site and ≥ 1 involved lymph node on same side of diaphragm (IIE)
III	Involvement of lymph nodes on both sides of diaphragm (III) or same side with localized involvement of extralymphatic site (IIIE), spleen (IIIS), or both (IIIS+E)
IV	Diffuse or disseminated involvement of 1 extralymphatic organ or tissues with or without lymph node enlargement

information and should be performed routinely as it is required for staging of disease. Although the yield of bilateral BM biopsy is moderately higher (15%) than that of unilateral biopsy, this is not now usually performed. Liver biopsy may be indicated based upon abnormal imaging or laboratory testing.

STAGING

The staging of NHL uses the Ann Arbor Classification (Table 80.4). CT scans have replaced lymphangiography. The impact of whole-body positron emission tomography (PET), which is included in the revised guidelines for aggressive lymphomas,¹⁶ has been much less studied in the indolent lymphomas. There is considerable heterogeneity in uptake of fluorine-18 fluorodeoxyglucose based upon histology, but PET demonstrates 94% sensitivity and 100% specificity for staging in FL.¹⁷ Although there is insufficient data yet to recommend PET scans routinely in patients with FL, these can be useful to direct biopsy in cases where transformation is suspected.

NATURAL HISTORY

Until recently there was little evidence that the natural history of FL had changed over the last 30 years from the median survival of 10 years from diagnosis.¹⁸ The survival of patients with FL presenting at St. Bartholomew's Hospital is shown in Fig. 80.2. There is clear evidence that the introduction of monoclonal antibodies in combination with chemotherapy has finally led to an improvement in survival, with the result that the median survival is now increased to 12–14 years.^{19,20} The clinical course is extremely variable, with some patients having an extremely aggressive course and death within 1 year, while others may live for more than 20 years and never require therapy. There is therefore a need for prognostic markers that can help identify those patients who will have a good or poor prognosis. The follicular lymphoma international prognostic index (FLIPI) is a five-factor prognostic index based upon the clinical characteristics age, stage, number of nodal sites, hemoglobin, and LDH level (Table 80.5), and

Fig. 80.2 OVERALL PROBABILITY OF SURVIVAL OF PATIENTS WITH FOLLICULAR LYMPHOMA TREATED AT ST. BARTHOLOMEW'S HOSPITAL.

TABLE 80.5

Factors Having Prognostic Significance in the Follicular Lymphoma International Prognostic Index (FLIPI),²¹ and FLIPI2²²

FLIPI Parameter	Adverse Factor	HR
Age	≥60 y	2.38
Ann Arbor stage	III–IV	2.00
Hemoglobin level	<120 g/L	1.55
Serum LDH level	>ULN	1.50
Number of nodal sites	>4	1.39
FLIPI2		
Parameter	Adverse Factor	HR (in Final Model)
β ₂ -microglobulin	>ULN	1.5

defines three prognostic risk groups of an almost equal numbers of patients.²¹ This tool is useful in assessing the likely need for early treatment of patients and potential outcome, as well as in comparing the outcomes of different clinical trials. A revised FLIPI2 (incorporating β₂-microglobulin, diameter of largest LN, BM involvement, and hemoglobin level) may better discriminate the outcome for patients requiring treatment, with 5-year overall survival of 96% for low-risk patients, 80% for intermediate-risk, and 50% for high-risk patients.²²

An important factor for the prognosis of FL is whether patients undergo histologic transformation.¹⁴ The actuarial risk of FL undergoing histologic transformation in the database of the patients treated at St. Bartholomew's Hospital is shown in Fig. 80.3 and the survival of patients with and without transformation is shown in Fig. 80.4. Despite a considerable body of information on the pathologic and molecular events associated with histologic transformation the pathogenesis of transformation remains elusive and the molecular events that have been identified have not been translated into changes in clinical practice. A major focus of research is the attempt to identify patients at high risk of transformation early in their clinical course, but this is not yet possible. The outcome of patients who undergo transformation after already having received multiple lines of therapy remains poor, but for those patients who undergo transformation and who receive their first therapy for the transformed disease, the use of chemoimmunotherapy has led to a significant improvement in the prognosis of patients.

Fig. 80.3 PROBABILITY OF RISK OF TRANSFORMATION OF PATIENTS WITH FOLLICULAR LYMPHOMA.

Fig. 80.4 OVERALL PROBABILITY OF SURVIVAL OF PATIENTS WITH FOLLICULAR LYMPHOMA WHO HAVE AND HAVE NOT UNDERGONE HISTOLOGIC TRANSFORMATION.

TREATMENT OF FOLLICULAR LYMPHOMA

For most cases of FL the goal of therapy has been to maintain the best quality of life and treat only when patients develop symptoms. Any alteration to this approach requires demonstration of improved survival with early institution of therapy, or identification of criteria that define patients sufficiently “high-risk” to merit early therapy. There are many available therapies and no consensus on an optimal first-line or relapse treatment. Despite the lack of any data demonstrating benefit for early therapy, patients are being treated earlier in their disease course. There is no clear cut treatment pathway for patients with FL and although we have a good evidence base to decide on a particular treatment, there are little or no data regarding the optimal sequencing of treatment approaches in this disease. In the absence of such data, treatment choices remain empiric and should always involve discussion regarding patient choice and the goal of therapy. This is becoming even more complicated because many novel agents are either approved or in clinical studies, particularly, novel monoclonal antibodies and agents that alter the B-cell receptor signaling pathways or antiapoptotic pathways. The impact of these new agents on practice will be dependent upon the results of the ongoing clinical trials.

Multiple treatment approaches exist for advanced stage low-grade lymphomas and these patients are best treated in the setting of clinical trials. Options range from a “watch and wait” expectant management approach, to single agent chemotherapy or monoclonal antibody therapy with rituximab, to combination chemoimmunotherapy, with use of autologous or allogeneic stem cell transplantation (SCT) (Table 80.6). Patients remaining on an expectant course should be followed every 3–6 months for 5 years and then annually if stable,

Palliative radiotherapy

Management of Follicular Lymphoma

Patients most often present with asymptomatic lymphadenopathy. The diagnosis should be made by excisional biopsy and reviewed by an expert hematopathologist. In the absence of symptoms requiring treatment, an expectant “watch and wait” approach is the treatment of choice. While in this phase of treatment patients should be followed every 3–6 months for history, physical, and laboratory examination with radiologic restaging as clinically indicated. Once a decision to treat has been made, there is no clear treatment algorithm and a number of treatment options are available. The treatment goal, whether palliative or potentially with curative intent, is dependent upon the age and performance status of patients. Enrollment in a clinical trial should be the treatment of choice. For younger patients in whom high-dose therapy may be indicated later in their disease course, it is best to avoid profoundly myelotoxic regimens. Rituximab maintenance therapy in first remission given 2-monthly for two years has been demonstrated to improve progression-free, but not overall survival. The role of maintenance therapy in first remission using interferon- α remains controversial. The choice of therapy after first relapse is also dependent upon the goal of therapy, but is also dependent upon the previous therapy given, response, and duration of response. Autologous or allogeneic stem cell transplantation has a role to play in selected younger patients with this disease.

with history, physical exam, and blood counts including LDH. Special attention should be paid to any change in symptoms that might be suggestive of transformation as these are an indication for a repeat biopsy to examine for histologic evidence to confirm transformation. Repeat scanning is not routinely performed unless this is indicated by symptoms or signs.

Since there is no clearly defined treatment algorithm for most patients with FL, eligible patients should be included whenever possible in clinical trials. This ensures delivery of optimal care and helps inform design of subsequent trials, hopefully leading to cure. Information on available clinical trials can be found at <http://www.clinicaltrials.gov>.

WHEN TO INSTITUTE THERAPY**Stage I–II Disease**

Involved site radiation therapy is the preferred treatment for the approximately 10% of patients who present with limited stage, nonbulky disease. Treatment with photons, electrons, or protons may

TABLE 80.7 Criteria for Delaying Treatment**GELF²⁶**

All of the following

- Maximum diameter of disease <7 cm
- Fewer than 3 nodal sites
- Absence of systemic symptoms
- Spleen <16 cm on CT
- No significant effusions
- No risk of local compressive symptoms
- No circulating lymphoma cells or marrow compromise (Hb ≤ 10 g/dL, WBC <1.5 or platelets <100,000/dL)

BNLI²⁷

Absence of all of the following

- B symptoms or pruritus
- Rapid generalized disease progression
- Marrow compromise (Hb ≤ 10 g/dL, WBC <3.0 or platelets <100,000/dL)
- Life-threatening organ involvement
- Renal infiltration
- Bone lesions

all be appropriate depending on clinical circumstances. This treatment option is offered with curative potential²³ but has to be weighed against the potential toxicity in terms of the radiation therapy to other tissues. In patients with large tumor burden or with other adverse risk factors, systemic therapy is indicated. There is no proven role of radiation consolidation therapy.

Bulky Stage II and Stage II/IV Disease

Expectant management is the treatment of choice for asymptomatic patients with low-bulk disease until clear indications for initiation of treatment are seen, except for those patients enrolled in a clinical trial assessing the impact of early therapy. This approach is based upon the demonstration of no survival advantage for institution of immediate treatment compared with deferred treatment until time of progression.²⁴ Three randomized trials, performed in the pre-rituximab era, confirmed no survival benefit for early therapy.^{25–27} In the National Cancer Institute study in 104 newly diagnosed patients with FL, deferred treatment was compared with immediate treatment with ProMACE-MOPP followed by total nodal irradiation. An updated analysis of this data is long overdue, but there was no difference in overall survival (OS) between the two arms at the time of the last analysis.²⁵ The Groupe pour l'Etude de Lymphome Folliculaire (GELF) used defined criteria for patients for whom immediate therapy was not felt to be indicated (Table 80.7) and randomized 193 patients to deferred treatment or to receive prednimustine 200 mg/m² per day for 5 days per month for 18 months or IFN- α 5 million units (MU)/day for 3 months followed by 5 MU three times per week for 15 months.²⁶ The median OS time was not reached and was the same in all three arms of the study. The British National Lymphoma Investigation (BNLI)²⁷ compared treatment in 309 patients with asymptomatic advanced-stage, indolent lymphoma in whom 158 patients were randomized to receive immediate therapy with oral chlorambucil 10 mg per day continuously and 151 patients were randomized to deferred treatment until disease progression (see Table 80.7). In both arms, local radiotherapy to symptomatic nodes was allowed. There was no difference in OS or cause-specific survival between the two groups with median follow up of 16 years. A subsequent multicenter study examined whether rituximab could delay the need for chemotherapy or radiotherapy

compared with watchful waiting.²⁸ A total of 463 patients were randomly assigned to watchful waiting, rituximab 375 mg/m² weekly for 4 weeks (rituximab induction), or rituximab induction followed by a maintenance schedule of 12 further infusions given at 2-monthly intervals for 2 years (maintenance rituximab). The rituximab induction arm was closed early and the study continued to accrue to the other two arms. There was a significant difference in the time to start of next treatment, with 46% of watchful waiting patients still not needing treatment at 3 years compared with 88% in the maintenance rituximab group ($p < .0001$) and 78% in the rituximab induction group.

A major clinical trial question is whether identification of clinical or molecular risk factors can guide which patients are candidates for early therapy. A survival predictor score has also been developed from gene expression profiling studies.⁴ The results from this study suggest that the molecular determinants of biologic heterogeneity are already present in the diagnostic LN biopsies rather than by the later acquisition of secondary genetic changes. A major component of the gene expression prognostic signature is related to immune cells in the tumor microenvironment.^{11,12,29} Whereas it is to be hoped that in the future guidelines for treatment will be based upon clinical staging systems, genetic profiles, and immune response signatures, it has not yet been established which factors help us to decide who should have immediate therapy. This may well have practical implications since it has been demonstrated that patients who progress within 2 years of diagnosis have poorer outcome³⁰ and might well benefit from earlier institution of treatment.

Although there are little available data to suggest that we should change our practice of “watch and wait” for the asymptomatic low-bulk patients, data suggest that this practice is becoming much less common in the United States.³¹ The National Lymphocare study is a prospective observational study designed to assess presentation, prognosis, treatment, and clinical outcomes in newly diagnosed FL. The treating physician determines management according to clinical judgment with no prescribed treatment regimen and data regarding histology, stage, therapy, response, relapse, and death are recorded. Among 2708 patients enrolled at 265 centers, only 17.7% of patients were initially observed and of these, 22% received active therapy within 1 year and 31% within 2 years, the majority with chemoimmunotherapy. This observation is in stark contrast to the data from the BNLI study which demonstrated, that, when censored for non-lymphoma death, 19% of patients and 40% of those older than 70 years who were randomized to expectant management still did not require therapy at 10 years.²⁷

TREATMENT APPROACHES

Treatment is indicated in patients with symptomatic disease, bulky lymphadenopathy and/or splenomegaly, risk of local compressive disease, marrow compromise, or steady progression of disease. Once indicated, numerous treatment approaches are available (Table 80.8). The concept that the approach can be to “do nothing” or discuss an approach with considerable morbidity and mortality even including

TABLE 80.9 Studies of Rituximab Maintenance Therapy in Indolent Lymphomas

approaches such as SCT is a confusing one for the newly diagnosed patient (as well as for the physician) and considerable consultation time is required to review available treatment approaches. Staging of response in FL is by the revised response criteria.¹⁶ Depending on the treatment approach used, restaging after two to three cycles of therapy can be useful to ensure responsiveness, and the patient is then fully restaged after completion of therapy. Whereas curative approaches are being sought in aggressive lymphomas, the failure to achieve complete remission (CR) or complete eradication of disease does not have the same implication in FL as in aggressive lymphomas and depending upon the goal of therapy a partial remission (PR) may be a sufficient response to alleviate symptoms. The more commonly used regimens in indolent lymphomas are shown in Table 80.9.^{32–41}

In the absence of a clear standard of care with curative potential, optimal first-line treatment remains enrolment in randomized clinical trials wherever possible. In the National Lymphocare study,⁴² academic sites are more likely than community sites to treat patients on clinical trials (12% versus 4%), but it is lamentable that only 6% of patients were enrolled in clinical trials. For patients who are not eligible for or who refuse entry into clinical trials, there is data demonstrating higher response rates and longer duration of responses, and perhaps improved survival with chemoimmunotherapy. Many investigators favor alkylator over fludarabine-based regimens for FL, based upon concerns regarding the ability to obtain stem cells for later use for autologous SCT (ASCT) in fludarabine-treated patients.⁴³ It is suggested that more aggressive first-line therapy should be offered to patients who progress within 1 year of presentation, since these patients have a worse outcome.²⁶ Older adult patients or those with poor performance status may remain candidates for single-agent chlorambucil, although this is given most often in combination with rituximab. Single-agent rituximab therapy is appropriate for patients who choose to avoid chemotherapy and is a reasonable treatment choice based upon the results of clinical trials of standard or prolonged induction with or without maintenance therapy with rituximab. Although data suggest a survival advantage with the use of interferon (IFN)- α in combination with chemotherapy, this is associated with a significant side effect profile and this agent is now rarely used. Optimal results are seen when radioimmunoconjugates are used earlier in the disease course. On the basis of results showing no benefit for ASCT, there is no indication for the use of high dose therapy and SCT in first remission in FL unless as part of a clinical trial.

Chemoimmunotherapy is now the treatment of choice for FL. No randomized trials demonstrate a benefit for the addition of anthracyclines, but cyclophosphamide, adriamycin, vincristine, prednisone, and rituximab (R-CHOP) is heavily favored over cyclophosphamide, vincristine, prednisone, and rituximab (CVP-R) or fludarabine-based regimens. Following demonstration of improved outcome using bendamustine plus rituximab (BR) compared with R-CHOP⁴⁴ or to fludarabine plus rituximab,⁴⁵ the use of BR has greatly increased. BR also has improved tolerability and can be given without the

complication of hair loss. Choice to initiate therapy was associated with FLIPI, stage, and grade but FLIPI was not associated with decision to use a specific treatment approach. In the Lymphocare study, significant regional and center differences are observed and strongly suggest that physician preference is the predominant factor that drives initial therapy. For example, initial “watch and wait” was used in 31% of patients in the Northeast, but in 13% of patients in the Southeast, whereas fludarabine-based chemoimmunotherapy was used in 18% of patients in the Southwest and in only 3% of patients in the Northeast.

Alkylating Agents

The alkylating agents, chlorambucil and cyclophosphamide, with or without prednisone and CVP or CHOP, and other alkylator-based combination chemotherapy regimens have been the standard of therapy for decades. Single-agent alkylators at different doses and schedules produce overall response (OR) rates of 50% to 75% in FL.^{46,47} Comparable response rates, but higher CR rates with longer progression-free survival (PFS) are seen with CVP compared with chlorambucil, but have no survival advantage.^{48,49} The addition of anthracyclines has not improved the response rate or duration of the response,^{50,51} but its use may be associated with a lower risk of histologic transformation.^{25,52} This finding has yet to be confirmed, particularly in the era of chemoimmunotherapy.

Purine Analogues

The purine analogues have been studied extensively in various types of indolent lymphoma. Fludarabine monotherapy produces response rates of 65% to 84%, with 37% to 47% CR in previously untreated patients with FL.⁵³ In a randomized trial of 381 previously untreated indolent lymphoma patients CR rates were higher with fludarabine than CVP.⁵⁴ Fludarabine combinations result in increased response rates, with 89% CR rate in an Eastern Cooperative Oncology Group (ECOG) trial combining fludarabine and cyclophosphamide,⁵⁵ while fludarabine and mitoxantrone (FM), produced a 91% overall response rate (ORR), 43% CR and 2-year disease-free survival (DFS) of 63%.⁵⁶ A higher CR rate was seen with FM (68%) compared with CHOP (42%) in a randomized trial.⁵⁷ The use of alkylator-based regimens or purine analog-based regimens appears to vary geographically, suggesting personal preference for the use of regimens in which the clinician has experience, rather than alterations of practice based on the results of the published studies.

Bendamustine

Bendamustine is a potent alkylating agent that has been demonstrated to have substantial efficacy in NHL patients, including those with FL. Bendamustine is highly effective in rituximab-refractory FL and in patients whose disease is refractory to other alkylating agents. It has also demonstrated considerable efficacy in previously untreated FL, both alone and in combination with rituximab or other chemotherapeutic agents.^{58,59} Increased understanding of the mechanisms of action of bendamustine and the efficacy of bendamustine in combination with rituximab in newly diagnosed or relapsed/refractory FL^{44,45,58} has led to investigation of other combinations. Ongoing studies are examining bendamustine with other agents.

Biologic Therapy

IFN- α is approved by the Food and Drug Administration (FDA) for the treatment of advanced stage FL in combination with anthracycline-based chemotherapy, based upon improved survival in clinical trials,^{21,60,61} and meta-analysis of phase III trial data.⁶² IFN- α was more widely used in Europe than the United States, where it is felt

that its toxicity profile outweighs potential benefit. In the Southwest Oncology Group (SWOG) study,⁶³ 571 patients with stage III and IV indolent lymphoma were treated with ProMACE-MOPP and 279 responding patients were randomized to 24 months of observation versus treatment with IFN- α . No statistically significant difference in PFS or OS was observed between observation and IFN- α groups at 4 years.

Monoclonal Antibody Therapy

Monoclonal antibodies remain the most exciting agents to emerge in the treatment of indolent lymphomas. The most widely used monoclonal antibody is rituximab, a chimeric unconjugated antibody against the CD20-antigen licensed by the FDA⁶⁴ and the European Agency for the Evaluation of Medicinal Products⁶⁵ for treatment of patients with relapsed or refractory, CD20-positive low-grade or FL; for the first-line treatment of CD20-positive FL in combination with CVP chemotherapy; and for the treatment of CD20-positive low-grade NHL in patients with stable disease or who achieve a PR or CR following first-line treatment with CVP chemotherapy. The use of this agent has a profound effect in finally leading to improvement in patient survival in FL.^{19,20,66}

Following phase I studies,⁶⁷ rituximab at a dose of 375 mg/m² weekly for 4 weeks was selected for the pivotal phase II trial⁶⁸ and although this remains the standard dose, the optimal dose and schedule of rituximab is still unknown. In relapsed patients with FL OR to rituximab monotherapy was 60% with a median PFS for responders of 13 months. Factors associated with lower response rates include chemoresistant disease,⁶⁸ bulky disease,⁶⁹ and treatment late in the disease course.⁷⁰ OR was 73% in previously untreated patients with low-bulk disease,⁷¹ and some of these patients needed no further treatment and had no evidence of polymerase chain reaction (PCR) detectable minimal residual disease (MRD) after 7 years.⁷² Extended use with 8 weeks instead of 4 is associated with improvement in OR and duration of response.⁷³ Comparable or even longer durations of response have been observed with retreatment.⁷⁴

A number of trials in front-line and in relapsed/refractory patients have investigated the potential benefits of extended or maintenance rituximab treatment^{37–41,75,76} and all demonstrated prolonged time to progression in patients receiving maintenance rituximab (see Table 80.9). The results from the E1496 randomized trial from ECOG and Cancer and Leukemia Group B comparing CVP alone to CVP followed by rituximab in patients with advanced-stage FL demonstrated that addition of rituximab maintenance significantly improved OS,³⁷ and led to FDA approval for rituximab therapy

in patients responding to CVP chemotherapy. The results of the primary rituximab and maintenance (PRIMA) study demonstrated an advantage in PFS for maintenance rituximab therapy offered after initial chemoimmunotherapy.⁷⁶ The study remains too premature to determine whether this will have an impact on OS and questions remain as to whether this should be standard of care.⁷⁷

Chemoimmunotherapy

In a phase II study, 40 patients with indolent lymphoma were treated with six infusions of rituximab (375 mg/m² per dose) in combination with six doses of CHOP chemotherapy (R-CHOP),³⁴ and OR was 95%, with 55% CR. In a phase II study of 40 patients with indolent lymphomas, rituximab in combination with fludarabine produced OR of 90%, with 80% CR, with similar response rates in treatment-naïve and previously treated patients.⁷⁸

A number of randomized trials show a benefit for the use of rituximab with chemotherapy compared with chemotherapy alone (Table 80.10).^{32,33,39,79,80} Each study showed an improvement in time to treatment failure and more recent follow-up data suggests improved OS in patients treated with chemoimmunotherapy compared with chemotherapy alone. A meta-analysis of these trials demonstrates that OS, OR and disease control are significantly better in those on chemoimmunotherapy compared with chemotherapy for FL and mantle cell lymphoma (MCL).⁸¹ Data from the German low grade study group (GLSG) suggest that it is the addition of rituximab that has led to the recent improvement in survival of patients with FL.²⁰ An independently assessed analysis of the clinical benefits provided by rituximab in relation to cost concluded that it is highly-cost effective.⁸²

The largest FL trial reported is the PRIMA study.⁷⁶ This study enrolled 1217 patients to receive initial chemoimmunotherapy from three possible regimens, but of note 75% received R-CHOP. All patients had fulfilled the criteria for treatment and 80% had FLIPI intermediate or high-risk features. Responding patients were randomized to receive no further therapy or to receive 12 doses (every 8 weeks) for two years.

Patients who received rituximab maintenance therapy had significantly better rates of 3-year PFS than did those who received observation (75% versus 58%) and the benefit to maintenance was observed in all FLIPI groups. Time to next treatment was also longer in the maintenance group than in the observation group. There were increased toxicities in the maintenance group, with most being infections, but these were largely self-limiting.

The type II anti-CD20 monoclonal antibody obinutuzumab is approved for use in combination with bendamustine for patients who

are refractory to or relapse early after use with rituximab containing regimens and showed improved outcome in the Gallium study comparing obinutuzumab plus chemotherapy head-to-head with rituximab plus chemotherapy (NCT01332968).

Conjugated Radio-Labeled Monoclonal Antibody Therapy

Complexing a radioisotope to a monoclonal antibody (radioimmunoconjugate) might be expected to improve efficacy over antibody therapy alone. Tositumomab complexes ¹³¹Iodine to the anti-B1 antibody and has been studied extensively in the treatment of heavily pretreated,⁸³ untreated,⁸⁴ and for retreatment of indolent lymphomas.⁸⁵ Best responses are seen in previously untreated patients with FL treated with a single treatment course with tositumomab in whom there was a 95% OR, 75% CR, and 80% of assessable patients achieved eradication of PCR detectable MRD patients.⁸⁴ Median PFS was 6.1 years, with 40 patients remaining in remission for 4.3–7.7 years and no cases of myelodysplastic syndrome were observed. A SWOG study investigated chemoimmunotherapy with six cycles of CHOP chemotherapy followed 4–8 weeks later by tositumomab in 90 patients with previously untreated, advanced-stage FL.⁸⁶ The OR was 91%, including 69% CR and at median follow-up time of 5.1 years, the estimated 5-year OS was 87%, and PFS 67%, 23% better than CHOP alone on previous SWOG protocols. Ibritumomab Tiuxetan is a ⁹⁰Y-labeled anti-CD20 antibody and produced OR of 74% and 15% CR in 57 FL patients refractory to rituximab.⁸⁸ Toxicity is primarily hematologic, with nadir counts occurring at 7–9 weeks and lasting approximately 1–4 weeks. The risk of hematologic toxicity increased with dose delivered and with degree of baseline BM lymphoma involvement.⁸⁹ An acceptable safety profile was observed in relapsed patients with less than 25% lymphoma marrow involvement, adequate marrow reserve, platelets greater than 100,000 cells/ μ L, and neutrophils greater than 1500 cells/ μ L.

High Dose Therapy as Consolidation of First Remission

The role of high dose therapy and ASCT in patients with FL during first remission was explored in phase II trials,^{90,91} and in three phase III randomized trials.^{35,87,92} The GLSG trial⁹² recruited 307 previously untreated patients up to 60 years of age and patients who responded after induction chemotherapy with two cycles of CHOP or mitoxantrone-chlorambucil-prednisone (MCP) and were randomized to ASCT or IFN- α maintenance. Among 240 evaluable patients, the 5-year PFS was 64.7% for ASCT, and 33.3% in the IFN- α arm ($p < .0001$). Acute toxicity was higher in the ASCT group, but early mortality was below 2.5% in both study arms. Longer follow-up is necessary to determine the effect of ASCT on OS. In the Groupe Ouest-Est des Leucémies Aigües et des Maladies du Sang study, 172 patients newly diagnosed with advanced FL were randomized either to cyclophosphamide, doxorubicin, teniposide, prednisone (CHVP), and IFN- α or to high-dose therapy followed by purged ASCT.⁸⁷ Patients treated with high-dose therapy had a higher response rate than patients who received chemotherapy and IFN- α (81% versus 69%, $p = .045$) and a longer median PFS (not reached versus 45 months), but this did not translate into a better OS because of an excess of secondary malignancies after transplantation. A subgroup of patients with a significantly higher event-free survival rate ASCT could be identified using the FLIPI. The GELF94 study enrolled 401 previously untreated patients with advanced-stage FL who were randomized to receive CHVP plus IFN- α compared with four courses of CHOP followed by HDT with total body irradiation (TBI) and ASCT and overall response (OR) rates were similar in both groups (79% and 78% respectively) and 87% of eligible patients underwent ASCT. Intent-to-treat analysis after a median follow up of 7.5 years showed no difference between the two arms for OS ($p = .53$) or PFS ($p = .11$). Long-term follow up demonstrated no statistically significant benefit in favor of first-line

ASCT in patients with FL, which the investigators conclude, should be reserved for relapsed patients. A meta-analysis concluded that high-dose therapy and ASCT does not improve overall survival in FL.⁹³ In view of these results, ASCT should be used in first remission only in the setting of clinical trials.

TREATMENT OF RELAPSED INDOLENT LYMPHOMA

The treatment options after relapse remain the same as for first-line therapy (see Table 80.6), and relapsed patients should ideally be treated in clinical trials. Agents approved for rituximab refractory disease include idelalisib and obinutuzumab. Relapsed asymptomatic disease is not necessarily an indication for treatment and patients can again be managed expectantly. A number of factors must be taken into account in planning therapy and it is not possible to define treatment at relapse without considering the goal of therapy (palliative versus potentially curative) performance status, previous therapy, response, and duration of response. Single-agent rituximab is approved for relapsed lymphoma and is widely used in this setting. A multicenter randomized trial in relapsed patients has demonstrated a survival advantage for chemoimmunotherapy with CHOP-R or CHOP followed by rituximab compared with CHOP alone, and a further benefit for rituximab maintenance therapy.³⁹ For younger patients who are suitable candidates for either ASCT or reduced intensity conditioning (RIC) allogeneic transplantation, referral to a transplant center should be considered early to discuss the potential role and timing of transplantation. Best results are seen when transplantation is considered sufficiently early in the course of disease that patients have not already become chemorefractory. High-dose therapy and ASCT remains an effective treatment approach for younger patients with chemoresponsive relapsed disease, SCT approaches must be considered in the context of the improving results that are being seen with novel salvage therapies.

The Role of Transplant in Relapsed Indolent Lymphomas

Unlike aggressive lymphomas, the use of high-dose chemotherapy with ASCT in the treatment of FL has not yet been fully established. The rationale for considering transplantation is that the disease is incurable using standard approaches, young patients with FL will die of their disease, and promising results have been observed in a number of phase II studies.^{94–96} Detection of MRD has been a useful surrogate marker for tracking long-term PFS in patients examining the autologous stem cells or serial samples after transplantation.^{96–100} A major concern relates to the risk of development of secondary myelodysplasia/acute myeloid leukemia.¹⁰¹ The European Bone Marrow Transplant Registry (EBMTR) sponsored CUP (conventional chemotherapy, unpurged, purged autograft) study is the only prospective randomized trial to assess the role of ASCT in patients with relapsed FL.¹⁰² The results of the study suggest a PFS and OS advantage of ASCT over conventional chemotherapy, with 4-year OS of 46% for the chemotherapy arm, versus 71% for the unpurged and 77% for the purged ASCT arms. The study was closed early because of slow accrual with 140 of the planned 250 patients accrued and only 89 randomized.

Novel Agents

There are a large number of novel approaches that are being studied in patients with FL. Recently approved agents for FL include idelalisib¹⁰³ and obinutuzumab, the first type II glycoengineered and humanized monoclonal anti-CD20 antibody.¹⁰⁴ Other agents under investigation include novel monoclonal antibodies, immunomodulatory agents, and novel kinase inhibitors. Combinations of monoclonal antibodies are being explored, such as combining anti-CD20 with anti-CD22 antibodies.¹⁰⁵ Kinases involved in the B-cell receptor

signaling pathway are logical targets for therapy in FL. In addition, idelalisib is approved for the treatment of rituximab-refractory follicular lymphoma and clinical trial data has been presented for kinase inhibitors that target Bruton tyrosine kinase (BTK),^{106,107} and spleen tyrosine kinase (SYK).¹⁰⁸ Novel agents are being examined in combination with monoclonal antibodies and chemotherapy. Since a hallmark of FL is overexpression of BCL2, this protein is also a logical target for small molecule inhibitors that can inhibit the antiapoptotic activity of BCL2. Clinical responses have been observed in the phase I study examining the efficacy of navitoclax in lymphoid malignancies.¹⁰⁹ The next generation agent venetoclax is now approved in chronic lymphocytic leukemia and clinical trials are ongoing in FL, both alone and in combinations.

Allogeneic Bone Marrow Transplant

There is a trend towards increasing use of allogeneic SCT (aSCT) in the management of indolent lymphomas. In a report of the International Bone Marrow Transplant Registry (IBMTR), results after SCT are described for 904 patients with FL.¹¹⁰ Among these patients, 176 patients underwent aSCT, 131 patients underwent ASCT using purged stem cells and 597 using purged autologous stem cells. The treatment related mortality (TRM) in these three groups was 30%, 14% and 8% respectively. Disease recurrence occurred in 21%, 43% and 58% and 5-year overall survival was 51%, 62% and 55% respectively. The use of TBI containing regimens was associated with increased TRM but decreased risk of relapse. The use of aSCT was associated with increased TRM, but significantly lower risk of disease recurrence in keeping with a graft versus lymphoma effect in this disease. Trends suggest that outcomes are improving and this is highly likely to continue with the increased use of reduced intensity conditioning regimens that have become used increasingly since the time this registry data was collated. Long-term PFS has been observed after aSCT even in patients with refractory FL.¹¹¹ In 29 patients with FL, 11 of whom had refractory disease, the nonrelapse mortality was 24% and there was a 23% incidence of relapse. The 5-year OS was 58% with 53% event-free survival. A group of patients with very poor outcome are those patients who have relapsed after previous ASCT. The outcome following myeloablative aSCT of 114 such patients has been reported from the IBMTR.¹¹² The treatment related mortality was 22% and the probability of disease progression was 52% at 3 years. The use of TBI conditioning regimens and achievement of CR at the time of aSCT were associated with improved outcome. The use of reduced intensity conditioning regimens appears to be associated with improved outcome. In 20 such patients, there was only one treatment related mortality from fungal infection and the 3-year PFS was an excellent 95%.¹¹³ The outcome following reduced intensity conditioning transplant regimen incorporating alemtuzumab immunosuppressive therapy has been reported for 81 patients with lymphoma and included 41 with low-grade, 37 with

high/intermediate-grade and 10 patients with MCL, 31 of whom had relapsed following previous ASCT.¹¹⁴ Patients received a conditioning regimen consisting of alemtuzumab, fludarabine, and melphalan, and received short course cyclosporin as graft-versus-host disease (GVHD) prophylaxis. The use of this conditioning regimen was associated with a low incidence of GVHD and the treatment related mortality was decreased in patients with low-grade compared with higher grade histology. The 3-year PFS was 65% for patients with low-grade lymphoma, 50% for patients with MCL and 34% for high-grade lymphoma ($p = .002$). Donor lymphocyte infusion (DLI) was given to 36 patients, 21 for relapsed or persistent disease and 15 for persistence of mixed chimerism. The use of DLI to treat relapse after aSCT is solely dependent upon the existence of a graft versus lymphoma effect. In seven patients with FL and small lymphocytic lymphoma who had relapsed after prior aSCT, six patients responded and four maintained CR for 43–89 months. The effectiveness of DLI to treat relapse after aSCT provides very strong evidence for a graft versus lymphoma effect that can be exploited in indolent lymphomas.^{114,115} The role of RIC aSCT has been evaluated by Cancer and Leukemia Group B in a phase II study to evaluate the safety and efficacy in patients with recurrent low-grade B-cell malignancies, including 16 patients with FL.¹¹⁶ The 3-year TRM was 9% and the 3-year OS was 81%. The incidence of grade II–IV acute GVHD was 29%, and extensive chronic GVHD was 18%.

MANTLE CELL LYMPHOMA

Vijaya Raj Bhatt, Roberto Ferro Valdes, and Julie M. Vose

INTRODUCTION

Mantle cell lymphoma (MCL) is a distinct subtype of mature B-cell non-Hodgkin lymphoma (NHL) that accounts for 5–10% of all NHL. Although a subset of patients with MCL may have an indolent course, MCL is generally an aggressive NHL. In the 1970s, the Kiel classification used the terminology *centrocytic lymphoma* to describe MCL, whereas Berard and Dorfman categorized it as *lymphocytic lymphoma of intermediate differentiation*. In the 1980s, the term *mantle zone lymphoma* was used to denote a distinct subtype of MCL characterized by the proliferation of atypical small lymphoid cells with wide mantles around benign germinal centers (GCs). In the Revised European-American Lymphoma classification in 1994 and later in 2001 and 2008, the WHO classification of tumors of hematopoietic and lymphoid tissues recognized MCL as a distinct disease under mature B-cell lymphomas. With the recognition as a distinct entity, in recent years, significant progress has been made toward understanding the underlying pathogenesis of MCL and translating that knowledge to design more effective therapies.¹

EPIDEMIOLOGY

MCL is two- to sevenfold more common in men than women and almost twofold more common in whites than African Americans. The average age at diagnosis varies between 60 and 70 years. The annual incidence is approximately 4 to 8 cases per million population in the United States and Europe.

PATHOBIOLOGY

MCL, characterized by an alteration in the regulation of the cell cycle, demonstrates cyclin D1 overexpression and increased replication. The tumor cells also demonstrate decreased response to DNA damage and resistance to apoptosis. The tumor cells originate from pre-B cells in the bone marrow that can follow at least two different molecular pathways of development.

The classical MCL originates from a naive B cell that has not entered the follicular GC, but has SOX11 expression, lambda light chain restriction, and limited or no immunoglobulin heavy chain variable (IgVH) somatic mutations. SOX11 expression is associated with the activation of histone marks and absence of DNA methylation. The second subset of MCL, an indolent form typically limited to peripheral blood and spleen, originates from post-GC B cells. This MCL subset has frequent IgVH mutations, typically lacks SOX11 expression, and has kappa light chain restriction. A few studies have demonstrated a correlation between SOX11 expression and aggressive tumors with high serum levels of lactate dehydrogenase (LDH) and high Ki-67 index. Conversely, SOX11-negative MCL may occasionally acquire complex karyotype and TP53 alterations and transform into aggressive tumor (Fig. 81.1).

Genetic Alteration of Proliferative Pathways

The three most common recurrent mutations in MCL involve CCND1 (also known as Cyclin D1, BCL1, or PRAD1), TP53, and

ataxia telangiectasia mutated (ATM) genes. The vast majority of MCL have the reciprocal translocation, t(11;14) (q13;q23), which juxtaposes CCND1 gene to the immunoglobulin heavy-chain locus. The consequent overexpression of CCND1 gene located at 11q13 encodes cyclin D1 protein. Cyclin D1 protein, which is not expressed in normal lymphocytes, is expressed in virtually all MCL, and at a lower level in Burkitt lymphoma and acute lymphoblastic lymphoma (ALL). A few cells with t(11;14) have been found in the blood of 1–2% of healthy individuals. Therefore, cyclin D1 overexpression is not sufficient for the transformation of normal B cells to MCL, rather it is thought to represent an early genetic event. Interestingly, the close physical proximity of the chromosomal regions of the IgVH and CCND1 loci in the nucleus of immature lymphoid B cells may facilitate the occurrence of recurrent translocations. Furthermore, colocalization and interaction of IgVH-CCND1 chromosomal segment and a transcription factor called *nucleolin* near the perinucleolar area leads to the transcription of cyclin D1 protein. Cyclin D1 protein then regulates the G1 phase by binding to cyclin-dependent kinase (CDK) 4 and CDK6. The cyclin D1-CDK complex phosphorylates retinoblastoma 1 (RB1) resulting in a release of E2F transcription factor, and transition of a cell from G1 to S phase. Additionally, the CDKN2A gene on chromosome 9p, which regulates INK4a protein, is deleted in 20–30% of highly proliferating MCL. The INK4a protein inhibits CDK4 and CDK6, and thus maintains the RB1 protein in its active, antiproliferative state. INK4a is frequently deleted in MCL and cooperates with CCND1 gene. Therefore, the CDKN2A-INK4a-CDK4-RB1 pathway is dysregulated in patients with MCL, particularly those with blastoid histology.²

Recent studies have described cyclin D1-negative MCL cases that demonstrate pathologic features and gene expression profile similar to cyclin D1-positive MCL. Cyclin D1-negative MCL is associated with the dysregulation in the expression of the following genes, often due to epigenetic changes: overexpression of cyclin D2 or D3; decreased CDK inhibitor 1B (CDKI1B or p27); upregulation of cyclin E; or inactivation of RB gene. CDKI1B protein regulates the cell progression from G1 to S phase by inhibiting the cyclin E/CDK2 complex (the latter also inactivates the RB protein). Although the diagnosis of cyclin D1-negative MCL is uncommon and requires caution, these cases highlight the relevance of the oncogenic dysregulation of the cell cycle, especially of the G1 phase in the pathogenesis of MCL.

Antiapoptotic and Prosurvival Pathways

Some patients with aggressive MCL, particularly the blastoid variant, have an increased number of chromosomal abnormalities, such as complex karyotype and tetraploidy. The accumulation of chromosomal abnormalities suggests alterations in the DNA damage response pathways. TP53 mutation and deletion or point mutation of the ATM gene (located at 11q22-q23) are recurrent mutations in MCL. TP53 mutations, associated with alterations of 17p chromosomal segment, are present in 10% to 28% of MCL cases. These point mutations are frequently missense mutations that compromise normal p53 expression. The TP53 tumor suppressor gene normally regulates the cell cycle, DNA repair, apoptosis, senescence, and autophagy through transcription-dependent and independent pathways. Disruption in TP53-dependent apoptosis has also been linked to deletion, mutation, or silencing of BIM and NOXA genes. The

Fig. 81.1 PROPOSED MODEL OF MOLECULAR PATHOGENESIS IN THE DEVELOPMENT AND PROGRESSION OF MANTLE CELL LYMPHOMA. Germline mutation of ataxia telangiectasia mutated (ATM) or cell cycle checkpoint kinase 2 (CHK2) genes may facilitate the early development of mantle cell lymphoma (MCL). The translocation t(11;14)(q13;q23), which occurs in an immature B cell results in the constitutive overexpression of CCND1 gene, initiation of the B-cell transformation process, and clonal B-cell expansion in the mantle zone of lymphoid follicles. Acquired alterations of DNA damage response pathways may facilitate genomic instability, acquisition of additional genetic changes, and the development of classical MCL. The accumulation of further chromosomal abnormalities involving proliferative pathways, complex karyotypes, tetraploidization, and 17p/TP53 alterations lead to more proliferative and aggressive variants of MCL. (From Jares P, Colomer D, Campo E: *Genetic and molecular pathogenesis of mantle cell lymphoma: perspectives for new targeted therapeutics*. Nat Rev Cancer 7:750, 2007.)

latter two genes transcribe proapoptotic proteins important in Bax/Bak-mediated cytochrome C release, which is essential to apoptosis. TP53 expression is also inhibited by the binding of PAX5 transcription factor to the TP53 promoter. PAX5 is upregulated by SOX11 in a significant number of patients with MCL. PAX5 represses PRDM1/BLIMP1 and negatively regulates differentiation of early lymphoid progenitors to plasma cells. Therefore, the SOX11-PAX5-PRDM1/BLIMP1 axis suppresses B-cell differentiation to plasma cells and plays an important role in the pathogenesis of MCL. MDM2 is another protein overexpressed in about 16% of MCL and mediates polyubiquitination and degradation of p53. This function of MDM2 protein is prevented by ARF protein, also known as p14 (encoded by CDKN2A gene); however, the homozygous deletion of the CDKN2A gene in MCL allows MDM2-mediated degradation of TP53 and dysregulation of apoptotic pathways.

Inactivation of the ATM gene, detected in about 40% of MCL, facilitates genomic instability by impairing responses to DNA damage. Intriguingly, the inactivation of ATM, perhaps an early phenomenon in MCL, is not commonly seen in other lymphomas except in T-cell prolymphocytic leukemia. ATM encodes the PI3K protein, which phosphorylates p53, promoting its stabilization and transcriptional activation, therefore leading to cell cycle arrest, DNA repair, or apoptosis. Consequently, inactivation of ATM causes genomic instability by inactivation of p53. Despite having similar pathogenic significance, ATM mutations do not impact overall survival, whereas TP53 mutations do predict for worse survival. In addition, ATM may play a role in activation of the nuclear factor kappaB (NFκB) by phosphorylation of the NFκB inhibitor, IκappaB. The NFκB signaling regulates transcription factors that activate numerous genes involved in cell survival, apoptosis, and cell migration. Its persistent activity is associated with tumor formation, tumor growth, metastasis, and drug resistance in B-cell lymphomas and other cancers. Notably, the PI3K-AKT pathway is upstream of the mammalian target of rapamycin (mTOR), which in turn is upstream of cyclin D1, CDK11B, and other regulatory proteins. Conversely, CHK2 and CHK1 are kinases downstream of ATM and prevent cell cycle progression in response to ATM. Downregulation or mutations of CHK2 and CHK1 are also commonly seen in MCL.

Wnt canonical and Sonic Hedgehog (SHH) pathways are also altered in MCL. The Wnt canonical pathway via β-catenin, important for normal cell growth and development, is constitutively activated in a subset of MCL and may promote tumor growth. Similarly,

SHH-GLI signaling molecules such as PTCH and SMO receptors as well as GLI1 and GLI2 transcription factors are expressed in MCL and may contribute to the proliferation of MCL.

Lastly, dysregulation of the B-cell receptor (BCR), a key player of normal B-cell differentiation and development, is involved in the pathogenesis of MCL. Activation of BCR-associated kinases, including spleen tyrosine kinase (SYK), Bruton tyrosine kinase (BTK), and protein kinase C-beta (PKC-β) is observed in MCL. BTK, a member of the Tec family of nonreceptor protein tyrosine kinases, has a well-defined role in the constitutively activated BCR signaling pathway in MCL. Amplification and overexpression of SYK have been found in a subset of MCL. SYK, LYN, and BTK are frequently phosphorylated in MCL, suggesting activation of the BCR pathway. Therefore, the BCR pathway appears to contribute to the growth and survival of MCL cells. The signaling pathways that contribute to the pathogenesis are summarized in Fig. 81.2.

CLINICAL MANIFESTATIONS

The early symptoms usually include fever, night sweats, unexplained weight loss, lymphadenopathy, and splenomegaly. Typically, the majority of patients present at an advanced stage (III or IV) with lymphadenopathy, hepatomegaly, splenomegaly, and bone marrow involvement. Splenomegaly is noted in 40% of patients, and approximately 50% of patients present with circulating lymphoma cells. MCL also tends to involve extranodal sites, especially in the gastrointestinal (GI) tract. Involvement of the GI tract, frequently in the form of lymphomatous polyposis, can be detected in up to 90% of patients; however, many patients do not have any pertinent GI symptoms. During disease progression, MCL can infiltrate other organs including the respiratory tract, breast, or orbit. Involvement of the central nervous system (CNS) is rare but may be relatively more common with blastoid MCL and relapsed disease.

LABORATORY MANIFESTATIONS

Cytopenias are typically present secondary to bone marrow involvement, whereas autoimmune cytopenias are rare. Elevation of LDH and uric acid correlates with tumor burden. Liver function tests may be abnormal if there is hepatic involvement. Other findings include

Fig. 81.2 THE SIGNALING PATHWAYS CONTRIBUTING TO MANTLE CELL LYMPHOMA PATHOGENESIS. CCND1 translocation and mutation of TP53 and ataxia telangiectasia mutated (ATM) genes are common genetic alterations involved in the pathogenesis of mantle cell lymphoma (MCL). Cyclin D1 protein regulates the G1 phase by binding to cyclin-dependent kinase (CDK) 4 and CDK6. The cyclin D1-CDK complex phosphorylates retinoblastoma 1 (RB1) resulting in release of E2F transcription factor and transition of a cell from G1 to S phase. Other major abnormalities include inactivation of the ATM, and cell cycle checkpoint kinase (CHK) 1 and 2 genes; MDM2-mediated degradation of TP53; activation of B cell receptor-associated kinases and constitutive activation of nuclear factor kappaB (NFκB), PI3K/AKT/mammalian target of rapamycin (mTOR), Wnt canonical, and Sonic Hedgehog (SHH) pathways.

elevated beta 2-microglobulin, and rarely hypogammaglobulinemia or monoclonal gammopathy.

Histologically, the 2008 WHO classification³ describes classical MCL as a monomorphic proliferation of small- to medium-sized lymphoid cells with an irregular nuclear border, dispersed chromatin, and inconspicuous nucleoli. The architectural patterns may include a vaguely nodular, diffuse, mantle zone, or rarely follicular growth pattern. Infrequent cases, referred to as in situ MCL, may exclusively involve the inner mantle zones or narrow mantles. Histologic transformation to large B-cell lymphoma does not occur; however, MCL can have several morphologic variants including aggressive blastoid and pleomorphic variants (Fig. 81.3; E-Slide VM03960).

1. Blastoid variant: lymphoma cells have a high mitotic rate (20–30 per 10 high-power fields) and dispersed chromatin; frequently resembles lymphoblasts.

2. Pleomorphic variant: cells have different forms including frequent large cells, pale cytoplasm, oval to irregular nuclear border, and often prominent nucleoli.
3. Small cell variant: cells are small and round with clumped chromatin; frequently resembles small lymphocytic lymphoma (SLL).
4. Marginal zone-like variant: this variant has clusters of marginal zone-like or monocytoid B cells with abundant pale cytoplasm.

DIAGNOSIS

The diagnosis of MCL is based on the morphologic, immunophenotypic, and genetic features evaluated on biopsied tissue. The inclusion of immunophenotyping increased the diagnostic consensus between expert hematopathologists in the International Non-Hodgkin

Fig. 81.3 HISTOPATHOLOGY OF MANTLE CELL LYMPHOMA.

Lymphoma Classification project from 77% (based on histology) to 87%. The characteristic immunophenotypic features of MCL include expression of the B cell–associated antigens CD19, CD20, CD22, and CD79a and aberrant expression of the T cell–associated antigens CD5 and CD43, and a lack of expression of CD3, CD10, and CD23. The identification of t(11;14)(q13;q32) and CCND1 oncogene can further aid to the diagnostic accuracy.³ The presence of CCND1 oncogene is revealed most accurately in stains of formalin-fixed, paraffin-embedded lymph nodes or soft tissue. Nonetheless, the cyclin D1 overexpression can also be seen in a subset of patients with ALL, Burkitt lymphoma, hairy cell leukemia and multiple myeloma. The t(11;14) is seen in more than half of patients on karyotyping and in virtually all the patients screened with fluorescence in situ hybridization. In patients with cyclin D1-negative MCL, overexpression of cyclin D2, cyclin D3, or SOX11 can help in establishing the diagnosis. However, cyclin D2 is also overexpressed in patients with chronic lymphocytic leukemia and lymphoplasmacytic lymphoma, and cyclin D3 can be overexpressed in the vast majority of B-cell malignancies. Overexpression of SOX11, present in more than 90% of the patients with MCL, can also be seen in ALL, T-cell prolymphocytic leukemia, and Burkitt lymphoma. However, these other entities are usually easier to differentiate by clinicopathologic and

other criteria; therefore, SOX11 is a very useful tool in cyclin D1-negative cases.

Differential Diagnosis

MCL should be differentiated from other B-cell NHL, particularly SLL/chronic lymphocytic leukemia, lymphoplasmacytic lymphoma, marginal-zone lymphoma, and follicular lymphoma. Additionally, with minimal differentiation, the blastoid variant MCL may resemble B-cell ALL and acute myeloid leukemia. Immunophenotypic markers are helpful in differentiating MCL (CD5⁺, CD10[−], CD19⁺, CD23[−], FMC⁺) from SLL/chronic lymphocytic leukemia (CD5⁺, CD10[−], CD19⁺, CD23⁺, FMC[−]), and follicular lymphoma (CD5[−], CD10⁺, CD19⁺). In CD5 negative or cyclin D1-negative MCL, careful exclusion of other lymphomas via detection of overexpression of cyclin D2, cyclin D3 or SOX11 and gene expression profiling may help in the diagnosis.

Staging

Staging procedures include a complete blood count, comprehensive metabolic panel, lactate dehydrogenase, evaluation of a bone marrow biopsy, and computed tomography (CT) of chest, abdomen, and pelvis. Although endoscopies of upper and lower GI tracts are frequently positive, such evaluation did not change management in a retrospective study. MCL has low to intermediate avidity for fluorodeoxyglucose (FDG); however, the blastoid variant is more FDG avid. Nonetheless, an integrated FDG positron emission tomography (PET) and CT scan is frequently utilized for staging of patients with MCL. Lumbar puncture is not routinely performed but should be done in patients with neurologic symptoms. Multi-gated acquisition scan or echocardiography is often performed prior to the use of anthracycline; however, their role in asymptomatic patients without cardiac disease is unclear. Hepatitis B serologies are performed prior to the use of rituximab because of a risk of reactivation.

THERAPY

MCL combines the worst features of both follicular lymphoma (noncurability) and diffuse large B-cell lymphoma (aggressive course). A paucity of randomized controlled trials consequent to disease rarity has resulted in a lack of standard therapy. Therapy options range from wait-and-watch strategy in select asymptomatic patients to intensified chemotherapy followed by upfront high-dose chemotherapy (HDT) and autologous hematopoietic stem cell transplant (ASCT) in young fit patients.¹ When a decision has been made to start treatment, several chemoimmunotherapy regimens are available: alkylator-based (cyclophosphamide, vincristine, and prednisone, CVP), anthracycline-based (cyclophosphamide, doxorubicin, vincristine and prednisone, CHOP), fludarabine-based (fludarabine, cyclophosphamide, mitoxantrone, FCM), bendamustine-based (bendamustine and rituximab, BR) as well as cytarabine-, and methotrexate-based (cyclophosphamide, vincristine, doxorubicin and dexamethasone alternating with cytarabine and methotrexate, Hyper-CVAD/MA) regimens, almost always combined with rituximab in the current era (Tables 81.1 and 81.2). More recently, attempts to incorporate bortezomib in upfront therapy have shown promising results. With conventional chemotherapy such as rituximab and CHOP (R-CHOP), the median remission duration is 1.5–3 years; consequently, many experts prefer upfront intensive therapy in younger patients. However, no single strategy is conclusively superior to the other in terms of an overall survival (OS). Blastoid-variant MCL has particularly poor prognosis with few long-term survivors, but histology is often not utilized in selecting therapies. Nonetheless, young patients with blastoid-variant MCL may benefit from intensified therapy and upfront ASCT. Ultimately, therapy selection has to be based on age and performance

TABLE 81.1**Outcomes of Nonintensive Rituximab-Based Therapy Utilized in Mantle Cell Lymphoma**

Author, Year	Number of Patients	Therapy	CR (%)	EFS/PFS	OS (%)
Howard, 2002 ⁴	40	R-CHOP	48%	16.6 months median	-
Forstpointer, 2004 ⁵	48	R-FCM vs. FCM	29% vs. 0%	4 vs. 8 months median ($p = .38$)	Not reached at a median follow-up of ~18 months vs. 11 months ($p = .004$)
Lenz, 2005 ⁶	122	R-CHOP vs. CHOP	34% vs. 7%, $p < .001$	Median time to treatment failure (21 vs. 14 months, $p = .013$) but similar PFS ($p = .31$)	76% at 2 years ($p = .93$)

^aR-MCP was not superior to MCP but the study population was small ($n = 90$).

^bSecond randomization to maintenance rituximab or interferon alpha demonstrated reduction of the risk of progression or death by 45% with rituximab. Rituximab maintenance improved OS among patients who had responded to R-CHOP.

^cOverall response rate was 86% vs. 78% for R-CHOP vs. FCR ($p = 0.06$).

BR, Bendamustine and rituximab; CHOP, cyclophosphamide, doxorubicin, vincristine and prednisone; CR, complete remission; DA-R-EPOCH, dose-adjusted etoposide, cyclophosphamide and doxorubicin along with prednisone, vincristine and rituximab; EFS, event-free survival; FCM, fludarabine, cyclophosphamide, mitoxantrone; FCR, fludarabine, cyclophosphamide and rituximab; PFS, progression-free survival; OS, overall survival; R, rituximab; R-CHOP, rituximab and CHOP; R-CVP, rituximab, cyclophosphamide, vincristine, and prednisone; RDHAP, rituximab, cisplatin, cytarabine, and dexamethasone; R-FCM, rituximab and FCM; R-Hyper-CVAD/R-MA, rituximab, cyclophosphamide, vincristine, doxorubicin, and dexamethasone alternating with rituximab, cytarabine, and methotrexate; R-MCP, rituximab, mitoxantrone, chlormabucil and prednisolone.

status of the patient, the presence of comorbidities, the individual's goals of care as well as the preferences of the patient and physician (Fig. 81.4).

Wait-and-Watch Strategy

The approach of watchful waiting, as utilized in other indolent lymphomas, has been advocated by some investigators in select patients with MCL. This recommendation is supported by a study from Weill Cornell Medical College among 97 patients with MCL, which compared the outcomes between early treatment and observation groups. Among the observation group, the median time to treatment was 12 months (4 to 128 months). Patients in the observation group had better performance status and were more likely to have lower-risk standard International Prognostic Index scores than the early treatment group. The study demonstrated that a delay in initiation of therapy did not influence OS in a multivariate analysis.³⁴ Good outcomes with initial wait-and-watch approach were demonstrated in other studies from the United Kingdom and Sweden. Although these retrospective studies may have limitations, the wait-and-watch strategy is reasonable in asymptomatic older patients, who emphasize on delaying the use of noncurative therapy to preserve the quality of life.

Stage I and II A (Nonbulky) Disease

MCL generally presents with stage III/IV disease with diffuse lymphadenopathy and involvement of blood, bone marrow, and spleen; stage I and II disease at presentation is uncommon. A retrospective study from Vancouver among stage I/II MCL patients ($n = 26$) demonstrated an improvement of progression-free survival (PFS) and possibly OS with the addition of radiotherapy to chemotherapy; however, this study had several limitations including small sample size, retrospective single-center study, and use of suboptimal chemotherapy. Another study from Sweden demonstrated a 3-year OS of 93% with curative intent radiotherapy among 43 patients with stage I–II MCL.³⁵ A large study based on Surveillance, Epidemiology, and End Results (SEER) database also demonstrated improvement in OS with the use of upfront radiotherapy.³⁶ For these reasons, the 2015 National Comprehensive Cancer Network (NCCN) guidelines for MCL support the use of radiotherapy (30–36 Gy) alone or combination with chemoimmunotherapy with or without radiotherapy for stage I/II MCL.

Role of Rituximab

Although the incorporation of rituximab to chemotherapy has improved the outcomes of MCL, the effects are not as profound as

TABLE 81.2**Outcomes of Intensive Therapy Utilized in Mantle Cell Lymphoma**

Author, Year	Number of Patients	Therapy	CR with induction therapy (%)	EFS/PFS	OS (%)
Khouri, 1998 ¹⁷	45	Hyper-CVAD/MA, then SCT	38	72% vs. 17% at 3 years for previously untreated vs. treated	92% vs. 25% at 3 years for previously untreated vs. treated

^aMedian PFS of 2.3 years for R-Hyper-CVAD only vs. 3.9 years for R-Hyper-CVAD and rituximab maintenance, and 4.5 years for R-Hyper-CVAD and HDT/ASCT

^bCHOP/R-DHAP included three cycles of each chemoregimen, followed by high-dose cytarabine containing myeloablative regimen; in R-CHOP group, high-dose therapy did not include cytarabine.

^cMedian follow-up was 51 months

ASCT, Autologous stem cell transplantation; BEAM/ BEAC, carmustine, etoposide, cytarabine, and melphalan/cyclophosphamide; CHOP, cyclophosphamide, doxorubicin, vincristine, and prednisone; CR, complete remission; EFS, event-free survival; FFS, failure-free survival; HDT, high-dose chemotherapy; Hyper-CVAD/MA, cyclophosphamide, vincristine, doxorubicin, and dexamethasone, alternating with methotrexate and cytarabine; Maxi-CHOP, dose-intensified CHOP; OS, overall survival; PFS, progression-free survival; R, rituximab; RDHAP, rituximab, cisplatin, cytarabine, and dexamethasone; VAD+C, vincristine, doxorubicin, dexamethasone, chlorambucil; SCT, stem cell transplantation; TTF, time to treatment failure; VcR-CVAD, bortezomib, rituximab, cyclophosphamide, doxorubicin, vincristine, dexamethasone.

seen in other CD20⁺ B-cell lymphomas. In one of the earliest studies ($n = 40$), R-CHOP resulted in an overall response rate of 96%, complete response rate of 48%, and median PFS of 16.6 months. Patients who achieved a molecular remission ($n = 9$, 36%), did not have improved PFS (16.5 vs. 18.8 months, $p = .51$) compared with patients without molecular remission. However, the study may have been underpowered due to a small sample size.⁴ Another larger study ($n = 122$) demonstrated a higher overall response rate (94% vs. 75%, $p = .005$), complete remission rate (34% vs. 7%, $p < .001$), and median time to treatment failure (21 vs. 14 months, $p = .013$), but similar PFS ($p = .31$) with R-CHOP, compared with CHOP.⁶ In the third study ($n = 48$), R-FCM resulted in a similar overall response rate (58% vs. 46%, $p = .28$) and median PFS (8 vs. 4 months, $p = .38$), but improved median OS (not reached vs. 11 months, $p = .004$) compared with FCM.⁵ In a large Nordic Lymphoma Group observational study, rituximab use was an independent predictor of improved OS.³⁵ The moderate benefit with incorporation of rituximab has led to its widespread use in MCL with most of the recent trials utilizing rituximab-based chemoimmunotherapy.

Low Intensity Therapy

Older patients (≥ 65 years or more) or patients who have major comorbidities, poor performance status, or a preference for a nonaggressive approach, are treated with a low intensity chemotherapy

regimen. Several therapy options are available as listed in Table 81.1; however, BR as well as R-CHOP are the two most commonly utilized regimens in newly diagnosed MCL. R-CHOP results in an overall response rate of approximately 90% with a complete remission in about one-third of patients. In various studies, median PFS has ranged from 16 to 22 months, whereas median OS were 76% at 2 years and 47% at 4 years. Recent studies have demonstrated a more favorable outcome with BR, as compared with R-CHOP in patients with indolent NHL including MCL. In a large randomized phase III noninferiority trial, BR resulted in a higher complete response rate (40% vs. 30%, $p = .02$) and median PFS (35 vs. 22 months, $p = .004$) compared with R-CHOP among patients with MCL. Additionally, BR was associated with lower risk for hematologic and other toxicities (except erythematous or allergic skin rash).¹⁴ In another study, BR was found to be noninferior to R-CHOP/R-CVP; among patients with MCL, complete response rate was 50% vs. 27% for BR vs. R-CHOP/R-CVP, respectively. BR was associated with a higher risk of vomiting (higher use of aprepitant in R-CHOP group), drug hypersensitivity (use of prednisone in R-CHOP/R-CVP), and a lower risk of neuropathy and alopecia. Grade III/IV lymphopenia was more common with BR, whereas the use of R-CHOP was associated with a higher risk of grade III/IV neutropenia and greater utilization of granulocyte colony stimulating factor.¹⁶ Given better tolerance and at least equivalent outcomes, many experts prefer BR over R-CHOP particularly in older patients. A recent phase 3 trial has demonstrated improved median PFS (30 vs. 16 months) and 4-year OS (64% vs.

Fig. 81.4 Algorithm for management of mantle cell lymphoma outside of a trial. *BR*, Bendamustine and rituximab; *CHOP*, cyclophosphamide, doxorubicin, vincristine and prednisone; *IFRT*, involved field radiotherapy; *R-CHOP*, rituximab and CHOP; *RDHAP*, rituximab, cisplatin, cytarabine, and dexamethasone; *R-Hyper-CVAD/R-MA*, rituximab, cyclophosphamide, vincristine, doxorubicin, and dexamethasone alternating with rituximab, cytarabine, and methotrexate.

54%) with bortezomib replacing vincristine in R-CHOP, as compared with R-CHOP.³⁷ The addition of bortezomib to R-CHOP and the use of ⁹⁰Y ibritumomab after R-CHOP have also shown promising results. Similarly, dose-adjusted infusional R-EPOCH (rituximab, etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin) with idiotype vaccine or bortezomib have resulted in excellent survival rates.

Upfront Intensified Therapy and Autologous Stem Cell Transplantation

Several studies have demonstrated improved outcomes with upfront intensified therapy and HDT/ASCT in young symptomatic patients with MCL. In the European MCL network randomized trial conducted in the pre-rituximab era, the use of myeloablative radiochemotherapy and ASCT versus α -interferon maintenance following CHOP-like regimen improved median PFS (39 vs. 17 months, $p = .01$) without OS benefit (83% vs. 77% at 3 years, $p = 0.18$) in 122 patients with MCL ≤ 65 years old in the first complete remission.³⁸ In the rituximab era, several nonrandomized prospective and retrospective studies have demonstrated better survival outcomes with intensified therapy and HDT/ASCT compared with historical controls. The second Nordic MCL trial among untreated patients with MCL < 66 years ($n = 160$) utilized a phase II protocol

with dose-intensified induction immunochemotherapy with maxi-CHOP-R (dose-intensified R-CHOP), alternating with rituximab and high-dose cytarabine, followed by HDT and rituximab-in vivo purged ASCT among the responders. This resulted in a 6-year OS and event-free survival (EFS) of 70% and 56%, respectively, with a higher proportion of molecular response rate (92% vs. 38%, $p < .001$) compared with a historical control in the first Nordic MCL trial.³⁹ Cancer and Leukemia Group B (CALGB) 59909 study demonstrated a five-year PFS and OS of 56% and 64%, respectively, among patients with MCL up to the age of 69 years ($n = 78$) who were treated with cytarabine- and methotrexate-based immunochemotherapy followed by HDT/ASCT.²⁴ Several other studies have demonstrated excellent outcomes with rituximab-based chemotherapy such as R-Hyper-CVAD or R-CHOP/RDHAP (rituximab, cisplatin, cytarabine and dexamethasone) and HDT/ASCT (Table 81.2).

Although these studies demonstrate improved PFS with HDT/ASCT consolidation, the optimal induction therapy is unclear. To determine the value of induction therapy an NCCN NHL database study compared the outcomes of patients with MCL < 65 years treated with several chemotherapy regimens. This study demonstrated a worse 3-year PFS with R-CHOP alone (18%) compared with R-Hyper-CVAD (58%, $p < .001$), R-CHOP and HDT/ASCT (56%, $p < .001$), and R-Hyper-CVAD and HDT/ASCT (55%, $p = .004$). PFS did not differ between the latter three groups. The 3-year OS was similar between R-CHOP alone (69%), R-Hyper-CVAD (85%),

^aNo difference in outcomes between relapsed and refractory patients.

EFS, Event-free survival; NA, not available; ORR, overall response rate; OS, overall survival; PFS, progression-free survival; TTP, time to progression

$p < .07$), and R-CHOP and HDT/ASCT (87%, $p < .20$). Multivariable analysis revealed that R-CHOP alone had worse OS compared with R-Hyper-CVAD, but not to R-CHOP and HDT/ASCT.⁴⁰ Similarly, the type of induction therapy or the timing of therapy did not predict OS in 118 patients with MCL treated with HDT/ASCT in another study. The use of R-Hyper-CVAD, compared with R-CHOP-like therapy, improved PFS for the entire MCL cohort ($p = .01$) but not among transplant recipients ($p = .26$).⁴¹ These studies indicate that intensive induction therapy such as R-Hyper-CVAD may be preferred to R-CHOP among patients who are not planned to undergo HDT/ASCT consolidation; however, the choice of initial therapy may not make a significant difference in OS of patients who are scheduled to undergo HDT/ASCT.

The use of rituximab during or after HDT/ASCT and incorporation of bortezomib to induction or conditioning regimen have demonstrated promising results. In a study, the use of pre-emptive rituximab therapy (375 mg/m² weekly for 4 weeks) for molecular relapse after upfront HDT/ASCT resulted in re-induction of molecular remission in 92%, and median molecular and clinical relapse-free survivals of 1.5 and 3.7 years, respectively.⁴² Rituximab maintenance after R-Hyper-CVAD or upfront HDT/ASCT may also improve PFS. The use of rituximab frequently increases the risk of neutropenia and hypogammaglobulinemia; however, this may not necessarily translate to a substantially increased risk of major infections.

Central Nervous System Prophylaxis

The incidence of CNS involvement at diagnosis and the role of primary CNS prophylaxis in MCL are controversial. In relapsed MCL, CNS involvement is noted in up to 5–20% of patients, particularly with blastoid variant, and portends a poor prognosis. CNS-penetrating agents such as high-dose methotrexate and cytarabine, with or without intrathecal chemotherapy, may provide sufficient CNS prophylaxis in patients undergoing intensive therapies. In other patients with high-risk features such as blastoid morphology or presence of neurologic symptoms, some centers perform lumbar puncture and utilize intrathecal methotrexate or high-dose systemic methotrexate.

Relapsed or Refractory MCL

The vast majority of patients with MCL will relapse and require subsequent therapies. The choice of therapy in relapsed or refractory MCL depends on the upfront chemotherapy regimen, outcomes with initial therapy, performance status, comorbidities, and desired goals. Several options are available including ibrutinib as well as bortezomib, bendamustine, lenalidomide, or temsirolimus, frequently combined with rituximab (Table 81.3). Ibrutinib received an accelerated approval in November 2013 based on a phase II study of relapsed or refractory MCL ($n = 111$), which demonstrated an overall response rate of 68% with an OS of 58% at 18 months.⁴³ Given its oral route of administration and tolerability, ibrutinib is increasingly utilized as the preferred option in relapsed or refractory MCL. However, other regimens appear to be equally efficacious and may be used as an alternative or as third-line options. Patients who have not undergone upfront HDT/ASCT may benefit from HDT/ASCT after salvage therapy. In one study, the use of HDT/ASCT demonstrated a median EFS and OS of 36% and 65%, respectively.⁴⁴ In this setting, the use of R-Hyper-CVAD salvage therapy prior to HDT/ASCT may result in lower relapse rates but similar PFS and OS.⁴⁵ Another study demonstrated a promising result with ¹³¹I-tositumomab prior to HDT/ASCT with a complete response rate of 91% and 3-year PFS and OS of 61% and 93%, respectively, highlighting the radiosensitive nature of MCL.⁴⁶

Allogeneic Stem Cell Transplantation

Although allogeneic stem cell transplantation (alloSCT) is potentially curative, lack of large-scale randomized trials and high transplant-related mortality (TRM) has limited enthusiasm toward the use of alloSCT in MCL. Nonetheless, alloSCT should be considered in young and fit patients with MCL with multiple relapsed disease or ASCT failure. The outcomes of alloSCT have been compared with those of ASCT in a few studies. In retrospective studies, alloSCT, compared with ASCT, is associated with higher TRM, lower relapse, and similar OS. In a study of 97 patients with MCL, the alloSCT group, compared with the ASCT group, was younger, more heavily pretreated, and less likely to be in first complete remission. AlloSCT

versus ASCT resulted in a greater mortality at 100 days (19% vs. 0%, $p < .01$), numerically lower but statistically similar relapse rate (21% vs. 56%, $p = .11$) and similar OS (49% vs. 47%, $p = .51$) at 5 years.⁴⁵ Similarly, in a Center for International Blood and Marrow Transplant Research (CIBMTR) study of chemosensitive patients with MCL ($n = 519$), reduced intensity conditioning (RIC) alloSCT, compared with ASCT, resulted in lower relapse/progression, which was offset by a higher nonrelapse mortality (NRM); hence, the 5-year OS was similar between the two groups. ASCT in first complete remission was associated with the highest OS and PFS confirming the results of prior studies of upfront HDT/ASCT.⁶⁰ The comparable OS with alloSCT, compared with ASCT, in these studies also demonstrates the efficacy of disease control with alloSCT in patients with multiple relapses. In clinical practice, therefore, alloSCT may be utilized in heavily pretreated patients.

RIC has been explored with a hope to reduce TRM and expand alloSCT to older patients or patients with other comorbidities. In a study, 70 patients with relapsed and refractory MCL including prior ASCT failures (34%) underwent RIC alloSCT, mainly with alemtuzumab-containing regimens. NRM, cumulative risk of relapse, PFS, and OS were 21%, 65%, 14%, and 37%, respectively, at 5 years. Among patients who relapsed, donor lymphocyte infusion (DLI) or a second RIC alloSCT resulted in a complete remission rate of 73%.⁶¹ In another study of 33 relapsed and patients with refractory MCL, nonmyeloablative conditioning with fludarabine and 2 Gy total body irradiation was associated with an overall response rate of 85%, 2-year NRM, disease-free survival, and OS of 24%, 60%, and 65% respectively.⁶² Hence, RIC and nonmyeloablative alloSCT along with DLI for relapse may be reasonable options in patients who are not candidates for myeloablative alloSCT.

PROGNOSIS

As discussed previously, complete remission is seen in up to two-third of patients with MCL, particularly with upfront intensive therapy; however, almost all patients will relapse and develop resistance to chemotherapy over time. Although the prognosis for newly diagnosed patients has improved over the last decades, the OS compares unfavorably with the more frequent NHLs such as follicular lymphoma and diffuse large B-cell lymphoma. A small subset of patients may follow a more indolent clinical course in the beginning, and these patients may have a clinical history that resembles a chronic lymphocytic leukemia.

Prior studies have identified several adverse prognostic factors, which include eastern cooperative oncology group (ECOG) performance status (PS) ≥ 2 , age > 65 years, elevated LDH, elevated serum β_2 -microglobulin, hemoglobin level < 12 g/dL, advanced stage, involvement of peripheral blood or extranodal sites ≥ 2 , high cell proliferation rate (Ki-67, mitotic index or proliferation signature), blastoid variant histology, deletion or mutation of TP53, and secondary chromosomal aberrations (the presence of gain 3q, 12q and 13q and losses of 6q, 9p, 11q, and 17p).⁶³ More recent studies have demonstrated that the MCL international prognostic index (MIPI), based on age, ECOG PS, LDH, and white blood cell count, is one of the most important prognostic factors in MCL. In a large study, MIPI categorized MCL patients into low risk (0–3 scores; OS not reached at a median follow-up of 32 months), intermediate risk (4–5 scores; median OS of 51 months), and high risk (6–11 scores; median OS of 29 months) categories with a significant difference in OS (Fig. 81.5). MIPI separated the survival curves better than IPI utilized for diffuse large B-cell lymphoma or follicular lymphoma (FLIPI). Cell proliferation (Ki-67), but not number of mitoses per square millimeter, was an independent prognostic score.⁶⁴ Ki-67 and MIPI have been shown to independently predict PFS and OS in other studies also. Prognosis may also be influenced by disease status at ASCT or alloSCT, achievement of molecular remission after therapy, moderate or strong expression of PIM1 (a serine/threonine kinase and proto-oncogene), and number of prior therapies before HDT/ASCT or alloSCT. In the modern era, molecular diagnostics such as gene

expression profiling, genome-wide miRNA profiling as well as a limited-gene model (based on five genes RAN, MYC, TNFRSF10B, POLE2, and SLC29A2) may also provide meaningful prognostic information; however, the lack of commercial testing and standardization, as well as high cost limit their use in clinical practice.

FUTURE DIRECTIONS

Since the recognition of MCL as a separate entity there has been significant advancement in the understanding of tumor biology, diagnostic, prognostic, and treatment approaches. This has resulted in a significant improvement in OS of patients with MCL at a population level, with approximately half of the patients in the United States surviving beyond 5 years in recent years.⁶⁵ A few studies have demonstrated poor prognosis of blastoid-variant MCL. Intensified therapy including upfront ASCT may overcome this poor prognosis, which needs further exploration in prospective studies. The roles of radiotherapy and CNS prophylaxis are currently not well established and should be investigated. Integration of clinical parameters and gene expression profiling has a potential to improve prognostication. Such prognostication may identify an indolent subgroup that can be observed, as well as an aggressive subgroup that may be better served with upfront intensive therapy. A development of prognosis-directed therapy is an ideal goal. Molecular markers such as t(11;14), clonal immunoglobulin heavy chain gene rearrangements, and SOX11 gene expression may be used to identify minimal residual disease. Although the correlation is not consistent, molecular remission has been correlated with long-term remission and PFS. Molecular relapse may precede clinical relapse and has been utilized to guide preemptive therapy, as discussed above. If confirmed in other prospective trials, minimal residual disease-based therapies may be utilized to improve PFS in the future. Elderly patients and patients with comorbidities generally have poor outcomes and should be enrolled in clinical trials of novel well-tolerated agents. Novel agents such as ibrutinib, idelalisib, lenalidomide, and bortezomib have shown promising results; their integration in upfront therapies has a potential to further improve outcomes with initial therapy. Improved prognostic tools, incorporation of minimal residual disease based preemptive therapy, translation of molecular tumor biology to bedside in the form of novel therapies, and integration of such therapies to upfront traditional chemoimmunotherapy regimens offer a potential to change the therapeutic landscape of MCL.

Pathogenesis

- Mantle cell lymphoma (MCL) is characterized by alterations in proliferative, antiapoptotic and prosurvival pathways.
- The vast majority of MCL have the reciprocal translocation, t(11;14)(q13;q23), which juxtaposes the CCND1 gene to the immunoglobulin heavy-chain locus. TP53 and ATM genes are other commonly mutated genes.
- Aggressive cases, particularly the blastoid variant, have an increased number of chromosomal abnormalities and complex karyotype.
- Dysregulation of the B cell receptor has also been implicated in the pathogenesis of MCL.

Diagnosis

- The majority of patients present at an advanced stage (III or IV) with lymphadenopathy, hepatomegaly, splenomegaly, and involvement of bone marrow and extranodal sites, especially the gastrointestinal tract.
- Morphologic findings include monomorphic proliferation of small to medium-sized lymphoid cells with irregular nuclear border, dispersed chromatin, and inconspicuous nucleoli.
- Histologic transformation to large B-cell lymphoma does not occur; however, MCL can have several morphological variants such as blastoid and pleomorphic variants.
- The characteristic immunophenotypic features (CD5⁺, CD10⁻, CD19⁺, CD23⁻, FMC⁺) and the identification of t(11;14)(q13;q32) or cyclin D1 overexpression improve diagnostic accuracy.

- Staging procedure includes a bone marrow biopsy and CT or PET-CT of chest, abdomen, and pelvis; however, lumbar puncture is not routinely performed. Although endoscopies of upper and lower gastrointestinal tracts are frequently positive, such evaluation may not change management.

Therapy and Prognosis

- MCL combines the worst features of both indolent lymphoma (noncurability) and aggressive lymphoma (aggressive course).
- Therapeutic strategy is not standardized and may include wait-and-watch strategy in select asymptomatic patients, rituximab-based immunochemotherapy (BR or R-CHOP) in older patients, and intensified chemotherapy such as R-Hyper-CVAD followed by upfront high-dose chemotherapy and autologous hematopoietic stem cell transplant in young fit patients.
- Recent studies have demonstrated improved response rate and less toxicity with BR, as compared with R-CHOP.
- Ibrutinib has emerged as an excellent option for the management of relapsed or refractory MCL. Other salvage therapy includes bortezomib, bendamustine, lenalidomide, or temsirolimus frequently combined with rituximab.
- Ki-67 level and MIPI (based on age, ECOG PS, LDH and white blood cell count) are two of the most important prognostic factors in MCL.
- Recent advances in the therapy of MCL have improved the OS at a population level, with approximately half of the patients in the United States surviving beyond 5 years in recent years.

DIAGNOSIS AND TREATMENT OF DIFFUSE LARGE B-CELL LYMPHOMA AND BURKITT LYMPHOMA

Kieron Dunleavy and Wyndham H. Wilson

Diffuse large B-cell lymphoma (DLBCL) and Burkitt lymphoma (BL) are the most common types of aggressive B-cell lymphoma. Although they share many clinical and biologic features, the approach to their management is different; therefore, an accurate histologic diagnosis is of utmost importance. There have been several recent therapeutic advances in the management of these diseases, and both DLBCL and BL have high cure rates with current treatment approaches. Therefore, it is imperative to promptly evaluate patients with these diseases and expeditiously institute appropriate therapy.

DIFFUSE LARGE B-CELL LYMPHOMA

Epidemiology

DLBCL is the most prevalent histologic subtype of non-Hodgkin lymphoma (NHL) (of which there are approximately 72,000 new cases in the United States each year) and comprises 30% to 40% of these diseases. Although the median age at diagnosis is in the seventh decade of life, DLBCL affects children and adults of all ages, and it is slightly more common in males than females. Though the etiology of DLBCL is unknown in most cases, it can arise from transformation of an indolent lymphoma. A history of immunodeficiency is a significant risk factor, and individuals who are human immunodeficiency virus (HIV) positive have in the range of 100 times higher incidence of developing DLBCL over those who do not have HIV.

Pathobiology

The pathobiology of DLBCL is very heterogeneous, and within DLBCL, there are several morphologic variants that include centroblastic, immunoblastic, T-cell rich or histiocyte-rich, (see E-Slide VM03959) and anaplastic subtypes. Recent progress using techniques such as molecular profiling and other high-resolution genetic technologies are further advancing this taxonomy. There are also several clinical-pathologic variants of DLBCL. Primary mediastinal B-cell lymphoma (PMBL), for example, commonly presents in young women and usually remains localized to the mediastinum (Fig. 82.1). Primary central nervous system lymphoma (PCNSL) is another rare subtype of DLBCL that rarely disseminates to extraneural sites and is much more commonly observed in HIV-positive individuals. It is important to recognize that DLBCL can also arise as a result of histologic transformation from an indolent lymphoma. Although this differentiation may not affect treatment choice initially, it will affect prognosis and natural history, and therefore needs to be recognized at diagnosis.¹

The neoplastic cells of DLBCL express pan B-cell markers, including CD20, and surface or cytoplasmic immunoglobulin is often demonstrated. CD10, BCL6, and IRF4/MUM1 are variably expressed, and the proliferation index as measured by Ki67 staining is typically high. Approximately 30% of cases show abnormalities involving the *BCL6* gene, and translocation of the *BCL2* gene, a hallmark of follicular lymphoma, is present in 20% to 30% of cases. Approximately 10% of cases of DLBCL harbor a t(8:14) MYC translocation, and recently, several groups have demonstrated that

this confers a much worse prognosis compared with MYC-negative cases when CHOP-type (cyclophosphamide, doxorubicin [Novantrone], vincristine [Oncovin], and prednisone) regimens are used.

Recently, gene expression profiling has defined a new molecular taxonomy for DLBCL. Morphologically indistinguishable tumors can show marked heterogeneity in gene expression, and these patterns of expression may be classified into signatures that correspond to the cellular origin of the lymphoma according to its stage of B-cell differentiation; on the basis of these signatures, DLBCL can be divided into at least three different subtypes: germinal center B-cell (GCB)-like, activated B-cell (ABC)-like, and primary mediastinal B-cell lymphoma (PMBL).² Importantly, these subtypes of DLBCL have disparate outcomes following standard therapy with the ABC subtype having an inferior survival in many retrospective studies.³

Clinical Features

The clinical presentation of DLBCL is variable and depends on a number of factors, including histology, patient age, and immune status. The disease typically presents with lymphadenopathy that can range from relatively asymptomatic to causing pain (Fig. 82.2), causing organ compromise such as ureteral obstruction or spinal cord compression. The involvement of bone marrow (BM) is much less frequent than with indolent lymphomas and is present in approximately 20% of cases.

Patients may have constitutional manifestations from the production of inflammatory molecules and a variety of other cytokines and chemokines produced by the lymphoma cells or host tissues. Such manifestations include weight loss, malaise, fevers, night sweats, and loss of appetite. Of these, unexplained weight loss of more than 10% of body weight and temperature higher than 38°C as well as drenching night sweats are referred to as “B” symptoms.

Investigation

History and Physical Examination

Patients should be questioned about systemic symptoms, and their performance status should be assessed (Table 82.1). It is important to determine if there is a history of potential causative factors such as prior malignancy, chemotherapy or radiation treatment, or autoimmune or immunodeficiency diseases. A history of infection with or exposure to various pathogens, including HIV and hepatitis B and C, should be excluded. A detailed physical examination should be performed with particular attention to lymph node (LN) regions. Skin involvement by DLBCL is rare (Fig. 82.3).

An accurate histologic diagnosis is imperative to determine the patient's prognosis and treatment; therefore, the single most important diagnostic test is a technically adequate and properly evaluated excisional tissue biopsy. With few exceptions, fine-needle aspiration is inadequate for diagnosis. Aggressive lymphoma should be diagnosed by an experienced hematopathologist familiar with the nuances and pitfalls of lymphoma diagnosis.

Fig. 82.1 COMPUTED TOMOGRAPHY SCAN OF THE CHEST SHOWING A LARGE 17-CM ANTERIOR MEDIASTINAL MASS. A biopsy was consistent with primary mediastinal B-cell lymphoma.

Fig. 82.2 COMPUTED TOMOGRAPHY SCAN OF THE ABDOMEN SHOWING A LARGE LEFT-SIDED PSOAS MASS. A biopsy was consistent with diffuse large B-cell lymphoma.

TABLE 82.1

Eastern Co-operative Group Performance Scale

Performance Status	Definition
0	Asymptomatic
1	Symptomatic but fully ambulatory
2	Symptomatic and in bed <50% of the day
3	Symptomatic and in bed >50% of the day
4	Bedridden

Laboratory Investigations

Laboratory tests should include a complete blood count; serum chemistry, including lactate dehydrogenase (LDH); and HIV and hepatitis serology tests (Table 82.2). The latter should be included due to the importance of identifying patients with active hepatitis and a history of hepatitis B because they will likely require treatment with antivirals, monitoring, or both (see box on [Hepatitis B Prophylaxis and Therapy During Lymphoma Treatment](#)). Epstein-Barr virus

Fig. 82.3 INFILTRATION OF THE RIGHT LOWER ANTERIOR CHEST WALL WITH DIFFUSE LARGE B-CELL LYMPHOMA.

Hepatitis B Prophylaxis and Therapy During Lymphoma Treatment

There is a risk of hepatitis B reactivation both from chemotherapy and rituximab, and this is a potentially fatal complication. We check hepatitis serology (hepatitis B surface antigen [HBsAg], hepatitis B surface antibody [anti-HBs], and hepatitis B core antibody [anti-HBc]) in all patients at diagnosis. Patients with active hepatitis B receive antiviral medication and liver function tests (LFTs) and hepatitis B viral loads are monitored closely. Patients with a history of hepatitis B infection should either receive antiviral prophylaxis or have the hepatitis B viral load monitored very closely (ideally on each cycle) with a low threshold to commence antiviral medications.

(EBV) viral loads may also be useful in specific lymphomas such as posttransplant lymphoproliferative disorders (PTLDs) and EBV-positive DLBCL of elderly adults. An elevated LDH level has adverse prognostic implications for patients with DLBCL.

Imaging and Staging

It is important to determine sites of disease involvement; therefore, imaging studies should include computed tomography (CT) scanning of the chest, abdomen, and pelvis as well as fludeoxyglucose positron emission tomography (FDG-PET) scanning in most cases. The use of other imaging modalities depends on the clinical presentation and sites of disease. For example, if central nervous system (CNS) involvement is highly suspected, evaluation of the head by CT or magnetic resonance imaging (MRI) may be indicated. Involvement of the bone is best evaluated by MRI and PET scans.

Because involvement of the BM may impact management, it should be assessed in all patients with DLBCL by a BM aspirate and biopsy. Patients at increased risk of CNS involvement should undergo lumbar puncture with evaluation of the cerebrospinal fluid (CSF) by cytology and flow cytometry.⁴ Specifically, clinical presentations with several extranodal sites and elevated LDH level as well as particular

TABLE 82.2 Staging Evaluation for Diffuse Large B-Cell Lymphoma

All Patients	As Clinically Indicated
History and physical examination	Other viral studies
CBC and chemistry (including LDH)	CT or MRI of the head
HIV and hepatitis B and C serology	Body PET scan
Chest radiograph	Additional imaging
CT scan of the chest, abdomen, and pelvis	CSF evaluation by cytology or flow cytometry
BM aspirate and biopsy	Other tests indicated by results of staging

BM, Bone marrow; CBC, complete blood count; CSF, cerebrospinal fluid; CT, computed tomography; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging; PET, positron emission tomography.

Intrathecal Prophylaxis in Diffuse Large B-Cell Lymphoma

In DLBCL, the role of intrathecal prophylaxis to prevent CNS recurrence is controversial and poorly studied, and there are several different approaches. Our approach is as follows. All patients at risk for CNS disease undergo a lumbar puncture at diagnosis, and CSF is checked by cytology and flow cytometry; if the results are positive, patients receive active treatment of the CNS. We administer intrathecal prophylaxis to all patients who fulfill either of the following criteria:

1. Two or more extranodal sites of disease involvement and an elevated LDH level.
2. Certain extranodal sites of involvement that have been associated with an increased risk of CNS spread such as BM and testis.

We use intrathecal methotrexate at a dose of 12 mg. We commence prophylaxis on cycle 3 day 1 and administer it on days 1 and 5 of cycles 3 through 6.

sites such as the testis and BM are associated with an increased risk of CNS disease, and intrathecal prophylaxis should be considered (see box on [Intrathecal Prophylaxis in Diffuse Large B-Cell Lymphoma](#)).

DLBCL is staged according to the Ann Arbor staging system ([Table 82.3](#)), which was originally developed for Hodgkin lymphoma (HL). However, because of the heterogeneity and hematogenous pattern of dissemination in NHL, in contrast to contiguous LN spread with HL, the staging system has more limited value. At the same time, important modifications to the Ann Arbor staging system made at the Cotswold Conference have made it more applicable to NHL.⁵

Prognosis

To identify prognostic factors in NHL, an international project to correlate clinical variables and outcome in 2031 patients with untreated aggressive lymphoma was undertaken. The following parameters were associated with inferior outcome: age older than 60 years, Ann Arbor stage III or IV disease, serum LDH level above normal range, Eastern Co-operative Oncology Group (ECOG) performance status of two or higher, and involvement of two or more extranodal sites. A clinical prognostic model, termed the International Prognostic Index (IPI), was developed using these five factors. In this model, one point was allocated for each feature and nicely stratified patients into four groups with 5-year survivals of 73%, 51%, 43%, and 26% for zero or one, two, three, and four or five risk factors, respectively, with CHOP-based treatment. Based on this model, the IPI has become the standard in DLBCL for assessing clinical prognosis and treatment stratification within and comparison between clinical trials. Recently, a revised prognostic model for R-CHOP, termed *Revised-IPI*, was published ([Table 82.4](#)).⁶

Although not yet routinely performed in aggressive NHL, gene expression profiling is emerging as an important prognostic tool. In

TABLE 82.3 Ann Arbor Staging System for Lymphomas

Stage ^a	Cotswold Modification of Arbor Classification
I	Involvement of a single LN region or lymphoid structure
II	Involvement of two or more LN regions on the same side of the diaphragm (the mediastinum is considered a single site, but the hilar LNs are considered bilaterally); the number of atomic sites should be indicated by a subscript (e.g., II ₃)
III	Involvement of LN regions on both sides of the diaphragm: III ₁ (with or without involvement of splenic hilar, celiac, or portal nodes) and III ₂ (with involvement of paraortic, iliac, and mesenteric nodes)
IV	Involvement of one or more extranodal sites in addition to a site for which the designation E has been used

^aAll cases are subclassified to indicate the absence (A) or presence (B) of the systemic symptoms of significant fever (>38.0°C [100.4°F]), night sweats, and unexplained weight loss exceeding 10% of normal body weight within the previous 6 months. The clinical stage (CS) denotes the stage as determined by all diagnostic examinations and a single diagnostic biopsy only. In the Ann Arbor classification, the term *pathologic stage* (PS) is used if a second biopsy of any kind has been obtained, whether the result was negative or positive. In the Cotswold modification, the PS is determined by laparotomy; X designates bulky disease (widening of the mediastinum by more than one-third or the presence of a nodal mass >10 cm), and E designates involvement of a single extranodal site that is contiguous or proximal to the known nodal site. LN, Lymph node.

TABLE 82.4 Revised International Prognostic Index (R-IPI)^a

No. of IPI Factors	IPI Score	Outcome	Overall Survival (%)
0	0	Very good	94
1–2	1–2	Good	79
3, 4, or 5	3–5	Poor	55

^aOne point is given for the presence of each of the following characteristics: age older than 60 years, elevated serum LDH level, ECOG performance status ≥2, Ann Arbor stage III or IV, and more than two extranodal sites.

ECOG, Eastern Cooperative Oncology Group; IPI, International Prognostic Index; LDH, lactate dehydrogenase

From Sehni LH, Berry B, Chhanabhai M, et al: The revised International Prognostic Index is a better predictor of outcome than the standard IPI for patients with diffuse large B-cell lymphoma treated with R-CHOP. *Blood* 109:1857, 2007.

DLBCL, overall survival is different in each group and in many studies superior in patients with the GCB compared with the ABC subtype. Using gene expression profiling, a molecular prognostic model of survival, independent of the IPI, has been developed for R-CHOP-treated DLBCL. In routine clinical practice, it has not been feasible to perform gene expression profiling and immunohistochemistry algorithms to predict cell of origin have been used up until now. While these have been somewhat helpful, they have demonstrated varying degrees of concordance with microarray results, limiting their usefulness. Therefore novel assays to more accurately predict cell of origin are needed and in that regard, the recent 20-gene predictor assay developed by the Lymphoma and Leukemia Molecular Profiling Project (LLMPP) is promising and potentially widely applicable ([Fig. 82.4](#)).

This increased understanding of the heterogeneous biology of DLBCL has led to the investigation of strategies and novel agents that have selective activity within molecular subtypes and sets the stage for an era of precision medicine in DLBCL therapeutics, where therapy can be ascribed based on molecular phenotype.⁵ This offers the chance of improving the curability of DLBCL, particularly in the activated B-cell subtype where standard approaches are inadequate for the majority of patients.

Fig. 82.4 PATIENTS WITH DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL) OUTCOMES FOLLOWING R-CHOP ACCORDING TO CELL ORIGIN (COO; IN THE INDEPENDENT VALIDATION COHORT). (A) Progression-free survival (PFS) for COO assignment using the “Hans” algorithm. (B) Overall survival (OS) for COO assignment using the “Hans” algorithm. (C) PFS in the COO groups as determined by the Lymph2Cx assay. (D) OS in the COO groups as determined by the Lymph2Cx assay. (E) PFS in the COO groups determined by the gold-standard method applying the previously described model to gene expression on frozen tissue (FT). (F) OS in the COO groups determined by the gold-standard method. The p -values are from log-rank tests comparing the activated B-cell (ABC) and germinal center B-cell (GCB) groups. The log-rank tests are one sided in the direction of greater hazard for ABC. RR, relative risk (with the 95% confidence interval in brackets) associated with the ABC group compared with the GCB group. (Republished with permission of the American Society of Hematology from Scott DW, Wright GW, Williams PM, Lih CJ, Walsh W, Jaffe ES, et al: Determining cell-of-origin subtypes of diffuse large B-cell lymphoma using gene expression in formalin-fixed paraffin-embedded tissue. *Blood* 123:1214, 2014. Permission conveyed through Copyright Clearance Center.)

Treatment

The mainstay of treatment for DLBCL is systemic chemotherapy; radiation treatment alone is inadequate and associated with high recurrence rates. For early stage disease, whether or not radiation treatment adds benefit to chemotherapy has been controversial. Based on a randomized study that showed a survival advantage of limited

course CHOP plus involved field radiation compared with full course CHOP in early stage (I/II) aggressive lymphoma, combined modality therapy became the standard. However, longer patient follow-up showed a convergence of the overall survival curves because of late systemic relapses in the combined modality arm, thus reopening the debate on radiation. In this regard, a prospective Groupe d'Etude des Lymphomes de l'Adulte (GELA) study randomized elderly patients

with favorable early stage aggressive lymphoma to receive CHOP alone (four cycles) or CHOP plus radiation, and found that combined modality therapy was not superior to chemotherapy alone. Given these results and the improved outcome of R-CHOP, it is difficult to justify the routine use of radiation in early stage disease.

A possible exception to the omission of radiation is in the treatment of primary mediastinal DLBCL (PMBL), depending on the chemotherapy regimen. In a study of 50 untreated patients with PMBL who received MACOP-B (methotrexate, ARA-C [Cytarabine], cyclophosphamide, vincristine, prednisone, and bleomycin) followed by radiation, 66% had persistently positive gallium scans after chemotherapy, suggesting active disease. After consolidation radiotherapy, however, only 19% of patients had a positive gallium scan, and 80% were event-free at 39 months of median follow-up. This important study suggested that radiotherapy was necessary after chemotherapy in PMBL. Furthermore, historical evidence indicated that dose-intense regimens such as MACOP-B or VACOP-B (etoposide, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin) were superior to CHOP for PMBL, raising yet another question about the optimal chemotherapy for this disease. Although the addition of rituximab to CHOP has improved the outcome for patients with DLBCL, there remains a high proportion of patients who do not achieve remission with R-CHOP, and require mediastinal radiation. Recent results with the pharmacodynamically dose-adjusted regimen of doxorubicin, vincristine, and etoposide infused over 96 hours with bolus intravenous cyclophosphamide, rituximab, and oral prednisone (DA-EPOCH-R) challenge the need for radiation in PMBL as in a prospective study of 53 patients, 93% were event-free with DA-EPOCH-R alone⁷ (see box on [Treatment of Primary Mediastinal B-Cell Lymphoma](#)). These results suggest that regimens such as DA-EPOCH-R obviate the need for radiation in a high proportion of patients with PMBL, thus eliminating the risk of long-term toxicities such as secondary malignancies and heart disease. An ongoing study by the International Extranodal Lymphoma Study Group (IELSG) is testing if mediastinal radiation can be omitted in patients who have a negative FDG-PET scan at the end of therapy.⁸

Today, most newly diagnosed patients with DLBCL receive rituximab in combination with a chemotherapy backbone consisting of cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) (Fig. 82.5). This backbone has been used since the early 1970s when doxorubicin was added to cyclophosphamide, vincristine, and prednisone (CVP) and CHOP became the first curative regimen in DLBCL, highlighting the critical role of anthracyclines. Later on, in an attempt to improve upon the results with CHOP, subsequent studies focused on the empiric addition of drugs to the regimen. However, this did not improve survival, as evidenced in a pivotal randomized study comparing CHOP to second and third generation regimens, where there was no evidence of superiority with the latter approaches, but there was much higher toxicity. Later on, other groups such as The Deutsche Studiengruppe für Hochmaligne Non-Hodgkin' Lymphome (DSHNHL) also made attempts to improve the outcomes that had been observed following CHOP. They carried out four-arm studies of CHOP where they tested different schedules of the regimen (every 14 versus every 21 days) with or without etoposide (CHOEP) in both older (>60 years) and younger (≤60 years) patients. While CHOEP-21 benefited patients

Treatment of Primary Mediastinal B-Cell Lymphoma

Patients with a diagnosis of PMBL undergo routine CT staging of chest, abdomen, and pelvis. We administer six cycles of DA-EPOCH-R. After four cycles of therapy, we repeat CT staging, and after six cycles, we perform CTs and an FDG-PET scan. If patients have responded and the posttherapy PET scan result is negative, we repeat CT scans every few months. If the FDG-PET result is positive, we attempt to perform a biopsy, and if there is residual disease, patients undergo mediastinal radiation treatment. If the FDG-PET result is suspicious (low SUV values), we repeat it in 4 to 6 weeks. If at this time, the result becomes negative, patients go into routine follow-up, and if it remains abnormal, we perform a biopsy and administer radiation if the biopsy confirms residual disease.

Fig. 82.5 EVOLUTION OF DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL) THERAPEUTICS. Schema of progress in DLBCL clinical trials over the past 30 years. This schema shows selected randomized studies in DLBCL from the pre- to post-rituximab eras and within molecular subtypes of DLBCL. *ACVBP*, Dose-intensified doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisone; *CHOP*, cyclophosphamide, doxorubicin, vincristine, and prednisone; *CHOEP*, CHOP with etoposide; *m-BACOD*, methotrexate, bleomycin, doxorubicin, cyclophosphamide, vincristine, dexamethasone; *R-CHOP-I*, R-CHOP ibrutinib; *R2-CHOP*, R-CHOP with lenalidomide (Revlimid); *RB-CHOP*, R-CHOP with bortezomib, in non-germinal center B-cell DLBCL.⁵

≤60 years and CHOP-14 benefited patients >60 years, these survival gains did not remain significant with the addition of rituximab, (following on from a GELA study that showed a survival advantage in older patients treated with R-CHOP versus CHOP). The RICOVER-60 study was a randomized comparison in elderly patients of six versus eight cycles of CHOP-14, with or without rituximab. Although the DSHNHL found no significant differences in survival between the two groups, they reached the conclusion that R-CHOP-14 should be adapted as the new standard based on historical comparisons in this population. Subsequently, however, two randomized studies, one in all age groups (≥18 years) and the other in older patients (>60 years), showed no benefit of R-CHOP-14 over R-CHOP-21.^{9,10} Therefore, R-CHOP-21 remains the standard.

Others have investigated the use of increased dose intensity approaches as an alternative to R-CHOP. Rituximab with doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisone (R-ACVBP) was compared to R-CHOP-21 in a randomized study performed by the GELA group in patients under 60 years with an age-adjusted international prognostic index score of 1.¹¹ While the R-ACVBP arm showed an improved progression free-survival (PFS) (87% versus 73%), the significant hematologic toxicity of the regimen confines its use to younger patients and it is not feasible for most patients with DLBCL who are over the age of 65 years. This restricts the potential of approaches like R-ACVBP to replace R-CHOP as the universal platform for this disease. Other intensive approaches such as using autologous stem cell transplantation in the upfront setting have been tried but they have never shown a clear benefit over R-CHOP alone and are associated with much higher toxicity.¹² Another increased dose-intensity regimen is dose-adjusted etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin with rituximab (DA-EPOCH-R).¹³ Following on from the promising activity of DA-EPOCH-R in DLBCL in NCI and multicenter Cancer and Leukemia Group B (CALGB) single-arm studies, a randomized study comparing it to R-CHOP recently completed accrual and results are awaited.¹⁴ This study aims to investigate if there are differential outcomes in DLBCL sub-types in R-CHOP or DA-EPOCH-R treated patients.

The appreciation that distinct subtypes of DLBCL have “targetable” pathways has led to novel drug development in DLBCL. In particular, in DLBCL of the ABC subtype, the understanding of various mechanisms of NFκB activation in ABC DLBCL has evolved significantly paving the way for the development of several new classes of agents that target NFκB. In particular, recent work has underlined the importance of chronic B-cell receptor (BCR) signaling as well as activating mutations in CARD11 and MYD88 in driving NFκB.¹⁵ As a result, several specific inhibitors of critical pathways that drive NFκB activation are in development and large scale randomized trials evaluating ibrutinib and lenalidomide particularly, are ongoing.

Over the past few decades, there have been significant improvements in the outcome of patients with HIV-associated DLBCL, and these can be attributed to the widespread availability of combination antiretroviral therapy (CART) as well as advances in the therapeutics of these diseases. Recently, the AIDS Malignancy Consortium in the United States reported excellent results with the DA-EPOCH-R regimen that were similar to survival outcomes in HIV-negative DLBCL.

PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

Primary central nervous system lymphoma (PCNSL) is a rare and highly aggressive lymphoma confined to the CNS and is of diffuse large B-cell histology in over 90% of cases. Its unique radiographic findings present challenges in evaluation. The incidence of PCNSL is particularly high in the setting of HIV infection, in which it often presents with multifocal disease and is virtually always associated with EBV. In contrast, PCNSL in HIV-negative patients often presents with solitary intracranial masses and is almost never associated with EBV (Fig. 82.6).

Fig. 82.6 THIS GADOLINIUM-ENHANCED MAGNETIC RESONANCE IMAGING SCAN OF THE BRAIN SHOWS AN ENHANCING INFILTRATIVE MASS IN THE MAJOR FORCEPS OF THE CORPUS CALLOSUM. A biopsy was consistent with primary central nervous system lymphoma.

Treatment of PCNSL differs from systemic DLBCL because many chemotherapy agents do not adequately penetrate the blood-brain barrier. Radiotherapy has been a mainstay of treatment because it is effective and sidestepped the limitations of chemotherapy, but responses are usually short lived, and virtually all patients relapse. High-dose methotrexate (HD-MTX), on the other hand, is a cytotoxic agent with good CNS penetration, but when used alone, PFS is relatively short. A logical step was to administer HD-MTX followed by whole-brain radiotherapy, and this resulted in an impressive 82% to 88% CR and median PFS rates of 32 to 40 months. Unfortunately, such combined modality treatment is associated with severe long-term neurotoxicity and recently, a high incidence of late relapses has been identified for this disease entity. For this reason, there has been much interest in developing regimens that obviate or defer the need for radiation until relapse.¹⁶ Interestingly, most DLBCLs that arise in the CNS are of the ABC subtype and a high proportion have mutations in the BCR and MYD88. Therefore, there is interest in pursuing strategies that target BCR signaling as well as using immunomodulatory agents in these diseases.

BURKITT LYMPHOMA

Epidemiology

BL mostly occurs in the first two decades of life, is more common in males, and accounts for some 2% of all lymphomas. There are three recognized clinical variants, and they vary in whom they affect and how they present, and they also have morphologic and biologic differences. Endemic BL occurs in equatorial Africa and Papua New Guinea, peaks in incidence in 4- to 7-year-old children, and is predominantly a male disease. Sporadic BL presents worldwide and is the most common variant in the Western world. It typically affects

Fig. 82.7 BURKITT LYMPHOMA (BL) INVOLVING THE UMBILICUS. This is an 18-year old man who presented with a history of abdominal pain. Computed tomography scan demonstrated a large intraabdominal mass extending up to the umbilicus, and a biopsy revealed it to be BL.

children and young adults and is more commonly observed in boys. Immunodeficiency-associated BL occurs in association with HIV infection and is approximately 1000 times more common in HIV-infected individuals.

Pathobiology

BL is highly aggressive and characterized by an extremely high proliferation fraction and a high fraction of apoptosis, and this accounts for its “starry sky” appearance (see E-Slide VM03958). Although a leukemic phase of BL can occur in patients with advanced disease, it is very rare for BL to present purely as acute leukemia. Biologically, BL is derived from a GCB cell as indicated by its CD20⁺, CD10⁺, and TdT-negative immunohistochemical profile and gene expression profiling. The neoplastic cells are usually negative or weakly positive for BCL2. Although EBV is virtually always detected in endemic BL, it is only present in 25% to 40% of sporadic and immunodeficiency-associated cases.

Although virtually all cases of BL have MYC translocations, usually at 8q24 to the IG heavy chain region, MYC translocations are not specific for BL and can be found in other aggressive B-cell lymphomas (Fig. 82.7). BL has a unique gene expression signature that is molecularly distinct from that of DLBCL. Studies have demonstrated that some cases of DLBCL by histology have gene expression profiles consistent with BL. Given that BL does not respond well to CHOP-based treatments, this distinction by molecular profiling is important, and gene expression profiling may be useful in rare cases that would otherwise be diagnosed as DLBCL. Additionally, there are cases with a profile intermediate between that of DLBCL and BL; these cases typically harbor MYC and have a poor outcome with CHOP-based regimens.

Clinical Features

The clinical presentation of BL is variable and depends on the epidemiologic subtype as well as other factors. In endemic BL, it is common for patients to present with jaw and other facial disease, and other extranodal sites of involvement include the ileocecum, gonads, kidneys, and breasts. The ileocecal area is the most common site of disease involvement in sporadic BL (Fig. 82.8), and jaw involvement is very rare. In immunodeficiency-associated BL, involvement of the ileocecum, LNs, and BM is commonly observed. Patients often present with advanced stage and bulky disease caused by the short doubling time of the tumor, and it is common for patients to develop tumor lysis syndrome (TLS) after the institution of therapy.

Fig. 82.8 FLUORESCENT IN SITU HYBRIDIZATION SHOWING AN MYC TRANSLOCATION IN A PATIENT WITH DIFFUSE LARGE B-CELL LYMPHOMA. This is a break apart probe (LSI-MYC) with one normal (fused) signal and one abnormal (separated green and red) signal indicating a translocation involving MYC.

Investigation

History and Physical Examination and Laboratory Investigations

Similar to patients with DLBCL, a detailed history and physical examination is required, and the diagnosis of BL should be made by an experienced hematopathologist. Given its association with HIV infection, it is imperative to perform an HIV test at diagnosis and to check hepatitis serologies.

Imaging and Staging

As with DLBCL, imaging studies should include chest radiography and CT scanning of the chest, abdomen, and pelvis. The need for additional imaging studies depends on the clinical presentation. A BM aspirate and biopsy should be performed in all patients, and depending on clinical presentation, patients should undergo a lumbar puncture with evaluation of the CSF by cytology and flow cytometry. Although BL in adults is staged according to the Ann Arbor staging system, the Murphy staging system is often used in children.

Prognosis

Age, large tumor volume, and CNS involvement have been associated with a poor prognosis in the past. Although early studies demonstrated that HIV-positive patients with BL had a worse outcome, this has not been the case with newer treatment approaches.

Treatment

BL is a systemic disease and requires chemotherapy for all disease stages. Importantly, locoregional radiation does not improve survival

and should be avoided. Although older studies demonstrated that surgical resection of abdominal disease improved outcome, indicating the importance of tumor volume, more effective and risk-adapted treatments have made surgical resection unnecessary except for specific complications such as obstruction, perforation, fistula, or bleeding.

Early treatment strategies for BL were modeled on acute lymphoblastic leukemia (ALL) regimens that used dose-intensive and prolonged treatment with induction, consolidation, and maintenance phases. These approaches stand in contrast to the significantly less dose-intensive regimens used in adults with “intermediate-grade” lymphoma, such as CHOP and CHOP-based regimens, that only produced a 50% to 60% event-free survival (EFS). Although dose intensity and dose density are important treatment components for BL, later studies indicated that shorter treatment durations were equally effective. Furthermore, the recognition that tumor volume is an important prognostic feature led to the use of risk adaptive approaches and a further reduction in treatment for patients with early stage disease. Several biologic characteristics of BL have helped guide treatment strategies, including its high proliferative fraction. It has been recognized for years that BL is sensitive to multiple chemotherapy classes, and in endemic BL, cures were occasionally achieved with single-agent cyclophosphamide. Despite initial sensitivity, however, patients frequently relapsed, particularly those with higher volume disease. This apparent dichotomy can potentially be explained by the high tumor proliferation rate, resulting in “kinetic” failure. One strategy to overcome “kinetic” failure is to increase the dose density through frequent chemotherapy administration, a strategy used in most current BL regimens. Another strategy is to increase the fractional cell kill or efficacy of chemotherapy, thereby reducing the number of tumor cells that can survive and proliferate between cycles. Hence, BL regimens commonly use multiple chemotherapy agents in high doses and alternating cycles. They typically include anthracyclines, epipodophyllotoxins, vinca alkaloids, and alkylators, as well as methotrexate and cytarabine, which are cell cycle active agents and take advantage of the high tumor proliferation. These agents, however, are administered in a variety of combinations and schedule, indicating the empiric nature of the actual combinations.

The risks of TLS and propensity for CNS dissemination in BL also have important treatment implications. All patients should receive TLS prophylaxis during the first cycle and undergo close monitoring of their electrolytes. The high risk of CNS involvement has prompted the use in the past of relatively high-dose intravenous methotrexate and cytarabine, both of which have CNS penetration, and intrathecal administration of these drugs. An important advance has been to reduce intrathecal treatment and eliminate whole-brain radiation for prophylaxis, which has significantly reduced CNS toxicity. A study published by the FAB/LMB demonstrated that patients with early stage BL had a high cure rate and very low rate of CNS relapse without the use of intrathecal chemotherapy.¹⁷

There are multiple highly effective regimens for BL; however, because of the rarity of the disease (there are only 1200 new cases in the United States each year) there are no good comparative studies of different therapies in BL. A variety of dose-intensive short-duration regimens have achieved durable CRs in a high proportion of patients. Included in these are the French LMB and German Berlin-Frankfurt-Munster (BFM) protocols and the National Cancer Institute CODOX-M/IVAC (cyclophosphamide, vincristine, doxorubicin, and HD-MTX alternating with ifosfamide, etoposide, and high-dose cytarabine; intrathecal methotrexate and cytarabine are also administered) regimen. These regimens are similar in their drug composition, short cycle length, and CNS prophylaxis. Although most BL occurs in children, Magrath and colleagues demonstrated that adults have a similar disease outcome when treated with the same regimen and reported cure rates approximately 90%. Other groups have confirmed the efficacy of this regimen albeit with lower survival rates. In the United Kingdom, Mead and colleagues reported an overall EFS of 65% at 2 years. The hyper-CVAD regimen has also been tested in BL with good results (recently with the addition of rituximab). Rituximab is typically used in this disease, and early

reports of randomized studies in both children and adults demonstrate that it adds a survival advantage.

Toxicity is an important clinical limitation of these regimens in adults, particularly in older patients and in patients who are immunosuppressed, in whom severe morbidity and even mortality occur. Therefore, one of the major therapeutic challenges in BL is to develop therapies that are as effective in achieving high cure rates as “standard” regimens but that also improve the therapeutic index and reduce toxicity complications. This approach has been investigated using EPOCH-R-based therapy in BL. Based on the efficacy of the regimen in a DLBCL study—which suggested that DA-EPOCH overcomes the adverse effect of high proliferation, likely because of its infusional schedule—a study was undertaken in BL and demonstrated a high PFS of over 90%.¹⁸ There were very low rates of TLS and other toxicities compared with conventional BL regimens and this low-intensity therapy is now under investigation in a multi-center study. In the setting of HIV infection, a concern with standard BL regimens has been toxicity and less toxic appear to be more appropriate.^{18,19}

SALVAGE THERAPY

The salvage treatment of relapsed DLBCL should be approached in an individual manner because the choice of treatment is influenced by the time to recurrence, prior therapy, medical condition, and the potential for cure. Although most relapsed aggressive lymphomas require combination chemotherapy for adequate disease control, it is important to recognize that patients with local disease may be salvaged with radiation therapy. Examples include primary mediastinal DLBCL, which can remain local even at relapse, and PTLs, which may have an isolated resistant EBV clone after chemotherapy.

A variety of active salvage chemotherapy regimens are available for relapsed or refractory DLBCL. Platinum-containing regimens, such as ESHAP (etoposide, methylprednisolone, cytosine arabinoside, and platinum) and ICE (ifosfamide, carboplatin, and etoposide), are currently among the most widely used salvage treatment. It is a commonly held notion that salvage treatment should include different agents from past treatment to avoid drug resistance. Recent evidence indicates, however, that sensitivity to apoptosis is a central cause of drug resistance and that drug-specific mechanisms are less important. Hence, salvage regimens developed around the most active upfront agents should show high activity. The addition of rituximab appears to enhance the activity of salvage regimens as demonstrated by results with R-ICE (rituximab, ifosfamide, carboplatin, and etoposide) and ICE, which showed CRs of 53% and 27%, respectively.

Patients with chemotherapy-sensitive disease have the best outcome with ASCT, and this is recommended at initial relapse; in the pre-rituximab era, this approach yielded overall survival (OS) and EFS rates in the range of 40% to 50% and 30% to 40%, respectively. However, the improvement in upfront curability of DLBCL because of immunochemotherapy has diminished the efficacy of ASCT at relapse, which was recently demonstrated in the CORAL study, in which the 3-year EFS of patients who had initially received rituximab was merely 21% after ASCT. Of course, patients with chemotherapy-resistant disease do poorly with ASCT and should be considered for experimental treatments such as allogeneic SCT. Recently, in B-cell lymphoproliferative disorders, chimeric antigen receptor T-cell therapy has been investigated in many different relapsed/refractory settings and has shown some promising activity in DLBCL.²⁰

The outcome for patients with BL who relapse after or progress during initial therapy is extremely poor, and there are no standard approaches that have been associated with good outcomes; therefore, experimental approaches should be considered.

Late Complications of Treatment and Follow-up

It is important to recognize that successful treatment may be associated with late complications that may not appear for decades. Among the major late-term complications are secondary malignancies,

ischemic heart disease, anthracycline-related cardiotoxicity, and radiation- or bleomycin-induced pulmonary toxicity. The risk of developing myelodysplastic disorders and acute myeloid leukemia is related to alkylator and topoisomerase inhibitor use and is enhanced by radiation. Radiation therapy increases the risk of malignancy in the treatment region, particularly breast cancer in women and lung cancer in smokers. Indeed, it is imperative to consider late-term toxicity when selecting treatment.

A general guideline for follow-up after initial therapy involves visits every 3 or 4 months for 2 years, and every 6 months or annually thereafter. During these visits, examination of the LN areas, abdomen, thyroid, and skin is important. CT scans are recommended in early follow-up but it is important to note that they are associated with a relatively high radiation exposure and projected risks and should not be used unnecessarily or for a prolonged amount of time. PET scans are not recommended for routine follow-up because the high rate of false-positive scans is unlikely to offset the value of early detection. Routine laboratory studies with blood counts, liver function tests, and LD should be performed. Thyroid-stimulating hormone levels should be monitored annually in patients who received neck radiotherapy. Mammography for women should begin 10 years from the diagnosis of lymphoma or at age 40 years, whichever comes first.

FUTURE DIRECTIONS

Over recent years, we have made significant advances in elucidating the molecular biology of DLBCL and BL, and this has led to an era of enhanced and exciting drug discovery. In DLBCL in particular, many critical pathways and novel mutations have been identified, and many small molecule inhibitors are being investigated and in development as a result of these advances. For example, in the ABC subtype of DLBCL, recent work has identified that chronic active B-cell receptor signaling is an important mechanism of ABC tumor cell survival; to test this clinically, studies in patients with ABC DLBCL are in progress targeting specific components of this pathway. In BL, cure rates are very high with conventional approaches, and the challenge for the future is to further develop strategies that maintain the efficacy of “standard” treatment but with much less toxicity. Recently, the discovery of novel mutations in BL has set the stage for the investigation of small molecule inhibitors in this disease also.²¹ To advance the therapeutics of these diseases, it is critical to wisely choose which drugs should be developed and incorporated into upfront clinical trials and to pair drug development with understanding of tumor biology.

VIRUS-ASSOCIATED LYMPHOMA

Jennifer A. Kanakry and Richard F. Ambinder

There are five well-characterized human viruses that are generally accepted as important in lymphomagenesis (Table 83.1). These viruses may infect tumor cells (or their progenitors) or may act at a distance. The genomes of Epstein-Barr virus (EBV), Kaposi sarcoma-associated herpesvirus (KSHV, also known as *human herpesvirus 8* [HHV-8]), and human T-lymphotropic virus-1 (HTLV-1) are present in tumor cells. The viral genes expressed in tumor cells modulate cellular metabolism, proliferation, and cell death. By contrast, the human immunodeficiency virus (HIV) genome is generally not detected in tumor cells. Whether hepatitis C virus (HCV) genomes are present in lymphoma cells remains a subject of controversy.

Although viral infection plays a role in the pathogenesis of some lymphomas, lymphomagenesis is unusual. Only a small subset of infected people develops lymphoma. Furthermore, although primary viral infection may be followed by lymphomagenesis within days or weeks in exceptional circumstances, most lymphomas arise years or decades after primary infection, speaking to the role of cofactors in the development of malignancy. Indeed the term *adult* in adult T-cell leukemia/lymphoma (ATL) reflects the time lag between HTLV-1 infection in infancy and the evolution to malignancy. Geography and associated environmental exposures, host genetic factors, and immune status all modify risk.

Aspects of the biology and epidemiology of each of these viruses and their relationship with lymphomagenesis are reviewed in this chapter. In addition, clinically important and distinctive features of diagnosis and treatment of the associated lymphomas are presented.

EPSTEIN-BARR VIRUS

Viral Biology

EBV is a gammaherpesvirus transmitted mainly through saliva.^{1,2} After primary infection, some of the infected cells are driven to proliferate and thereby spread infection throughout the B-cell compartment. Ultimately, in the normal host, there is an immune response that controls infection and eradicates virus-infected proliferating cells. Thereafter the viral genome is harbored mainly in resting memory B lymphocytes that persist for life. These B cells that harbor virus elude immune surveillance in part because of their very restricted viral gene expression, such that few viral antigens are presented. Occasionally there is activation of viral lytic gene expression (occurring at least in some instances in concert with plasma cell differentiation), leading to production of infectious virions that may infect other B cells. T cell-mediated immune function keeps such proliferation in check.³

In vitro, EBV immortalizes B cells such that they grow indefinitely as lymphoblastoid cell lines (LCLs) (Fig. 83.1). LCLs are tumorigenic in immunodeficient mice. In LCLs, viral genomes are present as circular, double-stranded deoxyribonucleic acid (DNA) episomes within the nucleus. The viral proteins required for immortalization include Epstein-Barr virus nuclear antigen-1 (EBNA1), a sequence-specific DNA-binding protein important in the maintenance of the viral episome; EBNA2, a transcription factor that has many effects similar to those of activated Notch receptors; and latent membrane protein-1 (LMP1), a constitutively activated member of the tumor necrosis factor receptor superfamily, which most closely resembles CD40.⁴ LMP1 activates the nuclear factor- κ B (NF κ B) pathway,

which modulates cell proliferation and apoptosis.⁵ Several other EBV proteins are also required for immortalization. Although EBV immortalization of B cells in vitro may offer some insights into tumorigenesis, some caution is required in using LCL as a tumor model. Most EBV tumors, including tumors of B-lineage cells, do not express many of the viral genes required for lymphocyte immortalization. The only tumors that express the full complement of viral proteins required for immortalization are those that arise in the most profoundly immunocompromised patients (organ or hematopoietic transplant recipients, patients with congenital immunodeficiency, or patients with far-advanced acquired immunodeficiency syndrome [AIDS]). Thus in posttransplant lymphoproliferative disorder (PTLD), tumor cells may resemble LCL in expressing many viral latency genes in association with normal karyotype (and few mutations of the cellular genome). It has been suggested that there is an inverse relationship between cellular mutations and viral gene expression in tumors.⁶

EBV gene expression may directly drive proliferation or inhibit apoptotic pathways, as illustrated by lymphocyte immortalization. However, viral gene expression may also perturb normal lymphocyte biology. Thus LMP1 expression upregulates activation induced (cytidine) deaminase expression, which facilitates somatic hypermutation and immunoglobulin class switching.⁷ LMP1 expression may also be important in the conversion of naïve B cells to postgerminal center memory B cells. LMP2A allows B cells that lack normal immunoglobulin expression to escape regulatory checkpoints and survive.⁸

Epidemiology of Viral Infection

EBV infection is ubiquitous. The vast majority of adults are infected worldwide. Primary infection is most often asymptomatic, especially when it occurs in childhood.⁹ Primary infection may be associated with the syndrome of infectious mononucleosis. Symptomatic primary infection occurs more frequently in older children and in adults than in younger children. Other possible determinants of symptomatic primary infection include genetic factors and possibly the size of the viral inoculum.

Strain differences in EBV are well recognized.¹⁰ However, the importance of these strain differences with regard to lymphomagenesis remains poorly understood. There is general agreement that the type 1 strain EBV is most common worldwide and in tumors. The type 2 strain virus has been identified in some African Burkitt lymphoma (BL) and in some AIDS-associated lymphoma. The type 1 strain virus is more efficient at lymphocyte immortalization in vitro and lymphomagenesis in mouse models. The two strains of virus differ mainly in the *EBNA2* gene, but differences are recognized in some other viral proteins as well.¹¹ Variations in the regulatory regions or coding regions of a variety of other genes, including *EBNA1*, *LMP1*, and *ZTA*, have been recognized and suggested to play a role in lymphomagenesis. A simple classification of latent viral gene expression recognizes three patterns, as shown in Table 83.2.

Epstein-Barr Virus Detection in Clinical Specimens

The sensitivity of polymerase chain reaction (PCR) makes detection of viral DNA straightforward, but the ubiquity of EBV infection, as

TABLE 83.1 Viruses and Lymphomagenesis

Virus	Viral Genome in Tumor Cell	Lymphoma Type
EBV	Episomal	B, T, NK
KSHV	Episomal	B
HTLV-1	Integrated	T
HIV-1	Absent	B
HCV	Uncertain	B

EBV, Epstein-Barr virus; HCV, hepatitis C virus; HIV-1, human immunodeficiency virus type 1; HTLV-1, human T-lymphotropic virus-1; KSHV, Kaposi sarcoma-associated herpesvirus; NK, natural killer.

TABLE 83.2 Patterns of Epstein-Barr Virus Gene Expression in Latency

Latency	EBNA1	EBNA2, EBNA3A, EBNA3B, EBNA3C	LMP1	LMP2A
I	+			
II	+		+	+
III	+	+	+	+

EBNA1, Epstein-Barr virus nuclear antigen 1; EBV, Epstein-Barr virus; LMP1, latent membrane protein 1.

Fig. 83.1 EPSTEIN-BARR VIRUS (EBV)–IMMORTALIZED B CELL. Normal B cells are readily immortalized *in vitro* with EBV. These cells express EBV nuclear and membrane proteins. The nuclear proteins include a protein expressed in all EBV-associated tumors, Epstein-Barr virus nuclear antigen 1 (EBNA1). This protein is required for episomal maintenance. Other viral nuclear proteins expressed are transcription factors. These include EBNA-LP, EBNA2, EBNA3A, EBNA3B, and EBNA3C. Two membrane proteins are expressed: latent membrane protein 1 (LMP1), which activates nuclear factor-κB (NFκB) pathways, and LMP2A, which mimics B-cell receptor (immunoglobulin) signaling.

well as the persistence of B cells that harbor EBV in all seropositive individuals, means that EBV DNA is readily detected in many specimens that include normal lymphocytes. Thus the diagnosis of an EBV association in general requires viral detection specifically in tumor cells. Techniques for viral DNA detection by fluorescence in

situ hybridization or related techniques, although greatly improved in recent years, remain the purview of research laboratories and are generally not readily applicable to clinical specimens. This reflects the relatively low copy number of the viral genome in tumor cells, typically 1–200 copies per cell. In contrast, *in situ* hybridization for the EBV-encoded ribonucleic acids (RNAs) has emerged as a clinical laboratory standard.¹² These RNAs are polymerase 3 transcripts that are expressed at very high copy number (perhaps millions of copies per cell) in latently infected cells. The functions of these RNAs are disputed, but their use for the detection of virus in a variety of tissue specimens is generally accepted.

Viral antigens are detected by immunohistochemistry. In clinical laboratories, immunohistochemistry for LMP1 is commonly employed and is sensitive for the detection of EBV in Hodgkin lymphoma (HL). In a variety of other EBV-associated B- and T-cell malignancies, expression of LMP1 is more variable. Thus failure to detect LMP1 expression does not exclude the presence of EBV, except perhaps in HL. In principle, detection of EBNA1 should be universally applicable, although the low level of antigen expression and the cross-reactivity of available monoclonal antibodies have prevented immunohistochemistry for this antigen from emerging as a standard tool.

Association With Particular Types of Lymphoma

Some lymphoma types are nearly 100% EBV associated, including endemic BL, extranodal natural killer (NK)/T-cell lymphoma of the nasal type, early PTLD, lymphomatoid granulomatosis, diffuse large B-cell lymphoma (DLBCL) associated with chronic inflammation, EBV-positive DLBCL of older adults, and AIDS primary central nervous system (CNS) lymphoma (PCNSL).^{13–16} Other lymphoma types are variably EBV associated. These include classic HL, PTLDs occurring many months or years after transplantation, and systemic AIDS-related lymphoma.

Some lymphoma types appear never or almost never to be EBV associated, including most indolent B-cell lymphomas, although there is growing evidence that exceptions do exist, particularly in the setting of immunocompromise. Nodular lymphocyte predominant HL was historically thought to always be EBV negative, but a recent pathologic review of over 300 cases suggests that 3%–5% are EBV positive.¹⁷ Low-grade lymphomas such as EBV-positive mucosa-associated lymphoid tissue (MALT) lymphomas have been reported in patients with congenital immunodeficiencies.¹⁸ Whereas low-grade lymphomas that arise posttransplant are not considered to be PTLD in the current classification, it is interesting to note that cases of EBV-positive, indolent B-cell lymphomas, particularly MALT lymphomas with a predilection to involve the subcutaneous or soft tissues, have been reported in transplant patients.^{19,20} Thus the spectrum of EBV-associated lymphomas continues to expand, and the presence of EBV might be an indication to consider an underlying immune defect in the patient.

Other lymphomas are typically not EBV associated but have the interesting feature of being associated with EBV upon transformation or upon development of *de novo* secondary lymphomas. Chronic lymphocytic leukemia (CLL) is a low-grade lymphoma that is not EBV positive; however, CLL can rarely transform to HL, and these transformed, clonally related lymphomas are often EBV positive.²¹ In angioimmunoblastic T-cell lymphoma (AITL) and other peripheral T-cell lymphomas, EBV-positive polyclonal proliferations of atypical B cells that have the appearance of Hodgkin and Reed-Sternberg cells can be present in the background of the tumor.²² A rare but consistently described phenomenon in AITL is the subsequent development of EBV-positive DLBCL.²³ The role of EBV in the setting of transformation or secondary lymphomagenesis remains to be defined.

Table 83.3 lists the lymphomas that have been associated with EBV, associated cofactors, viral antigen expression, and an estimate of the percentage of tumors within each lymphoma subtype that harbor viral genomes. The table serves to illustrate the range of EBV

TABLE 83.3**Epstein-Barr Virus-Associated Lymphoma**

Type	Cofactors	Viral Gene Expression	Approximate Percentage EBV Associated	Comment
PTLD	Immunosuppression, allograft	Latency II or III	50%–95%	Early days/months after transplant are more commonly associated with EBV
Sporadic BL		Latency I	20% in the United States	Higher in Latin America
Endemic BL	Malaria	Latency I	>95%	
AIDS BL	HIV	Latency I	30%	
HL		Latency II	30% in the United States	Higher percentage in mixed cellularity, in males, in Hispanics
AIDS PCNSL	HIV	Latency II or III	>95%	
Extranodal NK/T-cell lymphoma, nasal type	More common in Asia	Latency II	>95%	
AIDS PEL	HIV and KSHV	Latency I	>75%	Rare cases of PEL in HIV-negative patients are typically EBV negative
Lymphomatoid granulomatosis	Immunocompromise	Latency II	>90%	
Methotrexate-associated lymphoma	Methotrexate treatment	Latency III	>95%	May regress with withdrawal of methotrexate

AIDS, Acquired immunodeficiency syndrome; BL, Burkitt lymphoma; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; HL, Hodgkin lymphoma; KSHV, Kaposi sarcoma-associated herpesvirus; NK, natural killer; PCNSL, primary central nervous system lymphoma; PEL, primary effusion lymphoma; PTLD, posttransplantation lymphoproliferative disorder.

lymphomas as well as host features that increase risk, but it is not meant to be comprehensive.

Posttransplantation Lymphoproliferative Disorder

PTLD is a group of lymphoproliferative disorders ranging from polyclonal lymphoid hyperplasia to lymphomas that arise in patients after solid organ or hematopoietic stem cell transplant (HSCT).²⁴ PTLD, especially in the first few months after transplant, is highly associated with EBV (Fig. 83.2A, B). EBV gene expression in PTLD corresponds to latencies II and III.²⁵ Broad expression of viral proteins is seen only in immunosuppressed hosts, reflecting that many of these proteins are immunogenic and commonly targeted by cytotoxic T cells.

B cells that harbor EBV are able to proliferate in the setting of posttransplant immunosuppression, at least in part because of decreased T-cell surveillance.²⁶ HSCT patients who receive grafts that have been T-cell depleted develop EBV-associated PTLD at very high rates. Treatment of rejection in solid organ transplant recipients with agents such as the monoclonal antibody OKT3, which targets CD3⁺ cells, is associated with markedly increased risk for PTLD.²⁷ Treatment strategies such as the use of rituximab and infusion of EBV-specific cytotoxic T cells have been quite effective in treating or preventing PTLD (see box on [Epstein-Barr Virus–Associated Positive Posttransplant Lymphoproliferative Disorder](#)).

Hodgkin Lymphoma

Approximately 30% of classical HL tumors in the United States and Europe are EBV associated (Fig. 83.2C, D).^{29,30} Epidemiologic studies in Denmark and Sweden suggest that individuals with a history of symptomatic infectious mononucleosis are at increased risk for EBV-associated HL, but not for EBV-negative HL or other lymphomas.³¹ The period of risk peaks at about 2 years but continues to be elevated for at least 10 years after symptomatic mononucleosis.

Higher EBV associations are seen in Latin America, Africa, and parts of Asia. Factors associated with EBV tumor positivity include

Epstein-Barr Virus–Associated Positive Posttransplant Lymphoproliferative Disorder

A 55-year-old renal transplant patient presents with acute renal failure 5 months after transplant. She is found on imaging to have an obstructing mass in the transplanted kidney. She undergoes kidney biopsy, and Epstein-Barr virus (EBV)–positive posttransplant lymphoproliferative disorder (PTLD) involving the transplanted organ is diagnosed. Treatment options include rituximab; decreasing immunosuppression (acknowledging the associated risk for organ rejection); changing immunosuppressive agents—switching a calcineurin inhibitor for a mammalian target of rapamycin (mTOR) inhibitor; combination chemotherapy; or, in the case of renal transplant, removal of the transplanted organ and withdrawal of immunosuppression. In a recent retrospective study, renal transplant patients with PTLD had a response rate of about 30% when their immunosuppressive regimen was changed from a calcineurin inhibitor to rapamycin.²⁸

mixed cellularity and lymphocyte-depleted classic HL histologic subtypes, male sex, low socioeconomic background, history of symptomatic infectious mononucleosis, and Hispanic ethnicity.^{29,32,33} Organ and hematopoietic stem cell transplant recipients, patients with primary immunodeficiencies, and HIV-positive patients are more likely to develop HL than the general population, and approximately 90% of the tumors in these settings are EBV associated.³⁴

The EBV gene expression pattern in HL is latency II, even when HL occurs in immunocompromised populations.³⁵ LMP1 and LMP2A may mimic signaling of B-cell receptors and thus protect B cells lacking functional immunoglobulin expression from apoptotic signaling. Approximately 20% of HL lack productive immunoglobulin gene rearrangements. These tumors appear to be exclusively EBV associated.

The EBV association of HL may have prognostic significance because it has been associated with poorer survival in older patients in several reports.³⁰ Patients with EBV-positive HL quite reliably have EBV DNA detected in cell-free blood (plasma or serum) in the setting of active disease.^{36–38} Thus plasma EBV DNA is a potential tumor

Fig. 83.2 EXAMPLES OF EPSTEIN-BARR VIRUS (EBV)-RELATED LYMPHOMAS. Posttransplant lymphoproliferative disorder (PTLD), polymorphic type, EBV positive occurring in the gastrointestinal tract of a 15-month-old girl following an orthotopic liver transplant (A and B). There was a mildly atypical lymphocytic infiltrate in the duodenal mucosa composed of small lymphocytes, plasma cells, and occasional large cells (A). The infiltrate was EBV positive, as demonstrated by in situ hybridization for Epstein-Barr-encoded RNA (EBER) (B). Hodgkin lymphoma, nodular sclerosing type, EBV positive (C and D). The hematoxylin and eosin–stained section shows a portion of a lymph node from a cervical lymph node biopsy of an 8-year-old girl. There are bands of sclerosis forming a cellular nodule, and within the nodule there are a mixed inflammatory infiltrate and scattered large cells with contracted cytoplasm consistent with lacunar cells (C). The immunophenotype of these cells was that of classic Hodgkin lymphoma, and the cells were EBER positive (D). EBV is seen more frequently in mixed-cellularity Hodgkin lymphoma but can be seen in 10%–40% of cases of nodular sclerosing type. It is even more frequent in cases associated with human immunodeficiency virus (HIV; see text) and in resource-poor regions. Burkitt lymphoma, sporadic type, EBV positive (E and F). A section of the cervical lymph node biopsy of a 9-year-old girl with a rapidly enlarging neck mass is shown. The section illustrates the classic morphologic features of Burkitt lymphoma with a “starry sky” appearance, sheets of intermediate-sized cells with multiple small nucleoli and high mitotic rate. The cells were virtually all EBER positive (F). EBV can be seen in about 20%–30% of cases of sporadic Burkitt lymphoma and is essentially always positive in endemic cases.

marker in EBV-positive HL, and elevated EBV DNA in plasma prior to therapy has been associated with inferior failure-free survival in one study, even on multivariate analysis.³⁶ In addition, elevated EBV DNA in plasma after completion of first-line therapy for HL was also associated with inferior failure-free survival in this study.³⁶

Currently treatment regimens for EBV-positive HL do not differ from those used for EBV-negative HL. However, novel treatment strategies involving adoptive therapy with autologous EBV-specific T cells targeting type II latency LMP antigens appear to be associated with durable complete responses and low toxicity in some patients with EBV-positive HL, even in the setting of relapsed/refractory disease.³⁹

Burkitt Lymphoma

Endemic BL is nearly 100% associated with EBV, whereas sporadic and HIV-associated BL are much more variably EBV associated (see Table 83.3 and Fig. 83.2E, F).⁴⁰ Viral expression is latency I (i.e., EBNA1 is the only viral protein consistently expressed). The defining feature of BL is a translocation between c-Myc on chromosome 8 and one of the immunoglobulin genes on chromosome 2, 14, or 22. It has been generally presumed that falciparum malaria is a cofactor in endemic BL, and the distribution of BL in Africa corresponds to the distribution of holoendemic malaria. However, little is understood of the pathogenesis or interaction between these infectious cofactors. The characteristic presentation of BL is different in the endemic versus sporadic settings, but there is no evidence to link these presentations specifically with the virus. The virus-tumor association

does not currently guide diagnosis, therapy, or estimation of prognosis.

Diffuse, Large B-Cell Lymphoma Associated With Chronic Inflammation

EBV-associated lymphomas sometimes arise in the setting of longstanding chronic inflammation.¹⁵ This was first described in Japanese patients with a remote history of pulmonary tuberculosis treated with thoracoplasty with resulting chronic pyothorax. These patients developed EBV-associated DLBCL of the pleural lining and associated lung tissue decades after thoracoplasty. Similar cases of aggressive, EBV-associated B-cell lymphomas have been reported to arise in patients at the sites of chronic inflammation associated with various implants, surgical mesh, or in the lung after chronic empyema.

KAPOSI SARCOMA-ASSOCIATED HERPESVIRUS

Virus and Tumor Epidemiology

KSHV (HHV-8) is a gammaherpesvirus that, unlike EBV, has a low prevalence worldwide.⁴¹ The virus is endemic in certain areas, such as in sub-Saharan Africa and the Middle East, and has an intermediate prevalence in Mediterranean countries. Transmission is believed to be predominately through saliva. Similar to EBV, KSHV latently infects B cells, and viral genes that promote cell survival are implicated in lymphomagenesis.

Fig. 83.3 EXAMPLES OF KAPOSI SARCOMA–ASSOCIATED HERPESVIRUS (KSHV)–AND HUMAN T-LYMPHOTROPIC VIRUS-1 (HTLV-1)–ASSOCIATED LYMPHOPROLIFERATIVE DISEASE. Primary effusion lymphoma (A and B). (A) The pleural tap had a high cell count, and the cytospin preparation revealed a markedly pleomorphic cell population with large and giant cells with deep-blue cytoplasm. (B) A cell block was prepared (*top*) so that in situ hybridization studies could be performed. These studies showed the cells to be KSHV positive by immunohistochemistry for latency associated nuclear antigen-1 (LANA-1) (*bottom*) and EBV positive by EBER in situ hybridization (not shown). (C) Adult T-cell leukemia/lymphoma in a patient who was HTLV-1 positive. The peripheral smear showed the classic “flower” cells. EBER, Epstein-Barr–encoded RNA. (A and B, courtesy Dr. Elizabeth Hyjek, University of Chicago.)

KSHV was discovered in Kaposi sarcoma but is also present in rare lymphoproliferative diseases, including primary effusion lymphoma (PEL) (Fig. 83.3A, B) and multicentric Castlemann disease (MCD).^{16,42} Other KSHV-positive lymphomas have been characterized, all of which tend to occur in severely immunocompromised individuals and carry a poor prognosis.⁴³ One exception is germinotropic lymphoproliferative disorder, a KSHV-positive, EBV-positive tumor that carries a good prognosis in the HIV-negative setting.^{44,45} PEL occurs almost exclusively in HIV-positive patients, particularly in men who have sex with men, and typically when CD4 counts are less than 100/mm³. However, PEL has been reported very rarely in solid organ transplant patients and elderly men with some degree of immunocompromise.⁴⁶ KSHV is always present in PEL. In HIV patients with PEL, tumor cells are usually dually infected with EBV as well. By contrast, HIV-negative PEL is usually EBV-negative. KSHV-associated MCD, although much more common in HIV-infected populations, also occurs in the general population.

MCD is a KSHV-associated, immunoglobulin M (IgM) λ -producing, nonclonal lymphoproliferative disorder typically involving the mantle zone of lymph nodes and the spleen. The KSHV-positive cells in MCD are always EBV negative. These cells express a broad range of KSHV lytic antigens, and high KSHV copy numbers are reported in plasma. Evolution into or coassociation with an aggressive lymphoma, often of plasmablastic phenotype, is not uncommon. Within the HIV population, nearly all cases of MCD are KSHV-associated; this viral association is not as strong among HIV-negative MCD patients. High expression of viral interleukin-6 (IL-6) is thought to contribute to the systemic inflammation seen in this disorder.⁴⁷ The KSHV-associated lymphomas that arise in association with MCD are not nodal equivalents of PEL; rather, these plasmablastic lymphomas (see E-Slide VM03957) are uniformly EBV negative and express IgM λ .¹⁶

Diagnostic and Therapeutic Considerations

The requisite finding in PEL is a lymphomatous effusion, which can be pleural, pericardial, or peritoneal, without associated lymphadenopathy or masses, arising in the setting of immunocompromise. Often, patients with HIV/AIDS will present with PEL in addition to other KSHV-associated diseases, such as Kaposi sarcoma and MCD, so thorough evaluation and staging should be undertaken at diagnosis. On cytologic examination, the PEL tumor cells are large with prominent nucleoli. The effusion cells are clonal B cells with

CD45 positivity but typically lack other specific B-cell lineage markers, although CD30 and CD38 positivity can be seen. BCL6 mutations are frequently detected. Tumor cells always harbor KSHV, as demonstrated by staining for KSHV-associated latency-associated nuclear antigen-1. In MCD, there is characteristically λ light chain restriction.⁴⁸ This does not reflect clonality as assessed by study of immunoglobulin DNA rearrangements. Rather, it reflects a tendency for the virus to selectively infect cells expressing λ or to selectively drive such cells to proliferate.

Treatment of PEL is most commonly combination chemotherapy, although novel approaches such as intracavitary cidofovir have been reported to be successful in rare cases.⁴⁹ Outcomes remain quite poor. Treatment of MCD with targeted therapies has been more successful, including the use of rituximab and IL-6 inhibition.^{50,51} Siltuximab, a monoclonal antibody against human IL-6, is now approved in the United States for HIV-negative patients with KSHV-negative MCD, but it has not been studied clinically in those with virus-associated MCD.⁵² Antivirals such as ganciclovir and valganciclovir have shown clinical activity in MCD, because viral lytic replication is a feature of this disease.⁵³ Rituximab plus liposomal doxorubicin has been shown to be associated with high rates of clinical response in HIV-associated MCD, with minimal increased risk of worsening concurrent Kaposi sarcoma lesions during therapy.⁵⁴

HUMAN T-LYMPHOTROPIC VIRUS-1

Viral Biology

HTLV-1 is a retrovirus with a single-stranded RNA genome. Following infection there is reverse transcription and integration of proviral DNA into the host genome. HTLV-1 infects a variety of cell types but persists in the subset of CD4⁺ T lymphocytes that are regulatory T cells.⁵⁵ Viral infection within the host is spread from cell to cell through direct cell-to-cell contact. As with EBV, the proliferation of HTLV-1-infected lymphocytes plays a central role in ensuring viral persistence.

The HTLV-1 protein Tax is also a mediator of immune dysregulation, T-lymphocyte immortalization, and transformation (Fig. 83.4).^{56,57} Tax affects NF κ B and the serine/threonine kinase AKT pathways with diverse proliferative and antiapoptotic effects. As with some of the immunodominant EBV antigens expressed in proliferating lymphocytes, Tax expression is targeted by cytotoxic T cells. Another viral protein, Hbz, suppresses Tax expression, allowing

Fig. 83.4 HUMAN T-LYMPHOTROPIC VIRUS-1 (HTLV-1) AND THE EVOLUTION OF ADULT T-CELL LEUKEMIA/LYMPHOMA. Following HTLV-1 infection, many cells undergo apoptosis, but some infected CD4⁺ T cells are driven to proliferate by the effects of Tax on the nuclear factor-κB (NFκB) pathway and on the AKT pathway. Tax is also suggested to result in inactivation of p53, aneuploidy, and deoxyribonucleic acid (DNA) damage. Over many decades, malignancy evolves.

transformed T cells to elude immune surveillance.⁵⁷ Tax interferes with various DNA repair pathways and induces reactive oxygen species, facilitating the development of aneuploidy.^{56,58} Tax leads to functional inactivation of p53 and may interfere with the spindle assembly checkpoint that normally operates in mitosis to preserve euploidy.

Epidemiology of Viral Infection and Adult T-Cell Leukemia/Lymphoma

HTLV-1 is endemic in particular regions of Japan, Africa, South America, and some Caribbean islands.^{58,59} As assessed by seroprevalence, rates up to 37% are found on the southwestern Japanese islands of Shikoku, Kyushu, and Okinawa, whereas most other areas of Japan have an intermediate prevalence of 1%–5%. In the United States, the incidence in blood donors is 0.025%. It has been estimated that about 20 million individuals are infected worldwide. The major mode of transmission in endemic areas is from mother to child in breast milk, although infection is also transmitted through sexual intercourse, transfusion of cellular blood products, and the sharing of needles and syringes. Evidence has been presented that HTLV-1 infection persists in association with certain human leukocyte antigen (HLA) types and may be more readily transmitted from mother to child when these HLA types are shared.

ATL is more common in men than in women and typically presents in the fourth or fifth decade of life. Perhaps as a function of the long latency period, cases of ATL following blood transfusion or needle sharing are vanishingly rare. The lifetime risk for ATL has been estimated to be in excess of 6% in men who are HTLV-1 carriers in an endemic region of Japan, although in other settings the risk may be much lower.⁶⁰ As with EBV, the subset of the infected population that develops lymphoma is quite small.

Adult T-Cell Leukemia/Lymphoma Diagnostic Considerations

There is a spectrum of ATL.⁶¹ In the acute leukemic subtype of ATL, comprising around 60% of cases, leukocytosis, diffuse lymphadenopathy, and hypercalcemia are common. The classic findings on a peripheral blood smear are lymphocytes with flower-shaped nuclei (Fig. 83.3C). Twenty percent of patients with ATL present with a lymphomatous subtype dominated by lymphadenopathy and hepatosplenomegaly. Cutaneous infiltration, lytic bone lesions, malignant effusions, and involvement of the CNS and other extranodal sites are not uncommon.⁵⁷ There are also chronic and smoldering subtypes that behave much more indolently and may in some cases not require treatment upon diagnosis. Across all subtypes, presentations reflecting immune dysfunction such as strongyloidiasis with dissemination, *Pneumocystis jiroveci* pneumonia (PJP), mycobacterium, or cryptococcal infection are common. The immune dysfunction seen in patients with ATL may be due to the fact that the leukemic cells have a regulatory T-cell phenotype that fosters an immunosuppressive environment.

Histologically ATL shows lymph node effacement by large, atypical T cells usually expressing CD4⁺, CD25⁺, and CD52⁺, with variable CD30 and CD15 expression. Aneuploidy is consistent, although characteristic cytogenetic abnormalities have not been identified. Serologic analysis confirms the presence of HTLV-1 infection.⁶¹

Therapies Specific to HTLV-1 ATL

The leukemic and lymphomatous forms of ATL are aggressive and are associated with poor responses to chemotherapy, high relapse

rates, and low overall survival. In a phase III randomized trial in Japan, researchers compared two multiagent chemotherapy regimens (vincristine, cyclophosphamide, doxorubicin [Adriamycin], and prednisone [VCAP], doxorubicin [Adriamycin], ranimustine, and prednisone [AMP], and vindesine, etoposide, carboplatin, and prednisone [VECP] [together, VCAP-AMP-VECP] to cyclophosphamide, hydroxydaunomycin (doxorubicin), Oncovin (vincristine), and prednisone [together, CHOP-14]) in patients with poor prognosis ATL.⁶² VCAP-AMP-VECP was associated with higher complete response rates, with a trend toward improved overall survival, although the toxicity of this regimen is significant, and the treatment as planned was not tolerated by the majority of patients. In a randomized, phase II study, patients with newly diagnosed aggressive ATL were treated with VCAP-AMP-VECP with or without the humanized anti-CC chemokine receptor 4 antibody mogamulizumab.⁶³ Although patients treated with the chemotherapy-antibody combination had higher complete response rates that were deemed to be clinically significant, infections, severe skin rashes, and other adverse events were also more common in the combination arm. Several antivirals used in the treatment of HIV infection have activity against HTLV-1. Among them are zidovudine and lamivudine. The combination of interferon (IFN) and zidovudine has yielded promising results, particularly in the leukemic subtype.⁶¹ Proteasome and histone deacetylase inhibitors have attracted interest. Given high CD25 and CD52 expression in ATL, the efficacy of monoclonal antibodies aimed against these two receptors has been investigated. Thus far, alemtuzumab, an anti-CD52 monoclonal antibody, may have some activity in ATL based on small phase II studies and case reports.^{64,65} Arsenic trioxide combined with IFN- α has been shown to induce remissions in relapsed, refractory patients with ATL, although durable responses were limited. In a trial of 20 patients with ATL, all-*trans* retinoic acid was used, with 40% achieving remission. Allogeneic hematopoietic transplant has been increasingly recognized as an effective therapy for ATL.^{66,67}

HIV-ASSOCIATED LYMPHOMAS

Viral Biology and Pathogenesis

HIV-1 is a retrovirus that infects CD4⁺ T cells and monocytes.⁶⁸ It appears to establish a lifelong reservoir in CD4⁺ T cells.⁶⁹ Viral infection may lead to cell death or establishment of latency in resting cells. HIV infection is spread either through new rounds of virion production with cellular infection or cell-cell fusion. There is no evidence to suggest that infected cells are driven to proliferate. This is in contrast to HTLV-1 and EBV, where proliferation of infected cells appears to play a key role in establishing the long-term viral reservoir and perhaps in mediating lymphomagenesis. The lymphomas that are increased in HIV-infected patients (Table 83.4) are of B-cell lineage, and many are associated with EBV, KSHV, or both (see Table 83.4).

There is no substantial evidence that HIV infection of B cells is important in the pathogenesis of these lymphomas. Rather, it appears that the HIV infection compromises cellular immunity, decreasing immune surveillance of EBV- and KSHV-infected B cells. In addition, HIV infection stimulates proliferation of B lymphocytes and perhaps genetic aberrations in the proliferating cells.⁷⁰ Many possible mechanisms have been invoked, including (1) direct stimulation of B cells by HIV antigens or antigens associated with opportunistic infection; (2) stimulation of B cells by cellular proteins (CD40 ligand) incorporated into the HIV virion, leading to expression of activation-induced deaminase, an enzyme that mediates double-stranded DNA breaks; and (3) dysregulation of B cells as a consequence of T-cell dysfunction.^{16,70,71}

There is also some evidence that host biology may contribute to lymphomagenesis. In particular, there are a variety of genetic polymorphisms that influence susceptibility to HIV-1 infection, such as CCR5- Δ 32.^{72,73} Individuals who are homozygous for this polymorphism are much less likely than others to be infected by HIV. Some evidence has emerged to suggest that, in heterozygotes who are

TABLE 83.4

HIV-Associated Lymphoma

Lymphoma	CD4 Association (cells/mm ³)	EBV Association (%)	Other Cofactors
PCNSL	<50	>95%	
DLBCL	Variable	40%	
BL	>100	30%	
HL	>100	90%	
PEL	<100	>75%	KSHV

BL, Burkitt lymphoma; DLBCL, diffuse large B-cell lymphoma; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; HL, Hodgkin lymphoma; KSHV, Kaposi sarcoma-associated herpesvirus; PCNSL, primary central nervous system lymphoma; PEL, primary effusion lymphoma.

HIV Hodgkin Lymphoma

A 42-year-old human immunodeficiency virus (HIV)-positive patient, on highly active antiretroviral therapy (HAART) with a CD4 count of 324 cells/mm³ and undetectable viral load, presents with fever, weight loss, and a palpable axillary lymph node. Hodgkin lymphoma (HL) is diagnosed on excisional biopsy, and Epstein-Barr virus (EBV) positivity is demonstrated by EBV-encoded RNA (EBER) in the Reed-Sternberg tumor cells. Although he lacks additional lymphadenopathy, a bone marrow biopsy is performed, and it shows involvement by HL. He has stage IVB disease. *Pneumocystis jiroveci* pneumonia prophylaxis is started despite an adequate CD4 count in anticipation of chemotherapy. His HAART regimen is reviewed for potential antiviral-chemotherapy drug interactions. He receives six cycles of full-dose, first-line chemotherapy and achieves a complete remission.

infected, HIV progression is slowed, and there is less likelihood of lymphomagenesis.

Epidemiology

Lymphoma is increased in all HIV risk groups, in contrast to Kaposi sarcoma, which is rarely seen in injection drug users (or in hemophiliacs in an earlier era).⁷⁴ There is a well-established relationship between CD4⁺ cells per cubic millimeter overall and the risk for lymphoma, but the relationship is complex and differs among lymphomas (see Table 83.4).

The incidence of non-Hodgkin lymphoma (NHL) in the HIV population, particularly PCNSL (Fig. 83.5A–C), has decreased with the widespread use of highly active antiretroviral therapy (HAART), although patients with HIV on HAART still carry an increased risk for lymphoma compared with the HIV-negative population.^{75,76} In the HAART era, patients with HIV on average have higher CD4⁺ counts (often >100 cells/mm³) when diagnosed with lymphoma as compared with the pre-HAART era. Among patients with HIV with very low CD4⁺ counts,⁷⁵ NHLs are still seen at rates similar to the pre-HAART era. Patients with HIV are now living much longer because of effective antiretroviral regimens and decreased rates of opportunistic infection. As a result, malignancy has emerged as the major cause of mortality in HIV populations with access to antiretroviral therapy.^{77,78}

With the widespread use of HAART, the incidence of HL in HIV-seropositive patients has not declined; patients with CD4⁺ counts between 150 and 199 cells/mm³ actually have higher risk for HIV-associated HL than patients with CD4⁺ counts of less than 50 cells/mm³.⁷⁹

Diagnostic Considerations Specific to Lymphoma in Patients With HIV

Lymphomas in patients with HIV infection are more likely to present with B symptoms such as fever and night sweats, as well as advanced

Fig. 83.5 EXAMPLES OF HUMAN IMMUNODEFICIENCY VIRUS (HIV)–RELATED LYMPHOMAS. Primary central nervous system (CNS) lymphoma in HIV-positive patients (A–C). Gross appearance (coronal section) of the brain from an autopsy of a 24-year-old HIV-positive female patient with temporoparietal mass due to a primary CNS lymphoma (A). The patient died as a result of uncus and cingulate herniation. (B) Biopsy section from another patient showing a perivascular infiltrate of large lymphoma cells. This is the typical pattern of involvement by CNS lymphoma. The cells were shown to be CD20⁺ B cells and were EBER positive (C). A diagnosis can be made without biopsy when magnetic resonance imaging studies show characteristic features and EBV is demonstrated in the cerebrospinal fluid by polymerase chain reaction (see box on AIDS Primary Central Nervous System Lymphoma). Hodgkin lymphoma extensively involving the bone marrow in an HIV-positive patient with stage IVB disease (D–G). The bone marrow biopsy was entirely replaced with Hodgkin lymphoma associated with dense sclerosis (D). An EBER study shows scattered positive cells throughout the marrow (E), corresponding to the Hodgkin and Reed-Sternberg cells (F), which were CD30⁺ as illustrated (G). Hodgkin lymphoma infrequently involves the bone marrow in HIV-negative cases, but some HIV-positive patients can first present with extensive bone marrow disease (see box on [HIV Hodgkin Lymphoma](#)). (A, courtesy Dr. Peter Pytel, University of Chicago.)

stage, including bone marrow, extranodal, and CNS involvement. Thus the approach to diagnosis is somewhat different from the approach in the HIV-negative patient.

Unexplained fever and sweats in an HIV-seropositive patient, even in the absence of lymphadenopathy, are sufficient to warrant consideration of HL. Patterns of disease involvement also differ in HIV-infected patients. Contiguous spread so characteristic of classic HL in other settings is less common in HIV HL, and bone marrow-only presentations of HL are not uncommon (Fig. 83.5D–G).

Patients with HIV-associated NHL have higher rates of extranodal involvement, including bone marrow and CNS disease, as well as higher-stage disease and more aggressive tumors on average.⁸⁰ Therefore, it is recommended that all HIV-seropositive patients with aggressive NHL undergo a diagnostic lumbar puncture. The routine use of CNS intrathecal chemotherapy prophylaxis in all HIV-seropositive patients with NHL is controversial but reasonable and typically is done in particularly high-risk patients, such as those with BL, marrow or testicular involvement, or extranodal disease.

Imaging is often more difficult to interpret in patients with HIV than in other settings. Lymphadenopathy associated with HIV infection or opportunistic infection is common, and the presumption that enlarged lymph nodes reflect the presence of lymphoma in patients with known lymphoma or a history of lymphoma is not as safe as in other settings. Positron emission tomography–computed tomography (PET-CT), although useful, must also be interpreted with caution insofar as HIV infection itself, opportunistic infection,

and immune reconstitution following the initiation of antiretroviral therapy are all associated with signal on metabolic imaging with fluorodeoxyglucose.

CD4⁺ counts can help to guide evaluation insofar as CD4⁺ counts of greater than 300 cells/mm³ are typically associated with BL or HL,⁸¹ whereas these diagnoses would be unlikely in patients with very low CD4⁺ counts of less than 50 cells/mm³ (see box on AIDS PCNSL).⁸²

AIDS PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

In AIDS PCNSL, EBV PCR of the cerebrospinal fluid is positive approximately 90% of the time and rarely positive in patients with AIDS but without PCNSL. When EBV is detected in the cerebrospinal fluid of a patient with AIDS, coupled with characteristic magnetic resonance imaging findings, this is sufficient to diagnose AIDS PCNSL without a confirmatory brain biopsy.

Treatment

Aggressive chemotherapy for HIV-associated lymphoma was initially associated with morbidity and mortality related to immunocompromise. A phase III randomized study identified a reduced-dose regimen as preferable to standard dose.⁸³ Lower doses were not associated with

higher lymphoma cure rates but were associated with less chemotherapy-related morbidity and mortality. However, with the evolution of supportive care, including PJP prophylaxis and neutrophil growth factors, tolerance of chemotherapy improved. With effective antiretroviral therapy, long-term outcomes improved as well.^{84,85} With full-dose therapies, some evidence emerged to suggest that stage-for-stage outcomes might be as good or better in patients with HIV-associated lymphoma compared with those without HIV.⁸⁶ At the outset of therapy, a series of questions related to the chemotherapy regimen, dose, concomitant HAART, and supportive care must be addressed.

Regimen

There is general agreement that the inclusion of rituximab with multiagent chemotherapy improves outcome, at least in patients with CD4⁺ counts of greater than 50 cells/mm³. Rituximab, cyclophosphamide, hydroxydaunomycin, vincristine, and prednisone (R-CHOP) and dose-adjusted, infusional etoposide, prednisone, vincristine, cyclophosphamide, and hydroxydaunomycin with rituximab (DA-EPOCH-R) have emerged as standard regimens.^{87,88} As in the treatment of DLBCL, in patients without HIV infection, the value of infusional chemotherapy remains controversial. A pooled retrospective analysis favored the infusional regimen.⁸⁹ However, insofar as the trials were conducted sequentially (R-CHOP between 1998 and 2002, and R-EPOCH between 2002 and 2006), it is difficult to exclude other factors, such as the availability of better antiretroviral agents, improvements in supportive care, or changes in the population studied.

BL typically requires more intensive treatment regimens than those used for DLBCL.⁹⁰ Thus there has been concern about using these regimens in the HIV-seropositive population. A small retrospective study of cyclophosphamide, vincristine (Oncovin), doxorubicin, and methotrexate (CODOX-M)/ifosfamide, etoposide, and cytarabine (IVAC) for BL that included 14 patients with HIV showed HIV-seropositive patients to have similar progression-free survival, overall survival, and complete response rates as compared with the HIV-negative patients with BL. In a multicenter retrospective study, HIV-positive patients with BL treated with rituximab plus CODOX-M/IVAC had better progression-free and overall survival with no increase in toxicity as compared with HIV-positive patients who received CODOX-M/IVAC without rituximab.⁹¹ In a prospective Spanish study, HIV-seropositive and HIV-seronegative patients with BL were treated with six cycles of intensive chemotherapy and rituximab and were found to have comparable outcomes, regardless of HIV status.⁹² In this study all HIV-seropositive patients were required to be on HAART to enroll, and the majority had CD4⁺ counts of greater than 200 cells/mm³. Granulocyte colony-stimulating factor support was used throughout chemotherapy cycles, as well as PJP and other antimicrobial prophylaxis. Differences in induction-related mortality, duration of neutropenia, progression-free survival, or overall survival were not detected, although HIV-seropositive patients did have significantly more severe mucositis and infectious complications.

Dose

Most would agree that dose reduction is appropriate in patients with low CD4⁺ count (<100 cells/mm³), history of ongoing opportunistic infection, performance status below 75%, or compromised organ function. Some regimens begin with a 50% dose reduction in cyclophosphamide for a CD4⁺ count of less than 100 cells/mm³ with a built-in dose escalation for the next cycle if well tolerated.^{84,88}

Chemotherapy regimens of varying intensity depending on CD4⁺ count, performance status, and International Prognostic Index score have been studied, including a comparison of low-dose CHOP with standard-dose CHOP, with no differences found in overall

survival based on the intensity of the chemotherapy regimen.⁸⁶ In patients with very low CD4⁺ counts, low-dose chemotherapy is a reasonable treatment option, while maintaining the possibility of long-term disease-free survival in some. In a recent uncontrolled prospective study where HIV-positive patients with BL were given a shortened course of EPOCH with a double dose of rituximab (SC-EPOCH-RR), freedom from progression and overall survival outcomes were favorable and comparable to those seen in HIV-negative patients treated with the standard DA-EPOCH-R, with less toxicity and lower cumulative doses of chemotherapy in the SC-EPOCH-RR group.⁹³

Antiretroviral Therapy

A few key special issues in considering concurrent antiretroviral and lymphoma therapy include concerns about shared toxicities, drug-drug interactions, and risk for inability to comply with consistent antiretroviral dosing. Zidovudine is myelosuppressive and can exacerbate pancytopenia associated with lymphoma therapy. If patients are already on a zidovudine-containing regimen, it is generally possible to substitute an alternative regimen before the initiation of lymphoma therapy. Many antiretroviral agents alter the metabolism of drugs used in lymphoma treatment. This has been a particular concern when infusional chemotherapy regimens are used, and some investigators have chosen to stop chemotherapy before initiation of such regimens.⁸⁴ However, in trials involving infusional chemotherapy that allowed patients already on a stable antiretroviral regimen to remain on that regimen during lymphoma treatment, major problems were not noted.⁸⁸ Nausea and vomiting associated with chemotherapy regimens may interfere with regular antiviral dosing. Intermittent antiretroviral therapy raises concerns about the development of a resistant strain of HIV. Because of the concern that initiation of antiretroviral therapy with cytotoxic chemotherapy might result in such resistance, many recommend delaying initiation of antiretroviral therapy until an appropriate regimen to control nausea and vomiting is established. Stopping antiretroviral therapy also carries with it some risks. When antiretroviral therapy includes drugs with different half-lives, stopping treatment may result in the longest-lived agent being present in the absence of other antiretroviral agents. This is particularly an issue for long-lived nonnucleoside reverse transcriptase inhibitors. Even a single dose of such agents in the absence of other antiretroviral agents may lead to resistance to that class of agents. Thus when an interruption of antiretroviral therapy is planned, specific strategies have been advocated, including a "staggered stop" or a change to a regimen with components that have similar half-lives.⁹⁴

For patients already on antiretroviral treatment at the time of lymphoma diagnosis, the particulars of the regimen should be considered during the pretreatment evaluation. Atazanavir and indinavir are associated with hyperbilirubinemia as a result of UGT1A1 inhibition.⁹⁴ This is an unconjugated hyperbilirubinemia similar to that occurring with Gilbert syndrome. Elevated total bilirubin in such patients is not indicative of hepatic involvement or other serious hepatic dysfunction and should not guide decisions about chemotherapy dose adjustments. Ritonavir inhibits the clearance of midazolam, phenytoin, and voriconazole and other agents metabolized by the cytochrome P-450 CYP3A4 pathway.

Supportive Care

Although PJP prophylaxis is recommended only when the CD4⁺ count is less than 200 cells/mm³ for patients with HIV not receiving cytotoxic chemotherapy, prophylaxis is universally recommended for patients with HIV receiving cytotoxic chemotherapy. The following are also commonly used: fungal prophylaxis with fluconazole; herpes simplex and varicella prophylaxis with acyclovir, valacyclovir, or famciclovir; quinolone prophylaxis when neutrophil counts fall below 1000 cells/mm³; and granulocyte growth factors.

Autologous Bone Marrow Transplant in an HIV-Seropositive Patient With Hodgkin Lymphoma

A 38-year-old human immunodeficiency virus (HIV)-positive patient with a CD4⁺ count of 485 cells/mm³ is diagnosed with classic Hodgkin lymphoma (HL) and treated with doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine (ABVD), achieving a complete remission. Two years later he presents with retroperitoneal lymphadenopathy and is found on biopsy to have relapsed HL. He is treated with salvage chemotherapy and has a complete response, as well as good performance status and no active infections. His HIV remains well controlled on antiretroviral therapy. He is deemed an excellent candidate for high-dose therapy and undergoes consolidation with autologous bone marrow transplant.

Bone Marrow Transplant in Patients With HIV

Autologous bone marrow transplant has been successful in HIV-seropositive patients with NHL, with these patients having adequate stem cell mobilization, nonrelapse mortality rates comparable to those for HIV-negative patients, count recovery within 2 weeks of stem cell rescue, and maintained control of HIV viral loads and CD4⁺ counts after high-dose chemotherapy.^{95,96} There have also been successful reduced-intensity allogeneic bone marrow transplants in HIV-seropositive patients, making the possibilities for treating HIV patients with NHL even more vast, even in those patients with chemotherapy-resistant disease (see box on [Autologous Bone Marrow Transplant in an HIV-Seropositive Hodgkin Lymphoma Patient](#)).^{97,98} Outcomes of patients with HIV undergoing allogeneic bone marrow transplant have improved in the post-HAART era.^{99,100} The first national trial of allogeneic bone marrow transplant for patients with HIV and hematologic malignancy is ongoing. The role of transplant in curing HIV is an area of active investigation, including cell engineering strategies to render cells resistant to HIV.

HEPATITIS C VIRUS

Viral Biology and B-Lymphocyte Proliferation

HCV is an enveloped, positive-stranded RNA virus.^{101,102} Infection involves interactions between E2, a viral structural protein with two hypervariable regions, and a cellular protein CD81 present on hepatocytes and B lymphocytes. A polyprotein is translated from viral RNA and is cleaved by cellular and viral proteases, including NS3, to yield proteins required for viral replication. The RNA-dependent RNA polymerase that replicates the viral genome lacks proofreading capacity, thus generating genetic heterogeneity among viral progeny. Viral replication occurs predominantly in hepatocytes, but viral RNA and NS3 have also been detected in B cells, although HCV replication in B cells remains controversial.¹⁰³

Chronic infection can be associated with mixed cryoglobulinemia, a systemic immune disease that results from clonal expansion of B cells producing an IgM autoantibody against IgG, leading to deposition of immune complexes on endothelial surfaces and resulting in inflammation.¹⁰⁴ In this setting of B-cell proliferation, some patients develop B-cell NHL, which is classically of low-grade histology. Several hypotheses have been advanced with regard to how HCV might drive B-cell proliferation. There is controversy as to whether infection of B cells plays any role in this process. A lymphoma cell line that produces infectious HCV has been reported. Even in the absence of infection of B cells, interaction of the HCV E2 protein with CD81 on B cells may drive B-cell proliferation or lower the threshold for other B-cell stimuli to drive proliferation. Immunoglobulin signaling may be activated by immunoglobulin-virus complexes, and Toll-like receptor 7 signaling may be activated by viral RNA. Finally, it is noted that E2 binding triggers expression of activation-induced deaminase, an enzyme that is important in generating somatic hypermutation and that has also been implicated

in mediating mutations thought to play a role in DLBCL lymphomagenesis.¹⁰²

Epidemiology of Viral Infection and Associated Lymphoma

The association between HCV and lymphoma was first recognized in patients with HCV-associated type II mixed cryoglobulinemia, an autoimmune extrahepatic manifestation of HCV infection, although it is now recognized that patients with HCV but without type II mixed cryoglobulinemia also show a predisposition to B-NHL.¹⁰⁵ In systematic reviews, approximately 13%–18% of B-cell lymphomas are associated with HCV infection.^{106,107} Most commonly, these lymphomas are histologically indolent subtypes, with splenic marginal zone lymphoma (MZL), nongastric MALT, and lymphoplasmacytic lymphoma more often seen in association with HCV than aggressive histologies such as DLBCL.^{108–111} In cases of HCV-associated DLBCL, histologic transformation should be considered because studies have demonstrated that DLBCL in this setting more frequently has evolved out of low-grade lymphoma as compared with HCV-negative patients with DLBCL.¹¹² For example, in Taiwan, the rate of chronic HCV infection in patients with NHL was 11%, 10-fold higher than in the general Taiwanese population.¹¹³ Among HCV-infected patients with lymphoma, nodal and splenic MZL, but not MALT lymphomas, were increased. The HCV-lymphoma association is more apparent in some countries than in others, with the association being established most clearly in Italy and Japan. Several studies in regions or countries where HCV infection is less prevalent have failed to identify any association with lymphoma.^{114–116} In the United States, data from the National Cancer Institute Surveillance, Epidemiology, and End Results registry and the Department of Veterans Affairs have demonstrated a small but significant increase in B-NHL risk with HCV infection.^{109,117}

Further evidence in support of an etiologic relationship comes from studies in which successful treatment of HCV was followed by lymphoma regression.¹¹⁸ The most dramatic illustration comes from patients with splenic lymphoma with villous lymphocytes treated with ribavirin and IFN. Furthermore, clearance of HCV infection has been shown to reduce the incidence of B-NHL, with cumulative incidence of lymphoma among patients with a sustained virologic response of 0% at 15 years, as compared with 2.6% at 15 years among both nonresponders and untreated patients.¹¹⁹ However, the mechanisms by which chronic HCV infection contributes to lymphomagenesis remain largely undefined, although hypotheses include an indirect role related to B-cell activation and proliferation in the setting of chronic antigenic stimulation.¹²⁰

Certain HCV genotypes may confer increased risk for NHL, with genotypes 2a/III and 2b/IV seen more frequently in the HCV-seropositive patients who develop NHL. However, there is no clear association between genotype and NHL risk, and varying responses to antiviral therapy by genotype further complicate these analyses.

Diagnostic and Prognostic Considerations

In contrast to EBV-, KSHV-, or HTLV-1-associated tumors, there is no established role for studies demonstrating HCV nucleic acid or protein in tumor cells. Thus serologic study and measurement of HCV copy number are the only tools available for inferring an association. We recommend checking HCV serologic characteristics in all patients with B-cell lymphomas most commonly associated with chronic HCV infection.¹¹⁸ In addition, screening patients with chronic HCV for a monoclonal gammopathy and cryoglobulinemia may be of benefit to identify patients at highest risk for malignant transformation. Elevated serum γ -globulin levels have been found to be a predictor of NHL among patients with type II mixed cryoglobulinemia.¹²¹ In patients who are HCV seropositive, HCV RNA is evaluated in plasma. There seems to be a predilection of HCV-associated lymphomas to involve extranodal sites, particularly the

liver and salivary glands, as well as the spleen.¹²² Unusual presentations of low-grade HCV-associated lymphomas have been described, including subcutaneous “lipoma-like” MALT lymphoma predominantly in elderly, HCV-positive women.¹²³ An HCV prognostic score, comprised of poor performance status, hypoalbuminemia, and high HCV-RNA viral load, effectively risk stratified patients into three groups with significantly different progression-free and overall survival outcomes.¹²⁴

Therapy

In patients with indolent lymphomas and untreated HCV infection, antiviral treatment with pegylated IFN- α and ribavirin may obviate the need for cytotoxic chemotherapy and should be considered as an initial therapeutic strategy. Tumor regression with antiviral therapy was first reported in 2002 and is now further supported by subsequent reports.¹¹⁸ In a recent cohort study from Italy, antiviral treatment resulting in virologic response was shown to be effective as first-line treatment for indolent HCV-associated lymphomas, with not only high overall response rates but also a survival advantage on multivariate analysis.¹²⁵ Since 2011, new antiviral agents have become available, notably protease inhibitors specific for the HCV protease. Likelihood of response to older therapy is a function of viral genotype, host genetics (*IL28R* polymorphisms play a critical role in response to protease inhibitors), and other factors. The field is rapidly evolving, and colleagues with specific expertise in appropriate antiviral approaches should be consulted.¹⁰¹ In general, treatment of the underlying HCV is favored in chronically infected patients who develop indolent lymphoma, given the potential for tumor regression with antiviral therapy, as well as the theoretical reduction in relapse that might accompany virologic responses.

Rituximab has posed an interesting dilemma for the treatment of patients with HCV and lymphoma. It has been reported that HCV plasma RNA increases following rituximab treatment, and there is certainly the possibility that elimination of B cells for 3–18 months following treatment may compromise humoral responses to the evolution of HCV quasiespecies. However, in studies to date, overall survival is not inferior.¹²⁶ Similarly, combination chemotherapy is safe in patients with HCV infection.¹²⁷ Rituximab does not seem to increase the risk of hepatotoxicity with anthracycline-based chemotherapy regimens.¹²⁴ Rituximab is specifically recommended for the treatment of HCV-associated cryoglobulinemia (although, as in the treatment of Waldenström macroglobulinemia, it must be appreciated that the initial response to rituximab may be an increase in the IgM paraprotein level, necessitating plasmapheresis). Unlike in cases of indolent lymphoma, where antiviral therapy alone may be sufficient, rituximab-containing multiagent chemotherapy regimens are recommended for HCV-associated DLBCL, and attempts to concomitantly treat with antivirals are generally not advised, given the added risks of cytopenias and hepatotoxicity.

Aspects of Therapy

With regard to the use of rituximab to treat B-cell lymphomas in patients with HCV, overall survival is not inferior, although there do appear to be increased rates of hepatotoxicity and rises in HCV viral load during therapy. Similarly, combination chemotherapy is safe in patients with HCV infection, although HCV RNA levels can rise during treatment. Interestingly, patients with HCV and splenic MZL have had regression of their tumors with treatment for HCV infection with IFN- α and ribavirin, an effect not seen in HCV-negative patients with splenic MZL treated with the same regimen.

FUTURE DIRECTIONS

In this chapter, a variety of virus-associated lymphomas and lymphoproliferative diseases have been reviewed. For most of these lympho-

mas, standard antiviral drugs do not have a role in treatment. There are several exceptions, however, and these are worth highlighting. Antiviral therapy for HCV-associated splenic lymphoma with villous lymphocytes is accepted as a standard approach and likely has a role in the treatment of other HCV-associated indolent lymphomas. Similarly, ganciclovir or valganciclovir appears to have a role in the management of MCD associated with KSHV in patients with HIV. Of course, in addition, there is an established role for antiretroviral therapy in the treatment of patients with HIV patients and malignancy. There are virus-targeted therapies that are broadly accepted as standard, including adoptive immunotherapy with EBV-specific T cells for PTLT. The use of targeted T cells also has promise in other settings, including EBV-associated HL. Other virus-targeted therapies are being developed. Some involve vaccination; others involve induction of viral genes in tumor cells, rendering them more susceptible to pharmacologic treatment. Finally, it may ultimately be possible to prevent some kinds of lymphoma by preventing viral infection or altering the host response to viral infection.

MALIGNANT LYMPHOMAS IN CHILDHOOD

Kara M. Kelly, Birgit Burkhardt, and Catherine M. Bollard

Malignant lymphomas are the third most common malignancy among children and adolescents.^{1–3} Among children <15 years of age, non-Hodgkin lymphoma (NHL) is more frequent; however, in patients up to 18 years of age, Hodgkin lymphoma (HL) is predominant. NHLs in children are usually extranodal, diffuse, high-grade tumors, whereas low- and intermediate-grade nodal lymphomas predominate in adults. These differences are speculated to reflect maturational changes in the function and composition of the immune system.² The different histologies explain in part the differing clinical features, disease course, and treatment strategies used in adults and children.

The differences in treatment approach and disease subtypes are less striking in adults and children with HL. However, there are significant challenges in the management of children with HL. These primarily comprise the sequelae of therapy, such as radiation-induced bone growth abnormalities, endocrine dysfunction, and chemotherapy-related sterility. Of greater concern are the radiation- and chemotherapy-related second malignancies and late cardiac deaths. Current trials are examining ways to reduce the toxicity of therapy without compromising the excellent outcome generally achieved.

NON-HODGKIN LYMPHOMA

Epidemiology

The incidence of NHL increases steadily throughout life, in contrast to Hodgkin disease, which has a bimodal age distribution peaking in early and late adulthood.² Although NHLs may occur at any age in childhood, they are infrequent among children younger than 3 years of age; the median age at presentation is approximately 10 years. NHL is two to three times more frequent in boys than in girls and is almost twice as common in whites as in African Americans. The reasons for these differences have yet to be determined.⁴

Specific populations at risk for the development of NHL include those with either congenital or acquired immunodeficiency conditions.⁵ Inherited immunodeficiency syndromes include Wiskott-Aldrich syndrome, X-linked lymphoproliferative syndrome (XLP), and ataxia telangiectasia (AT). The recognition of these syndromes in children with newly diagnosed NHL is important for appropriate therapeutic design. For example, involved field irradiation and radiomimetics should be avoided in children with AT. Additionally, children with AT are at increased risk for the development of cyclophosphamide-induced hemorrhagic cystitis; therefore, they should receive vigorous hydration and uroprotectants (e.g., mesna) when administering any dose of cyclophosphamide. XLP should be considered in any male with a high-grade B-cell lymphoma who either develops a late recurrence (second occurrence) of a high-grade B-cell lymphoma or has a brother with either a high-grade B-cell lymphoma or fatal infectious mononucleosis. Children with acquired immunodeficiency conditions predisposing them to the development of NHL include those who have received posttransplant immunosuppressive therapy and those with acquired immunodeficiency syndrome (AIDS).

There are differences in both the incidence and proportion of histologic subtypes in different parts of the world. For example, the NHLs are very rare in Japan but occur quite frequently in equatorial Africa. Burkitt lymphoma, which accounts for about one-half of all childhood cancers in equatorial Africa, is the predominant NHL

histologic subtype in both equatorial Africa and northeastern Brazil.⁶ There are also geographic differences in both the clinical and biologic features of certain NHL subtypes.^{7,8}

Classification

After Thomas Hodgkin described the disease bearing his name in 1832, various schemes emerged to classify the tumors now collectively referred to as the NHLs. Several classification schemes were developed on the basis of histopathologic features and the putative cell of origin. In an attempt to reduce the confusion of multiple classification schemes, the National Cancer Institute (NCI) sponsored a workshop to design a single classification scheme for clinical use. This scheme, published in 1982 and referred to as the NCI Working Formulation, was widely accepted for almost two decades. In the Working Formulation, the NHLs of childhood are predominantly diffuse high-grade tumors and can be divided among three major subgroups: lymphoblastic, small noncleaved cell, and large-cell lymphomas.

In the past decade, additional classification schemes were designed to improve upon the NCI Working Formulation. Because of the problems associated with attempts to classify lymphoid neoplasms into categories based on presumed normal cell counterparts, the International Lymphoma Study Group proposed a classification system for lymphoid neoplasms⁹ predicated on a practical approach to categorizing these diseases using available immunologic and molecular genetic techniques in addition to the standard morphologic criteria. This Revised European-American Classification of Lymphoid Neoplasms (REAL Classification) has been endorsed by many of the world's leading lymphoma pathologists and has served as the basis for the World Health Organization (WHO) classification of hematopoietic and lymphoid tumors.¹⁰ Both the REAL and WHO classification systems include related lymphoid leukemias and recognize that NHL and acute lymphoblastic leukemia (ALL) represent different stages of evolution within specific morphologically and immunologically defined disease categories, an observation recognized by clinicians caring for children with lymphoid neoplasms and reflected in current clinical practice, which prescribes similar therapies for lymphomas and leukemias of related phenotype.

In the REAL and WHO classification systems, NHLs are classified on the basis of phenotype (B lineage vs. T lineage vs. natural killer [NK] cell lineage) and differentiation (precursor vs. mature). Hence, NHLs that occur commonly in children appear in three major categories: lymphoblastic lymphoma (LBL; precursor B-cell lymphoma and precursor T-cell lymphoma), mature B-cell NHL (Burkitt and Burkitt-like lymphoma and diffuse, large B-cell lymphoma [DLBCL]), and anaplastic large-cell lymphoma (ALCL; mature T-cell or null-cell types). The current version of the WHO classification introduced pediatric follicular lymphoma, marginal zone lymphoma, and gray zone lymphoma. The clinical and biologic characteristics of NHL in children are summarized in Table 84.1 and illustrated in Fig. 84.1A–C.

Lymphoblastic Lymphoma

Whether LBL and ALL are two clinical presentations of the same disease or two different diseases is the subject of ongoing discussion.

Patients with a mass and less than 25% bone marrow (BM) lymphoblasts are designated as having LBL, whereas patients with at least 25% BM involvement have ALL. In contrast to ALL, more than 75% of patients with LBL demonstrate a precursor T-cell immunophenotype (T-LBL), with the remainder showing a precursor B-cell immunophenotype (pB-LBL).^{11–13}

TABLE 84.1 Characteristics of Non-Hodgkin Lymphoma in Children

Subtype	Proportion of Cases in BFM Studies (%) ¹¹	Phenotype	Primary Site
Lymphoblastic	26	T cell; B cell	Mediastinum or head and neck; lymph nodes, skin, soft tissue, bone
Burkitt	49	B cell	Abdomen or head and neck
DLBCL	13	B cell	Lymph nodes, mediastinum, abdomen, head and neck
ALCL	13	T cell indeterminate	Mediastinum, abdomen, head and neck, bone, soft tissue, or skin

ALCL, Anaplastic large-cell lymphoma; BFM, Berlin-Frankfurt-Münster; DLBCL, diffuse large B-cell lymphoma; Ig, immunoglobulin.

Epidemiology

LBL constitutes 22% to 28% of childhood NHL. There is a 2:1 male predominance for LBL, but the incidence of LBL remains constant across the pediatric age group for both boys and girls.¹⁴

Pathobiology

LBL arises from precursor T or B lymphoblasts at varying stages of differentiation. The morphology is similar to that of ALL, with lymphoblasts of small or medium size and with scant cytoplasm, round or convoluted nuclei, fine chromatin, and indistinct or small nucleoli. Immunophenotyping shows terminal deoxynucleotidyl transferase (TdT) positivity. T-LBL are usually positive for CD7 and surface or cytoplasmic CD3, with variable expression of CD2, CD5, CD1a, CD4, and CD8. Staining for TdT, CD3, myeloperoxidase, and a B-cell marker—like pax5 or CD79a—are recommended parts of a resource-saving diagnostic staining panel.¹⁵ CD10 expression is more frequent in T-LBL (40%) than in T-ALL (less than 10%), possibly related to maturational stage, with T-ALL more frequently demonstrating an immature phenotype.^{13,16,17} B-lineage markers are positive in pB-LBL. Unlike ALL, there are no known cytogenetic prognostic factors for LBL. Recurrent cytogenetic anomalies are seen in about half of childhood T-ALL but have not been well-defined in T-LBL. Literature is scarce regarding typical chromosomal aberrations for T-LBL. The commonest chromosomal translocations for both T-LBL and T-ALL involve the T-cell receptor (*TCR*) gene loci at chromosome 14q11 or 7q34, resulting in the juxtaposition of an oncogenic partner gene with the regulatory region of one of the *TCR* gene loci and subsequent deregulation of a reciprocal partner gene, such as *TAL1*, *MYC*, *HOXA* gene cluster, and *MYB*. Certain molecular genetic alterations were analyzed in relevant patient series of pediatric T-LBL, including NOTCH1, FBXW7 mutations, alterations of chromosome 9p containing *CDKN2A/CDKN2B* loci, and chromosome 6q.^{18,19} Prospective systematic validation is required to evaluate whether one of these markers or a combination of molecular

Fig. 84.1 HISTOLOGIC AND CLINICAL FEATURES OF THE NON-HODGKIN LYMPHOMAS OF CHILDHOOD. The *upper panels* demonstrate the appearance in hematoxylin and eosin–stained sections of (A) lymphoblastic lymphoma, (B) Burkitt lymphoma, and (C) anaplastic large cell lymphoma. The *insets* in (A) and (B) demonstrate the appearance of Wright's-stained specimens of the L3 blasts of Burkitt lymphoma and the L1 blasts of lymphoblastic lymphoma, respectively. The *lower panels* show common clinical presentations of the two histologic subtypes of lymphoma: (D) airway compression by lymphoblastic lymphoma of the anterior mediastinum on computed tomography of the chest and (E) encasement of the bowel lumen by Burkitt lymphoma visualized by abdominal computed tomography, and (F) tibial bone disease in primary lymphoma of the bone. (Reproduced, in part, with permission from Sandlund JT, Downing JR, Crist WM: *Non-Hodgkin's lymphoma in childhood*, N Engl J Med 334:1238, 1996.)

markers are of stable prognostic relevance and can be used to optimize current treatment stratification systems.

Clinical Manifestations

The clinical features at presentation vary with primary site and extent of disease spread. Almost all patients with T-LBL present with an anterior mediastinal mass that may cause respiratory symptoms, airway compromise, dysphagia, or superior vena cava syndrome (see Fig. 84.1D). Pleural effusions are common (75%), and lymphadenopathy above the diaphragm is frequent. Bone, skin, BM, central nervous system (CNS), abdominal organs, other lymph nodes, and occasionally testes may also be involved. Children with B-LBL are less likely to present with a mediastinal mass, but there is a higher frequency of cutaneous, soft tissue, or bone involvement with pB-LBL.^{20–23} CNS involvement at diagnosis is seen in 4% to 5% of patients with LBL.^{22,24}

Differential Diagnosis

LBL is distinguished from ALL by having less than 25% BM involvement and from myeloid malignancies being positive for TdT and T- or B-cell markers and negative for myeloperoxidase. T-LBL and pB-LBL are differentiated by flow cytometry. In cases of insufficient biopsy material or incomplete diagnostic staining, LBL cases are sometimes misdiagnosed (for example, as Ewing sarcoma or other small-, round-, blue-cell tumors).

Prognosis (Staging)

After obtaining malignant effusion or tissue diagnosis, staging is performed with imaging (ultrasound and magnetic resonance imaging or computed tomography [CT] of neck, chest, abdomen, and pelvis), bilateral BM evaluation, and lumbar puncture. Bone scans are done only if clinically indicated. Childhood NHL, including LBL, is most commonly staged using the Murphy classification (Table 84.2) and the analogue Revised International Pediatric Non-Hodgkin Lymphoma Staging System.^{25,25a}

With current therapies based on ALL protocols, LBL has a long-term survival greater than 90% in low-stage disease and greater than

80% in advanced-stage disease²⁶ (Table 84.3). The Children's Oncology Group (COG) demonstrated that minimal disseminated disease at diagnosis has prognostic value, as indicated by flow cytometric evidence of tumor cells in BM. In 99 children with T-LBL treated in the A5971 study, 2-year event-free survival (EFS) was 68.1% $\pm$ 11.1% for patients with $\geq 1\%$ T-LBL cells in BM by flow cytometry,

TABLE 84.2

Staging of Non-Hodgkin Lymphoma

Stage I

A single tumor (extranodal) or involvement of a single anatomic area (nodal), with the exclusion of the mediastinum and abdomen

Stage II

A single tumor (extranodal) with regional node involvement

Two or more nodal areas on the same side of the diaphragm

Two single (extranodal) tumors, with or without regional node involvement on the same side of the diaphragm

A primary gastrointestinal tract tumor (usually in the ileocecal area), with or without involvement of associated mesenteric nodes, that is completely resectable

Stage III

Two single tumors (extranodal) on opposite sides of the diaphragm

Two or more nodal areas above and below the diaphragm

Any primary intrathoracic tumor (mediastinal, pleural, or thymic)

Extensive primary intraabdominal disease

Any paraspinal or epidural tumor, whether or not other sites are involved

Stage IV

Any of the above findings with initial involvement of the central nervous system, bone marrow, or both

Based on the classification proposed by Murphy SB, Fairclough DL, Hutchison RE, Berard CW: Non-Hodgkin's lymphomas of childhood: an analysis of the histology, staging, and response to treatment of 338 cases at a single institution. *J Clin Oncol* 7:186, 1989.

as compared with $90.7\% \pm 4.4\%$ for patients with lower degree of marrow involvement.²⁷ Minimal disseminated disease at diagnosis was associated with an increased likelihood of BM or distant recurrence but not local recurrence. In NHL-BFM trials, adolescent girls with T-LBL had poorer outcomes than adolescent boys despite similar presenting characteristics. In 45 adolescents with T-LBL, the 5-year EFS was 57% for girls and 92% for boys ($p = .004$). This sex difference was not observed in children less than 15 years old in NHL-BFM trials.²⁸ One adult study of T-cell ALL has demonstrated poorer outcomes in females than in males,²⁹ but a prognostic impact of sex has not been found in other pediatric or adult studies of LBL. Whereas adolescent age itself has not been established as a poor prognostic factor as it has for ALL, adult outcomes of LBL are inferior to pediatric outcomes.³⁰

Therapy

Two potentially life-threatening situations requiring urgent intervention must be considered in children with LBL: (1) mediastinal tumor with airway obstruction or superior vena cava syndrome and (2) tumor lysis syndrome. Owing to the cardiac and respiratory risks of anesthesia or sedation in children with a large mediastinal mass, the least invasive procedure should be chosen to establish a tissue diagnosis. In children with relevant pleural effusion, pleural puncture and morphologic combined with immunologic diagnostics by flow cytometry allow adequate diagnosis. In children with peripheral lymphadenopathy, lymph node biopsy under local anesthesia may be possible. In children who cannot tolerate a procedure, pretreatment with steroids may be necessary to stabilize the patient. Because pretreatment may diminish the ability to accurately diagnose a patient, a tissue diagnosis should be obtained as soon as it is possible to do so safely. Tumor lysis syndrome is characterized by metabolic consequences of the breakdown of lymphoma cells causing renal failure if severe. Hyperuricemia, hyperkalemia, and hyperphosphatemia must be aggressively managed by hyperhydration, rasburicase, and/or allopurinol, as well as close monitoring. Children with NHL can also present with epidural masses and associated neurologic deficits caused by spinal cord compression. If the diagnosis is known, chemotherapy should be started as soon as possible. If the diagnosis is not known, or if there is a sluggish response to chemotherapy, low-dose radiation therapy may be considered in consultation with a radiation oncologist.

ALL treatment strategies achieved favorable outcome in LBL and are accepted as standard treatment as, for example, the Berlin-Frankfurt-Münster (BFM) combination chemotherapy with induction, consolidation, and maintenance phases lasting a total of 24 months with 90% 5-year EFS.²⁶ Even patients with stages III and IV LBL had good outcomes on ALL-type therapy.^{39,42} This ALL-like therapy has now become standard for LBL (Table 84.3). CNS prophylaxis is needed for LBL, but chemotherapy prophylaxis has not proven inferior to prophylactic cranial irradiation in CNS-negative patients, even those with advanced-stage disease.^{22,34,38} Additionally, the Pediatric Oncology Group did not demonstrate a survival advantage of high-dose methotrexate for T-LBL, although its utility in T-ALL is still being evaluated.³⁹

Burkitt Lymphoma

Burkitt lymphoma (BL) was first described in Uganda by Dennis Burkitt in the 1950s.⁴³ First thought to be endemic to equatorial Africa, it was subsequently observed in Europe and North America. The WHO classification recognizes three variants: (1) sporadic BL, occurring throughout the world and more common in children, adolescents, and young adults; (2) endemic BL, occurring primarily in sub-Saharan Africa and New Guinea, with some unique clinical features but morphologically identical to sporadic BL; and (3) immunodeficiency-associated BL, observed primarily in patients with HIV and less commonly in the setting of other immunodeficiencies. The WHO and REAL classifications also recognize the controversial entity of Burkitt-like lymphoma, with features intermediate between

BL and DLBCL (gray zone lymphoma). Burkitt-like lymphoma is rare in children, and the clinical value of this classification is unclear. When there is marrow involvement, it is designated Burkitt leukemia (French-American-British [FAB] classification L3 leukemia) but is treated similarly to BL.^{10,44}

Epidemiology

Sporadic BL constitutes approximately 50% of childhood NHL and is much commoner in boys than in girls (4:1 ratio), with a peak incidence between 5 and 14 years of age.^{11,14} Endemic BL associated with Epstein-Barr virus (EBV) in more than 85% of cases accounts for approximately half of all childhood cancers in equatorial Africa. In contrast, sporadic BL is most common in the United States and Europe and is associated with EBV in only 10% to 15% of cases.^{45,46}

Pathobiology

BL is composed of monomorphic, small, noncleaved cells with round nuclei, clumped chromatin, and basophilic cytoplasm. A high uniform proliferation index is seen, with the Ki-67 positivity approaching 100%. The classic “starry sky” appearance of BL seen under low-power microscopy is caused by tingible body macrophages scattered among malignant cells. BL cells show mature B-cell features and usually express surface immunoglobulins. B-cell markers such as CD19, CD20, and CD22 are usually present, and the majority express CD10 (common acute lymphoblastic leukemia antigen). BL is negative for TdT and BCL2. CD21, the EBV receptor, is more commonly seen in endemic BL than in sporadic BL.

Characteristic chromosomal translocations suggest that BL develops from genetic aberrations during somatic hypermutation or attempted immunoglobulin class switching in a B-cell precursor. These translocations, usually t(8;14) or infrequently t(8;22) or t(2;8), juxtapose the *c-myc* gene (involved in cellular proliferation) with immunoglobulin locus regulatory elements, resulting in *c-myc* overexpression. In sporadic cases, the predominant chromosome 8 breakpoints usually occur within the *c-myc* gene, whereas they are upstream of the gene in endemic cases. For the rare event of *c-myc*-negative BL, characteristic aberrations of chromosome 11q characterized by interstitial gains, including 11q23.2–11q23.3 and telomeric losses of 11q24.1-qter, were reported.⁴⁷ Other cytogenetic abnormalities, such as gain of 7q and deletion of 13q, are uncommon.^{48,49} Recently published large-scale next-generation sequencing studies unveiled sets of recurrently mutated genes in tumor cells of pediatric and adult patients with B-NHL and introduced functionally related inhibitor of DNA 3 (*ID3*), transcription factor 3 (*TCF3*), and cyclin D3 (*CCND3*) as potential drivers of BL lymphomagenesis.^{50–52}

Clinical Manifestations

BL is an extremely fast-growing malignancy. The most common primary sites of sporadic BL are the abdomen and the lymph nodes of the head and neck.^{53,54} Abdominal disease presentation, often associated with nausea, vomiting, and abdominal pain, carries a risk of intestinal perforation, obstruction, and gastrointestinal bleeding. Abdominal lymphoma often arises from the distal ileum, causing intestinal obstruction secondary to intussusception or compression by an expanding mass encasing the bowel (Fig. 84.1E). BL can involve testes, bone, skin, BM, and CNS. CNS involvement at diagnosis, occurring in about 9% of patients, is associated with a worse outcome.²⁴ Endemic BL frequently involves the abdomen, jaw, paraspinal region, orbit, and CNS.

Differential Diagnosis

In DLBCL, another mature B-cell lymphoma, the cells are usually larger, and additional cytogenetic abnormalities such as BCL-6 gene rearrangements or t(14;18) may be seen, although these abnormalities are more common in adult DLBCL. Ki-67 staining in less than 95% of the cells or positivity for BCL2 are helpful in excluding a diagnosis of BL. Burkitt-like lymphoma is a controversial diagnosis with some morphologic features more similar to DLBCL, including larger cells, but commonly with *c-myc* translocations and a clinical behavior

TABLE 84.4 French Society of Pediatric Oncology Risk Group Classification of Mature B-Cell Lymphomas

Group	Extent of Disease
Group A	Completely resected stage I Completely resected abdominal stage II

similar to that of classic BL.^{55,56} TdT negativity is helpful in distinguishing BL from B-LBL.

Prognosis (Staging)

The risk group classification developed by the French Society of Pediatric Oncology (SFOP) is widely used in current protocols incorporating risk-adapted therapy (Table 84.4). This system accounts for the adverse prognosis associated with CNS or BM involvement and whether localized disease has been resected. Patients with localized or CNS-negative advanced-stage BL have greater than 90% long-term survival with current therapies.⁵⁷ Combined CNS and BM involvement and suboptimal response to initial cytoreduction are also associated with worse prognosis, and poor responders are often stratified to more intensive chemotherapy in current regimens.⁵⁸ High lactate dehydrogenase (LDH) at diagnosis also carries a worse prognosis and is frequently incorporated in risk classification schemes, such as that of the BFM group (Table 84.5).⁵⁹ Age greater than 15 years has a worse outcome for mature B-cell malignancies, but this may be due primarily to DLBCL rather than to BL.

Therapy

Tumor lysis syndrome must be anticipated as a major risk in newly diagnosed BL. To help prevent this complication, children at risk should be vigorously hydrated (3–4 L/m²/day with D5 1/4 NaCl and 40 mEq/L NaHCO₃; there should be no added potassium) and started on allopurinol, a xanthine oxidase inhibitor. The urine pH should be maintained at about 7.0; at a more alkaline pH, phosphorus is less soluble, and at a more acidic pH, uric acid is less soluble. In some cases, mannitol followed by furosemide is required to maintain urine output. Uricolytic agents (e.g., uricozyme), which has been used for many years in Europe, directly cleaves the uric acid molecule and results in a precipitous drop in serum uric acid levels within a

few hours. The use of uricolytic agents (e.g., urate oxidase, uricase, rasburicase) has proven to be superior to allopurinol to reduce the level of serum uric acid rapidly and improve renal function. Rasburicase has significantly reduced the need for hemodialysis consequent upon tumor lysis syndrome. Recent protocols incorporate a prophylaxis of reduced intensity to decrease the risk of severe tumor lysis syndrome.⁶⁰ In the setting of abdominal BL, intestinal perforation, obstruction, or gastrointestinal bleeding may not occur until after the initiation of chemotherapy as the lymphoma begins to regress.

Localized, resected mature B-cell NHL (including both BL and DLBCL) could be cured without significant toxicity by two courses of chemotherapy.^{59,61–63} Advanced-stage BL requires aggressive combination chemotherapy with CNS prophylaxis (Table 84.6). Cyclophosphamide, methotrexate, and cytarabine at high doses have been used most recently, with or without anthracyclines and epipodophyllotoxins. Therapy should be started as quickly as possible upon presentation because this tumor grows very rapidly, and subsequent cycles should be administered in an intensive fashion as soon as recovery from the last cycle occurs. CNS prophylaxis is needed because without it approximately 30% to 50% of patients will relapse in the CNS,⁶⁴ whereas 6% to 11% develop CNS relapse if adequate prophylaxis is given.²⁴ CNS prophylaxis includes high-dose methotrexate and cytarabine to penetrate the CNS, together with intensive intrathecal chemotherapy. Risk-adapted therapy used in the FAB/LMB-96 study and the NHL-BFM95 study conferred an excellent EFS in advanced-stage patients.^{58–60} Treatment intensity was escalated on the basis of tumor burden and response to therapy. These are the best published outcomes to date, but these regimens have significant hematologic toxicity. Researchers in both the FAB/LMB-96 study and the NHL-BFM 95 study successfully reduced therapy for low- and intermediate-risk patients without a compromise in survival. However, both studies failed to safely reduce the intensity of therapy for patients with advanced stages of disease.

Rituximab is a mouse/human chimeric monoclonal antibody against CD20, highly expressed in BL and DLBCL. In adults, the addition of rituximab to cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) chemotherapy is beneficial for DLBCL and has been given safely in combination with intensive BL therapy. In children, single-agent rituximab showed activity for BL in a phase II window study for newly diagnosed patients,⁶⁵ and the COG showed the safety of adding rituximab to the LMB backbone for the treatment of BL.^{66,67} Current clinical trials address the question whether rituximab added to standard chemotherapy can improve the EFS of patients with advanced disease.

Local radiation therapy has no role in BL, because it is chemosensitive and often diffuse. CNS radiation has been used in the past for CNS involvement at diagnosis but did not show an impact on outcome in this group. Surgery is no longer routinely used for BL. However, patients with localized disease who undergo resection at diagnosis are eligible for reduced chemotherapy as noted above.

Diffuse Large B-Cell Lymphoma

DLBCL includes a heterogeneous group of neoplasms of transformed B cells, accounting for 10% to 13% of pediatric NHL.¹¹ DLBCL has some distinctive biologic and clinical features, described in more detail below.⁶⁸ DLBCL involving the mediastinum needs to be distinguished from primary mediastinal large B-cell lymphoma (PMBCL), which represents a distinct subtype of B-NHL in the WHO classification. In addition, the current version of the WHO classification introduced pediatric follicular lymphoma, marginal zone lymphoma, and gray zone lymphoma.

Epidemiology

The incidence of DLBCL increases with age, being commoner in the second decade of life.^{14,69} It is rare in children younger than 4 years of age. Although commoner in boys than girls in a 2:1 ratio, the sex difference is less than in BL. PMBCL is more common in adolescents, with no sex difference.^{68,70}

Pathobiology

Most pediatric DLBCL cases have a germinal center mature B-cell phenotype.⁶⁹ Nuclei are usually more than twice the size of normal lymphocytes. They express pan-B-cell antigens, including CD19, CD20, CD22, and CD79a, with or without surface immunoglobulin. Most express CD10 and BCL6, and approximately 40% express BCL2. However, breaks or translocations in *BCL2* and *BCL6* are rare in pediatric DLBCL. Unlike adult DLBCL, pediatric cases rarely demonstrate the t(14;18) translocation.^{68,69} Gene profiling has led to subclassification of adult cases into germinal center B-cell-like, activated B-cell-like, and type 3 (not belonging to the first two groups) phenotypes. The great majority of children have the germinal center B-cell-like phenotype.^{69,71} Interestingly, this phenotype has a better prognosis in adults, and childhood DLBCL outcomes are better than adult outcomes. Morphologic variants of DLBCL include centroblastic, immunoblastic, anaplastic, and T-cell/histiocyte-rich variants.⁷² Although DLBCL is clearly heterogeneous, the clinical value of these distinctions is unclear in children.

PMBCL is thought to originate from medullary thymic B cells. B-lineage antigens and CD30 are often positive, but surface immunoglobulin and human leukocyte antigen (HLA) classes I and II molecules are absent or incompletely expressed.⁶⁸ *MYC*, *BCL2*, and *BCL6* genes are not rearranged. PMBCL is associated with gains in chromosome 9p (involving *JAK2*) and 2p (involving *c-rel*). They commonly demonstrate inactivation of *SOCS1*.^{73,74} Variable degrees of sclerosis occur in PMBCL,⁷⁵ as well as occasional lymphocytes, eosinophils, and Reed-Sternberg-like cells, sometimes leading to confusion with HL.

Clinical Manifestations

DLBCL is often more localized than BL and is less likely to involve the BM or CNS.²⁴ Nodal disease is commoner in DLBCL than in BL, but extranodal disease is frequent. Common sites of involvement include the head and neck, abdomen, mediastinum, and bone. PMBCL is locally invasive and frequently associated with superior vena cava syndrome or airway compression. Pleural or pericardial effusions are present in approximately 40% of PMBCL cases,⁷⁵ and kidney metastases are frequent.⁶⁸

Differential Diagnosis

The differential diagnosis of DLBCL encompasses BL, B-LBL, and nodular lymphocyte predominant HL. BL is distinguished from DLBCL by morphology, although atypical BL shows more pleomorphism than typical BL. BCL2 negativity, high cell proliferation, and translocations involving *c-myc* may suggest BL but are not definitive. DLBCL, with its mature phenotype, differs from B-LBL by a lack of TdT expression. DLBCL and nodular lymphocyte predominant HL share some similar features and derive from a common B-cell clone. DLBCL may represent the clonal progression of nodular lymphocyte predominant HL. PMBCL can also be confused with HL, and an adequate biopsy is essential for diagnosis. PMBCL and other DLBCL are distinguished clinically because PMBCL typically reside within the thymic area, whereas mediastinal DLBCL usually involve mediastinal lymph nodes.

Prognosis (Staging)

The Murphy classification is used to stage DLBCL.⁷⁶ There is no difference in outcomes between BL and DLBCL based on histology,

and the treatment is identical in children.⁶⁸ Outcomes for pediatric DLBCL are superior to those for adults, with 5-year overall survival (OS) of 90% for current therapies. Adolescent girls fared worse than adolescent boys with DLBCL on NHL-BFM protocols.²⁸ BCL2 expression is not an unfavorable prognostic factor in children with DLBCL, in contrast to adults with DLBCL.⁶⁹ Prognosis is poorer for children and adolescents with PMBCL (5-year EFS of 65% to 75%).^{48,75} In the setting of PMBCL, LDH of 500 U/L or more has a worse prognosis.⁷⁵ For adult patients with PMBCL, favorable outcome was reported using a dose-adjusted EPOCH-rituximab regimen with continuous infusions of etoposide, doxorubicin, vincristine, and bolus administrations of cyclophosphamide and prednisone.⁷⁷ In a small pediatric series, similar excellent results were observed, but they require systematic prospective validation.⁷⁸

Therapy

In children, all mature B-cell lymphomas are usually treated similarly with good results. Despite biologic and clinical differences, BL therapy is effective in DLBCL (Table 84.6).⁶⁸ Risk-adapted therapy with LMB (SFOP) or B-NHL (BFM) backbones consists of short, dose-intensive courses of chemotherapy including steroids, vincristine, high-dose methotrexate, cyclophosphamide, doxorubicin, cytarabine, etoposide, and intrathecal chemotherapy.^{42,57,60,79} As described for BL, risk-adapted therapy based on FAB/LMB-96 and NHL-BFM 95 are also the current standard of care for childhood DLBCL.^{57,59,60} Rituximab can improve adult outcomes for DLBCL when added to CHOP or CHOP-like therapy, but the benefit has not been proven in children.^{80–82} Adult data suggest that rituximab may allow diminished use of agents with serious acute or late toxicities, warranting further study.⁸⁰ Having evolved from BL regimens, DLBCL treatment has traditionally included intrathecal chemotherapy for CNS prophylaxis. Because the risk of CNS involvement is lower for DLBCL than for BL, it is unclear if CNS-directed therapy should be as intensive.^{24,68} Local radiation has no role in frontline DLBCL therapy.⁶⁸ As mentioned above, the optimal treatment strategy for PMBCL has not been established yet, but might be influenced by the preliminary favorable results with DA-R-EPOCH.

Anaplastic Large Cell Lymphoma

Epidemiology

Most childhood NHLs previously classified as large-cell lymphomas fall into the category of ALCL in the REAL and WHO classifications. This entity was first described in 1985 as a clinicopathologic variant of large-cell lymphoma with a predilection for young patients.⁸³

Pathobiology

ALCL are characterized by the proliferation of large, pleomorphic cells with one or more prominent nucleoli (Fig. 84.2). The cells preferentially involve lymph node sinuses and extranodal sites (notably skin, bone, and soft tissue), where they grow in a cohesive pattern. The cells express epithelial membrane antigen and CD30 (Ki-1) antigen, a 120-kDa membrane-bound molecule that is a member of the tumor necrosis factor receptor superfamily, previously found in association with Hodgkin disease. A soluble (88-kDa) form of the CD30 molecule is found at high levels in the serum of nearly all patients with ALCL.⁸⁴ Marked elevation of soluble CD30 levels in patients with ALCL correlates with higher risk of relapse, and soluble CD30 levels correlate with clinical disease status, returning to normal with attainment of complete remission and increasing with disease recurrence.

The ALCL are associated with chromosomal rearrangements involving the long arm of chromosome 5 at position q35.⁸⁵ In most cases, this translocation includes material from chromosome 2p23 [t(2;5)(p23;q35)], resulting in the fusion of the nucleophosmin (*NPM*) nucleolar phosphoprotein gene on chromosome 5q35 to anaplastic lymphoma kinase (*ALK*), a tyrosine kinase gene

Fig. 84.2 HISTOLOGIC AND IMMUNOPHENOTYPIC FEATURES OF ANAPLASTIC LARGE-CELL LYMPHOMA. The section shows anaplastic cells including a “wreath cell” and a staining pattern with bright CD30 (Ki-1) positivity (*top right*) and anaplastic lymphoma kinase (ALK) positivity (*bottom right*). The nuclear and cytoplasmic staining by ALK would predict that the case has the t(2;5) translocation.

on chromosome 2p23. The hybrid protein produced from the translocation links the amino terminus of NPM with the catalytic domain of ALK.⁸⁶ Deregulated expression of the truncated ALK may contribute to malignant transformation. The chimeric NPM-ALK protein is clearly oncogenic, perhaps through triggering of antiapoptotic signals via phosphatidylinositol 3-kinase/Akt, although secondary molecular events may be required for lymphomagenesis.

Immunologic and molecular biologic studies reveal that most cases of Ki-1⁺ ALCL are derived from activated T cells, although non-T, non-B cell (null cell) cases, and more rarely B cell cases, occur.⁸⁷ On the basis of extended testing for T-cell antigens and examination of the configuration of T-cell receptor genes, many “null” cell cases are, in fact, T-lineage neoplasms, although a minority may be derived from NK cells.⁸⁸ The diagnosis of ALCL can be difficult, and many cases are initially misdiagnosed as Hodgkin disease. Molecular techniques (reverse-transcriptase polymerase chain reaction [RT-PCR]) to detect the fusion gene produced of the t(2;5) in many cases of ALCL confirms the diagnosis. Variant translocations where *ALK* is involved with other partner genes on other chromosomes limit the application of RT-PCR for diagnosis. However, the t(2;5) results in the expression of the NPM-ALK fusion protein, whereas the variant translocations result in upregulation of *ALK*. The ALK1 monoclonal antibody recognizing the formalin-resistant epitope of both the NPM-ALK chimeric protein and normal ALK thus serves as a useful diagnostic reagent for identifying cases of ALCL. It should be noted that the distribution of ALK staining varies, depending on the translocation. Further, ALK expression is a feature of inflammatory myofibroblastic tumors; however, confusion with ALCL can be minimized by testing for other hematopoietic markers, and the distinction is not usually difficult for experienced pathologists.

Clinical Manifestations

ALCL is rare, accounting for approximately 8% to 13% of childhood NHLs and roughly 30% to 40% of the pediatric large-cell lymphomas. Approximately one-third of the cases present with localized disease, whereas the majority have advanced disease at presentation, although BM and CNS involvement is uncommon.⁸⁹ A rare leukemic presentation of ALCL possibly associated with the small-cell variant of ALCL has been described. Systemic symptoms (fevers, weight loss) are frequently present in advanced-stage disease. Cutaneous (spontaneously regressing) lesions sometimes accompany disease at other sites, but skin involvement is not universal.⁸³ A variety of presenting sites—both nodal and extranodal—can occur, including the

TABLE 84.7 Outcomes for Anaplastic Large-Cell Lymphoma

Protocol	Number of Subjects	Stage	Regimen	EFS

COG ANHL0131 ⁹⁴	125	III or IV	APO versus APV	74% (3 yr) in APO group 79% (3 yr) in APV group

^aALCL and diffuse large B-cell lymphoma combined.

ALCL, Anaplastic large cell lymphoma; APO, doxorubicin, prednisone, vincristine, methotrexate, 6-mercaptopurine; APV, doxorubicin, prednisone, vinblastine, methotrexate, 6-mercaptopurine; BFM, Berlin-Frankfurt-Münster; CCG, Children's Cancer Group; CHOP, cyclophosphamide, doxorubicin, vincristine, prednisone; EFS, event-free survival; NHL, Non-Hodgkin lymphoma; POG, Pediatric Oncology Group.

mediastinum, gastrointestinal tract, and bone. Further, tumors may invade adjacent structures and be associated with ascites and other intraabdominal sites of disease, including kidney, liver, and lymph nodes. The outcome of children with ALCL in most series has been good (with survival ranging from 70% to 85%), albeit inferior to that of children with BL and DLBCL (Table 84.7).

Diagnosis and Differential Diagnosis

Immunophenotyping and immunohistochemistry are critical for the definitive diagnosis of ALCL. The typical ALCL immunophenotype is CD30⁺CD15⁺CD45⁺, in contrast to HL, which is typically CD30⁺CD15⁺. Over 60% of cases of ALCL express one or more T-cell antigens (CD3⁺, CD43, or CD45RO), and ALK protein is detected in most cases (over 60%).

Prognosis (Staging)

The disease stage of ALCL is determined according to the staging system described by Murphy (Table 84.2).²⁵ As for other types of childhood NHL, stages I and II are considered limited-stage disease, whereas stage III represents advanced-stage disease. Stage IV is reserved for children with BM or CNS involvement. For elderly patients with cutaneous CD30⁺ ALCL, the 5-year disease-free survival (DFS) appears to be determined by the extent of limb involvement; however, this has not been shown in children, possibly owing to the fact that primary cutaneous ALCL is rare in the pediatric population.⁹⁵

For systemic ALCL, studies have suggested that the stage of disease may be more important than the expression of the ALK protein. The European Intergroup for Childhood Non-Hodgkin Lymphoma defined three factors (mediastinal involvement, visceral involvement, and skin lesions) associated with poorer prognosis in childhood ALCL.⁹³ This group conducted a multivariate analysis (merging preexisting databases from BFM, SFOP, and United Kingdom Children's Cancer Study Group studies) and identified poor prognosis (one or more risk factors) and standard risk groups with 5-year PFS of 61% and 89%, respectively. However, it is important to note that this study was not done as a prospective collaborative study. In contrast, the Children's Cancer Group Study 5941 researchers reported that only BM involvement significantly changed the 5-year survival rate.⁹¹

The presence of ALK autoantibodies appears to be associated with decreased clinical risk factors and lower clinical stage, resulting in a lower cumulative incidence of relapses.⁹⁶ There is no correlation between outcome and the ALK translocation type. However, recently, the SFOP group showed that, for patients with ALK⁺ ALCL, the presence of a small-cell or lymphohistiocytic component is associated with a worse prognosis.⁹⁷

Therapy

The optimal treatment approach for patients with ALCL has yet to be determined, as evidenced by a wide range of successful treatment strategies. In the United States, children with advanced stage CD30⁺ ALCL are generally treated with non-ALCL large-cell lymphoma regimens, with long-term EFS rates ranging from 60% to 75%^{90–93} (Table 84.7). In a randomized trial performed by the POG, addition of intermediate-dose methotrexate and high-dose cytarabine did not improve upon the 70% 4-year EFS achieved with doxorubicin, prednisone, vincristine, methotrexate, and 6-mercaptopurine (APO) alone.⁹⁸ The BFM reported 3-year EFS of about 80% using a BL-based strategy.⁹² Regimens designed specifically for children with CD30⁺ ALCL have been developed by the SFOP and German study groups.⁹⁹ The SFOP also reported the successful salvage of patients with ALCL with the weekly administration of single-agent vinblastine.¹⁰⁰

The impact of incorporating vinblastine into two different front-line treatments for ALCL (the BFM B-cell approach [multinational European trial] and APO [COG trial in the United States]) was then studied in randomized fashion. In the European study, patients receiving the vinblastine plus chemotherapy regimen had a better EFS in the first year after therapy (91%) than those not receiving vinblastine (74%); however, at 2 years of follow-up, EFS was 73% for both groups.¹⁰¹ Similarly, the researchers in the COG ANHL0131 study evaluated whether a maintenance regimen including vinblastine compared with APO alone would result in superior EFS. Postinduction patients were randomized to receive APO with vincristine every 3 weeks or a regimen that substituted vincristine with weekly vinblastine (APV). In this study of 125 patients, no difference was observed between the patients randomized to the APO versus APV arms in either EFS (3-year EFS 74% vs. 79%; $p = .68$) or overall survival (OS 84% vs. 86%; $p = .87$).⁹⁴

In addition, the European study also showed that infusing methotrexate 1 g/m² over 24 hours was comparable to 3 g/m² over 3-hour infusions without intrathecal methotrexate.¹⁰² However, 3 g/m² of methotrexate had less toxicity. Other studies have come to no firm conclusions. For example, (1) the POG-9317 trial demonstrated no benefit of adding methotrexate and high-dose cytarabine to 52 weeks of their APO (doxorubicin, prednisone, and vincristine) regimen,⁹⁸ and (2) the CCG-5941 study, which evaluated a more intensive induction and consolidation with maintenance for a 1-year total duration of therapy again had similar outcomes, but with significant hematologic toxicity.⁹²

Targeted therapy options are important areas of investigation for future studies because crizotinib, an ALK inhibitor, has had outstanding results in pediatric phase I studies in children with ALCL, showing a nearly 100% response rate and minimal toxicity.¹⁰³

In addition, with the remarkable activity of brentuximab vedotin (tubulin inhibitor-conjugated monoclonal anti-CD30) in ALCL,¹⁰⁴ this has led the COG researchers to pursue testing the efficacy and toxicity of adding these two targeted biologic agents with standard ALCL-99 chemotherapy in pediatric patients newly diagnosed with ALCL (ANHL12P1).

Relapsed Non-Hodgkin Lymphoma Management

There is no standard treatment for relapsed NHL. Treatment usually consists of intensive chemotherapy to induce a complete or partial response, followed by autologous or allogeneic stem cell transplant. Recent studies suggest that allogeneic transplant may be more effective than autologous transplant for relapsed NHL, particularly for LBL.¹⁰⁵ Outcomes are significantly better for patients with complete remission prior to transplant. Radiation may be useful prior to transplant in selected patients with an incomplete response to chemotherapy.

Outcomes vary by histologic subtype. Relapsed BL and DLBCL are often chemoresistant, and survival is only 10% to 20%. The COG used rituximab, ifosfamide, carboplatin, and etoposide for salvage therapy in this population, achieving a 60% response rate (complete and partial).¹⁰⁶ Patients who achieve a complete remission should proceed to stem cell transplant. Relapsed LBL is also frequently chemoresistant, and reported survival is 10% to 40%.^{107–109} Salvage regimens used for ALL may be employed for LBL, and nelarabine has demonstrated a 40% response rate in this setting for T-ALL and T-LBL in a phase II COG study.¹¹⁰ Survival for relapsed ALCL is better than for other NHLs, reaching 40% to 60%.^{28,107,111} Vinblastine monotherapy as salvage therapy resulted in a complete remission rate of 83% in one study.¹¹² Brentuximab vedotin, an antibody against CD30, has been used successfully in adults with relapsed ALCL but has not been well-studied in children yet.¹¹³ Crizotinib, an ALK inhibitor, has also shown promise in adults in early clinical trials for patients with relapsed ALCL and has shown remarkable results in phase I studies in children.¹⁰³ Autologous transplant has been used successfully for some patients, but allogeneic transplant may have better outcomes and is preferred for patients with BM or CNS involvement, early relapse, and CD30⁺ ALCL.^{28,105,114}

Posttransplant Lymphoproliferative Disease

Posttransplant lymphoproliferative disease (PTLD) is discussed in other chapters in this book. Therefore, this section serves merely to summarize the issues specific for the pediatric population. The major pediatric populations where PTLD is seen most frequently are patients with congenital immune deficiencies or patients after BM or solid organ transplant (SOT). Further, stem cell transplant recipients with underlying immunodeficiencies such as Wiskott-Aldrich syndrome represent an independent risk group for EBV-associated lymphoproliferative disease (LPD).¹¹⁵ Patients with primary, congenital immunodeficiencies such as X-linked agammaglobulinemia and AT have an incidence of EBV-associated LPD ranging from 0.7% to 15%.¹¹⁶ The incidence of PTLD after SOT is higher in children than in the adult population. The disease is heterogeneous, but in children it is most frequently of B-cell origin and EBV-associated. In the United States, approximately 150 new cases are diagnosed in children each year.

Numerous therapeutic approaches to PTLD have been explored in children, but generally there has been a paucity of multicenter collaborative studies for this disease. Withdrawal or reduction of immunosuppression is often considered as firstline therapy for PTLD, but the choice depends on whether the patient has a recovering immune system sufficient to eradicate EBV-infected B cells and on stage and disease histology. For the pediatric hematopoietic stem cell transplant (HSCT) patient, strategies have included reduction in immune suppression, rituximab,¹¹⁷ donor lymphocyte infusions,¹¹⁸

and EBV-specific T-cell direct therapy.¹¹⁹ The advantage of T cell-based therapies over antibody therapy is that EBV-specific T-cell immune reconstitution is restored, thus reducing the risk for disease recurrence. Responses to donor-derived EBV-specific T-cell therapies developed at multiple centers for pediatric patients range from 70% to 85%.^{119,120} Immune-based therapies are generally preferred in this population because the use of chemotherapy in patients with LPD post-HSCT is associated with high mortality rates secondary to increased infectious complications.¹²¹ However, hydroxyurea- and immune-based therapies may be an option for patients with CNS disease.¹²² After SOT, modalities such as radiotherapy or surgical resection for localized LPD can result in complete remission. One study evaluated the efficacy of low-dose cyclophosphamide and prednisone for pediatric patients with PTLD after SOT. Efforts at reducing the immune suppression had failed in all patients, and all had received six cycles. The 2-year EFS and OS were 67% and 73%, respectively.¹²³ Subsequently, in a phase II study (COG-ANHL0221), the COG evaluated the addition of the CD20 monoclonal antibody to the previously reported regimen of low-dose cyclophosphamide and prednisone regimen (<http://clinicaltrials.gov/show/NCT00066469>). All patients had refractory PTLD after SOT or CD20⁺EBV⁺ PTLD in pediatric patients following SOT. The study showed that the addition of the CD20 monoclonal antibody to the previously reported regimen of low-dose cyclophosphamide and prednisone had EFS and OS of 71% and 83%, respectively.¹²⁴ Therefore, to build on the success of this first cooperative group trial for PTLD, the COG now propose to administer “off-the-shelf” third-party allogeneic latent membrane protein cytotoxic T lymphocytes (EBV/LMP-CTLs)¹²⁵ to determine its safety and efficacy in combination with rituximab in patients with PTLD post-SOT. This would represent the first multicenter study of its kind combining antibody therapy with off-the-shelf antigen-specific T-cell therapy for this disease. Finally, for patients refractory to these low-dose regimens or patients with definitive features of malignancy, standard lymphoma chemotherapeutic regimens are used, depending on histologic subtype (e.g., BL- vs. DLBCL- vs. HL-directed therapy).

HODGKIN LYMPHOMA

Epidemiology

HL comprises 10% of all lymphomas and approximately 10% of pediatric cancers² and has a bimodal incidence, with one peak at 15–34 years of age and a second peak in the sixth decade of life. In children, the highest peak is among 15–19-year-olds (29 per million per year) and is least frequent in children under 5 years of age. There is an age-dependent sex predominance, with a male predominance in children under 5 years old (male:female ratio of 5.3:1) and a slight female predominance in children aged 15–19 years (male:female ratio of 0.8:1). HL (especially the nodular sclerosing subtype) is classically associated with higher socioeconomic status, increased incidence in single-family homes, smaller family sizes, and a higher level of maternal education. In contrast, mixed cellularity HL is inversely related to socioeconomic status. It is commonly postulated that delayed exposure to some environmental antigen may trigger development of HL, and that higher rates of certain childhood infections (e.g., varicella, measles, mumps, rubella) are negatively associated with HL development.¹²⁶ HL has been shown to have a genetic predisposition, although this is incompletely understood. Siblings of patients with HL have a two- to ninefold increased risk of developing HL. There is also an increased risk among parent-child pairs, though not between spouses, supporting a genetic rather than a uniquely environmental predisposition. Environmental factors are nevertheless involved in HL. Approximately 40% of all HL cases in economically developed countries harbor EBV in the Hodgkin and Reed-Sternberg (HRS) cells. EBV positivity of the malignant HRS populations is more common in children under 10 years of age and is highly associated with childhood HL with mixed cellularity subtype (approximately 80% of cases), characteristically seen in developing countries.

The EBV protein LMP1 may be the key in the oncogenic process because it can elicit B-lymphocyte transformation *in vitro*.¹²⁷

There is also a relationship between the development of HL and cell-mediated immune deficiency, with an increased incidence in patients with HIV,¹²⁸ patients on chronic immunosuppressive therapy following SOT, and common variable immune deficiency. It remains unclear whether the underlying immune deficiency commonly seen in HL is primary, secondary, or both.¹²⁷

Pathobiology

HL is generally considered to be slow-growing with a tendency to spread to contiguous lymph nodes. Only in advanced stages is there evidence of blood vessel invasion and spread to more distant organs.¹²⁹ Over the past 30 years, significant advances have been made in the treatment of pediatric HL, such that over 85% of children are cured with chemotherapy and/or radiation even with stage III/IV disease.

HL is notable for the characteristic B cell–derived HRS cells found in a background of an inflammatory microenvironment usually comprising regulatory T cells, Th2 T cells, macrophages, and eosinophils. The REAL and WHO classification systems identify two main subtypes: classical HL and lymphocyte-predominant HL. Classical HL accounts for the majority of cases in adolescents and young adults and is characterized by HRS cells that are usually CD15⁺ and CD30⁺. HRS cells do not express B-cell markers such as CD19 and CD79A, although CD20 is expressed in approximately 5% to 10% of cases. Mixed cellularity HL accounts for approximately one-third of cases diagnosed in children younger than 10 years old. The histopathology shows frequent HRS cells on a background of normal reactive immune cells, including T lymphocytes, plasma cells, eosinophils, macrophages, and histiocytes. Lymphocyte-predominant HL and lymphocyte-rich classical HL may both have nodular appearances, but the former is more commonly CD15[−] and usually has strong CD20 and CD45 positivity, thus distinguishing it from classical HL.¹³⁰

Clinical Manifestations

The majority of pediatric patients with HL present with painless, firm, “rubbery” lymphadenopathy, most commonly in the cervical/supraclavicular regions. Over 70% of adolescents and young adults present with mediastinal disease, which can be asymptomatic. This presentation is less frequent in younger children, possibly related to a lower incidence of nodular sclerosis HL and a greater frequency of mixed cellularity or lymphocyte-predominant HL in this group. Approximately one-fourth of patients present with systemic “B” symptoms, including fevers, weight loss, and drenching night sweats. The majority of pediatric patients presenting with HL have stages I–III disease (involvement of lymph nodes and/or the spleen only) with a minority (approximately 15%) presenting with stage IV disease (noncontiguous extranodal involvement such as BM, lung, liver, and/or bone).

Staging

Pediatric HL is staged using the Ann Arbor staging system (with subsets A and B used for the absence or presence of B symptoms, respectively).¹³¹ Briefly, stage I involves a single lymph node region. Stage II involves two or more lymph node regions on the same side of the diaphragm. Stage III involves lymph node regions above and below the diaphragm. For stages I–III, if there is extension to an adjacent extralymphatic region/organ, then this is designated E (for example, stage IIE). For stage III, if there is splenic involvement, this is designated stage IIIS. Finally, for Stage IV disease, there is noncontiguous involvement of one or more extralymphatic organs or tissues with or without involvement of associated lymph nodes.

Treatment

Despite the excellent outcomes for children with HL, there is still no ideal therapeutic approach. Generally, combination chemotherapy with low-dose involved-field radiation is used with varying intensities and durations, usually depending on disease stage and prognostic factors such as disease bulk and B symptoms. However, studies of late effects in these patients¹³² have fueled cooperative groups in particular to explore regimens with decreased radiation and/or chemotherapy doses, especially for children with low-risk disease. Risk stratification for treatment assignment varies considerably between the pediatric HL research groups, thus limiting comparisons between trial results. The general consensus, however, is that chemotherapy should be given to all patients with HL, with or without radiation. The exception to this approach is patients with stage I, completely resected, nodular lymphocyte-predominant HL, who can achieve cure with surgery alone.¹³³

Chemotherapeutic agents used for the initial treatment of pediatric HL are similar to those used in adults and include alkylating agents, corticosteroids, vinca alkaloids, antimetabolites, doxorubicin, bleomycin, dacarbazine, and etoposide. However, doxorubicin (or Adriamycin) is associated with cardiac toxicity; bleomycin can lead to pulmonary fibrosis; and alkylators may impair fertility. Therefore, many cooperative group studies have developed hybrid regimens using lower cumulative doses of alkylators, doxorubicin, and bleomycin, especially for low-risk (stages I–IIA, no bulk, no B symptoms) and intermediate-risk (all stages I and II patients not classified as early stage; stage IIIA; and variably stage IVA) disease. Results of clinical trials conducted by the major international pediatric HL study groups are summarized in Table 84.8. Trials differ by the use of chemotherapy regimens of varying dose intensity, as well as the criteria for omission of radiotherapy. The German Society of Pediatric Oncology, and now in conjunction with other European pediatric oncology centers (Euronet Consortium), has investigated OEPA (vincristine, etoposide, prednisone, doxorubicin) for low risk groups and OEPA with COPDac (cyclophosphamide, vincristine, prednisone, dacarbazine) for intermediate- and high-risk groups.¹³⁴ In North America, the COG has primarily evaluated ABVE-PC (doxorubicin, bleomycin, vincristine, etoposide, prednisone, cyclophosphamide) and its derivatives across the risk groups.^{135–138}

Radiotherapy use varies considerably. In the only recent large randomized trial to evaluate omission of radiotherapy, the COG reported that radiotherapy may be safely omitted in intermediate-risk patients who have a rapid reduction in tumor dimensions by CT after two cycles of chemotherapy.^{142,143} The European consortium has omitted radiotherapy for low-risk patients achieving a complete response after two cycles of OEPA.¹³⁴ The utility of response by positron emission tomography (PET) has been evaluated in trials recently completed or in progress by all the major groups. In general, pediatric radiotherapy approaches use lower doses (15–25 Gy) and fields (involved field or node).

Therapies targeting CD30, a transmembrane glycoprotein that is present on Reed-Sternberg cells but is not expressed in most normal tissue, have been an area of significant interest as a means of improving efficacy and replacing agents with long-term toxicities. Brentuximab vedotin is an antibody drug conjugate composed of a monoclonal anti-CD30 antibody linked to the antimetabolic agent monomethyl auristatin E. In a phase II study evaluating brentuximab vedotin in relapsed HL, the overall response rate was 75%, with complete remission achieved in 34%.¹⁴⁴ Incorporation of brentuximab vedotin in frontline chemotherapy regimens is currently under investigation in a phase II trial of pediatric high-risk HL by the Stanford, St. Jude, Dana-Farber Cancer Institute consortium and a randomized phase III trial by the COG.

Management of Relapsed Hodgkin's Lymphoma

For patients who relapse, response depends on whether they had favorable disease at diagnosis and whether the relapse is confined to

TABLE 84.8 Treatment Outcomes for Pediatric Low-Risk Hodgkin Lymphoma

ABV, Doxorubicin, bleomycin, and vinblastine; AVPC, doxorubicin, vincristine, prednisone, and cyclophosphamide; CCG, Children's Cancer Group; COPP, cyclophosphamide, vincristine, procarbazine, and prednisone; CR, complete response; DBVE, doxorubicin, bleomycin, vincristine, and etoposide; DFS, disease-free survival; EFS, event-free survival; IF, involved field; OEPA, vincristine, etoposide, prednisone, and doxorubicin; OPPA, vincristine, procarbazine, prednisone, and doxorubicin; OS, overall survival; POG, Pediatric Oncology Group; PR, partial response; VAMP, vincristine, doxorubicin, methotrexate, and prednisone; VBVD, vinblastine, bleomycin, etoposide, and prednisone.

an area of initial involvement after chemotherapy and no radiation. Time to relapse and response to reinduction therapy are strong predictors of outcome.¹⁴⁵ These patients can generally be salvaged with chemotherapy and involved-field radiation therapy, and results are very acceptable even without HSCT. For all other patients, treatment of refractory, progressive, or relapsed disease includes induction chemotherapy with multiple chemotherapeutic agents not generally used in the initial therapy (e.g., gemcitabine, vinorelbine, carboplatin/cisplatin, ifosfamide, and more recently brentuximab vedotin, alone or currently being investigated in combination with gemcitabine or bendamustine), followed by high-dose chemotherapy and autologous stem cell rescue. Conditioning regimens are generally alkylator-based,¹⁴⁶ and the frequently reported regimens are CBV (cyclophosphamide, carmustine, and etoposide), BEAM (carmustine, etoposide, cytosine arabinoside, and melphalan), and BEAC (carmustine, etoposide, cytarabine, and cyclophosphamide).^{147–149} None of these conditioning regimens produce a superior outcome in pediatric patients, and CVB and BEAM remain the most widely used. The role of local radiation therapy either before or after HSCT is still unclear, although total body irradiation is now generally not used.^{150,151} Although an overall DFS of approximately 50% is consistently reported with this approach, the reported range is 20% to 60% because outcomes are related to prognostic factors such as disease burden and chemosensitivity.^{147,148,152,153}

The role of allogeneic HSCT has also been investigated for patients with relapsed/refractory HL, although never in a prospective, randomized manner.¹⁵⁴ The use of submyeloablative regimens (generally fludarabine-based) may reduce transplant-related mortality rates while still achieving a graft-versus-lymphoma effect in patients with

lymphoma receiving allografts, and it warrants further investigation in the pediatric population.^{155,156}

Among the more promising approaches to activating therapeutic antitumor immunity in HL is the blockade of the immune checkpoint, programmed cell death protein 1 (PD-1) pathway. Classical HL is characterized by HRS cells surrounded by an extensive but ineffective inflammatory cell infiltrate. Increased PD-1 expression by T lymphocytes in the microenvironment and increased PD-1 ligand expression by HRS cells allow evasion of T cell–mediated destruction of HRS cells. Blocking the interaction between PD-1 and its ligands through the administration of PD-1–blocking antibodies can result in T-cell activation and a more florid tissue inflammatory response.¹⁵⁷ Nivolumab is associated with a high objective response rate of 87% among heavily pretreated patients with HL.¹⁵⁸ Another anti-PD-1 drug, pembrolizumab, was associated with a 66% response rate in a similar cohort of patients. Researchers are now investigating these agents in conjunction with other targeted therapies, including brentuximab vedotin. Finally, investigational therapies such as targeted T-cell therapies are being explored for pediatric HL patients associated with EBV either as adjuvant therapy after transplant or for relapsed disease.^{159,160}

In summary, most children with HL are initially treated with risk-adapted chemotherapy alone or in combination with low-dose involved-field or involved-node radiotherapy involving carefully designed bystander fields to achieve local disease control while minimizing bystander organ toxicity. Especially for low-risk patients, some studies suggest that the overall survival for patients receiving chemotherapy alone may be similar to that for patients receiving chemotherapy plus radiotherapy, despite possible differences in EFS. This

is owing to the fact that it is usually possible to salvage relapse after initial therapy.¹⁶¹ If salvage therapy for such patients can be targeted and relatively nontoxic (e.g., by using novel agents such as brentuximab),¹⁶² then using a less intense initial regimen may be appropriate. Currently, however, salvage therapy for the majority of patients is typically more toxic and can lead to an unacceptable incidence of late events such as cardiac toxicities and secondary malignancies.¹⁶³ Therefore, strategies using a less intense frontline regimen should be investigated only within the context of a clinical trial. Researchers in future clinical studies therefore will attempt to address this important issue by evaluating the prognostic significance of achieving PET-negative disease after one or two cycles of chemotherapy and the use of frontline brentuximab to replace more toxic modalities such as bleomycin and radiation therapy.

RARE SUBTYPES OF LYMPHOMA

Other subtypes that are observed rarely in children deserve mention, but the rarity of these neoplasms in children make generalizations and therapeutic recommendations difficult. Follicular lymphomas (characterized by the arrangement of malignant cells in aggregates separated by normal cells), which account for approximately 30% of adult NHLs, are extremely rare in children. Children with follicular lymphomas tend to present with cervical lymph node involvement (although primary tumors of the testis have been reported¹⁶⁴) with early-stage disease and have an excellent prognosis.^{165,166} Unlike most cases of follicular lymphoma in adults, where aberrant expression of BCL2 [usually as a result of the t(14;18) translocation] is thought to play an important role in lymphomagenesis, the majority of cases of follicular lymphomas in children demonstrate neither the t(14;18) translocation nor BCL2 expression. BCL2 expression appears to occur more frequently in older children and is associated with advanced-stage disease at presentation and a more aggressive clinical course.¹⁶⁵

Marginal zone B-cell lymphomas arising in mucosa-associated lymphoid tissue can arise in extranodal sites. They tend to present with localized disease and infrequently disseminate. NK cell lymphoma and NK-like T-cell lymphomas usually involve the upper aerodigestive tract (midline lethal granuloma, angiocentric T-cell lymphoma), but they can present in the skin as well.^{167–169} They are rare in children, follow a very aggressive clinical course, and are often fatal, but they may respond to high-dose chemotherapy with stem cell transplant.¹⁶⁹ Peripheral T-cell lymphomas include a variety of neoplasms that have not yet been further specified. These lymphomas are rare in children but in advanced stage at presentation, often in association with systemic symptoms; hemophagocytic syndrome is common; and an aggressive course is the rule.

FUTURE DIRECTIONS

Although there have been dramatic improvements in the treatment of children with NHL and HL over the past 25 years, approximately 25% of children with these tumors still relapse or fail to respond to initial therapy. Additionally, late effects such as anthracycline-related cardiomyopathy, secondary malignancies such as epipodophyllotoxin-related acute myeloid leukemia, and endocrine abnormalities such as cyclophosphamide-related azoospermia remain a concern.^{163,170} Thus, a major task is to develop treatment strategies that provide a cure for the remaining 25% while reducing treatment-related morbidity. Several approaches appear promising.

The identification of both clinical and biologic features at the time of diagnosis that predict treatment failure will enable investigators to refine existing risk-adapted therapeutic approaches. Strategies to be considered for children at high risk for treatment failure include the intensification of existing regimens and the incorporation of new active or novel agents. More intensive therapy may require either autologous or allogeneic hematopoietic stem cell support. The administration of colony-stimulating factors may be necessary in

some cases, although its role in therapy remains controversial. Novel approaches include the incorporation of immunotherapeutic agents into multiagent chemotherapy regimens. For example, there is increasing experience with the anti-CD20 antibody rituximab in pediatric patients with B-cell lymphomas.⁶⁵ A radiolabeled form of this product (Yttrium-90; Zevalin) has also yielded promising preliminary results in children.¹⁷¹ CD30⁺ lymphomas such as ALCL, mediastinal B-large cell lymphoma, and HL are also candidates for CD30 antibody therapy. Novel immunotherapeutic approaches include the use of surface protein-specific cytotoxic T lymphocytes; this approach is effective in the prevention and treatment of EBV-related PTLD, NHL, and HL.^{119,125} Agents targeting specific molecular lesions (e.g., the ALK inhibitor for ALCL) are promising and are already in phase I studies in children, and the implementation of anti-idiotypic and antisense strategies are also being studied.

The continued investigation of molecular abnormalities and pathogenic mechanisms of malignant transformation associated with childhood lymphomas is essential. Microchip gene arrays have already identified clinically relevant subtypes of large B-cell lymphomas in adults.¹⁷² Gene array analyses of BL, ALCL, and T-lymphoblastic disease have also been reported.¹⁷³ Similar studies are ongoing for childhood lymphomas, and preliminary results for T-lymphoblastic leukemia/lymphoma have been published.¹⁷⁴ Flow-sorting tissue for HRS and intratumor T cells and optimizing low-input exome sequencing are beginning to overcome the limitations of genomic evaluation in HL.¹⁷⁵ Comprehensive molecular characterization of childhood lymphomas may help to further refine disease classification, provide a means of detecting minimal residual disease (MRD) during clinical remission, and enhance assessment of early response.¹⁷⁶ Monitoring is facilitated by the finding that the level of MRD in the peripheral blood is comparable to that in the BM in children presenting with advanced-stage lymphomas. Additionally, a more complete understanding of the molecular pathogenesis of pediatric HL and NHLs will provide clues to new and better treatments directed toward tumor-specific molecular lesions.

T-CELL LYMPHOMAS

Owen A. O'Connor, Govind Bhagat, Karthik A. Ganapathi, Jason Kaplan, Paolo Corradini, Joan Guitart, Steven T. Rosen, and Timothy M. Kuzel

The T-cell lymphomas are a heterogeneous group of diseases. They are generally divided into those that predominantly arise within the skin, and are thus referred to as the *cutaneous T-cell lymphomas* (CTCLs), and those that do not primarily arise in the skin, namely, the mature or peripheral T-cell lymphomas (PTCLs). Like the B-cell malignancies, each of these subcategories of T-cell lymphoma can be divided into indolent and aggressive diseases, each associated with its own characteristic biology and treatment principles. Although CTCL is considered a mature T-cell lymphoma, these diseases are for the most part indolent in nature. They are characterized by a variety of clinical entities, each with its own unique biology and presentation. The mature or peripheral T-cell lymphomas typically arise in lymph nodes, extranodal sites, or with a leukemic disease, and are for the most part very aggressive diseases. The separation of the T-cell lymphomas into cutaneous or noncutaneous is largely intended to highlight some of the general differences in behavior, although clearly there is overlap. Some forms of CTCL can involve nodal and extranodal sites, and some forms of PTCL can involve the skin. Given the marked differences in biology, clinical behavior, and treatment of these two categories of T-cell lymphoma, in this chapter we have organized them into different sections.

THE PERIPHERAL T-CELL LYMPHOMAS (NONCUTANEOUS)

The mature or peripheral T-cell lymphomas are a heterogeneous group of diseases. Most PTCL entities are highly aggressive diseases that respond poorly to conventional chemotherapy. Among the most common subtypes are PTCL, not otherwise specified (NOS), angioimmunoblastic T-cell lymphoma (AITL), and the anaplastic large-cell lymphomas (ALCLs). Although these diseases are considered to carry an unfavorable prognosis compared with their B-cell counterparts, select molecular entities, such as anaplastic lymphoma kinase (ALK)-positive ALCLs, are associated with a highly favorable prognosis, comparable to or better than diffuse large B-cell lymphoma (DLBCL).

It is estimated that there were approximately 66,360 cases of non-Hodgkin lymphoma (NHL) in the United States in 2011, of which the T-cell lymphomas account for approximately 5%–10% of all cases. The median age at diagnosis is 59 years, which is lower than the median age of 66 for patients with NHL in general. Like other forms of lymphoma, T-cell lymphomas are diseases of older adults, with approximately 40% of cases occurring between the ages of 55 and 74 years, and only about 5% of cases occurring after the age of 85 years. Between 2004 and 2008, Surveillance Epidemiology and End Results (SEER) reported the age-adjusted incidence rate of T-cell lymphoma as approximately 1.8 per 100,000 men and women. The incidence rates among all races in males and females are approximately 2.3 and 1.4 per 100,000 individuals, respectively, in contrast to 24 and 16.5 cases per 100,000 males and females, respectively, for NHL. The disease is almost twice as frequent in males as females. In general, PTCLs are far more common in Asia. For example, the International Peripheral T-Cell and Natural Killer/T-Cell Lymphoma Study noted that T-cell lymphomas accounted for only 5%–10% of all NHL cases in Western countries and about 10%–20% in Asian countries. Rudiger et al have reported that the frequency of PTCL in Vancouver

(Canada), for example, was roughly 1.6%, compared with the 18.3% frequency in Hong Kong.

Although rare in the West, subtypes of PTCL are not uncommon in the Eastern hemisphere and in Central and South America. Geographic and ethnic variability have been cited as reasons for the differences in the prevalence of some types of PTCL. Exposure to certain infectious or environmental agents is thought to account for some of the geographic variation, especially with regard to human T-lymphotropic virus-1 (HTLV-1) infection and occurrence of adult T-cell leukemia/lymphoma (ATLL), as well as Epstein-Barr virus (EBV) infection and the development of natural killer (NK)/T-cell lymphoma (NKTCL) in Asia, the Caribbean, and Central and South America. Globally the three most common subtypes of PTCL are PTCL-NOS (25.9%), AITL (18.5%), and ALCL (12%). PTCL-NOS is recognized as being slightly more common in North America, with a lower incidence in Europe and Asia, whereas AITL appears to be more common in Europe compared with Asia or North America. Enteropathy-associated T-cell lymphoma (EATL) is associated with celiac disease, which itself is associated with human leukocyte antigens DQ2 or DQ8, both being more common in European populations. Similarly, EBV-associated lymphomas are primarily seen in Japan, Korea, and northern China, as well as immigrant populations from South America in North America. These data suggest that there may be a variety of both genetic and environmental factors that may predispose to T-cell lymphomas, many of which are only now being identified in larger epidemiologic studies.

Classification

The classification of PTCLs has evolved substantially over the past several decades. Older classification schemes failed to incorporate all the necessary immunophenotypic, cytogenetic, morphologic, and clinical data to subclassify these diseases, as now presented in the context of the World Health Organization (WHO) classification system. The WHO classification published in 2008 recognizes more than 22 different subtypes of T-cell lymphoma distributed among four different subcategories. As shown in Table 85.1 and Fig. 85.1, these subcategories are divided into nodal, extranodal, cutaneous, and leukemic, each based on the predominant clinical behavior of that disease entity.

The nodal group consists of PTCL-NOS, which is the most common subtype of PTCL, accounting for roughly one-quarter of all PTCL cases. Other subtypes include ALCL and AITL. In ALCL there is a significant impact of specific cytogenetic features on prognosis. The ALK-positive forms of ALCL (Fig. 85.2), which are characterized by the nucleophosmin (NPM)-ALK translocation [t(2;5)] have a highly favorable prognosis, whereas those variants that are ALK negative carry a relatively poor prognosis. Other than the presence of the ALK translocation as determined by fluorescence in situ hybridization (FISH), there is no way to differentiate these diseases on strictly morphologic or immunophenotypic grounds. As such, the appropriate therapeutic recommendations for these two diseases obligatorily involve an understanding of this specific cytogenetic feature. Each of these ALCL variants accounts for about 5%–6% of all cases of PTCL. Similarly, it is often a significant diagnostic challenge to discriminate ALK-negative ALCL from PTCL-NOS.

TABLE 85.1**WHO Classification of the Mature T-Cell Lymphomas**

Leukemic	T-cell prolymphocytic leukemia T-cell large granular lymphocytic leukemia Aggressive NK-cell leukemia Indolent large granular NK-cell lymphoproliferative disorder (provisional) Adult T-cell leukemia (HTLV-1, ATL)
Extranodal	Extranodal NK/T-cell lymphoma, nasal type Enteropathy-associated T-cell lymphoma Monomorphic epitheliotropic intestinal T-cell lymphoma Hepatosplenic T-cell lymphoma Subcutaneous panniculitis-like T-cell lymphoma ($\alpha\beta$ -T-cell lineage only) Primary cutaneous $\gamma\delta$ T-cell lymphoma
Nodal	ALCL, systemic or cutaneous ALCL:ALK positive [t(2;5)] ALCL:ALK negative AITL PTCL-NOS
Cutaneous	Mycosis fungoides/Sézary syndrome Primary cutaneous CD30 ⁺ T-cell LPD LyP and primary cutaneous ALCL Primary cutaneous CD4 ⁺ small/medium T-cell lymphoma (provisional) Primary cutaneous CD8 ⁺ aggressive epidermotropic cytotoxic T-cell lymphoma (provisional)
Other	Systemic EBV-positive T-cell LPD of childhood Hydroa vacciniforme-like lymphoma

AITL, Angioimmunoblastic T-cell lymphoma; ALCL, anaplastic large-cell lymphoma; ALK, anaplastic lymphoma kinase; ATL, adult T-cell leukemia/lymphoma; EBV, Epstein-Barr virus; HTLV-1, human T-lymphotropic virus-1; LPD, lymphoproliferative disease; LyP, lymphomatoid papulosis; NK, natural killer; NOS, not otherwise specified; PTCL, peripheral T-cell lymphoma; WHO, World Health Organization.

AITL is the second most common subtype of PTCL, accounting for about 18%–19% of all cases of PTCL. It, uniquely, can also be associated with an EBV-infected clonal B-cell population.

The extranodal subtypes of PTCL are associated with their own unique clinical behavior. This subcategory can include very rare and aggressive diseases such as hepatosplenic T-cell lymphoma (HSTL). Normal T cells express either of the two dimeric forms of the T-cell receptor (TCR) protein on their surface, $\alpha\beta$ and $\gamma\delta$. Approximately 95% of all PTCLs possess TCR proteins with the $\alpha\beta$ heterodimer, whereas the $\gamma\delta$ T-cell lymphomas, like the majority of HSTLs and certain types of intestinal T-cell lymphomas and CTCLs, possess a TCR composed of the $\gamma\delta$ chains. HSTLs are thought to be derived from a primitive $\gamma\delta$ T-cell that has a penchant for infiltrating the liver and spleen. EATL accounts for 5%–10% of all PTCL cases. EATL is highly associated with celiac disease, which itself is far more prevalent in Europe. As a result, EATL accounts for only about 6% of all PTCL cases in North America, about 10% in Europe, and less than 2% in Asia, where celiac disease is very uncommon. Subcutaneous panniculitis-like T-cell lymphoma is another subtype of extranodal PTCL. It accounts for less than 1% of all cases of PTCL and is associated with a very aggressive course and resistance to chemotherapy. The immunophenotype of this lymphoma is CD3 and CD8 positive and CD4 negative. This rare form of lymphoma is often misdiagnosed, frequently being confused with the panniculitic-like lesions seen in lupus. It usually presents with subcutaneous nodules that may be indurated or necrotic, rendering the diagnosis challenging.

The leukemic subtypes of T-cell lymphoma largely consist of ATLL, which is commonly associated with the HTLV-1 retrovirus. The immunophenotype is typically CD3 and CD5 positive, CD7 negative, with positivity for CD4 and CD25 in the majority of cases. ATLL is associated with clonal integration of HTLV-1 in neoplastic

T cells in 100% of cases. Typically the interval between viral infection and onset of lymphoma is long, on the order of 10–40 years, with usually less than 5% of infected individuals actually developing ATLL. The disease is typically very aggressive, often involving the bone marrow and lymph nodes, although smoldering and chronic forms of ATLL do exist and are often managed differently.

Pathobiology

The PTCLs comprise many rare subsets of NHLs that arise from post-thymic T cells or NK cells, which can occur at nodal or extranodal sites. Over recent years there has been some progress in disease characterization and classification. Unlike B-NHLs, the pathogenesis of PTCL is poorly understood, and the cell of origin of many PTCL entities is unknown at present. Progress in understanding the etiology of PTCL and the associated pathogenetic molecular alterations is hampered by the rarity and heterogeneous nature of this disease.

Peripheral T-Cell Lymphoma, Not Otherwise Specified

PTCL-NOS is the most common subtype of PTCL, accounting for 20%–30% of all PTCLs occurring worldwide. It is a clinically heterogeneous entity that comprises cases lacking morphologic (Fig. 85.3) and phenotypic features of other PTCL subtypes, and is associated with poor survival. Early gene expression profiling studies were able to differentiate PTCL from T-lymphoblastic leukemia and distinguish certain entities based on different signaling pathways. More recent studies suggest a relationship with either activated helper CD4⁺ or cytotoxic CD8⁺ T cells, with lymphomas manifesting expression profiles similar to the latter being associated with inferior survival. PTCL-NOS lack specific cytogenetic abnormalities, although complex cytogenetic aberrations have been associated with a poor prognosis. Recurrent gains of chromosome 7q that target cyclin-dependent kinase 6 and 8q involving the *MYC* locus have been reported. A recurrent translocation t(5;9)(q33;32) resulting in the fusion of the IL-2-inducible T-cell kinase (*ITK*) gene with the spleen tyrosine kinase (*SYK*) gene has been identified in a subset of PTCL-NOS. Interestingly, transgenic mice expressing the *ITK-SYK* fusion transcript develop a T-cell lymphoma mimicking the human disease. Additionally, overexpression of total and phosphorylated Syk tyrosine kinase, even in the absence of *SYK* translocations, raises the possibility of Syk being a therapeutic target in this disease.

Translocations involving the interferon regulatory factor-4 (*IRF4*) gene have been identified in a small subset of PTCL-NOS. However, like Syk, *IRF4* overexpression in PTCL-NOS can be seen in the absence of *IRF4* rearrangement as a consequence of a CD30/nuclear factor kappa-B (NFκB) positive feedback mechanism, at least in certain cases, suggesting a role for CD30 and/or NFκB inhibitors in disease subsets.

Next-generation sequencing analyses have identified recurrent rearrangements of the *TP53* family member, *TP63*, with *TBL1XR1* or *ATXN1* genes in PTCL-NOS, resulting in the expression of an oncogenic mutant p63 protein, which is associated with adverse clinical outcomes. Recent gene expression profiling of a large cohort of PTCLs identified two subgroups of PTCL-NOS based on expression of *GATA3* (required for T-helper type 2 cell [Th2] development and function) and *TBX21* (required for T-helper type 1 cell [Th1] development and function). The *GATA3* subgroup, enriched in MYC, phosphatidylinositol 3-kinase (PI3K), and β -catenin gene signatures, was associated with an inferior outcome. The *TBX21* subgroup, enriched in interferon-gamma (IFN- γ)-induced and NF- κ B gene signatures, overall, had a more favorable clinical outcome, except for cases exhibiting a cytotoxic T-cell signature. Targeted mutation analysis has uncovered coexisting *TET2* and *DNMT3A* mutations in a significant proportion of PTCL-NOS, suggesting roles for the modification of the T-cell epigenome in disease pathogenesis and the use of demethylating agents as potential therapy. Recent whole-exome sequencing of PTCL

Fig. 85.1 WHO CLASSIFICATION OF THE MATURE T-CELL NEOPLASMS. *NK*, Natural killer; *NOS*, not otherwise specified; *TCL*, T-cell lymphoma.

Fig. 85.2 ANAPLASTIC LARGE-CELL LYMPHOMA. Anaplastic large-cell lymphoma has variable morphologic features but is typically composed of large, highly irregular “anaplastic” cells, which include giant cells sometimes with a wreath-like or horseshoe-shape nuclei, and “hallmark” cells, which are cells with a folded up nucleus with an embryo shape (A). The cells are typically brightly CD30⁺ (B). ALK1 staining with cytoplasmic and nuclear localization (C) is associated with the t(2;5)(p23;q35) translocation, whereas other patterns are associated with the variant translocations (C). Whether *ALK1*-negative cases should be considered as a separate group or classified together with peripheral T-cell lymphoma not otherwise specified is somewhat debatable (see text).

has revealed recurrent mutations in *RHOA* and *FYN* in a small subset of PTCL-NOS, but their prognostic import is currently unknown.

Angioimmunoblastic T-Cell Lymphoma

AITL is the second-most common PTCL subtype worldwide that has a characteristic clinical presentation, often manifesting features of

immune dysregulation, which is derived from T-follicular helper (T_{FH}) cells, based on phenotypic features and overexpression of genes characteristic of normal T_{FH} cells (Fig. 85.4). Early gene expression profiling studies could not reliably distinguish between AITL and subsets of PTCL-NOS. However, recent studies have shown a unique genetic signature for AITL, including four prognostically relevant subsets; those displaying a B-cell, monocytic, cytotoxic, or p53-induced target gene signature, with cases exhibiting the B-cell

signature associated with a more favorable outcome. Recurrent gains of chromosomes 3q, 5q, and 21 have been noted in AITL, although the genes affected by these abnormalities remain unknown. Mutations of genes involved in epigenetic processes have been observed in AITL more frequently than in the other PTCLs. Inactivating *TET2* mutations are observed in 33%–76% of AITL and 38% of PTCL-NOS, especially in cases expressing T_{FH} markers, suggesting a biologic relationship between AITL and a subset of PTCL-NOS exhibiting the T_{FH} phenotype. Similar to PTCL-NOS, *DNMT3A* mutations are also detected in AITL, with a significant fraction of cases (73%) also harboring *TET2* mutations, suggesting oncogenic cooperation and epigenetic deregulation in disease pathogenesis. Recent studies have shown *IDH2* mutations at the R172 residue to occur exclusively in AITL (20%–45% of cases), with the majority of cases also harboring *TET2* mutations. However, the prognostic implications of these alterations, if any, are unclear at present. Unlike other neoplasms, *IDH1* mutations have not been detected in this entity. More recent whole-exome and -genome sequencing analyses have revealed recurrent *RHOA* G17V mutations in 53%–68% of AITL, with concomitant *TET2* mutations being observed in 65%–100% of cases. The *RHOA* G17V mutation interferes with RHOA signaling, possibly by inhibiting wild-type RHOA function, which could alter cell motility,

proliferation, or cytokine signaling. A low frequency of recurrent mutations has also been observed in genes that impact important T-cell functions such as TCR signaling (*CD28*, *FYN*).

Anaplastic Large-Cell Lymphoma, ALK-Positive

ALCL, ALK+ represents one of the few subtypes of PTCL defined by recurrent chromosomal translocations. These involve the *ALK* gene located on chromosome 2p23, with the nucleophosmin gene (*NPM*), on 5q35, being the most common translocation partner (55%–85% of cases), resulting in t(2;5)(p23;q35); variant translocations involving *ALK* and other partner genes are detected in the remaining cases. The translocation t(2;5)(p23;q35) results in the fusion protein NPM-ALK, which leads to constitutive activation of the ALK tyrosine kinase and alterations in downstream signaling, metabolic, and prosurvival pathways, among others. These include the Janus kinase 3 (JAK3)/signal transducer and activator of transcription (STAT)3, phosphatidylinositol 3-kinase (PI3K)/protein kinase (AKT)/mammalian target of rapamycin (mTOR), and the phospholipase C- γ (PLC- γ)-mediated RAS-extracellular signal-regulated kinase (ERK) pathways. Activation of Notch1 signaling has also been reported. Overexpression of *MYC* is noted in a significant number of cases and secondary *MYC* translocations have been associated with aggressive behavior. The cell of origin of ALCL, ALK+ is unclear at present. It is speculated that different T-cell subsets could acquire a cytotoxic phenotype as a consequence of cellular reprogramming due to genetic or epigenetic aberrations, and some tumors show activation of a Th17 differentiation program and increased expression of NF- κ B target genes.

Variant translocations involving ALK and other partner genes can be suspected based on the pattern of immunohistochemical staining for ALK (cytoplasmic, membranous, or nucleolar instead of the nuclear and cytoplasmic). Pathologic consequences and molecular alterations in signaling pathways as a consequence of variant *ALK* translocations are not completely understood yet, but partial overlap with gene expression profiles of *NPM-ALK* has been described.

While differences in gene expression profiles between certain morphologic subtypes of ALCL, ALK+ have been reported, array CGH analysis of *NPM-ALK* and variant *ALK* translocations have revealed similar recurrent secondary genetic abnormalities including gains at 17p and losses at 4q and 11q.

Anaplastic Large-Cell Lymphoma, ALK-Negative (ALCL, ALK-)

ALCL, ALK- was considered a provisional entity in the WHO 2008 classification, but recent studies suggest it to be a unique subtype of

Fig. 85.3 PERIPHERAL T-CELL LYMPHOMA NOT OTHERWISE SPECIFIED. Peripheral T-cell lymphoma not otherwise specified is morphologically heterogeneous. Typically, cases have a spectrum of small-to-large lymphoma cells, frequently with irregular nuclear borders and sometimes with clear cytoplasm. Other cases can have a predominance of small or large cells. Features of the other defined types of T-cell lymphoma should be lacking.

Fig. 85.4 ANGIOIMMUNOBLASTIC T-CELL LYMPHOMA. A prominent feature of angioimmunoblastic T-cell lymphoma is the prominent vasculature in the background. The vessels usually show branching and prominent endothelial cells (A). The cellular composition is a mix of plasma cells, immunoblasts, and small lymphocytes; the lymphoma cells can be of intermediate or large size, and they tend to cluster and exhibit clear cytoplasm (A, B). Some cases can develop a superimposed Epstein-Barr virus-driven large B-cell lymphoma.

PTCL. While it shares morphologic and immunophenotypic features with ALCL, ALK+, including CD30 expression, it characteristically lacks *ALK* translocations, occurs in older individuals, and has a poorer prognosis. Additionally, a subset of PTCL-NOS can express CD30 and distinguishing ALCL, ALK- from these lesions can be challenging. Refined, supervised gene expression analysis could reliably differentiate ALCL, ALK- from PTCL-NOS and metaanalysis of the transcriptional profiles of a large series of PTCLs revealed a three-gene model, comprising *TNFRSF8*, *BATF3*, and *TMOD1*, that could accurately separate ALCL, ALK- from PTCL-NOS. Recently, an enrichment of *MYC*, *IRF4* targets, mTOR and PI3K pathway gene signatures were described in ALCL, ALK-, while hypoxia-inducible factor 1- α targets, interleukin (IL)-10-induced genes and H/K-ras-induced genes appear enriched in ALCL, ALK+.

Array comparative genomic hybridization (CGH) analysis of ALCL, ALK+ and ALCL, ALK- has highlighted differences in secondary genetic aberrations between the two subtypes, and differential expression of microRNAs. Genome-wide single-nucleotide polymorphism profiling has shown recurrent losses of 17p13.3-p12 (*TP53*) and 6q21 (*PRDM1*) at a significantly higher frequency in ALCL, ALK- compared with ALCL, ALK+. In addition to loss, *PRDM1* mutations were also detected in a subset of ALCL, ALK- cases, and loss of either *PRDM1* and/or *TP53* conferred a worse prognosis.

Next-generation sequencing analysis has identified a recurrent balanced translocation t(6;7)(p25.3;q32.3) in 10% of ALCL, ALK-, leading to juxtaposition of the *DUSP22* phosphatase gene (6p25.3) with the fragile site *FRA7H* (7q32.3) locus, resulting in the down-regulation of *DUSP22* and upregulation of *MIR29* microRNAs on 7q32.3. Mutually exclusive and recurrent rearrangements of *DUSP22* and *TP63* have been identified in 30% and 8% of ALCL, ALK-, respectively, and differences in morphology and phenotype have been reported for the different subsets. Cases with *DUSP22* rearrangements have a significantly better prognosis compared with those with *TP63* rearrangements. Recent whole-exome sequencing analysis of ALCL, ALK- identified recurrent and concurrent mutations in *JAK1* and *STAT3*. Interestingly, a subset of cases lacking mutations in either *JAK1* or *STAT3* harbored chimeric fusion proteins involving NF- κ B2 and tyrosine kinases *ROS1* and *TYK2*, which result in constitutive *STAT3* activation. Hence, activation of the *STAT3* pathway may represent a common and critical event in the pathogenesis of ALCL, ALK- and possibly a therapeutic target.

Enteropathy-Associated T-Cell Lymphoma

EATL is a rare subtype of PTCL, accounting for 5%–10% of PTCLs, that is derived from small intestinal intraepithelial lymphocytes. Although two types of EATL were recognized in the 2008 WHO

classification, EATL types I and II, recent studies have suggested distinct differences between these entities and proposed to designate EATL type II as “monomorphic epitheliotropic intestinal T-cell lymphoma” (MEITL). EATL type I, now simply referred to as EATL, occurs in individuals with celiac disease and is associated with the HLA DQ2 or DQ8 haplotypes. Homozygosity for HLA-DQ2 has been shown to increase the risk of developing EATL. Refractory celiac disease (RCD), especially RCD type II, is considered a precursor of at least a subset of EATL. Cytogenetic analysis of RCD II has shown recurrent gains of chromosome 1q22-q44, a feature shared with EATL, indicating early acquisition of chromosome 1q abnormalities in the pathogenesis of EATL.

Genomic analyses of EATL have revealed additional recurrent chromosome abnormalities. Gains or amplifications of chromosome 9q34 are the most frequent (40%–58%), but recurrent gains at 5q and 7q and losses of 8p, 9p, and 13q have also been reported. The pattern of aberrations suggests at least two subtypes of EATL. Segmental amplifications of the chromosome 9q31.3-qter region, encompassing known protooncogenes (e.g. *NOTCH1*, *ABL1*, *VAV*), or, alternatively, deletions at 16q12.1 have been reported in greater than 80% of EATLs, while a small subset exhibit allelic imbalances at 3q27.

MEITL has a wider geographic distribution than EATL and it appears to be more common in Asians and Hispanics. Serologic evidence of celiac disease is lacking in the vast majority of cases and the morphology is distinct from EATL. Recent studies from Asia have reported 23%–78% of MEITLs to manifest the TCR $\gamma\delta$ phenotype, and a lack of TCR expression has been described in up to a third of cases. On comparing genomic profiles of EATL and MEITL, mutually exclusive segmental amplifications of 9q31.3-qter and deletions of 16q12.1 have been detected in both disease types, with gains of 1q and 5q occurring more frequently in EATL and gains of the *MYC* locus (8q24) more often observed in MEITL. These data suggest the possibility of common as well as distinct genetic alterations associated with the pathogenesis of the two subtypes of intestinal T-cell lymphomas.

Hepatosplenic T-Cell Lymphoma

HSTL is a rare subtype of PTCL that has been associated with underlying immune dysfunction (Fig. 85.5). It is most commonly of $\gamma\delta$ T-cell lineage; however, lymphomas bearing the $\alpha\beta$ TCR have been described, as have occasional cases lacking surface TCR. Isochromosome 7q [i(7)(q10)] is reported to be a frequent recurrent chromosomal aberration, but specific abnormalities of particular genes have not been defined. Of interest, i(7)(q10) has been detected in hepatosplenic T-cell lymphoma irrespective of the phenotype ($\gamma\delta$

Fig. 85.5 HEPATOSPLENIC T-CELL LYMPHOMA. Hepatosplenic $\gamma\delta$ T-cell lymphoma is commonly diagnosed from a bone marrow biopsy specimen in a patient being evaluated for hepatosplenomegaly. The bone marrow typically shows a subtle lymphoid infiltrate (A), which becomes more evident with a T-cell stain such as CD3 (B). This highlights the classic sinusoidal distribution of the lymphoma. Lymphoma cells may be seen in the circulation or in the marrow aspirate and can resemble monocytes or blasts (C). The lymphoma is typically associated with isochromosome 7q, as illustrated in the partial karyotype (D).

or $\alpha\beta$). Moreover, an increase in the number of 7q signals, often accompanied by trisomy 8, has been associated with disease progression. The gene expression profile of HSTL appears distinct from other types of PTCL and is characterized by overexpression of NK cell-associated molecules such as killer cell immunoglobulin (Ig)-like receptor (KIR) genes and killer lectin-like receptors. Mutually exclusive *STAT5B* and *STAT3* mutations have been reported in a subset of HSTL cases.

Extranodal Natural Killer/T-Cell Lymphoma

Extranodal NK/T-cell lymphoma (ENKTCL) is an aggressive PTCL associated with clonal episomal EBV infection of NK or T cells. It is less common in the western hemisphere but it has a significantly higher incidence in Asia, excluding Japan. It occurs most commonly in the nasopharynx (nasal type) and less frequently at other anatomic sites (extranasal). Cooperating genetic and environmental factors are likely to play roles in disease pathogenesis. Gene expression profiling of ENKTCL has revealed overexpression of cytotoxic proteins (granzyme H) and PDGFRA. Early studies showed recurrent deletions of chromosome 6q21–25 in ENKTCL and array CGH analysis detected recurrent gains of 2q, and losses of 6q16.1–q27 and 11q22.3–q23.3, with loss of potential tumor suppressor genes *PRDM1*, *ATG5*, and *AIM1* located on 6q12–25. Oligonucleotide array CGH and functional studies have identified *FOXO3* in addition to *PRDM1* (*BLIMP1*) as candidate tumor suppressor genes located at 6q21. Analysis of a small cohort of ENKTCL cases described recurrent loss of 8p11.23 in 46% cases, which was associated with an adverse prognosis. Genetic analysis of this locus showed recurrent mutations in *ADAM3A*, a metalloproteinase family member. Recent studies have shown *JAK3* and *STAT3* mutations resulting in the constitutive activation of these transcription factors as well as loss of *PTPRK* on 6q22, which can also lead to *STAT3* activation. These findings suggest a role for JAK-STAT signaling in the pathogenesis of ENKTCL. Similar to other types of PTCLs, mutations in epigenetic modifier genes are also frequent in this disease.

Human T-Lymphotropic Virus-1–Associated Adult T-Cell Leukemia/Lymphoma

HTLV-1 is a retrovirus endemic in Japan, central Africa, Iran and the Caribbean basin. HTLV-1 infection is transmitted via infected T cells present in body fluids, especially breast milk and semen, and blood of carriers of the HTLV-1 provirus. HTLV-1 infection leads to the clonal expansion and immortalization of CD4⁺ T cells. Disease pathogenesis involves viral and host factors. A variety of viral proteins cooperate in cellular transformation, including Tax and HBZ, which modulate multiple signal transduction pathways (CREB/ATF, NF- κ B, JAK-STAT, mTOR-AKT). This leads to deregulated cytokine production and impairment of host immunity, which allows survival of HTLV-1–infected lymphocytes. Clinicopathologic subsets of ATLL include leukemic, lymphomatous, smoldering, and chronic. Array CGH studies have identified differences in chromosome alterations between acute and lymphomatous subtypes, and have suggested distinct oncogenic pathways in disease pathogenesis. Single-nucleotide polymorphism array and genomic PCR analysis have revealed rearrangements at 10p11.2 involving the *EPC1* gene locus and *ASXL2* as a partner fusion gene. Gene expression profiling has uncovered dysregulation of *MYC*, *REL-1*, and *NOTCH-1* genes, all known to be upregulated by the Tax protein. Cases exhibiting C-REL and IRF4 overexpression have been associated with resistance to antiviral agents. Somatic gain-of-function *CCR4* mutations have been reported in 26% of ATLL, leading to enhanced activation of the PI3K/AKT pathway. Hyperactivity of PI3K secondary to inhibition of protein phosphatases is known to play an important role in ATLL pathogenesis and has been linked to the formation of the characteristic multilobated “flower-like” nuclei in tumor cells. Recent comprehensive genomic analysis of a large series of ATLL samples identified mutations or alterations in T-cell

receptor signaling and NF- κ B pathway genes, as well as defects in immunosurveillance mechanisms.

Clinical Manifestations

PTCLs, with the exclusion of CTCL, recapitulate the general presentation of aggressive NHL, which can vary depending on histologic features, patient age, and immune status. PTCL generally presents with lymphadenopathy, and patients can range from being asymptomatic to presenting in extremis with diverse symptoms and significant end-organ compromise. PTCL can present as discrete nodal, extranodal, leukemic, or cutaneous disease, or with any combination of these involved sites. An extranodal presentation is common in PTCL and often contributes to a delay in the diagnosis. When compared with aggressive B-cell lymphomas, patients with PTCL tend to present with more advanced disease, a poorer performance status, and frequently B symptoms. Patients may have constitutional manifestations because of the production of inflammatory cytokines and chemokines produced by the lymphoma cells and host tissues. Paraneoplastic syndromes, including eosinophilia, hemophagocytic syndrome, and autoimmune phenomena, have been well described in different PTCL subtypes. For example, AITL is often characterized by systemic symptoms, skin rash, organomegaly, hypergammaglobulinemia, and hemolytic anemia. It affects older adults, and patients frequently present with peripheral lymphadenopathy, hepatosplenomegaly, skin rash, and constitutional symptoms. In contrast, hepatosplenic T-cell lymphoma, which often occurs in young adults, is characterized by marked hepatosplenomegaly and bone marrow involvement.

Laboratory Manifestations

Laboratory tests should include a complete blood count, serum chemistry determination (including lactate dehydrogenase [LDH]), titers, and viral studies, including HTLV-1 status and EBV in appropriate cases. The level of β_2 -microglobulin is usually normal compared with that found with the B-cell lymphomas. Peripheral blood flow cytometry and bone marrow biopsy can be helpful in understanding the extent of disease.

Differential Diagnosis

Accuracy in the diagnosis of PTCLs more often than not requires the consensus of hematopathologists with a specific expertise in this field. Diagnosis is based on examination of peripheral blood or tissue biopsy specimens for histologic features supplemented by detailed immunohistochemistry, flow cytometry, cytogenetics, and molecular genetics. Expert hematopathologic review is essential for the correct classification of the different subtypes, given the often poor concordance among hematopathologists in matching the diagnosis. Detailed clinical information is essential for the hematopathologist to make the correct diagnosis. For example, in patients from Japan, information regarding HTLV-1 status is essential to aiding the pathologist in distinguishing between lymph node involvement due to PTCL-NOS and ATLL. Because this disease also occurs in the West, HTLV-1 status should be evaluated in patients at high risk for the disease or from endemic areas. Other diagnoses such as AITL and EATL are often clarified by the clinical information. For cases in which it is difficult to distinguish between different entities, gene expression profiling may become helpful in the future for confirming the correct diagnosis.

Prognostic Factors

The majority of PTCLs are associated with a very poor prognosis compared with their B-cell counterparts (Fig. 85.6). Treatment

Fig. 85.6 (A) Overall survival of patients with the common subtypes of peripheral T-cell lymphoma (PTCL). (B) Overall survival of patients with less common subtypes of PTCL. (C) Overall survival of patients with natural killer/T-cell lymphoma. (Data from Vose J, Armitage J, Weisenburger D: *International peripheral T-cell and natural killer/T-cell lymphoma study: Pathology findings and clinical outcomes*. J Clin Oncol 26:4124, 2008.)

outcomes for PTCL patients are substantially inferior to those for their B-cell lymphoma counterparts. Lymphomas derived from the T-cell lineage have been shown to be an independent negative prognostic factor. The adverse prognosis of patients with relapsed or refractory PTCL has been highlighted in a recent experience from the British Columbia Cancer Agency (BCCA). In this series, the BCCA identified 153 patients who relapsed or progressed after primary therapy. They identified 153 patients with a variety of PTCL

subtypes including PTCL-NOS, AITL, ALK+ and ALK- T-cell lymphomas. The median time from diagnosis to relapse or progression of disease after primary therapy was 6.7 months. The median overall survival (OS) and second progression-free survival were only 5.5 and 3.1 months, respectively, which was only marginally improved if those patients went on to receive subsequent chemotherapy. This experience underscores the poor performance of conventional treatment regimens in the treatment of the disease, highlights the

Fig. 85.7 OVERALL SURVIVAL AND FAILURE-FREE SURVIVAL OF 340 PATIENTS WITH PERIPHERAL T-CELL LYMPHOMA NOT OTHERWISE SPECIFIED. (Data from Weisenburger DD, Savage KJ, Harris NL, et al: *Peripheral T-cell lymphoma, not otherwise specified: A report of 340 cases from the International Peripheral T-cell Lymphoma Project*. Blood 117:3402, 2011.)

importance of first-line treatment, and suggests that relapse alone is a profoundly adverse prognostic feature, in contrast to many B-cell lymphomas.

The International Peripheral T-Cell and Natural Killer/T-Cell Lymphoma study reported that the OS and failure-free survival (FFS) at 10–15 years was only 10%. The International Prognostic Index (IPI), which is based on age, performance status, LDH level, stage, and extranodal involvement, appears to be useful in determining the prognosis for certain PTCL subtypes. However, even patients in the best risk categories (IPI 0 or 1) do not have a favorable outcome, and patients in the high-risk categories have a very short survival. When compared with the IPI curves seen for patients with B-cell lymphoma, the curves seen for patients with T-cell lymphoma essentially identify two risk categories, those with IPI 0 or 1 having a relatively more favorable outcome, and those with IPI 2 or higher with an unfavorable outcome. In contrast to what is seen in patients with B-cell lymphoma, there is limited separation of the curves. When analyzed as a function of the histopathologic subset, the 5-year OS for patients with PTCL-NOS and AITL with IPI 0 or 1 was only 56% and 50%, respectively, whereas for those patients with IPI 4 or 5 it was 11% and 25%, respectively. Among patients with ALCL, the 5-year survival for IPI 0 or 1 is roughly 90% and 74% for the ALK-positive and ALK-negative patients, respectively. Patients with IPI 2 or higher have a poor outcome, with 5-year survivals of only 33% and 13% in the ALK-positive and ALK-negative populations, respectively. These observations confirm that IPI is an important predictor even in ALK-positive ALCL. The IPI has been less useful in stratifying patients with other subtypes of PTCL, including those with ATLL, EATL, hepatosplenic T-cell lymphoma, or extranodal NKTCL.

Other prognostic models have been developed specifically for patients with PTCL. The Prognostic Index for PTCL (PIT) was developed based on risk factors that include age, LDH level, performance status, and bone marrow involvement. When applied to a PTCL-NOS population, the PIT stratified patients into more distinct prognostic groups compared with the IPI. Of 322 patients studied, 20% had no adverse features, 34% had one, and 20% had three or more. The 5-year OS for the most favorable subgroup with no adverse prognostic features was 62% compared with 18% for patients with three or four prognostic factors. Despite improved stratification, the so-called *favorable-risk population* of patients with PTCL still had a strikingly poor outcome.

Efforts to improve on the more traditional clinically based scoring systems have been proposed. The Bologna scoring system was developed integrating both patient-specific and tumor-specific characteristics (age >60 years, performance status, LDH level, and Ki-67

protein $\geq 80\%$), stratifying patients into low-risk (score 1), intermediate-risk (score 2), and high-risk disease (score 3), with median OS of 37, 23, and 6 months, respectively. Although the scores seem to stratify the patient population, it is clear that there is no really favorable population of patients. The prognostic capability of the Bologna score was validated by Briones et al.

Recently the International Peripheral Lymphoma Study (IPLS) showed that the 5-year OS of 340 patients with PTCL-NOS was only 32% (after 3 years' follow-up), whereas the 5-year FFS was only 20% (Fig. 85.7). In this analysis, each of the prognostic factors in the IPI was a highly significant predictor of OS and FFS ($p < .001$) (Fig. 85.8). The overall IPI was predictive of both OS and FFS, whereas the PIT was predictive of only survival. Bone marrow involvement was not a robust predictor of OS ($p = .03$) or FFS ($p = .06$) (Fig. 85.9). The PIT did not prove to be superior to the IPI in predicting the survival of patients with PTCL-NOS. Only one group with relatively good FFS was identified using both models. The IPLS evaluated other potential predictive factors by univariate analysis, establishing that the following factors were adverse prognostic factors of OS and FFS, respectively: B symptoms ($p = .004$; $p = .014$), bulky disease ≥ 10 cm ($p = .005$; $p = .004$), elevated serum C-reactive protein level ($p = .018$; $p = .008$), circulating tumor cells ($p < .001$; $p < .001$), and a platelet count of less than $150 \times 10^9/L$ ($p < .001$; $p < .001$). For unclear reasons, hypergammaglobulinemia fell out as a favorable prognostic factor for OS and FFS ($p = .04$; $p = .03$). When the data were analyzed in a multivariate analysis, after controlling for IPI, only bulky disease ≥ 10 cm was still predictive of survival with a hazard ratio (HR) of 2.1 for OS ($p = .019$) and 2.5 for FFS ($p = .003$), whereas a platelet count of less than $150 \times 10^9/L$ was predictive of FFS (HR = 1.6, $p = .016$).

The IPLS also explored the impact of several pathologic features that were associated with inferior OS and FFS, including the following: Ki-67 index more than 25%, the presence of transformed tumor cells more than 70%, significant numbers of EBV-positive B cells (Epstein-Barr-encoded ribonucleic acid [EBER] 3–4+), and CD56 and CD30 expression by more than 20% on tumor cells. EBV positivity was predictive of an adverse survival only in patients younger than 60 years and was independent of a history of immunosuppressive therapy or autoimmune disorders. Factors that appeared to be favorably associated with improved OS and FFS included lymphoepithelioid (Lennert) variant and background CD8+ T cells constituting more than 10% of the population. Several clinicopathologic factors were identified to be of prognostic significance by univariate analysis, but only bulky disease (>10 cm) and thrombocytopenia ($<150 \times 10^9$ cells/L) were predictive of OS.

Fig. 85.8 OVERALL SURVIVAL (A) AND FAILURE-FREE SURVIVAL (B) OF 315 PATIENTS WITH PERIPHERAL T-CELL LYMPHOMA NOT OTHERWISE SPECIFIED ACCORDING TO THE INTERNATIONAL PROGNOSTIC INDEX. (Data from Weisenburger DD, Savage KJ, Harris NL, et al: *Peripheral T-cell lymphoma, not otherwise specified: A report of 340 cases from the International Peripheral T-cell Lymphoma Project*. Blood 117:3402, 2011.)

Probably the most important prognostic factor for any subtype of PTCL is the presence or absence of ALK in ALCL. The OS of ALK-positive ALCL is substantially better than that seen for ALK-negative ALCL ($71\% \pm 6\%$ vs. $15\% \pm 11\%$, respectively). However, within the good prognostic category of ALK-positive ALCL, survival was $94\% \pm 5\%$ for the low/low-intermediate risk group (age-adjusted IPI 0–1) and $41\% \pm 12\%$ for the high/high-intermediate risk group (age-adjusted IPI ≥ 2). Multivariate analysis identified ALK expression and the IPI as independent variables that were able to predict survival among T/null primary, systemic ALCL.

More recently, recognizing the biologic and clinical heterogeneity of PTCL, investigators have begun to develop subtype-specific prognostic models. Although potentially interesting, these models still need to be validated in large studies.

Therapy

Standard of Care

CHOP-Like Therapy in Mature T-Cell Lymphomas

Treatment approaches employed for patients with PTCL have largely mirrored the strategies employed for the treatment of DLBCL. Consequently, CHOP (cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], and prednisone) has emerged as the “standard of care” despite disappointing outcomes. The milestone Southwest Oncology Group (SWOG) trial that compared CHOP with the second- and third-generation dose-intensive regimens in aggressive

lymphoma established that CHOP exhibited the same efficacy and less toxicity than the other regimens. This landmark trial was based on the use of a histopathologic classification system when immunophenotyping was not yet routinely applied to all cases. Unfortunately, there are no large randomized prospective studies that compare the benefit of anthracycline-based therapies to other combination regimens in PTCL.

Conventional front-line chemotherapy such as CHOP has led to disappointing results in patients with T-cell lymphomas. Analysis of the data as a function of the primary PTCL subtypes revealed that only ALCL with the t(2;5) translocation (NPM-ALK fusion protein) had an equivalent or superior prognosis compared with patients with DLBCL. The LNH87 study conducted by the Groupe d’Etudes des Lymphomes de l’Adulte showed that the use of anthracycline-containing chemotherapy regimens in T- and B-cell lymphomas were able to induce the complete remission (CR) in 54% versus 63% of the patients, with an OS of 41% and 53%, and an event-free survival (EFS) of 33% and 42%, respectively. The same group published the results of the LNH84 study, in which they employed a dose-intense consolidation. Again, although there was no difference in the response rate (RR), patients with T-cell lymphomas relapsed more frequently and earlier compared with patients with B-cell lymphoma. More recently the CHOEP regimen (cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], etoposide, and prednisone) was retrospectively studied by the German High-Grade Non-Hodgkin Lymphoma Study Group in 343 patients with T-cell lymphoma, including PTCL-NOS, ALCL, and AITL, who had been included in seven German high-grade phase II or III aggressive NHL treatment

Fig. 85.9 OVERALL SURVIVAL (A) AND FAILURE-FREE SURVIVAL (B) OF 315 PATIENTS WITH PERIPHERAL T-CELL LYMPHOMA NOT OTHERWISE SPECIFIED ACCORDING TO THE PROGNOSTIC INDEX. *PTCL-NOS*, Peripheral T-cell lymphoma not otherwise specified. (Data from Weisenburger DD, Savage KJ, Harris NL, et al: *Peripheral T-cell lymphoma, not otherwise specified: A report of 340 cases from the International Peripheral T-cell Lymphoma Project*. Blood 117:3402, 2011.)

studies. The main purpose was to determine whether the addition of etoposide or shortening of the interval of chemotherapy from 3 weeks to 2 weeks affected survival. In older adult patients, neither shortening the interval nor the addition of etoposide improved the EFS and OS.

A recent literature review and meta-analysis reported a CR rate of 52% achieved with CHOP/CHOP-like regimens (excluding ALK-positive ALCL), with an estimated 5-year OS of only 35% in PTCL. This is in contrast to the 65% or better long-term survival frequently reported in DLBCL. Select studies reporting on the activity of various combination regimens in PTCL are presented in Table 85.2.

Anaplastic Large-Cell Lymphoma

ALCL is a unique subtype of an aggressive mature T-cell lymphoma that carries a highly favorable prognosis, especially for patients with who carry the *ALK* translocation [the NPM-*ALK*; t(2;5)] with IPI 1 or 2 disease. Virtually all cases of ALCL express CD30, and about half of the patients with this disease harbor the t(2;5)(p21;q35) translocation. This chromosomal aberration leads to fusion of the *NPM* gene with the *ALK* tyrosine kinase, leading to its constitutive activation. The presence of the *ALK* translocation confers a highly favorable prognosis, and determination of *ALK*'s status by FISH is imperative in all cases of ALCL, especially those in which the differential diagnosis also includes PTCL-NOS. The National Comprehensive Cancer Network guidelines recommend standard CHOP-based chemotherapy for these patients, sometimes combined with radiation for bulky disease, which typically produces remission rates

close to 80%. Patients who experience relapse of their disease generally exhibit the same poor prognosis as patients with other subtypes of PTCL. Patients with ALK-negative ALCL carry the same poor prognosis as other subtypes of mature T-cell lymphoma, and may be suitable candidates for clinical trials in both the upfront and relapsed settings.

Nasal NKTCL: Combined-Modality Versus Single-Modality Approaches

Radiotherapy is considered the most active treatment for early-stage nasal NKTCL. For patients with limited stage IE or stage IE disease without any adverse factors, radiotherapy alone should be pursued with curative intent. Radiation produces complete RR of up to 70%; however, approximately 50% of patients who receive radiation alone will relapse, with about 25% of patients experiencing a systemic relapse. Hence, the addition of chemotherapy is intended to reduce the risk or recurrence, and is essential for advanced stages of nasal and extranasal NKTCL. For patients with extensive stage I and II disease, radiotherapy followed by consolidation with chemotherapy is commonly used. Because of the intrinsic drug resistance frequently seen in this disease, chemotherapy is not recommended as primary treatment in early-stage nasal NKTCL. Extranodal NKTCL is generally refractory to CHOP-based chemotherapy and is often associated with the expression of multidrug resistance (MDR) genes.

Despite the benefit of radiotherapy in this disease, a uniformly accepted standard of care has yet to be identified. Recently a phase

**TABLE
85.2****Summary of Retrospective Up-Front Studies in Peripheral T-Cell Lymphoma**

Regimen	PTCL Subtypes	n	CR (%)	OS
Anthracycline based	NK/T nasal	24	66.7	Not reported

AITL, Angioimmunoblastic T-cell lymphoma; ALCL, anaplastic large-cell lymphoma; CHOP, cyclophosphamide, hydroxydaunomycin, vincristine (Oncovin), and prednisone; CMT, combined modality therapy; COPBLAM-V, cyclophosphamide, vincristine (Oncovin), prednisone, bleomycin, doxorubicin (Adriamycin), and procarbazine; CR, complete remission; CT, chemotherapy; EATL, enteropathy-associated T-cell lymphoma; NK, natural killer; NOS, not otherwise specified; OS, overall survival, PTCL, peripheral T-cell lymphoma; RT, radiotherapy.

I/II study using concurrent chemotherapy and radiotherapy was reported. Patients were treated concurrently with radiotherapy and chemotherapy, which included carboplatin, etoposide, ifosfamide, and dexamethasone. Among the 26 patients reported, the objective response rate (ORR) was 81% with 77% CR. The most common grade 3 nonhematologic toxicity was mucositis (30% of patients), which was attributed to the radiotherapy. With a median follow-up of 32 months, the study reported a 2-year OS of 78%, which compares very favorably with the historical control group, which received radiotherapy alone (45%). Increasingly, many physicians are considering combined-modality therapy as the best upfront treatment for this disease, despite the potentially significant associated toxicity.

Newer approaches for patients with advanced NKTCLs have explored integrating L-asparaginase into a dexamethasone (steroid), methotrexate, ifosfamide, and etoposide-based backbone (SMILE). Yong et al treated 18 patients that were refractory to CHOP with L-asparaginase, vincristine, dexamethasone, and involved field radiotherapy. The ORR was 83.3%, with 10 (55.6%) of the patients achieving CR, and five (27.8%) achieving partial response (PR). The 5-year OS rate was 55.6%. Results of the preliminary clinical study indicated that the L-asparaginase-based salvage regimens significantly improved the RR and 5-year survival rate. A prospective phase II trial has been reported with the SMILE regimen in patients with newly diagnosed stage IV or relapsed refractory NKTCLs. Among the 39 patients treated, 29 (74%) completed the planned treatment. The responses included 15 patients in CR and 14 in PR, with early deaths due to infection in four patients. Infection was the most commonly observed toxicity, seen in 41% of the patients. Based on these studies, we conclude that L-asparaginase may have a role either in the upfront setting or for patients with relapsed or refractory disease.

Efforts to find approaches with a more favorable safety profile have led to the development of regimens built on drugs that are not affected by P-glycoprotein. The GELOX regimen (gemcitabine, oxaliplatin, and L-asparaginase) with involved field radiotherapy sandwiched between chemotherapy was studied in patients with stage IE/IIIE extranodal NKTCL (EN-NKTCL) by the Chinese. The prospective study reported a ORR of 96.3% with a 74% rate of CR. Grade 3 or 4 toxicities were minimal, and no treatment-related deaths occurred. The rates of 2-year OS and PFS were both 86%, with patients achieving a CR doing substantially better than patients not in CR. These data, while now being studied in larger patient populations, is promising, and may afford a new and improved approach to patients with EN-NKTCL.

Adult T-Cell Leukemia/Lymphoma: Role of Antiviral Agents

The results of traditional chemotherapy in patients with ATL, like in other forms of PTCL, have been uniformly poor, leading to a consensus recommendation to enroll patients when possible in a clinical trial in either the upfront or relapsed or refractory setting. This recommendation is relevant for patients with most subtypes of PTCL. Although there is again no standard of care for these patients, the general sentiment is that CHOP-based chemotherapy regimens are inadequate. Owing to the comparatively higher incidence of ATL in Japan, many studies regarding the management of ATL come from Asia. The Japanese evaluated a complex combination regimen of VCAP (vincristine, cyclophosphamide, doxorubicin [Adriamycin], and prednisone), AMP (doxorubicin [Adriamycin], ranimustine [MCNU], and prednisone), and VECP (vindesine, etoposide, carboplatin, and prednisone) against CHOP-14 in ATL. A total of 118 patients were enrolled in the trial and treated with either six courses of VCAP-AMP-VECP every 4 weeks or eight courses of biweekly CHOP. The CR rate was higher in the VCAP-AMP-VECP arm than in the CHOP-14 arm (40% vs. 25%, respectively), and the progression-free survival (PFS) at 1 year was 28% in the VCAP-AMP-VECP arm compared with 16% in the CHOP arm. The OS at 3 years was 24% in the VCAP-AMP-VECP arm and 13% in the CHOP arm. Overall, the toxicity in the VCAP-AMP-VECP arm was

higher than in the CHOP-14 arm, with substantially more grade 3 or 4 cytopenias in the VCAP-AMP-VECP arm, which included three toxic deaths. Because most patients with ATL do not have curable disease when treated with these chemotherapy regimens, it is reasonable to consider allogeneic stem cell transplantation (aSCT) in patients who show responses to chemotherapy. Although this experience is very limited, there is some suggestion that there may be benefit in some patients.

Infection with HTLV-1 can cause ATL. Nineteen patients with acute or lymphomatous forms of ATL were treated with oral zidovudine (200 mg five times daily) and IFN- α (Intron A; 5–10 million units subcutaneously each day). Seven of these patients either relapsed or were refractory to combination chemotherapy. Major responses were achieved in 58% of the patients (11 of 19), including CR in 26% (5 of 19). Four patients in whom prior cytotoxic therapy had failed experienced major responses, two of which were CRs. Six patients have survived for more than 12 months, with the longest remission since the discontinuation of treatment lasting more than 59 months. A recent metaanalysis evaluated 116 patients with acute ATL, 18 patients with chronic ATL, 11 patients with smoldering ATL, and 100 patients with ATL lymphoma. The 5-year OS rates were 46% for 75 patients who received first-line antiviral therapy ($p = .004$), 20% for the 77 patients who received first-line chemotherapy, and 12% for the 55 patients who received first-line chemotherapy followed by antiviral therapy. The metaanalysis suggested that patients with acute, chronic, and smoldering ATL significantly benefited from first-line antiviral therapy, whereas patients with ATL lymphoma experienced a better outcome with chemotherapy. In acute ATL, 82% of patients were alive at 5 years with antiviral therapy, and 100% of patients with chronic and smoldering ATL were alive at 5 years. Multivariate analysis showed that first-line antiviral therapy significantly improved OS (HR = 0.47; 95% CI, 0.27–0.83; $p = .021$). Prospective studies are warranted to better define the role of antiviral therapy in treatment of ATL.

Given the activity of the anti-cc chemokine receptor 4 antibody (CCR4) mogamulizumab in ATL, a randomized phase II study explored integration of the biological into the mLSG15 regimen (the VCAMP/AMP/VECP regimen discussed earlier). Fifty-three patients with acute, lymphomatous, and chronic ATL were randomized to the mLSG15 ($n = 24$) or mLSG15 plus mogamulizumab ($n = 29$) regimens. The respective ORR and CR rates were 86% and 52% in the mogamulizumab-containing arm, and 75% and 33% in the sLSG15 alone arm. While the PFS was improved in the mogamulizumab arm (8.5 vs. 6.3 months), there was no difference in OS. In addition, there was substantially more toxicity in the antibody-containing arm, raising issues regarding how best to optimally integrate novel drugs such as mogamulizumab into standard cytotoxic regimens like mLSG15.

Angioimmunoblastic T-Cell Lymphoma: The Role of Cyclosporin and Rituximab

AITL is one of the most common forms of PTCL, with peculiar clinical and pathologic features. Although the normal counterpart has been recently identified as the T_{FH} cell, the nonneoplastic cells typically represent the quantitatively major component of AITL. Clinically the manifestations of the disease reflect a dysregulated immune and/or inflammatory response rather than being the direct complication of aberrant tumor growth, supporting the concept of a paraneoplastic immunologic dysfunction. Despite the use of different intensive anthracycline-based chemotherapies, AITL is an aggressive disease compared with other PTCLs, for which the optimal therapeutic strategy is still not defined. Given the considerable immune dysregulation present in AITL, the possible role of cyclosporine A (CsA) has been investigated in a small number of patients. Twelve patients were treated with the immunomodulatory CsA, 10 of whom had failed prior therapy with either chemotherapy and/or steroids (one to two prior regimens). Two patients were untreated because of age or comorbid conditions. Three patients achieved CR and five a PR for an overall RR of 67%, suggesting a possible role for CsA in this setting. In AITL, symptoms linked to B-lymphocyte activation

Treatment of Peripheral T-Cell Lymphoma

Given that the mature T-cell lymphomas are relatively rare diseases, there is a lack of large randomized clinical trials comparing the “standard” CHOP (cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], and prednisone) and CHOP-like regimens to other more intensified chemotherapy strategies, or even other novel drug platforms. Our approach involves tailoring the treatment to the specific histologic subtype and age of the patient. From the outset, we send HLA typing for possible allogeneic stem cell transplant, assuming the patient is eligible, and request immunohistochemical staining of the primary tissue for CD30. Where possible, we preferentially try to put all patients on a clinical trial. For the majority of peripheral T-cell lymphomas, our standard initial approach is to use an etoposide-based regimen (CHOEP [cyclophosphamide, hydroxydaunomycin, vincristine (Oncovin), etoposide, and prednisone] or EPOCH [etoposide, prednisone, vincristine (Oncovin), cyclophosphamide, and hydroxydaunomycin]), especially for young patients or older adult patients with an excellent performance status. As alluded to earlier, there are some data to suggest a reduced failure-free interval and higher complete response rate. For patients with a poor performance status or older adult patients, standard CHOP administered on an every-21-day basis for six to eight cycles would be our preferred recommendation. In select cases, where an older adult patient is not a candidate for combination chemotherapy and requires palliative care, we have successfully used single-agent gemcitabine to obtain disease control and improve performance status. Those patients who attain a complete remission are usually referred for an autologous stem cell transplant. Those patients who do not attain a complete remission with standard front-line chemotherapy are typically referred for treatment with one of the drugs recently approved by the Food and Drug Administration for patients with relapsed or refractory disease, including pralatrexate, romidepsin, belinostat, or brentuximab vedotin (if CD30⁺), or clinical studies exploring the merits of these agents in combination. For patients who relapse or are refractory to front-line and beyond therapy, we typically consider allogeneic stem cell transplant, assuming they are transplant eligible and have an appropriate human leukocyte antigen match.

are common, and variable numbers of CD20⁺ large B-blasts, often infected by EBV virus, are found in the neoplastic tissues. It has recently been suggested that the disruption of putative B- and T-cell interactions and/or depletion of the EBV reservoir by anti-CD20 monoclonal antibody (rituximab) might improve clinical outcome observed with conventional chemotherapy. Twenty five newly diagnosed patients were treated in a phase II study with eight cycles of rituximab plus chemotherapy (R-CHOP21). The complete RR was 44%, the 2-year PFS rate was 42%, and OS was 62%. This trial showed no clear benefit of adding rituximab to conventional chemotherapy (see box on [Treatment of Peripheral T-Cell Lymphoma](#)).

Role of Stem Cell Transplantation in Treatment

Because of the poor outcomes often seen with conventional chemotherapy in patients with PTCL, many investigators have explored high-dose chemotherapy followed by autologous or aSCT as front-line therapy and in patients who have relapsed. Despite the growing number of reports, one must keep in mind a number of limitations associated with these reports: (1) most of the studies are retrospective; (2) randomized trials comparing chemotherapy and SCT have not been published to date; (3) many prospective studies of autologous SCT include both front-line treatment and relapsed patients with diverse subtypes of PTCL, making the results difficult to interpret.

High-Dose Chemotherapy and Autologous Stem Cell Transplantation

High-dose chemotherapy followed by autologous SCT is currently accepted as the treatment of choice for patients with relapsed

aggressive B-cell lymphomas, resulting in 40%–50% long-term disease-free survival. The role of autologous SCT in PTCL is less clear, and whether or not autografting during first or subsequent remissions may be of clinical benefit remains uncertain.

Autologous SCT is usually performed as front-line consolidation therapy for young patients with PTCL. In this setting there are several prospective and retrospective studies evaluating this approach (see [Table 85.1](#)).

In a retrospective analysis, the Japan registry demonstrated that long-term outcome of PTCL was better in patients transplanted during first CR or partial remission (PR) than those not in remission (5-year OS, 72.9% vs. 45.8%; progression-free survival [PFS], 73.1% vs. 42.2%). The British Society of Bone Marrow Transplantation (BSBMT) and Stanford University reported similar data. The 2-year OS and PFS were 62% and 59%, respectively, for patients receiving autologous SCT as consolidation during first CR³. The Spanish group published a retrospective analysis of 74 patients undergoing autologous SCT after the achievement of CR with front-line anthracycline-based induction chemotherapy. After a median follow-up of 67 months, 5-year OS and PFS were 68% and 63%, respectively, and the main cause of death was disease progression. After a multivariate analysis, only the PIT score was significantly associated with OS and PFS. Although data about ALK expression were lacking, patients affected by ALCL had a significantly better outcome compared with other PTCL subtypes. The same authors published the results of a prospective study in 26 high-risk nodal PTCL patients, excluding those with ALK-positive ALCL. The patients who were positron emission tomography positive after three cycles of dose-escalated CHOP (MegaCHOP) received salvage chemotherapy followed by autologous SCT. After a median follow-up of 35 months, the 3-year OS and PFS of the entire cohort of patients were 73% and 56%, respectively, whereas those patients who were rescued by high-dose chemotherapy achieved a 2-year disease-free survival of 63%.

An Italian multicenter prospective study employed high-dose sequential chemotherapy followed by autologous SCT as front-line therapy in 62 patients with high-risk PTCL (stage III–IV and/or age-adjusted IPI >1) including 19 ALK-positive ALCL patients. On an intent-to-treat analysis, only 46 of 62 patients (74%) completed the whole program. Progressive disease during the induction phase was the main obstacle for proceeding to autologous SCT and the main reason for treatment failure. The high progression rate led to disappointing 12-year OS and EFS curves (34% and 30%, respectively). However, in the cohort of patients who did undergo autologous SCT, the RR was high: 89% of these patients achieved a CR. As in the Spanish study, patients with ALCL had the most favorable OS and EFS (62% and 54%, respectively, compared with 21% and 18%, respectively, of non-ALCL). On the other hand, when patients with PTCL-NOS were in CR at the time of transplant, the EFS was 62% versus 10% for those not in CR. The CR status remained a significant predictor of long-term outcome in multivariate analysis.

The German group published the results of a prospective multicenter study employing myeloablative doses of cyclophosphamide and total-body irradiation as the conditioning regimen for 83 ALK-negative ALCL patients who were at least in PR after six cycles of CHOP. Similar to the Italian data, 34% of patients did not complete the study because of progressive disease. The estimated 3-year OS was 71% for patients who received an autologous SCT compared with 11% for those who did not. A large registry study from the Swedish group confirmed a survival advantage for those patients who received an autologous SCT as front-line consolidation therapy. In this study, ALK-positive ALCL patients were excluded. Also after multivariate analysis, front-line ASCT was associated with a favorable PFS and OS compared with the cohort treated without autologous SCT. Of note, the addition of etoposide to CHOP chemotherapy was associated with a higher PFS in patients younger than 60 years, but this was not true for OS.

Although most of the published data include different histologic subtypes of PTCL, efforts have been made to define the role of autologous SCT in specific subtypes of PTCL. Some studies have

focused on the results obtained with PTCL-NOS and ALCL patients, emphasizing that the histologic subtype can influence the outcome after autologous SCT. The Toronto group compared relapsed and refractory PTCL patients with those achieved with DLBCL patients, who were transplanted for the same indication over the same period of time. The 3-year OS and EFS were 48% and 37%, respectively, for PTCL patients, compared with 53% and 42%, respectively, for DLBCL patients. Nevertheless, a significantly different outcome has been reported when the subtypes of PTCL were analyzed individually. Patients with PTCL NOS had an inferior EFS (3-year EFS, 23%) when compared with patients with DLBCL. By contrast, patients with ALCL exhibited similar outcomes to patients with DLBCL. These results are consistent with data from a retrospective study performed at the Memorial Sloan-Kettering Cancer Center that reported a 5-year PFS of 24% for relapsed or refractory ALK-negative ALCL. The more favorable prognosis of ALCL after autologous SCT was confirmed by Northern Europe Investigators.

AITL patients have a median survival of 18 months after conventional chemotherapy, with less than 50% of the patients achieving a CR. A retrospective analysis of the European Group for Blood and Marrow Transplantation (EBMT) of autologous SCT in 146 AITL patients demonstrated an OS and PFS of 59% and 42%, respectively, at 4 years. PFS was longer in patients who received an autologous SCT in CR, 56% at 4 years, compared with 23% in the case of patients with chemotherapy-refractory disease.

EATL is another very poor prognosis PTCL subgroup, commonly associated with celiac disease. Because of its rarity, very few data on EATL treatment are available. In a prospective observational study using aSCT as front-line treatment, 5-year OS was 60% versus 22% for patients treated with standard chemotherapy. A retrospective study from EBMT confirmed these results on a cohort of 44 patients affected by EATL and treated with autologous SCT with a 4-year PFS and OS of 54% and 59%, respectively. Being in first CR or PR at the time of autologous SCT was associated with a trend for better survival compared with patients with a less favorable disease status (4-year OS 66% vs. 36%, $p = .062$).

Besides the differences in outcomes based on histologic subtypes and induction therapies, a common feature of PTCLs is that only two thirds of young patients are able to undergo the final autografting phase with a satisfactory disease response.

To increase the number of patients undergoing autologous SCT in CR or at least PR, some trials were designed with a more intense pretransplant phase. The Nordic Lymphoma Group included a dose-dense induction phase for 160 PTCL patients. After six cycles of CHOEP every 2 weeks, 85% of patients achieved CR and 70% proceeded with autologous SCT at last follow-up. Five-year OS and PFS were 50% and 43%, respectively. A Spanish group used alternating CHOP and ESHAP (etoposide, methylprednisolone, cytarabine, cisplatin) during the induction phase of 41 ALK-negative patients: 58% of the patients were in CR or PR after the induction phase, but only 41% underwent autologous SCT. More recently, the Italian Lymphoma Foundation performed an intensive front-line induction chemotherapy before transplant in young PTCL patients (excluding ALK-positive ALCL cases). Two cycles of CHOP plus alemtuzumab were followed by two cycles of HyperCHidam (methotrexate followed by hyperfractionated cyclophosphamide and cytarabine). Patients achieving a CR or PR received consolidation therapy with an autologous SCT or aSCT (in case of a compatible donor). With an intent-to-treat analysis, the 4-year PFS and OS were 44% and 49%, respectively. In fact, a clinical response was obtained in 62% of the study cohort, highlighting the need for more effective induction therapy for PTCLs.

Finally, the prognosis of PTCL patients seems poor when autologous SCT is used in patients with relapsed disease, where long-term remissions have been observed in less than one third of patients. Those who benefit the most are patients with ALK-positive ALCL in CR at time of transplant or those with a low IPI. A registry analysis from the Center for International Blood and Marrow Transplant Research (CIBMTR) confirmed these results. One hundred and fifteen patients received autologous SCT as front-line consolidation

therapy ($n = 40$) or as a component of a subsequent course of therapy ($n = 75$), with survival outcomes in favor of the front-line group: 3-year PFS of 58% versus 50% and 3-year OS of 70% versus 53%. Patients affected by ALCL were an exception. In this group, autologous SCT after first CR was still associated with good survival outcomes (3-year PFS 50% and OS 74%). Of note, ALK status was not available for these analyses.

In conclusion, the role of autologous SCT for the therapy of patients with PTCL may be summarized as follows: (1) young patients affected by PTCL appear to have an advantage when receiving an autologous SCT while in first CR; (2) ALK-positive ALCL patients have a more favorable outcome after autologous SCT, but they also do well with conventional chemotherapy, allowing this strategy to be possibly delayed to the salvage setting; (3) clinical protocols should be designed with more innovative pretransplant therapies in order to achieve optimal disease control prior to transplantation and thereby increasing the number of patients who are eligible to receive an autologous SCT.

Allogeneic Stem Cell Transplantation

aSCT has been most frequently used in PTCL patients with progressive or refractory disease after several courses of chemotherapy or in the case of relapse after an autologous SCT. This strategy is associated with the infusion of a lymphoma-free graft and the generation of a potentially active graft-versus-lymphoma (GvL) effect. Survival after myeloablative aSCT has been hampered by the high nonrelapse mortality (NRM) caused by graft-versus-host disease, infections, and acute organ toxicities.

Retrospective comparative analyses of autologous SCT versus aSCT in PTCL suffer the limitation of significant selection bias. In fact, patients receiving aSCT usually had more advanced disease, more prior lines of therapy, and/or bone marrow involvement. However, these studies have demonstrated that aSCT is associated with a lower relapse risk compared with autologous SCT, but also with a higher NRM, which offsets the survival benefit. The results of aSCT as a therapeutic strategy are listed in [Table 85.2](#). A small retrospective comparative study conducted by the Spanish Lymphoma/Autologous Bone Marrow Transplant Study Group (GELTAMO) compared the outcome of patients receiving autologous SCT ($n = 29$) versus aSCT ($n = 7$) for PTCL. The 3-year OS was 39% and 29% for autologous SCT and aSCT, respectively. However, the majority of patients in the group receiving allogeneic grafts in CR died because of transplant-related complications. In 2006 a Japanese group published the first large analysis on the outcome of PTCL after myeloablative aSCT from matched related and unrelated donors. Kim and colleagues recently compared outcomes of patients affected by PTCL treated with autologous SCT ($n = 135$) versus myeloablative or reduced-intensity conditioning (RIC) aSCT ($n = 96$). No differences in survival was noted between the two groups (5-year OS 46% vs. 48%, $p = .34$), even though the aSCT group had more unfavorable features than the autologous SCT group in terms of prior courses of therapy and disease status at the time of transplant. Of note, despite a higher NRM, aSCT was able to induce a prolonged OS in 40% of patients who had chemorefractory disease, showing the efficacy of this salvage strategy for that group of PTCL patients that cannot achieve a response with standard chemotherapy. Similarly, Smith and colleagues compared 241 PTCL patients who received an autologous SCT ($n = 115$) or aSCT ($n = 126$). Also in this study, the two groups were different in terms of prior courses of therapy, chemosensitive disease, and histologic subtypes. In fact, the aSCT group had more unfavorable features including a lower number of ALCL patients. Two interesting results emerged from this study: the first was to confirm that performing a transplant (either autologous or allogeneic) later during the course of disease (after two or more prior courses of therapy) was associated with a threefold increased risk of relapse, fivefold increased risk of overall mortality, and a sevenfold risk of NRM; the second one was that autologous SCT at relapse was beneficial for those patients affected by ALCL (ALK

status was not available) with superior overall survival compared with aSCT.

During the last 15 years, RIC regimens have been increasingly used in patients with relapsed lymphomas in order to reduce NRM, thus making this strategy feasible in older adults or heavily pretreated patients. In 2004 one of the first reports of RIC aSCT in PTCL patients reported that 56% of patients were alive and in CR after 1.4 years. The first prospective study evaluated the outcome of 17 relapsed PTCL patients after a fludarabine-based RIC regimen: 14 of 17 enrolled patients were alive (12 in CR) after a median follow-up of 28 months, with an estimated 3-year NRM, OS, and PFS of 6%, 81%, and 64%, respectively.

In this study, there were some data suggesting the existence of a GvL effect, based on the following observations: (1) the achievement of durable responses with aSCT in patients who had already failed a prior autologous SCT; and (2) the demonstration of clinical responses to donor lymphocyte infusions. These preliminary results were supported by a larger Italian multicenter retrospective study with a longer follow-up. In this study, the 5-year outcomes showed a NRM, OS, and PFS of 12%, 50%, and 40%, respectively, and a plateau in the survival curves after 36 months, suggesting a probable cure for these patients. Following multivariate analysis, being older than 45 years and having refractory disease were independent prognostic factors, highlighting that timing of an aSCT can significantly influence the final outcome. Similarly, in a French retrospective study of 77 PTCL patients receiving aSCT with both RIC or myeloablative conditioning regimens, those patients with chemosensitive disease or with less than two prior courses of chemotherapy at the time of transplant experienced better survival outcomes.

In both the Italian and French studies, survival was not significantly different among the histologic subtypes of T-cell lymphoma (of note, the ALK mutational majority of the ALCL patients was unknown), although patients with AITL did slightly better. In support of this finding, an EBMT retrospective analysis of 45 PTCL patients undergoing aSCT between 1998 and 2005 had a relapse risk of 20% at 3 years, with a PFS of 53% and an OS of 64%.

Several studies have reported survival outcomes of aSCT for PTCL patients when employed as front-line consolidation therapy. The only prospective study of this strategy showed encouraging 4-year PFS and OS of 69% using a RIC regimen and an HLA-compatible donor. Other retrospective studies have confirmed these data with a 2-year PFS and OS between 35%–65% and 40%–75%, respectively.

In conclusion, aSCT can be offered in relapsed and refractory PTCL based on the following observations: (1) in all studies survival curves seem to reach a plateau after 24–36 months, suggesting the potential curability of the disease; (2) delaying aSCT too long from the time of diagnosis may significantly compromise the outcome, thus aSCT should be performed during a chemosensitive relapse; (3) RIC regimens have increased the feasibility of performing aSCT by reducing NRM, and aSCT may be used in older and heavily pretreated patients. Hopefully in the future we will see if the combination of new agents with aSCT can improve the outcomes of a significant proportion of patients with refractory disease.

Emerging New Drugs for PTCL

There is little question that one of the most promising new areas in PTCL research is new drug development. Over the past several years, four new drugs, all with relatively unique mechanisms of action, have been approved for the treatment of patients with relapsed or refractory disease. These drugs, which all now have substantial data demonstrating their marked single-agent activity in these diseases, have created a unique opportunity to build non-CHOP–based platforms for treatment. In addition to the four drugs already approved, many new drugs are in various stages of clinical development, with very promising signals (Table 85.3). We will discuss some of these new agents and how they are beginning to change the treatment paradigms for PTCL.

Pralatrexate

Pralatrexate was the first drug approved for the treatment of patients with relapsed or refractory PTCL in 2009. Pralatrexate is a novel antifolate with very high affinity for the reduced folate carrier, designed to enhance its intracellular transport. The reduced folate carrier is an oncofetal protein expressed at relatively high levels on the surface of malignant cells. The carrier is responsible for transporting into the cell natural folate required for DNA biosynthesis. Pralatrexate, designed to have a high affinity for the folate receptors, is rapidly internalized into the cell, where it undergoes efficient polyglutamylation by the folylpolyglutamate synthase, which enhances the affinity of the drug for dihydrofolate reductase and increases its intracellular retention.

TABLE 85.3

Recent FDA-Approved and Emerging New Drugs in Peripheral T-Cell Lymphoma

Drug	Disease/No. of Patients	Overall Response Rate	Complete Response Rate	PFS/DOR
Pralatrexate (accelerated approval 2009)	Relapsed/refractory PTCL N = 111	29%	11%	Median DOR = 10.1 months
Romidepsin (accelerated approval 2011)	Relapsed/refractory PTCL N = 130	25%	15%	Median DOR = 17 months
Brentuximab vedotin (accelerated approval 2011)	CD30 ⁺ anaplastic large-cell lymphoma N = 58	86%	57%	Median DOR = 12.6 months
KW-0761	HTLV-1 ATL N = 27	13 of 26 (50%)	8 of 13 (61%)	PFS = 5.2 months
Bortezomib	Relapsed/refractory CTCL and PTCL N = 12	8 of 12 (67%) (2 patients with PTCL)	2 of 12 (17%) (1 of 2 patients with PTCL)	Not reported
Lenalidomide	Relapsed/refractory PTCL N = 10 (Zinzani) N = 24 (Dueck)	30% 30%	3 of 10 0 of 7	Not reported Median PFS 96 days
Alisertib	Relapsed/refractory PTCL N = 8	4 of 8 (50%)	2 of 4	Not reported

ATL, Adult T-cell leukemia/lymphoma; CTCL, cutaneous T-cell lymphoma; DOR, duration of response; FDA, Food and Drug Administration; HTLV-1, human T-lymphotropic virus-1; PFS, progression-free survival; PTCL, peripheral T-cell lymphoma.

A phase “II–I–II” study of pralatrexate in patients with relapsed or refractory NHL established the maximum tolerated dose as 30 mg/m² weekly for 6 of 7 consecutive weeks of treatment. The dose-limiting toxicity was determined to be mucositis, which was largely controlled with the addition of folic acid and vitamin B₁₂. These data revealed an ORR of 31% among the entire population of patients with both B- and T-cell lymphoma ($n = 48$ evaluable), of which eight patients obtained a CR. Among the 20 evaluable patients with B-cell lymphoma, the ORR was 5%, of which there were no CRs. Among the 26 evaluable patients with T-cell lymphoma, the ORR was 54%, of which there were eight CRs. All the CRs, many of which were very durable and included patients who had responded to prior methotrexate, were seen exclusively in patients with PTCL.

These data gave rise to a pivotal study of pralatrexate in patients with most subtypes of relapsed or refractory PTCL. The Pralatrexate in Patients With Relapsed or Refractory Peripheral T-Cell Lymphoma (PROPEL) study was an international, open-label, single-arm trial in which pralatrexate was administered at a dose of 30 mg/m² weekly for 6 of 7 consecutive weeks. At the time, it was the largest study ever conducted in this patient population. Of 115 patients enrolled, 111 were treated with pralatrexate. Overall, the patient population was very heavily pretreated, with the median number of prior therapies being 3, with a range of 1 to 12. Twenty percent of patients in PROPEL had received more than five lines of prior chemotherapy. Of all the new drug studies that have emerged recently, the PROPEL study accrued the greatest diversity of patients with PTCL including patients with blastic NK/T-cell lymphoma, ATLL, and transformed mycosis fungoides (MF), which are variably excluded from other studies. In addition, the PROPEL population was, to date, the most heavily treated population of the studies reported. The RR among the 109 evaluable patients was 29%, which included 12 CRs (11%), with an updated median duration of response of over 121 months. The most common grade 3 or 4 toxicities included thrombocytopenia and mucositis. These data led to pralatrexate becoming the first drug ever approved by the United States Food and Drug Administration (FDA) for PTCL, receiving accelerated approval in late 2009.

Detailed population pharmacokinetic and pharmacodynamics studies have demonstrated that two variables had the greatest impact on the risk of mucositis from pralatrexate, including: (1) area under the curve of exposure; and (2) pretreatment methylmalonic acid and homocysteine levels. These observations have given rise over the past few years to several modifications of drug administration. The first has involved the incorporation of leucovorin into the standard administration of pralatrexate. Given the profoundly greater affinity of pralatrexate for the reduced folate carrier, risks of mitigating efficacy with coadministration seem to be far less. Albeit early, these evolving experiences suggest that leucovorin after and prior to pralatrexate can markedly reduce the risk of mucositis, and in some cases allows for higher doses of the drug to be tolerated, at least in preclinical models. Similarly, the contribution of idiosyncratic AUC drug exposure has been addressed with a titrated dose-escalation approach (10 mg/m² week 1; 20 mg/m² week 2; and 30 mg/m² week 3, on a 4-week dosing basis), allowing for a tailoring of the dose to the idiosyncratic disposition of the drug in a given patient. These approaches, while preliminary in nature, are being studied in larger populations of patients.

Probably the greatest advances in recent years with not just pralatrexate, but all these agents emerging in PTCL, has been the emergence of both preclinical and clinical data confirming marked synergy with pralatrexate and other drugs, including gemcitabine, bortezomib, histone deacetylase (HDAC) inhibitors (HDACIs) such as romidepsin, and belinostat. Much of this preclinical experience has now been translated into early proof-of-principal clinical studies.

Histone Deacetylase Inhibitors

The HDACIs appear to exhibit a consistent pattern of activity in T-cell neoplasms, with little to no activity in B-cell lymphoid malignancies. Acetylation of histone proteins facilitates an open chromatin

structure, leading to access by transcription factors and thus transcriptional activation. Conversely, HDACs facilitate deacetylation of chromatin, which leads to a closed chromatin structure and transcriptional silencing. Although the modulation of chromatin structure has been long postulated as one of the key mechanisms for HDACI activity, it is now widely recognized that these drugs are more appropriately recognized as more general protein deacetylase inhibitors. In this capacity, it is also recognized that HDACIs may functionally affect tumor cell growth and survival by modulating the posttranslational state of different proteins, which leads to activation or inactivation of various tumor suppressor genes or oncogenes. While it is not precisely known how or why this class of drugs work consistently in PTCL, overexpression of HDAC1, HDAC2, and HDAC6, as well as acetylated histone 4 (H4) have been seen in select subtypes of the disease.

To date, three HDAC inhibitors have been approved for the treatment of cancer, including: (1) vorinostat for the treatment of relapsed or refractory CTCL; (2) romidepsin approved for relapsed or refractory CTCL and PTCL; and (3) belinostat approved for the treatment of relapsed or refractory PTCL. The first HDACI approved for the treatment of cancer was vorinostat, or SAHA. Vorinostat is a hydroxamic acid derivative known to be a potent class 1–2 inhibitor of HDAC. Early developmental clinical studies performed with both intravenous and oral vorinostat demonstrated that the drug could inhibit HDACs, leading to accumulation of acetylated H3/H4. These studies also demonstrated that the drug was well tolerated for extended periods of time, with dose-limiting toxicities of fatigue, diarrhea, and anorexia for the oral formulations, and myelosuppression for the intravenous formulations. Expanded phase II experiences with vorinostat confirmed single-agent activity in HL-transformed lymphomas and CTCL. These data gave rise to pivotal studies in CTCL, leading to FDA approval in 2006.

Romidepsin is a potent macrolide HDAC inhibitor isolated from *Chromobacterium violaceum*. An early phase I–II trial demonstrated that romidepsin exhibited marked single-agent activity in patients with relapsed or refractory CTCL and PTCL. In fact, among 47 patients with relapsed or refractory PTCL, excluding patients with transformed MF and HTLV-1 ATL, which were included in the PROPEL study, an ORR of 38% was noted, including eight patients who attained a CR. The most common toxicities were very similar to those reported for vorinostat and included nausea, fatigue, and transient thrombocytopenia. The median duration of response was roughly 8.9 months, and responses were seen in most of the PTCL subtypes studied. These data gave rise to an international, open-label, pivotal phase II study of romidepsin in patients with relapsed or refractory PTCL who had received at least one line of prior therapy. Of the 131 patients enrolled, 130 had histologically confirmed PTCL. The median number of prior therapies was 1, with a range of 1 to 8. The ORR was 25%, which included 19 (15%) CRs, and the median duration of response was 17 months. These data led to a conditional approval of romidepsin in patients with relapsed or refractory PTCL by the FDA in June of 2011.

In 2014 belinostat became the third HDAC inhibitor approved for the treatment of cancer, specifically patients with relapsed or refractory PTCL. Belinostat is a hydroxamic-based pan class I and II HDAC inhibitor. It is currently approved for patients with relapsed or refractory PTCL who have received at least one line of prior therapy. The original phase II (CLN-6) trial included patients with various subtypes of T-cell lymphomas (TCLs; $n = 24$), and produced an ORR of 25% in relapsed/refractory PTCL. This activity was the basis for initiating the BELIEF study, where 129 patients with relapsed and refractory disease received belinostat. The median number of prior therapies was 2. The ORR was 26% (11% CR; 15% PR), with a PFS and OS of 1.6 and 7.9 months, respectively, and a median duration of response of 13.6 months. Forty-six percent of patients with AITL experienced a response.

Recent data have now suggested that pralatrexate potentially synergizes with other HDAC inhibitors in models of T-cell lymphoma. These data are now being used as a rationale to support a multicenter phase I study that will define the maximum tolerated dose of this

regimen, and then the tolerability and activity in a subpopulation of patients with PTCL.

Brentuximab Vedotin

Monoclonal antibodies have emerged as potentially important new therapeutic tools in the treatment of many subtypes of NHL. Monoclonal antibodies are now being developed against a host of other cell surface proteins, including the chemokine receptor CCR4, and other surface proteins such as CD4 and more recently CD30. CD30 (also known as *TNFRSF8*) is a 120-kD transmembrane protein of the tumor necrosis factor family and a known tumor marker found on many kinds of lymphoma. The receptor is found on the surface of only activated T cells, and some B cells. CD30 is found on virtually all cases of ALCL, and the majority of cases of Hodgkin lymphoma (HL), where it is seen on the surface of the Reed-Sternberg cell. It is also expressed by several nonlymphoid malignancies, including embryonal carcinoma and some cases of non-small-cell lung cancer. Clinical trials with the chimeric anti-CD30 monoclonal antibody were uniformly disappointing in patients with ALCL and HL. For example, among 38 patients with HL and 41 patients with ALCL treated with SGN-30, no responses were seen in patients with HL, whereas two patients with ALCL achieved a CR. Similar results have been reported with other anti-CD30 monoclonal antibodies.

Conjugation of small molecules to highly targeted monoclonal antibodies to create an antibody–drug conjugate offers a promising way to deliver highly toxic drugs to select populations of cells. The conjugation of a highly potent antimicrotubule agent, monomethyl auristatin E to the anti-CD30 monoclonal antibody creates a novel antibody–drug conjugate called *SGN-35*, or *brentuximab vedotin*. Clinical trials of this drug in patients with HL and ALCL have demonstrated remarkable activity in these CD30-expressing diseases. A pivotal trial of brentuximab vedotin in patients with relapsed or refractory ALCL produced an ORR of 86%, with a CR rate of 57%. These remissions were found to be very durable, with a median response duration of 12.6 months and a median duration of response among patients in CR of 13.2 months. The majority of patients enrolled in the study exhibited poor prognostic features: 72% of patients had ALK-negative ALCL, 63% of patients were refractory to front-line therapy, and 22% of patients had never responded to any prior therapy. These results recently led the FDA to grant accelerated approval to brentuximab vedotin in patients with ALCL. A subsequent experience in non-ALCL PTCL ($n = 35$ patients), essentially restricted to PTCL-NOS and AITL, revealed an ORR of 41% (24% with a CR), with a median PFS and duration of response of 2.6 months and 7.6 months, respectively. Ongoing studies are now exploring the benefits of this drug in combination with standard upfront chemotherapy regimens such as CHOP.

KW-0761

Another novel cell surface protein for which there is now a targeted drug is the CCR4 chemokine receptor, which is encoded by the *CCR4* gene. CCR4 has also recently been designated *CD194*. The CCR4 protein belongs to the G-protein–coupled receptor family and is a receptor for many different cytokines that influence the behavior of leukocytes. CCR4 is known to be expressed on Th2 cells and regulatory T cells. Several studies have demonstrated that CCR4 is expressed at relatively high levels on select T-cell neoplasms, including HTLV-1 ATLL. KW-0761 is a defucosylated humanized IgG1 anti-CCR4 monoclonal antibody that enhances antibody-dependent cellular cytotoxicity and has been evaluated in multicenter phase I and II studies in patients with relapsed, aggressive CCR4+ ATL.

Patients received intravenous infusions of KW-0761 once a week for 8 weeks at a dose of 1.0 mg/kg. The phase II study of KW-0761 was conducted in 28 patients with relapsed or refractory ATL. The overall RR was 50%, including eight complete responses, and the median PFS and OS were 5.2 and 13.7 months, respectively. The

most common adverse events were infusion reactions (89%) and skin rashes (63%), which were manageable and reversible in all cases. Albeit relatively early, this study demonstrated clinically meaningful antitumor activity in patients with relapsed aggressive ATL, with an acceptable toxicity profile. Another study in 2014 evaluated 37 patients with relapsed CCR4+ PTCL. The authors noted objective responses for 35% of the patients including 14% with a CR. The ORR was 34% in patients with PTCL (three of 16 for PTCL-NOS, six of 12 for AITL, and one of one for ALCL, ALK negative). The median PFS and OS for patients with PTCL were 2 months (8.2 months for PTCL responders) and 14.2 months, respectively. Interestingly, the total ORR did not significantly correlate with CCR4 expression level. Further investigation of KW-0761 for treatment of ATL and other T-cell neoplasms are now warranted.

Miscellaneous Agents

The drugs mentioned earlier all represent agents that have been studied in a reasonable number of patients with T-cell lymphoma, and have been approved by regulatory agencies for select diseases. In addition to these there are other agents with very early and potentially promising signals of activity in PTCL.

Proteasome Inhibitors

The proteasome inhibitors, including bortezomib and carfilzomib, have marked activity in multiple myeloma and mantle cell lymphoma. Although the experience in PTCL is modest, 10 patients with CTCL and two with PTCL were treated with bortezomib at a dose of 1.3 mg/m² on a day 1, 4, 8, and 11 schedule. Although the ORR was reported to be 67%, dramatic responses were seen in patients with advanced CTCL, and one of the two patients with PTCL experienced a CR. Emerging data have now demonstrated that the proteasome inhibitors potently synergize with the HDACIs and pralatrexate, which is now leading to combination studies in patients with PTCL.

Immunomodulatory Drugs

Another novel class of drugs with a signal of activity in the T-cell lymphomas includes the immunomodulatory drug lenalidomide. This class of drugs is thought to increase the immunologic synapse by increasing NK cell activity against the lymphoma cells. In one report, lenalidomide was administered orally for 21 days on a 28-day cycle at a dose of 25 mg daily in 24 patients with relapsed or refractory PTCL with an ORR of 30% being reported (seven responses among 23 evaluable patients), with no CR. Responses were seen in patients with ALCL, AITL, and PTCL-NOS. The median PFS was 96 days. Similar results were reported among 10 patients with relapsed and refractory PTCL-NOS, where three CRs were reported.

Alisertib (Aurora A Kinase Inhibitor)

Preliminary reports from a phase II study of a novel aurora A kinase inhibitor, MLN8237/alisertib, in patients with aggressive NHL have recently demonstrated activity in patients with PTCL. An initial phase II trial of alisertib in patients with B- and T-cell lymphoma demonstrated an ORR of 27%, and in eight patients with PTCL, a RR of 50%. Recently, SWOG-1108 evaluated alisertib in 37 patients with PTCL in the relapsed and refractory setting. In this study, Barr et al reported two CRs and seven PRs, with an ORR of 24% and 33%, respectively, for the most common subtypes (PTCL-NOS, AITL, and ALCL). The LUMIERE trial, which is a phase III study of alisertib versus investigator's choice (pralatrexate, romidepsin, gemcitabine) in relapsed/refractory PTCL has recently closed and we eagerly await these results.

Bendamustine

The BENTLY trial evaluated bendamustine in 60 patients with relapsed or refractory PTCL. The ORR was 50%, including a CR rate of 28% and a PR rate of 22%. The drug showed consistent efficacy independent of major disease characteristics. The median

PFS and duration of response were 3.6 and 3.5 months, respectively.

Sorafenib

Sorafenib is a multikinase inhibitor that modulates multiple intracellular pathways, including PDGFR/VEGFR and MAP kinase signaling. One report evaluated sorafenib in 12 patients with T-cell lymphomas (three with PTCL and nine with CTCL). While the population was not that heavily treated (median number or prior treatments = 2), three achieved a CR and one underwent aSCT. The median EFS for the entire cohort was 3.5 months. At a median follow-up of 11.2 months, 10 patients were alive (83%) and disease stabilization or reduction was noted in 75% of patients.

Duvelisib

Duvelisib (IPI-145) is an oral inhibitor of PI3K- δ and - γ . Mutation in PI3K has been found to be a recurring finding across all of cancer biology, as this pathway plays a critical role regulating many cellular processes including cell survival, proliferation, and differentiation. PI3K- δ and PI3K- γ isoforms are preferentially expressed in leukocytes with distinct roles in T-cell function. A phase I trial of duvelisib was performed which included 16 patients with PTCL. The median number of prior therapies was four. Of the 31 patients evaluable, an ORR of 42% was observed and in PTCL, the ORR was 47%, with two CRs and five PRs.

Plitidepsin

Plitidepsin is a cyclic depsipeptide originally isolated from the tunicate *Aplidium albicans* and is commercially produced by chemical synthesis. It displays a broad spectrum of anticancer activities, including induction of apoptosis and G1/G2 cell cycle arrest. Plitidepsin has demonstrated reproducible activity against a variety of malignant cell lines, including leukemias and lymphomas. A phase II trial evaluated plitidepsin in 67 patients, which included 34 patients with relapsed/refractory noncutaneous PTCL. Of the 29 evaluable patients with noncutaneous PTCL, six patients demonstrated an objective response to plitidepsin (two CRs and four PRs; ORR = 20.7%) with a median PFS and duration of response of 1.6 and 2.2 months, respectively.

FUTURE DIRECTIONS

Over the past several years there has been a remarkable increase in our understanding of the diversity within the PTCLs. The appreciation that the mature T-cell lymphomas represent a vast spectrum of both indolent and aggressive subtypes, commonly associated with diverse clinical pictures with substantial global variation, has shaped how we now classify and think about these diseases. Even prognosticating the outcomes of patients with these diseases has become remarkably complicated, because each subtype of PTCL is now widely recognized as possessing its own unique clinical behavior and thus its own unique response to different therapeutic approaches. Eventually these prognostic models will be used to better risk-stratify patients at diagnosis, allowing physicians to institute an optimal treatment plan earlier, which may include ASCT for select patients and aSCT for those with relapsed or refractory disease.

Unquestionably, however, the increase in the number of new drugs available for the treatment of this group of diseases has begun to reshape our options when considering the management of patients with relapsed or refractory disease. As these new drugs are used with increasing frequency, each having significant single-agent activity in these traditionally chemotherapy-resistant diseases, the emergence of novel non-CHOP-based drug combinations will likely emerge. Perhaps most exciting is the recent demonstration that combinations of these agents are associated with marked synergy in the preclinical setting, including combinations of drugs such as pralatrexate and romidepsin, hypomethylating agents and HDAC inhibitors, and aurora A kinase inhibitors, and romidepsin, many of which are being translated to the clinical setting with early promise of tolerability and

marked activity. It is likely that a systematic analysis of agents with lineage-specific activity in PTCL will form the basis of novel, PTCL-specific treatment platforms that will create future non-CHOP-based opportunities for front-line care.

CUTANEOUS T-CELL LYMPHOMAS

This portion of the chapter focuses on the disorders that would be encompassed by the diagnosis *cutaneous T-cell lymphoma* (Table 85.4). The most common subtypes of CTCLs are the epidermotropic variants MF and the related leukemic variant, Sézary syndrome (SS).

Epidemiology

CTCLs account for 71% of the 3844 cutaneous lymphomas diagnosed in the United States between 2001 and 2010. MF and SS are the most common CTCL subtypes worldwide, constituting 54% of

TABLE 85.4 Comparison of EORTC and WHO Classifications of Primary Cutaneous Lymphoma

EORTC Classification	WHO Classification
Cutaneous T-Cell Lymphoma	
Indolent clinical behavior	Mycosis fungoides
Mycosis fungoides variants	Mycosis fungoides variants
Follicular mycosis fungoides	Follicular mycosis fungoides
Pagetoid reticulosis	Pagetoid reticulosis
CTCL, large cell, CD30 ⁺	Primary cutaneous CD30 ⁺ ALCL (CD30 ⁺ lymphoproliferative disease, including lymphomatoid papulosis)
Lymphomatoid papulosis	
Aggressive clinical behavior	
Sézary syndrome	Sézary syndrome
CTCL, large cell, CD30 ⁻	Peripheral T-cell lymphoma, unspecified (most); extranodal NK/T-cell lymphoma, nasal type
Provisional Entities	
CTCL, pleomorphic, small/medium sized	
Subcutaneous panniculitis-like T-cell lymphoma	Subcutaneous panniculitis-like T-cell lymphoma
Cutaneous B-Cell Lymphoma	
Indolent clinical behavior	Extranodal marginal zone B-cell lymphoma
Primary cutaneous immunocytoma (marginal zone B-cell lymphoma)	
Follicle center cell lymphoma (any grade)	
Intermediate clinical behavior	
Primary cutaneous large B-cell lymphoma of the leg	
Provisional Entities	
Primary cutaneous plasmacytoma	Plasmacytoma
Intravascular large B-cell lymphoma	Diffuse large B-cell lymphoma (intravascular)

ALCL, Anaplastic large-cell lymphoma; CTCL, cutaneous T-cell lymphoma; EORTC, European Organization for Research and Treatment of Cancer; NK, natural killer; WHO, World Health Organization.

the CTCLs and an annual incidence of approximately four cases per million people. MF and SS are the most common primary lymphomas involving the skin. Data collected from the SEER program showed a rapidly increasing incidence from 0.2 cases per 100,000 people in 1973 to 0.4 cases per 100,000 people in 1984. This increasing trend has stabilized in the last decade, with an incidence of 10.2 new annual cases per million during the period 2005–2009 (PMID: 24005876).

Whether this represented a true increase in incidence or was attributable to a better awareness and therefore more frequent recognition of this disease has not been resolved. Since that time the incidence rate of CTCL has stabilized at 0.36 cases per 100,000 persons, and the mortality rate has declined. The incidence of MF/SS increases with advancing age, as does the incidence of NHLs in general. The average age at presentation is approximately 50 years. Although cases in very young patients have been reported, most patients are at least 30 years of age. MF/SS is seen in all racial groups. There is a 1.6:1 ratio of African-Americans to whites and a 2.2:1 ratio of men to women with this disorder. MF is less common in the Asian population. Identification of clusters of CTCL in certain geographic regions has been reported using two distinct cancer registries (PMID: 25728286; PMID: 25046454).

Clusters of cases of MF/SS within families have been reported. An association with histocompatibility antigens AW31, AW32, B8, BW35, and DR5 has been described. However, a solid genetic predisposition or inherited genetic defect has not been demonstrated.

Pathobiology

The T lymphocyte is central to the body's ability to mount an immune response and is the precursor of neoplastic cells in MF/SS. Sézary cells respond to phytohemagglutinin and perform T-cell immunoregulatory functions similar to normal lymphocytes. The clonal nature of CTCL has been demonstrated by Southern blotting or polymerase chain reaction methods for analysis of the TCR.

The development of monoclonal antibodies directed against different T-cell antigens has allowed for more precise identification of surface markers on the malignant T cells. Most cases of MF and SS are comprised of the helper memory or effector T cells with a CD4⁺CD45RO⁺ phenotype. In most instances, the cells express the pan-T-cell antigens CD2 (the sheep erythrocyte receptor), CD3, and CD5. CD7 is a T-cell marker expressed in early differentiation, but usually absent in T-cell homing to the skin. Although benign conditions may show some downregulation of CD7, marked deletion of CD7 is commonly used by the pathologist as an ancillary confirmatory test for CTCL. Flow cytometry provides a sensitive method for detecting early peripheral blood involvement in patients by detection of CD4⁺CD26[−] T-cell populations. A small subset of MF is characterized by the expression of CD8, a marker that is essentially never expressed in SS. Low expression of the α -chain component of the IL-2 receptor (CD25) is detected with heterogeneous expression by the malignant cells in less than half of the patients. The implication of this finding is of uncertain significance, because both activated T cells and immunoregulatory T cells can express CD25. Key signaling pathway alterations that affect MF and SS include Notch overexpression, Fas underexpression, and the association of PKC inhibition with apoptosis. Also of particular relevance is the observation of increased expression of programmed death-1 (PD-1) on SS cells, compared with CD4⁺ cells from healthy volunteers and from MF patients, likely contributing to the impaired immunity (antitumor and antiinfectious) noted in SS patients. Overexpression of KIR3DL2 (CD158k) has also been observed in SS and advanced MF, and may assist in distinguishing CTCL cells from normal ones, but more important, it may have targeted therapeutic implications. Increased mRNA expression of *PLS3*, *DNM3*, and *TWIST1* have also been reported in most cases (PMID: 18033314).

Cytogenetic analyses have demonstrated numeric and structural chromosomal abnormalities in MF/SS, although usually in advanced-stage disease. Hyperdiploidy and complex karyotypes are common.

Nonrandom deletions of chromosomes 1p, 6, 8, 9p10q, and 17p have been reported, with gains in chromosome 17q and 4p occurring in more than 25% of cases. Regions of the genome that include genes encoding the TCR do not appear to be involved, suggesting that the genetic basis for malignant transformation in MF/SS appears to be different from that involved in other T-cell malignant disorders.

Modest data exist on the aberrant expression of oncogenes and suppressor genes in MF/SS. Loss of heterozygosity is identified in 30%–60% of patients, commonly at 9p, 10q, 1p, and 17p. Loss of heterozygosity in early stages of disease is associated with a threefold increase in mortality. Various mutations involving the Fas pathway are commonly seen from the early stages of lymphomagenesis, reflecting an initial accumulation of abnormal lymphocytes secondary to abnormal proapoptotic pathways. Mutant forms of the *p53* tumor suppressor gene are rarely observed, usually in tumor stage and large-cell transformation of MF. LYT-10, a member of the NF κ B family of transcription factors associated with translocations in lymphoid malignancies, is rearranged in a small proportion of cases. However, *BCL2*, a gene whose rearrangement is characteristic of follicular B-cell lymphomas and which slows programmed cell death, is overexpressed in MF. Constitutive phosphorylation of STAT3 (a member of the transcription factor family that contributes to the diversity of cytokine responses) has been reported and suggests that these malignant T cells are activated. Altered expression or release of select cytokines or their receptors, including IL-1, IL-2R, IL-4, IL-5, IL-6, IL-7, IL-8, IL-12, and TGF- β receptor II, has been noted. IL-7 and IL-15 have been identified as growth factors for MF/SS and shown to regulate expression of the *BCL2* and *MYB* oncogenes and stimulate DNA binding of STAT proteins. NF κ B has also been demonstrated to be constitutively activated in CTCL and leads to transcription of antiapoptotic genes (e.g., *Bcl-2*, *cIAP1*, and *cIAP2*), proinflammatory genes, and antiinflammatory genes, resulting in increased survival and the immunosuppressive nature of CTCLs. Constitutive activation of c-Jun N-terminal kinases (JNKs) and JAK may lead to elevated levels of VEGF, resulting in increased angiogenesis. Massive parallel targeted sequencing of a set of 524 genes from CTCL samples revealed frequent mutations of the NF κ B, JAK/STAT, and PLC pathways. Three samples harbored mutations of *PLCG1*, the gene that encodes for phospholipase C, gamma 1. Further analysis of another cohort of samples from 42 CTCL patients revealed the presence of *PLCG1* S345F mutation in 19% of the cases and was associated with increased signaling of calcineurin/nuclear factor of activated T cells (NFAT). In vitro inhibition of PLC and calcineurin led to decreased cell proliferation and increased apoptosis in mutant cells. There is also evidence of the role of the mTOR-containing complex 1 (mTORC1) pathway in CTCL pathogenesis, along with evidence to support the beneficial role of its inhibition simultaneously with inhibition of MNK kinase. Various cancer-testis antigens, normally observed only in testicular germ cells, appear to be ectopically expressed in CTCL, as does B-lymphoid tyrosine kinase (Blk), a member of the Src kinase family, which is normally only expressed in B cells and thymocytes. Supporting the tumorigenic role of Blk, there was antitumor activity of dasatinib, a Src kinase inhibitor, within a Blk⁺ CTCL cell line and a xenograft mouse model. There is recent evidence suggesting that SS and MF may follow different molecular pathways with dysregulation of genes encoding c-Myc and c-Myc regulatory proteins commonly associated with SS but not with MF.

The cause of MF/SS remains unknown. It is considered to be a sporadic disease without compelling evidence of transmissibility. Several viruses have been implicated in the pathogenesis of MF/SS, including HTLV-1 and HTLV-2, herpes simplex virus, human herpesvirus 6, and EBV. However, a viral cause of MF/SS has not been proven, and no epidemiologic evidence supports these hypotheses (PMID: 23806159).

Investigators have suggested that prolonged antigenic stimulation via exposure to contact allergens or superantigen stimulation associated with infections may lead to enhanced immune responses, with subsequent mutations in apoptotic pathway leading directly or indirectly to the development of MF/SS. Sézary cells respond in vitro to superantigenic exotoxins, and colonization by *Staphylococcus aureus*

may influence disease activity. Several reports suggested that exposure to metals or their salts, pesticides or herbicides, and organic solvents (halogenated or aromatic hydrocarbons) could be related to the development of MF/SS. However, two well-designed case-control studies have failed to support these observations.

Various theories have been advanced to explain the epidermotropism of malignant T cells in MF/SS. Organ-specific affinity to skin and other organs has been recognized in subsets of normal T cells. Homing of CTCL cells to the skin is probably mediated by more than one adhesion receptor mechanism. CTCL cells express cutaneous lymphocyte antigen, a skin-homing receptor that interacts with E-selectin expressed by dermal venules. Furthermore, the cutaneous lymphocyte antigens T lymphocytes also typically express the CCR4 chemokine receptor, which binds to chemokines produced by the skin, such as the CC-chemokine ligands 17 and 22. Peripheral blood mononuclear cells bind to cultured keratinocytes exposed to IFN- γ . The major histocompatibility complex class II proteins along with intercellular adhesion molecule 1 present on keratinocytes, and attract and bind lymphocytes. Additional chemokine receptors, such as CXC chemokine receptors 3 and 4, as well as unique integrins, have been shown to have corresponding ligands or integrin receptors on dermal Langerhans cells, suggesting a relationship between the malignant T cells and host immune cells. The chemokine receptor CCR4 is expressed by a spectrum of CTCL cells, and an anti-CCR4 monoclonal antibody has significant activity against these diseases.

An additional feature of MF/SS cells is the production of a cytokine profile consistent with Th2 cells. Th2 cells produce IL-4, IL-5, and IL-6, and they are inhibited by IFN- γ . The expression of immunomodulatory molecule IL-17 is also increased in MF and SS. Th2 cells are critical for stimulating antibody- and eosinophil-mediated responses. Hypergammaglobulinemia and eosinophilia are occasionally seen in advanced cases of MF/SS and are consistent with a Th2 profile. Stimulation of Th2 cells inhibits the Th1 subpopulation of lymphocytes involved in cell-mediated immunity. Progression of MF/SS is associated with immune suppression as a result of depletion of this T-cell subset. The Th2 cytokine profile may explain the decrease in tumor-infiltrating lymphocytes during tumor progression. In addition to the effect of cytokines secreted by the neoplastic cells, malignant CD4⁺ cells express antigens (e.g., Fas ligand) that may directly mediate elimination of the CD8⁺-infiltrating lymphocytes by induction of apoptosis. CD4⁺ T cells from MF skin lesions have an effector memory phenotype, whereas T cells from SS skin lesions display central memory characteristics with the expression of the lymph node chemoattractant CCR7, which is not expressed in MF.

Clinical Presentation

Alibert reported the first case of MF in 1806. His patient developed a skin eruption that progressed into mushroom-like tumors, prompting the term *mycosis fungoides*. Later in the 19th century, Bazin defined the three classic cutaneous phases (patch, plaque, and tumor stage) of the disease. The recognition of the clinical triad of intensely pruritic erythroderma, lymphadenopathy, and abnormal hyperconvoluted cells in the peripheral blood led to the description of SS.

MF is the prototype of CTCL observed in over 50% of CTCL cases. The initial course of patients with MF is usually indolent. Most patients give a history of antecedent skin lesions, usually non-specific erythematous patches that can mimic eczema or psoriasis. In many cases, there is an orderly progression from limited patches to more generalized patches, plaques, tumors, and nodal or visceral involvement. However, some patients may present with extensive skin involvement and tumor lesions, whereas other patients have limited patch disease that remains unaltered for the patient's entire life. The characteristic patch lesion is typically well demarcated with fading edges, lightly erythematous, and scaly, with a predilection for sun-protected areas, such as the lower abdomen or buttocks (Fig. 85.10). The texture can vary from poikilodermatous atrophic cases to serpiginous annular lesions or markedly keratotic patches. Plaque lesions are more indurated, have fairly well-demarcated margins, and

Fig. 85.10 ERYTHEMATOUS AND SCALY PATCH LESION OF MYCOSIS FUNGOIDES.

Fig. 85.11 PLAQUE LESION OF CUTANEOUS T-CELL LYMPHOMA.

some scaling (Fig. 85.11). Plaques can arise from patch lesions or previously uninvolved areas of skin. The distinction between a patch and a plaque is often subjective, with a low rate of interpersonal agreement among experts. Tumor lesions tend to appear in advanced cases, frequently associated with previous patches or plaques, and are

commonly associated with histologic evidence and large-cell transformation. They can be located on any part of the body. Ulceration of these lesions is common, and secondary infection is a major cause of morbidity (Fig. 85.12). Tumors may be the initial presentation in a small percentage of patients (d'emblée presentation, Vidal and Brocq, 1889).

SS patients present with generalized desquamative erythroderma, pruritus, and circulating malignant cells. Peripheral blood usually shows a significant number or percentage of hyperconvoluted atypical lymphocytes (Fig. 85.13). Approximately 5%–10% of all newly reported cases of CTCL are SS. In its most advanced form, patients with SS suffer from alopecia, ectropion, leonine facies, hyperkeratosis, nail dystrophy, fissuring of the palms and soles, and severe pruritus and cutaneous pain. Many other entities can clinically mimic this disease, including drug eruptions, atopic dermatitis, contact dermatitis, and erythrodermic psoriasis. A number of variant presentations of CTCL are described in the following sections.

Cutaneous Lymphoid Dyscrasias (Clonal Dermatitis)

Cutaneous lymphoid dyscrasias or clonal dermatitis, which include a variety of lymphocyte-rich dermatoses, are often characterized by clonal T-lymphocyte proliferations that occasionally progress to bona fide mycosis fungoides. Clinically they exhibit a myriad of cutaneous presentations from poikiloderma (atrophic patches) to hyperpigmented areas resembling pigmented purpuric dermatosis or an acneiform presentation of follicular mucinosis.

Fig. 85.12 ULCERATED TUMORS ARISING FROM MYCOSIS FUNGOIDES PLAQUES.

The term *large-plaque parapsoriasis* has also been traditionally used for these types of poorly defined lesions that may evolve into MF. It most commonly consists of a few scattered, erythematous-to-brown plaques that are usually larger than 6 cm. There is a predilection for the buttocks and intertriginous areas. Histologic examination shows a superficial lymphocytic infiltrate with minimal nuclear atypia. Epidermotropism is scant or absent, and dermal fibrosis correlates with the chronicity of the process. Plaques can persist for decades before a frank evolution to MF occurs. Approximately 10%–30% of patients ultimately develop an overt malignant transformation. Large-plaque parapsoriasis is more likely to evolve into MF than small-plaque lesions.

Idiopathic Follicular Mucinosis

Follicular mucinosis is also considered a variant of cutaneous lymphoid dyscrasias that manifests with grouped erythematous follicular papules or boggy or indurated nodular plaques, notably devoid of hair (Fig. 85.14). There is a predilection for the head and neck area, especially the forehead, which has the highest density of pilosebaceous units. Histopathologic evaluation reveals cells in sebaceous glands often associated with destruction of hair follicle structures due to infiltration by a T-lymphocytic process. This idiopathic condition can evolve or be associated with folliculotropic MF. Even idiopathic cases

Fig. 85.14 FOLLICULAR MUCINOSIS SHOWING A PATCH OF ALOPECIA WITH FOLLICULAR PROMINENCE.

Fig. 85.13 SÉZARY CELLS. Peripheral smear (A) with Sézary cells associated with eosinophilia. Note the cerebriform nuclei with fine chromatin (B–D). The hyperconvoluted nature of the nuclei is evident as complex nuclear folds seen through the chromatin.

can be associated with clonal T-lymphocytic infiltration. In general, patients older than 40 years with a more generalized cutaneous involvement and a chronic course are more likely to develop associated MF. No cases of MF have been reported in children with alopecia mucinosa, although a few reports of HL have been reported in children with follicular mucinosis. Patients with folliculotropic MF and follicular mucinosis are reported to have a worse prognosis, stage for stage, which may be caused by inability of topical treatment to penetrate to the deeper layers of the process.

Lymphomatoid Papulosis

Lymphomatoid papulosis (LyP) is characterized by recurrent crops of self-healing, red-brown, centrally necrotic, asymptomatic papules and nodules (Fig. 85.15). This entity represents 10%–15% of all CTCL cases. Patients may have a few lesions or more than 100 at a time. Histologic evaluation reveals an atypical CD4⁺ lymphocytic infiltrate with a variable mixed inflammatory infiltrate (Fig. 85.16). These may be primarily small cerebriform cells similar to those seen in MF (type B), but most often there are larger CD30⁺ cells with prominent nucleoli resembling Reed-Sternberg cells (type A). A third variety of LyP (type C) with sheets of anaplastic large cells resembling CD30⁺ large-cell lymphoma (CD30⁺ LCL) has also been reported. Lately other subtypes have been reported. Type D, commonly seen in the pediatric population, is characterized by pagetoid or highly epidermotropic small atypical lymphocytes with CD8 expression. Such cases may be difficult to distinguish from pityriasis lichenoides acuta (PMID: 22688398).

Type E LyP is characterized by hemorrhagic and necrotic lesions often showing evidence of vasculitis on histological evaluation (PMID: 23026936).

The prognosis of these new subtypes is not different to the other subgroups. *TCR* gene rearrangement studies demonstrate a clonal

Fig. 85.15 LESIONS OF LYMPHOMATOID PAPULOSIS APPEAR IN CROPS AND CONSIST OF ULCERATED PAPULES AND SCARS.

origin. Although the typical course is usually indolent, spanning decades, approximately 15% of patients develop MF, HL, or NHL during their lifetime. A direct link between LyP, CTCL, and HL was demonstrated in a patient with the three lymphoproliferative disorders arising from a common T-cell clone, as shown by *TCR* gene studies.

Pagetoid Reticulosis

Pagetoid reticulosis (i.e., Worringer-Kolopp disease) is a rare condition affecting young adults. It typically manifests with a solitary, hyperkeratotic, often verrucous plaque on the lower limb. Biopsy results show atypical cerebriform lymphocytes with a perinuclear halo almost exclusively localized within the intraepidermal compartment. Extracutaneous dissemination is exceedingly rare. Most cases have a CD8⁺ phenotype, although CD4⁺ cases or double-negative (CD4⁺/CD8⁺) cases have been reported. Frequently the tumor cells express CD30, but *TCR* gene rearrangement study results are often negative. Whether pagetoid reticulosis should be considered a localized form of MF or a reactive pseudomalignant process is debatable. Although most cases have an indolent protracted course, generalized and sometimes aggressive variants have been reported. Cases presenting with a solitary lesion are extremely indolent and could be considered a reactive or pseudolymphomatous process. At the opposite end of the spectrum there are patients with extensive ulcerative plaques formerly known as *generalized pagetoid reticulosis* or *Ketron-Goodman disease* that are now diagnosed as the CD8⁺ aggressive intraepidermal T-cell lymphoma.

Granulomatous Slack Skin

In granulomatous slack skin syndrome, an extremely rare disorder, clonal CD4⁺ T cells elicit a reactive granulomatous response that destroys the elastic fibers, rendering skin slack, fibrotic, and inelastic (Fig. 85.17). Changes characteristic of MF are often found within the epidermis and papillary dermis, and the reticular dermis contains numerous histiocytes with multinucleated giant cells and elastophagocytosis. Some patients with granulomatous MF do not have destruction of the elastic fibers with slack skin changes. The differential diagnosis includes sarcoidosis and tuberculoid leprosy. An increased incidence of HL has been reported in this patient population.

Laboratory Manifestations

The gold standard in the diagnosis of MF/SS is light microscopic examination of a skin biopsy specimen. Characteristic findings include a band-like infiltrate involving the papillary dermis containing small, medium-sized, and occasionally large mononuclear cells with hyperchromatic, hyperconvoluted (cerebriform) nuclei, and

Fig. 85.16 LYMPHOMATOID PAPULOSIS. Low power (A) shows a moderately dense dermal infiltrate of lymphoid cells admixed with inflammatory cells, including neutrophils and eosinophils (B). The lymphoid cells are varied but include atypical large forms (C), which are brightly positive for CD30 (D). (Courtesy Drs. Vesna Petrovic-Rosic and Mark Racz, University of Chicago.)

variable numbers of admixed inflammatory cells often expanding into adnexal structures (hair follicles and sweat glands). Epidermal exocytosis of single or small clusters of neoplastic cells is a characteristic finding (Fig. 85.18A, C, and D). The presence of Pautrier microabscesses, defined as four or more atypical lymphocytes arranged in an aggregate in the epidermis, is classic but is seen in only a minority of cases. Reticular fibroplasia of the papillary dermis is also a common finding. Tumor-stage lesions demonstrate a more diffuse, superficial, and deep dermal infiltrate with fewer reactive cells and an absence of epidermotropism (Fig. 85.18B, E, and F). The malignant T-cell clone often evolves into large-cell morphology during tumor progression, although rare cases show large-cell morphology from the early patch lesions. The presence of large cells in a skin lesion should be distinguished from “large-cell transformation,” which displays rapid skin, node, and visceral progression, is refractory to treatment, and is associated with poor survival. The histologic features in SS may be

Fig. 85.17 LESIONS OF GRANULOMATOUS SLACK SKIN WITH DESTRUCTION OF THE DERMAL ELASTICITY.

similar to those of MF. However, the cellular infiltrates in SS are more often monotonous, and epidermotropism may be absent.

Lymph node involvement initially involves the paracortical regions. Progression is associated with small-to-large clusters of atypical cells with preserved nodal architecture, followed by partial or total effacement of the node by neoplastic cells. Visceral involvement is a late clinical feature. Variable peripheral blood involvement can be demonstrated in all stages of skin disease, although it is most prevalent in patients with tumor or erythrodermic presentations. Patients with SS present with large numbers of circulating neoplastic cells, typically more than 1000 cells/mL (B2), but a lower count may be noted initially (B1). Bone marrow biopsy results are typically negative. However, some involvement may be detected by flow cytometry in many cases of SS or advanced MF but rarely influences management outside an investigational setting. A staging bone marrow aspirate and biopsy is not recommended, unless unexplained cytopenias are seen.

The malignant cells are typically CD3⁺, CD4⁺, CD45RO⁺, CD8⁺, and CD30⁺ by immunohistochemical analysis. CD7 is not expressed by cells from the early disease stages. More aggressive variants and advanced forms of CTCL may have cells with multiple pan-T-cell antigen deletions, especially CD2, CD5, and even CD4. *TCR* genes are clonally rearranged and can be documented in most cases by Southern blotting or polymerase chain reaction assays when a sufficient malignant infiltrate exists.

Analysis of peripheral blood may reveal an elevated LDH level, mostly in patients with high-blood-burden SS and bulky advanced MF. Eosinophilia and hypergammaglobulinemia are occasionally observed in advanced SS. In addition, several reports of SS and other CTCL variants have been reported to be associated with B-cell lymphoproliferative conditions, or small peripheral B-cell clones or monoclonal gammopathy (PMID: 19481294). Elevated serum β_2 -microglobulin and IL-2 receptor levels have also been observed in advanced cases.

Imaging studies for classic MF/SS are generally of modest utility. Computed tomographic scans of the chest, abdomen, or pelvis should be reserved for patients with SS, nodal involvement, or CTCL variants. In an investigational setting, electron microscopy, cytogenetics, and molecular analyses have shown that a higher percentage of patients have occult involvement of internal organs.

Fig. 85.18 MYCOSIS FUNGOIDES, PLAQUE STAGE, AND TRANSFORMED TUMOR STAGE. Plaque stage (A, C, D) demonstrates a band-like infiltrate (A, C) with some epidermotropism in the form of Pautrier microabscesses (D). In the tumor stage (B, E, F) there is a deep and dense infiltrate without significant epidermotropism. The cells are mostly large and atypical (E, F) and CD30⁺ (not shown). (Courtesy Drs. Vesna Petrovic-Rosic and Mark Racz, University of Chicago.)

Differential Diagnosis

Primary CTCL represents a heterogeneous group of disorders with considerable variability in histologic characteristics, phenotype, and prognosis. The Kiel Classification, the Working Formulation, and the Revised European-American Lymphoma (REAL) classification system were developed for NHLs and were not designed to provide an adequate characterization of the spectrum of CTCLs. To address the deficiencies of the previously proposed systems, a more clinically useful classification was developed by the European Organization for Research and Treatment of Cancer (EORTC). WHO has proposed a classification with nearly 90% concordance with the EORTC classification (see Table 85.4). A number of other disorders in which malignant T cells infiltrate the skin should be distinguished from MF/SS. These disorders are discussed in the following sections.

CD30 Lymphoproliferative Disorders

CD30 lymphoproliferative disorders include LyP, primary cutaneous ALCL, and a spectrum of borderline cases. By definition, ALCL presents with single or multiple tumors measuring more than 2 cm and with a tendency for ulceration and steady growth. Borderline lesions are smaller but also tend to have a prolonged course, often with spontaneous resolution.

Lymphomatoid Papulosis

LyP is characterized by recurrent crops of self-healing, red-brown, centrally necrotic, asymptomatic papules and nodules. This entity represents 10%–15% of all CTCL cases. Patients may have a few lesions or more than 100 at a time. Histologic evaluation reveals an atypical CD4⁺ lymphocytic infiltrate with a variable mixed inflammatory infiltrate. These may be primarily small cerebriform cells similar to those seen in MF (type B), but most often there are larger CD30⁺ cells with prominent nucleoli resembling Reed-Sternberg cells (type A). A third variety of LyP (type C), also considered borderline ALCL, presents with sheets of large cells resembling CD30⁺ large cells. *TCR* gene rearrangement studies demonstrate a clonal origin. Although the typical course is usually indolent, spanning decades, approximately 15% of patients develop MF, cutaneous ALCL, and very rarely HL or NHL during their lifetime. A direct link between LyP, CTCL, and HL was demonstrated in a patient with the three lymphoproliferative disorders arising from a common T-cell clone, as shown by *TCR* gene studies.

CD30⁺ Cutaneous T-Cell Lymphoma

Primary cutaneous CD30⁺ LCL typically occurs in adults presenting with solitary or localized (ulcerating) nodules or tumors (Fig. 85.19). Regional lymph node involvement is seen in 25% of patients at

presentation. These primary cutaneous CD30⁺ LCLs are probably closely related to LyP, regressing atypical histiocytosis, and primary cutaneous HL. The tumor has a favorable prognosis, and often complete or partial spontaneous regression occurs. This is in contrast to primary noncutaneous CD30⁺ LCLs, which can be seen in children or adults and which carries a poor prognosis. These primary cutaneous lesions, in contrast to nodal or pediatric cases, have been shown to rarely have the chromosomal translocation t(2;5) associated with overexpression of ALK (ALK negative). Histopathology consists of diffuse nonepidermotropic infiltrates with cohesive sheets of large CD30⁺ tumor cells (Fig. 85.20). In most instances, the tumor cells have anaplastic morphologic characteristics, showing round, oval, or irregularly shaped nuclei; prominent (eosinophilic) nucleoli; and abundant cytoplasm. Less commonly, the neoplastic cells have a pleomorphic or immunoblastic appearance. Reactive lymphocytes are often present, but infiltrating eosinophils are often less conspicuous. The immunophenotype of this disorder is characteristically CD4⁺, with more than 75% of neoplastic cells expressing CD30. In contrast to the poor outcome of MF that has transformed to a CD30⁺ large-cell variant, primary cutaneous CD30⁺ LCLs are associated with an excellent prognosis. Radiotherapy is the preferred treatment for solitary or localized disease, with combination chemotherapy reserved for patients with generalized skin lesions or extracutaneous dissemination. Surgical excision may be adequate in many cases. In advanced cases, 5-year survival exceeds 30%.

CD30⁺ Cutaneous T-Cell Lymphoma

These rare presentations often classified as CTCL, NOS, or d'emblée presentation, tend to have an aggressive clinical course. Patients present with localized or generalized plaques, nodules, or tumors.

Fig. 85.19 LESIONS OF CD30⁺ LARGE-CELL LYMPHOMA WITH ULCERATION.

Fig. 85.20 CUTANEOUS ANAPLASTIC LARGE-CELL LYMPHOMA. Sheets of tumor cells are present in the dermis (A) and are associated with marked pseudoepitheliomatous hyperplasia. The cells are quite varied and bizarre (B), and frequently show abnormal “embryoid” shapes (C) constituting the “hallmark” cells. There is bright staining with CD30 (D). ALK staining (not shown) is typically negative.

Histopathologic evaluation demonstrates that infiltrates are nonepidermotropic, with variable numbers of medium-sized to large pleomorphic T cells with or without cerebriform nuclei and immunoblasts. The tumor cells are CD4⁺, with CD30⁺ expression restricted to a few scattered tumor cells. The infiltrate is often accompanied by a mixed infiltrate with reactive B cells and granulomatous or histiocytic component. Multiagent chemotherapy is used in most instances, with radiation therapy reserved for patients with localized disease. The 5-year survival rate is less than 20%.

Pleomorphic Small- or Medium-Sized Cutaneous T-Cell Lymphoma

Pleomorphic small- or medium-sized CTCL is a rare entity. Patients typically present with a single red-purplish nodule or tumor involving the head and neck regions. Rarely are multiple nodules noted. The neoplastic cells are accompanied by many reactive B cells and histiocytes, which has led to the hypothesis that they may arise from a follicular T-helper cell population expressing BCL6, PD-1, and CD10. Typically, CD30 is negative, and CD4 expression is strong. TCR should be positive. In our opinion, cases presenting with a single lesion should not be diagnosed as having lymphoma; despite its clonal nature, the prognosis is invariably benign. These lesions were called *pseudolymphomas* in the past without significant consequences. However, patients presenting with multiple lesions are part of the d'embée presentation and should be approached more aggressively, including full staging and systemic therapy. Patients with more generalized disease have been treated with regimens used for indolent NHLs. Five-year survival rates are 100% in unilesional cases and exceed 60% in patients with more extensive disease.

Subcutaneous Panniculitis-Like T-Cell Lymphoma

Subcutaneous panniculitis-like T-cell lymphoma is a rare entity. Patients, typically younger and female, present with asymptomatic deep subcutaneous nonulcerated nodules and plaques involving the legs. Systemic symptoms are common, including fevers, fatigue, and anorexia. Overlapping or preceding signs of systemic lupus erythematosus or other autoimmune conditions are commonly observed. Histopathologic examination reveals a subcutaneous infiltrate with pleomorphic medium-sized T cells mixed with a reactive lymphoid infiltrate and some histiocytes. Tumor cell necrosis, karyorrhexis, and erythrophagocytosis are common findings. Differential diagnosis includes the frequently fatal but nonneoplastic cytophagic histiocytic panniculitis. Neoplastic infiltration of deep blood vessels can be noted in some cases. Immunophenotyping reveals postthymic T-cell markers with a CD8⁺ phenotype and expression of cytotoxic markers such as TIA-1 and granzyme B. By definition the tumor cells are negative for EBV markers and lack expression of the $\gamma\delta$ heterodimer. However, T-cell clonality including the γ - or β -gene is commonly identified. The prognosis is fairly good, with a 5-year survival rate over 80% with the exception of patients with a concurrent hemophagocytic syndrome (fevers, cytopenias). Cases in which the panniculitic findings coexist with systemic lupus erythematosus may behave in a clinically indolent fashion.

Primary Cutaneous $\gamma\delta$ -T-Cell Lymphoma

Cutaneous $\gamma\delta$ T-cell lymphoma is a rare condition that tends to present with extensive panniculitis-like plaques on the extremities with a tendency to ulcerate during the course of the disease. A subset of patients present with single lesions resembling an infectious process or with extensive chronic erythematous and scaly patches resembling MF. Several of our patients had comorbidities associated with immune suppression, including autoimmune conditions or other lymphoproliferative conditions or malignancies. Chronic antigen stimulation has been hypothesized to play a role in the pathogenesis

of cutaneous $\gamma\delta$ T-cell lymphoma. Patients often present with a high level of LDH and constitutional symptoms and succumb to the disease, often associated with hemophagocytic syndrome. For the most part, all therapies have shown modest effectiveness. Sustained remissions have not resulted from radiation, immune therapy, or multiagent chemotherapy. However, a case with CR for 23 months following aSCT has been reported. Cytotoxic features such as necrosis, hemorrhage, and vasculitis are commonly encountered. The immunophenotype is characterized by CD4/CD8 double negativity (with some CD8⁺ cases), lack of CD5 expression, and expression of cytotoxic granules.

Primary Cutaneous Aggressive Epidermotropic CD8⁺ T-Cell Lymphoma

This extremely rare condition, formerly known as *generalized pagetoid reticulosis* or *Ketron-Goodman syndrome*, constitutes less than 1% of all cutaneous lymphomas. The term *Berti lymphoma* is often used to refer to this condition. Men are affected more commonly, and patients present with extensive erosive patches with frequent mucosal involvement. Occasionally the lesions are exophytic and hemorrhagic, resembling pyogenic granuloma. The course is invariable and rapidly fatal with exceptional cases reported surviving following ASCT. Histologically the infiltrate is markedly epidermotropic and adnexotropic, infiltrating into hair follicles and sweat glands, eventually becoming hemorrhagic and ulcerated. The cells are also of intermediate size, always expressing CD8 as well as other T-cell markers such as CD7 and CD45RO.

Extranasal Natural Killer/T-Cell Lymphoma

EBV-induced extranasal NKTCLs rarely appear in the skin as the initial site of presentation. This condition is mostly reported in Asia and Latin America with rare cases seen in the United States. Although occasional cases remain localized in the skin, most of these lymphomas eventually involve other sites such as the testes or the gastrointestinal tract. A careful ear, nose, and throat evaluation to rule out nasopharyngeal involvement is important. The lesions are mostly large ulcerated tumor lesions with hemorrhagic and necrotic appearance. Histologically the tumor is composed of a deep infiltrate with intermediate-sized lymphocytes with cytotoxic changes, hemorrhage, and necrotic debris. A histologic landmark is the presence of angiocentric and angiodestructive features. The immunophenotype is characterized by the expression of CD3 ϵ in the cytoplasmic membrane, as well as CD56. Cytotoxic cytoplasmic granules are always identified, and EBV in the tumor cells can be demonstrated by the expression of EBER or LMP1. A lymphoproliferative disorder resembling hydroa vacciniforme has been reported almost exclusively in Latin America, especially in the Andes region, where the combination of high altitude with intense ultraviolet rays triggers this process, which is mostly seen in vulnerable indigenous patients. These patients present with facial edema, hepatosplenomegaly, and necrotizing hemorrhagic lesions triggered by sun exposure or an arthropod bite reactions. These conditions are associated with a very aggressive clinical course and patients often succumb to hemophagocytic syndrome. Multiagent chemotherapy has not been effective, and perhaps the only hope for these individuals is an ASCT.

Lymphomatoid Granulomatosis

Lymphomatoid granulomatosis is a rare multiorgan disease of the lungs, nasopharynx, joints, and peripheral and central nervous systems. Cutaneous involvement occurs in 25%–50% of patients. Although nodules are most common, some patients have nonspecific macules, papules, or ulceration. Histologic evaluation reveals an angiocentric, polymorphous infiltrate of atypical lymphocytes and histiocytes surrounding and invading blood vessels within the dermis.

Molecular and immunologic studies suggest a mature clonal helper T-cell process. However, reports have suggested a massive reactive T-cell infiltrate driven by a small number of clonal B cells.

EBV DNA sequences are frequently present, and their role in the pathogenesis of this disorder remains poorly defined. Although the clinical course is variable, the prognosis for patients with diffuse pulmonary involvement or evolution to high-grade lymphoma is poor, with a median survival of less than 2 years. Treatment depends on histologic findings and extent and location of disease, and may include corticosteroids, radiotherapy, and chemotherapy. IFN has shown significant activity against this disease. Related conditions include the recently reported EBV-induced mucocutaneous ulcer seen in immunosuppressed patients and B-cell lymphomas of older adults.

Adult T-Cell Leukemia

ATL is in most instances a rapidly progressive T-cell neoplasm expressing a helper phenotype that is described earlier in this chapter. It is endemic in southern Japan and the Caribbean islands, and is associated with the retrovirus HTLV-1. However, most HTLV-1-infected patients remain asymptomatic, and only 2%–4% develop ATL. The clinical presentation is polymorphous and can resemble MF or SS. Cutaneous lesions are variable, ranging from a rash simulating a viral exanthem, to annular lesions resembling erythema multiforme, to large tumors and plaques similar to MF (Fig. 85.21). Advanced stages of the disease, which affects a younger population than seen with MF, are characterized by visceral involvement, immunodeficiency, elevated LDH level, and hypercalcemia. Malignant lymphocytes often have convoluted or multilobed nuclei and can be detected in the peripheral blood in 75% of patients. The neoplastic T cells express high levels of the IL-2 receptor (CD25). For purposes of treatment and prognosis, it is wise to view ATL as a spectrum with two subgroups—acute and all others—with treatment, although inadequate, reserved for those with acute ATL. Therapeutic options

Fig. 85.21 SKIN LESIONS IN ADULT T-CELL LYMPHOMA/LEUKEMIA.

include multiagent chemotherapy and antibody or recombinant toxins directed against the IL-2 receptor. Patients with acute ATL have poor survival rates, with a median duration of 4–6 months. Patients with disease that is not “acute” are considered to have “smoldering” disease and have lesions that may wax and wane in size and shape despite treatment.

Prognosis

The goals of treatment in MF are the relief of symptoms with improved quality of life, generally through prevention or delay in development of advanced skin disease and improvement in cosmetics. Despite some uncontrolled clinical trial results that have been reported to suggest “cures” in this disease, the general perception remains that this disease is not curable with standard therapies available today. The disease behaves similarly to other low-grade lymphomas, with periods of remission gradually becoming shorter with subsequent therapeutic interventions. Unlike B-cell low-grade lymphomas, however, advanced-stage MF is associated with a relatively short median life expectancy. Patients with significant nodal involvement (LN3 or LN4) or extensive skin involvement (T4) have median life expectancies of 30–55 months (Table 85.5). A driving force in the development of treatments for this disease is the goal of altering the natural history for this group of poor-prognosis patients. No clinical trial has determined that aggressive early therapy is better than sequential palliative approaches or investigational approaches, and new treatments continue to be developed and tested for these patients.

In 1979 the staging committee at an international workshop on MF proposed a staging system based on the international tumor-node-metastasis (TNM) system (see Table 85.5). This classification was based on the evaluation of 347 patients and a multivariate analysis of potential prognostic factors. This group identified several independent prognostic factors: extent of skin disease at diagnosis (T), type of lymph node (N) involvement, presence or absence of peripheral blood (PB) involvement, and presence or absence of visceral (M) involvement. In 2007 this staging system was revised by the International Society for Cutaneous Lymphomas (ISCL) and the EORTC to incorporate advances related to tumor cell biology and diagnostic techniques, including status of blood involvement, and to improve inter-investigator communication and development of standardized clinical trials (see Table 85.5). Investigators at the National Cancer Institute retrospectively analyzed 152 patients who underwent uniform pathologic staging. They were able to identify three distinct prognostic groups. Good-risk patients had plaque-only skin disease without lymph node, blood, or visceral involvement, and a median survival of more than 12 years. Less than 10% of patients with stage 1A (limited patch) and less than 30% with stage 1B (extensive patch or plaque) progress to more advanced disease. Intermediate-risk patients had skin tumors, erythroderma, or plaque disease with lymph node or blood involvement (but no visceral disease) and a median survival of 5 years. Poor-risk patients had visceral disease or complete effacement of lymph nodes by lymphoma, and a median survival of 2.5 years.

In addition to the classic TNM staging, implementation of techniques such as flow cytometry, cytogenetic analysis, and determination of nuclear contour indices may also improve diagnostic and prognostic specificity. Flow cytometry and cytogenetic analysis are complementary techniques. Flow cytometry allows the detection of cell populations with a normal (diploid) number of chromosomes versus abnormal (aneuploid) numbers, and cytogenetic analysis precisely identifies the individual chromosomal structure and number. Bunn et al demonstrated that in MF/SS the presence of aneuploidy during the clinical course was associated with more aggressive disease. Hyperdiploid cell clones were demonstrated in patients with large-cell histology, aggressive disease, and shortened survival time. Specific chromosomal deletions also influenced prognosis.

The nuclear contour index has been used by several groups in an effort to separate “benign” cutaneous lymphocytic disorders, such as LyP and pityriasis lichenoides, from MF/SS. Electron microscopy

TABLE 85.5 ISCL/EORTC Revision to the Classification of MF and SS (Adaptation)

TNMB Stages	
Skin	
T ₁	Limited patches, papules, and/or plaques covering <10% of the skin surface. May stratify into T _{1a} (patch only) vs T _{1b} (plaque ± patch).
T ₂	Patches, papules or plaques covering ≥10% of skin surface. May stratify into T _{2a} (patch only) vs T _{2b} (plaque ± patch).
T ₃	One or more tumors (≥1-cm diameter)
T ₄	Confluence of erythema covering ≥80% body surface area
Node	
N ₀	No clinically abnormal peripheral lymph nodes; biopsy not required
N ₁	Abnormal peripheral lymph nodes; histopathology Dutch grade 1 or NCI LN ₀₋₂
N ₂	Abnormal peripheral lymph nodes; histopathology Dutch grade 2 or NCI LN ₃
N ₃	Abnormal peripheral lymph nodes; histopathology Dutch grades 3–4 or NCI LN ₄
N _x	Abnormal peripheral lymph nodes; no histologic confirmation
Visceral	
M ₀	No visceral organ involvement
M ₁	Visceral involvement (must have pathology confirmation and involved organ should be specified)
Blood	
B ₀	Absence of significant blood involvement: ≤5% of peripheral blood lymphocytes are atypical (Sézary) cells
B ₁	Low blood tumor burden: >5% of peripheral blood lymphocytes are atypical (Sézary) but does not meet the criteria for B ₂
B ₂	High blood tumor burden: ≥1000/μL Sézary cells with positive clones
Clinical Staging	
IA	T ₁ , N ₀ , M ₀ , B _{0,1}
IB	T ₂ , N ₀ , M ₀ , B _{0,1}
IIA	T _{1,2} , N _{1,2} , M ₀ , B _{0,1}
IIB	T ₃ , N ₀₋₂ , M ₀ , B _{0,1}
IIIA	T ₄ , N ₀₋₂ , M ₀ , B ₀
IIIB	T ₄ , N ₀₋₂ , M ₀ , B ₁
IVA ₁	T ₁₋₄ , N ₀₋₂ , M ₀ , B ₂
IVA ₂	T ₁₋₄ , N ₃ , M ₀ , B ₀₋₂
IVB	T ₁₋₄ , N ₀₋₃ , M ₁ , B ₀₋₂

allows the calculation of a value based on the degree of nuclear folding; this nuclear contour index is significantly greater in patients with MF than in other benign conditions.

The density of epidermal Langerhans cells in biopsy samples, as determined by immunoperoxidase stains, has been identified as a prognostic feature. Epidermal Langerhans cells are necessary for antigen recognition and processing in the normal immune response. Patients with Langerhans cell densities greater than 90 cells/mm² had a significantly reduced risk for death from MF/SS compared with those with lower densities. There was no prognostic significance identified for the presence or absence of CD30⁺ cells. It has been noted that the presence of cytotoxic CD8⁺ T lymphocytes in the skin infiltrate is associated with a more favorable prognosis.

Occasionally patients may develop a more clinically aggressive lymphoma concurrent with a change in the histologic appearance of the neoplastic cells and the pace of their disease. This progression

from typical small, convoluted lymphocytes to larger lymphocytes, such as those associated with large-cell lymphoma, has been documented. Whether this conversion is secondary to prior therapeutic modalities used remains uncertain.

The gold standard for the diagnosis of MF is still routine histopathologic evaluation with adequate clinical correlation. Early lesions of MF are frequently accompanied by heavy infiltrates of benign reactive T cells, hampering the detection of abnormal T-cell clones by any laboratory method. Hence most adjuvant laboratory methods are not helpful at the precise time when they are most needed.

Therapy

Therapy can be conveniently divided into two approaches: topical (skin directed), such as psoralen plus ultraviolet A (PUVA), topical chemotherapy application (nitrogen mustard or carmustine), external beam radiotherapy, and total-skin electron beam radiotherapy, and systemic (skin and viscera directed), such as IFNs, oral or parenteral chemotherapy, photopheresis, oral retinoids, and investigational new compounds (Table 85.6). No studies have demonstrated that one topical therapy is more effective than another, and patient and investigator preference remains the most important discriminating factor governing choice. However, as the biology of the neoplastic cell has become better understood, it is clear that some therapies may actually have topical and systemic effects through alterations in the body's cytokine milieu and ability to mount a host response against the neoplastic cell. Furthermore, knowledge regarding signaling pathways in the neoplastic cells in MF/SS offers hope that future development of targeted treatment approaches will soon be available. Investigational approaches combining therapies also remains an active research strategy (see box on [How We Manage Mycosis Fungoides/Sézary Syndrome](#)).

Phototherapy

8-Methoxypsoralen (8-MOP) is a member of a family of photoactivated compounds (furocoumarin derivatives), which may inhibit DNA and RNA synthesis through formation of monofunctional or bifunctional thymine adducts, gene mutations, or sister chromatid exchanges. The cross-strand formed between DNA strands results in a halt in cell division, as well as oxidative damage to cytoplasmic organelles and cell membranes. These drugs are active only if the tissue containing the psoralen compound is exposed to ultraviolet A (UVA). The mechanism of cell cytotoxicity for many cancer therapies involves the induction of apoptosis. Yoo et al demonstrated that peripheral blood mononuclear cells from SS patients and controls

How We Manage Mycosis Fungoides/Sézary Syndrome

There is no current accepted standard first-line approach or subsequent lines of therapy for patients with mycosis fungoides and Sézary syndrome. Published guidelines include active drugs/treatment approaches, but unfortunately few randomized trials have been completed to allow for comparative effectiveness. Our philosophy regarding management is to try to avoid the side effects of therapy being worse than the symptoms from the disease. Thus for patients with limited cutaneous only disease (stage I–IIa) we favor topical therapy alone with either limited topical steroid/drug applications for T1 stage disease (and for more extensive T2 stage disease our preference is ultraviolet light-based approaches, but other centers utilize topical chemotherapy or total skin electron beam radiation therapy). For patients with T2 thicker plaque disease we would consider a topical plus systemic therapy such as interferon (IFN) or targeetin depending upon ages and comorbidities of patients. For patients with tumor stage or generalized erythroderma/Sézary syndrome, and visceral involvement (stages IIb–IVb) we would favor initially a systemic agent such as IFN or targeetin with some topical agents, and total body ultraviolet light or extracorporeal photopheresis (Sézary), and limited radiation to tumors (stage IIb). If these approaches do not control disease we favor attempting any of the systemic chemotherapy drugs or ideally an appropriate clinical trial. For younger/healthier patients with heavily pretreated refractory disease we consider earlier use of allogeneic stem cell therapy.

exposed in vitro to PUVA undergo apoptosis. Unfortunately, normal and neoplastic lymphocytes were equally sensitive to the apoptosis induced by PUVA (as opposed to with psoralen alone). However, macrophages appeared to be resistant to apoptosis induction and phagocytized apoptotic lymphocytes (but not nonapoptotic lymphocytes). Apoptosis induction may be the ultimate end point yielding benefit, but an immunologic effect due to monocyte phagocytosis and antigen presentation resulting from effector cells may also be present.

Photochemotherapy units with UVA lamps emit a continuous spectrum of long UVA in the range of 320–400 nm with peak emission between 350 and 380 nm. Initial exposure times of patients to high-output UVA are based on the degree of pigmentation before therapy, history of ability to tan, and the output of the photochemotherapy units. Exposure times are increased with each treatment depending on the patient's response and evidence of erythema. The initial UVA dose is between 0.5 and 2.0 J/cm² and can be increased by approximately 0.5 J/cm² per treatment as tolerated. The psoralen compound is ingested 2 hours before the UVA exposure. Topical psoralen protocols are also available. UV-blocking glasses should be worn for 24 hours after administration of 8-MOP. Therapy is typically given three-times weekly until complete clearing occurs. The frequency of treatments can then be reduced, but some maintenance therapy (once every 2–4 weeks) may prolong the duration of remission. As data have emerged regarding the long-term risks of secondary skin malignancies after PUVA, the advisability of this maintenance therapy has been questioned.

Initial trials using PUVA benefited psoriasis patients. Clinical trials with PUVA for patients with MF soon followed. These studies all demonstrated high rates of remission in the early stage (patch or plaque stage of disease). The Scandinavian study group reported a 58% CR rate for these patients within 4–12 months of initiation of therapy. Maintenance therapy was associated with a remission duration of up to 53 months. In these early studies, the same group also reported a surprisingly high rate of objective remissions in tumor-stage patients of 83%. In a large series, 82 patients were followed for a median of 43 months. An ORR was observed in 95% of patients, with a 65% complete clearance rate. Ninety percent of these patients had early-stage disease (stage IA–IIA). A single patient with tumor-stage disease attained a short remission with PUVA alone. Two of six patients with generalized erythroderma cleared completely (no evidence of circulating neoplastic lymphocytes). Given the difficulty in treating advanced-stage patients with PUVA alone, we usually restrict

PUVA therapy to patients with stage IA–IIA disease (see Table 85.5), monitoring patients with tumor disease closely for progression.

Side effects associated with PUVA are quite tolerable. Nausea or vomiting due to psoralen ingestion is observed occasionally, and erythema, pruritus, and chronic dry skin are effects of the UVA damage. Long-term PUVA exposure has been associated with a number of delayed effects. These include dry skin, lichenification, keratosis, and rarely amyloid deposition in the skin. Most important is the late development of iatrogenic (basal and squamous) carcinomas, secondary malignant melanomas of the skin, and rarely cataract formation. Because the cumulative dose of PUVA is correlated with the risk for developing a second skin cancer, routine use of maintenance therapy may be less desirable, especially for patients with an excellent prognosis (stage IA). Despite these problems, the long remissions induced, the ease of administration, and the lack of interactions with other therapeutic modalities make PUVA an attractive early intervention.

Narrow-band UVB (wavelength of 311 nm) is emerging as a valid alternative to PUVA for patients with limited patch or plaque disease. Although probably not as effective as PUVA, initial studies reported RRs near 70%. The advantages of narrow-band UVB are that oral psoralen is not required and there may be less of a photocarcinogenic effect. The role for maintenance therapy has not been established.

UVA-1 is a modality of phototherapy that uses high-energy UVA1 (340–400 nm) output, which penetrates deep into the dermis. Resolution of tumor lesions has even been reported using this therapeutic approach. However, the reduction in circulating CD4⁺ cells raises the possibility that chronic use of this modality could be immunosuppressive.

Radiation Therapy

The CTCLs have been shown to be radiosensitive. External-beam radiation adequately controls local areas of otherwise resistant MF or provides palliation in cases of bulky tumor lesions. Unfortunately, the cumulative dosage that can be given to patients over time is limited due to organ toxicity. Side effects consisting of leukopenia, thrombocytopenia, and radiation-induced dermatitis may prevent long-term therapy with other agents. Newer techniques involving total nodal irradiation, fractionated total-body irradiation, and limited fraction lesional irradiation all may have a role to play in the development of multimodality approaches to this disease. There has been little comparative research into methodology for external beam radiation that provides guidance to clinicians.

We recently reviewed our outcomes with a single fraction of external beam radiation, which was hypothesized to optimize convenience and minimize expense to patients. Two hundred and seventy individual lesions in 58 patients were primarily treated with more than 700 cGy (97%). With a mean follow-up of 41 months, 94.4% of lesions completely responded, and 3.7% partially responded. Predictors of poor response included lower extremity lesion, tumors, and lesions exhibiting large-cell transformation. Lesions treated with electron beams had a higher CR rate than those treated with photon beams. Cost estimates have suggested multifractionated radiation was 200% more expensive than the single fraction.

The limitations of external beam radiation led to increasing use of electron beam radiotherapy for cases of MF confined to the skin. Linear accelerator-generated electron beams are scattered by a penetrable plate placed at the collimator site. The energy of the electrons is reduced to 4–7 MeV and allows adequate field distribution. Because of this low energy level, the beam only penetrates the surface several millimeters to 1 cm into the dermis. Patients may be treated using six-field or rotational treatments. The total skin surface can be treated without significant internal organ toxicity. Most patients are able to tolerate total doses of approximately 3000–3600 cGy over an 8–10-week period.

An excellent review compared results of external beam therapy at Stanford University with those achieved in Hamilton, Ontario (Canada). The results cited in this paper reflect the extensive expertise

of both centers in the delivery of this therapy and may not be applicable to centers where this approach is less frequently used. For patients with stage IA–IIA disease (see Table 85.5), almost 65%–95% of patients achieved a CR. Treatment delivered without adjuvant therapies is associated with a relatively high rate of relapse in patients of all stages except stage IA. Ten-year relapse-free survival rates at the two centers ranged from 33% to 52% for this good-prognosis group. However, for stage IB and more advanced disease, 10-year unmaintained remission rates were only 16% or less. Higher risk patients may be “induced” with external beam radiation and then placed on topical chemotherapy or systemic treatments such as extracorporeal photopheresis for “maintenance.” Still the benefits of therapy may extend beyond crude estimates of relapse rates or survival. Patients with tumor lesions, generalized erythroderma, peripheral blood or nodal involvement, and even visceral spread can be successfully palliated with electron beam radiation therapy as well. Side effects, however, can be occasionally extreme, including scaling, dryness of skin, erythema, edematous extremities, telangiectasia formation, skin ulceration, and hair or sweat gland loss (usually transient but occasionally permanent). Careful radiation dosimetric techniques are required to ensure adequate skin treatment without excessive organ toxicity. We do not use electron beam radiotherapy early in the course of the disease because other topical therapies have been developed that yield similar RRs with less potential toxicity. The long duration of remissions observed in patients with stage IA disease does not equate with cure, because their life expectancy is essentially the same as age-matched controls, and these patients may simply have indolent biology. One group has reported their experience with multiple courses of therapy. Fifteen patients with relapsed MF had a mean of 41 months after the initial course of electron beam therapy were retreated. All patients had received intervening therapies for disease control. Eleven of the 15 had a CR with their first cycle of radiation. The second course achieved six CRs and nine PRs. The median duration of the initial CR was 11 months. The median duration of CR to the second course of therapy was only 3 months, suggesting radiation resistance had developed between the first and second cycles in many patients. In general, toxicity was thought to be tolerable.

Topical Drug Therapy

The initial therapies for MF focused on treatment of the skin disease. Patients have long been known to benefit from the application of topical steroids. Zackheim et al reported a 63% complete RR with twice-daily applications in stage T1 patients but only a 25% complete RR in stage T2 patients. Novel approaches by dermatologists to apply chemotherapy topically to avoid systemic therapy complications have also been devised. Mechlorethamine hydrochloride was the first topical agent evaluated to demonstrate efficacy in MF. The solution used for topical application contains 10–20 mg of mechlorethamine dissolved in 50–100 mL of tap water (no vesicant activity at this low concentration). Although several methods may be used for administration, self-administration at home to the entire skin surface is preferred. The concentration may need to be varied depending on patient tolerance and sensitivity. The time to initial response is usually short, approximately 1–2 weeks, but long-term application is usually required to obtain the maximum response.

Several large studies have been completed demonstrating the benefit of mechlorethamine, especially in early-stage disease. One by Vonderheid et al reported their experience with topical mechlorethamine and found that it compared favorably with results achieved with electron beam treatment. CRs were seen in 80%, 68%, and 61% of patients with limited plaque, extensive plaque, and tumor lesions, respectively. The corresponding median duration of remissions was in excess of 15, 5, and 12 months, respectively. It is difficult to draw definite conclusions from these data, because many patients included in the analysis also received intravenous mechlorethamine or methotrexate, and some may have received radiation therapy. Several patients have relapsed as long as 8 years after the completion of therapy, suggesting that follow-up times must be long to compare

various topical therapies for early-stage disease. Hoppe et al confirmed these findings using an ointment-based (Aquaphor or polyethylene glycol) topical mechlorethamine, which may be associated with a lower incidence of cutaneous sensitivity. A mechlorethamine, 0.02%, gel preparation has been developed and, compared with the other preparations, has a longer stability and a consistent potency. It is also quick drying, greaseless, and developed under good manufacturing practices (not compounded in pharmacy). This gel preparation received FDA approval in 2013 for the treatment of previously treated stage IA/IB MF after a 12-month phase II multicenter randomized trial involving 260 subjects demonstrated noninferiority to mechlorethamine, 0.02%, ointment. Responses, as measured by the Composite Assessment of Index Lesion Severity (CAILS) score occurred in 58.5% of the patients on the gel arm and 47.7% of the patients receiving the ointment. Time to 50% RR was significantly earlier with the gel (26 weeks vs. 42 weeks; $p < .01$). Patients who tolerated therapy without achieving a CR were enrolled in a 7-month extension study assessing the efficacy and tolerability of a mechlorethamine, 0.04%, gel. Twenty six (26.5%) of the 98 patients who received treatment achieved confirmed CAILS responses including six CRs, and an additional 14 patients (14.3%) had their first response at their final visit, yielding an unconfirmed RR of 40.8%.

For early-stage disease, topical mechlorethamine offers an efficient, convenient (outpatient treatment), and relatively inexpensive treatment option. Side effects consist of delayed hypersensitivity in approximately 35% of patients, although ointment-based solutions appeared to offer a reduced risk for allergic contact dermatitis. Once hypersensitivity develops, patients can be desensitized by injecting minute daily doses of mechlorethamine over a period of several weeks. This should be done only in a medical setting with appropriate anaphylaxis precautions observed. Other investigators had difficulty replicating the results using this risky procedure, and topical desensitization has become much more common. Constantine et al propose that therapy should be transiently discontinued until clearance of the allergic dermatitis is achieved (using topical steroids if necessary). Then 0.01–0.1 mg per 100 mL of the drug should be applied daily for 1 week. If this dilution is tolerated, the dosage is doubled weekly until the dose achieved is often identical to the initial concentration that induced the hypersensitivity.

Some clinicians, however, believe that a mild hypersensitivity reaction may have beneficial antitumor effects. Ratner et al previously demonstrated that plaque lesions of MF cleared when exposed to topical doses of 2,4-dinitrochlorobenzene, a known universal inducer of delayed hypersensitivity responses. Anergic individuals failed to improve. Other known sensitizing agents yielded similar but less dramatic responses. Some hypersensitivity may be beneficial; the generalized erythroderma and pruritus are usually poorly tolerated when severe, however, and some alteration in therapy is required.

An increased risk for secondary skin cancers in patients receiving long-term mechlorethamine has been observed. Some physicians have expressed concern regarding the safety of family members or health-care workers secondarily exposed to the topical solutions. Home treatment with topical mechlorethamine has been shown to result in aerosolized drug levels, which may result in mucous membrane or ocular irritation. However, we are unaware of any documented adverse outcomes and believe this to be a theoretical concern rather than a practical one.

Several other topical agents have been tested and shown to be of benefit in the treatment of MF, including cytarabine, dianhydrogalactitol, dacarbazine, guanazole, teniposide, hydroxyurea, thiopeta, and methotrexate. However, topical carmustine is the only one of these agents that has demonstrated clinical use. A stock solution is created with 300 mg carmustine in 150 mL of 95% ethanol (sufficient for 30 days of treatment). The patient then adds 5 mL of the 0.2% stock solution to 60 mL of room-temperature tap water. This solution can then be applied to the general body surface, with the exception of the head, genitals, palms, soles, and intertriginous zones, unless involved by disease. Applications are planned to occur daily for 2–6 months, if necessary. Brief exposures to double-dose solution can be used for resistant disease. Results in 188 patients with patch

or plaque disease demonstrate efficacy similar to that of topical mechlorethamine. For limited patch disease, there was a failure-free rate of 90% at 3 years. For more extensive patch-stage disease, the freedom from treatment failure rate at 3 years was 62%. Some patients have been managed for as long as 10 years with topical carmustine. Side effects of contact dermatitis are less frequent with this agent, but systemic side effects, mainly leukopenia, are more common. This drug may be helpful for the treatment of patients who do not tolerate topical mechlorethamine, because there is no cross-sensitivity. A topical agent undergoing clinical investigation in a phase Ib multi-center, double-blind, placebo-controlled, randomized trial in early-stage CTCL patients is the hydroxamic acid HDAC inhibitor SHP-141. A 2014 update reported that six of the 18 patients enrolled had achieved a clinical objective response (>50% improvement by CAILS) and incremental weekly CAILS improvement throughout the dosing period. Time to response was noted to be as early as day 7. Skin biopsy histology revealed increased dermal acetylation, and pharmacokinetics results confirmed lack of SHP-141 peripheral blood exposure.

Hamminga et al performed one of the few prospective trials comparing total-skin electron beam radiation to topical mechlorethamine. A total of 42 patients with MF localized to the skin (no documented nodal or visceral involvement) were treated. Patients were not randomized to their treatment; rather, the physician based the decision on patient health, availability of the linear accelerator, and the distance the patient lived from the clinic. In patients with minimal skin disease, no difference in outcome was observed. In more advanced skin disease, a trend toward superior initial response was seen with electron beam therapy, but there was a high relapse rate in those patients, necessitating subsequent therapy.

Systemic Chemotherapy

Currently systemic chemotherapy is reserved for those patients with relapsed or refractory disease after topical interventions or for those patients with advanced nodal or visceral disease at presentation. Many of the patients treated with chemotherapy have also previously been treated with cytokine-based or other nontraditional chemotherapeutic agents before systemic chemotherapy is considered. With that in mind, a number of trials have been published reporting results using agents developed many years ago for other indications but still in use for the treatment of MF/SS today. Recently, novel agents are being increasingly studied for efficacy in MF/SS based upon a rationale developed with molecular or proteomic data. An example of such agents is the HDACI. Vorinostat (SAHA) has been approved by the FDA for the treatment of the cutaneous manifestations of CTCL in patients in whom bexarotene therapy (see [Retinoids](#)) has failed, and a related HDAC inhibitor, romidepsin (depsipeptide or FR901228), has been approved for the treatment of both CTCL and PTCL.

Approved Chemotherapy Agents for CTCL

Vorinostat 400 mg daily orally was tested in an open-label trial of 74 patients who had progressed on at least two prior systemic therapies. The ORR (skin only) was 29.5%, with 1 CR and 18 PRs. Common adverse events included diarrhea (49%) and fatigue (46%). Grade 3 events were less common but included fatigue (5%), deep venous thromboses/pulmonary emboli (5%), and thrombocytopenia (4%).

Reports from the National Cancer Institute with romidepsin have provided confirmatory results of the use of this class of agent for the treatment of patients with T-cell lymphomas, including some with MF/SS. In several phase I and II trials, 10 of 20 patients with MF/SS appeared to have had a PR. Two additional clinical trials demonstrated activity in CTCL. In a large, multicenter, open-label phase II trial of romidepsin, 96 patients with relapsed stage IB–IVA MF/SS (71% had stage IIB or higher) received standard dosing of 14 mg/m², on days 1, 8, and 15 every 28 days. Importantly in these trials, total disease burden, not just skin involvement, was assessed to determine the RRs. The overall RR was 34%, with 7% of patients

achieving a CR. The median response duration was 15 months. Common adverse events included nausea/vomiting in over 56% of patients, asthenia in 44%, and diarrhea in 14%, but again grade 3 toxicities were much less frequent, but also included fatigue in 6%. The HDACI have been linked to cardiac abnormalities and especially arrhythmias. However, in this large trial, events such as cardiac failure, atrioventricular block, and ventricular tachycardia were rare, occurring typically in less than 1% of patients. Avoiding other drugs that may also cause cardiac arrhythmias seems prudent in patients treated with HDACI. The second confirmatory trial was led by investigators at the National Cancer Institute. Seventy one patients (87% with stage IIB or higher) with heavily pretreated MF/SS (median four prior treatments) were treated with romidepsin at the same dose as described earlier. Again the overall RR was 34% with 6% CR. Although GI disturbances and fatigue were common in this trial in over 40% of patients, myelosuppression was seen more frequently, with 5%–10% of patients experiencing grade 3 neutropenia and thrombocytopenia. Cardiac arrhythmias were again uncommon, but T-wave/ST changes were seen in the majority of patients, and grade 1 QTc prolongation was seen in 10% of patients.

In general then, toxicity to romidepsin and vorinostat has included alterations in the cardiac conduction that could potentially predispose to arrhythmias, and treatment of patients has required ongoing telemetry monitoring in some trials, but no evidence for acute or chronic impairment in cardiac function has been noted. Vorinostat therapy led to drug-related grade 1 electrocardiographic changes in five patients and grade 2 in one patient. Therefore it appears safe to use these agents in the outpatient setting with a periodic assessment of cardiac rhythm and QTc interval with an electrocardiogram base.

Unfortunately, romidepsin has been shown to be a substrate for the MDR protein (a P-glycoprotein) and upregulates the expression of MDR1. Preliminary molecular analyses confirmed the upregulation of MDR1. These data suggest that when resistance to this agent develops, other chemotherapeutic drugs handled by MDR1 may be rendered ineffective. Several patients demonstrated increased surface expression of the CD25 component of the high-affinity IL-2 receptor after treatment. This protein is a target for denileukin diftitox (DD), discussed elsewhere in this chapter as a therapy for MF, suggesting that strategies for combination therapy approaches could be devised to enhance responses to both agents.

Approved Chemotherapy Agents for Cancer But not for CTCL

Older agents studied previously include alkylating agents such as chlorambucil or cisplatin, the microtubule inhibitors etoposide, vincristine, and vinblastine, or the antitumor antibiotics, such as bleomycin and doxorubicin. In general, the RRs are modest, and duration of response is typically less than 6 months.

McDonald and Bertino reported particularly good results with the antimetabolite methotrexate administered intravenously followed by oral citrovorum factor. Patients received 1–5 mg/kg of intravenous methotrexate every 5 days. If a patient tolerated the lowest dose, each subsequent dose was escalated. After five intravenous doses, patients were switched to oral methotrexate (25–50 mg) with oral citrovorum as weekly maintenance. All 11 patients achieved “good” or better clearing (>60%) for a median duration of 24 months. Mucositis and skin ulcerations were the most significant toxicity witnessed. Myelosuppression was mild in general. The related compound, trimetrexate has also been reported to be effective in treating CTCL.

As discussed previously, a newer folate analogue, pralatrexate, has also been shown to have substantial activity against PTCL. In early-phase trials several patients with CTCL were felt to benefit, and therefore a trial was designed specifically for MF/SS patients to identify an effective and tolerable dose. Starting with a dose de-escalation design at 30 mg/m²/week intravenously for 3 of 4 weeks, ultimately 15 mg/m²/week was identified as the recommended dosage for further exploration. Twenty nine patients received this dose for a median of four cycles, and the ORR was 45% (1 CR unconfirmed [CRu]/12 PR). No median response duration had been identified at the time of publication but ranged from 1 day to 372

days. Mucositis (17% grade 3), skin toxicity (7% grade 3), and fatigue (3% grade 3) were common with the use of this agent at the recommended dose. To date no comparison trials of pralatrexate to methotrexate have been performed to assess the relative cost and benefit differences.

Subsequently, the benefits of adding 5-fluorouracil to the methotrexate-based regimen, exploiting the synergy between these agents, were evaluated. The methotrexate was administered as a 24-hour continuous infusion at 60 mg/m². Immediately after this infusion, 5-fluorouracil (20 mg/kg every 24 hours) was continuously infused for 36–48 hours. Oral citrovorum factor (10 mg/m²) was administered intravenously 6 hours after cessation of the methotrexate infusion and then orally for five additional doses. The methotrexate dose was escalated to a maximum of 120 mg/m², as allowed by toxicity and response. Ten patients were treated for an average duration of 33 months (range, 3–78 months). The number of cycles administered ranged from 5 to 45. All patients achieved a PR. Initial cycles were given every 5–8 days. Once a good response was achieved, cycles were administered every 3 months as maintenance. Other groups anecdotally reported success with low doses of oral methotrexate. In general these regimens appear to be fairly well tolerated.

The purine antimetabolites have been shown to be active in the treatment of MF/SS. These compounds do not have a single mechanism of action, but all ultimately interfere with intracellular regulation of deoxyribonucleotide pools and this imbalance partially explains the cytotoxicity. This family of drugs includes 2'-deoxycytosine (DCF), fludarabine phosphate, and 2-chlorodeoxyadenosine (2-CdA).

DCF is a transition state inhibitor of adenosine deaminase. Inhibition of this enzyme, necessary for the conversion of adenosine to inosine, results in accumulation of 2-deoxy-ATP and subsequent inhibition of the enzyme ribonucleotide diphosphate reductase necessary for DNA synthesis in dividing cells. DCF is also effective against cells in the resting state, where ribonucleotide diphosphate reductase levels are barely detectable. It has been shown that deoxy-ATP accumulation in resting lymphocytes results in increased DNA strand breaks over time; this results in the activation of Ca²⁺/Mg²⁺-dependent endonuclease that produces double-stranded DNA breaks at internucleosomal regions and also activation of a poly-adenosine diphosphate (ADP)-ribose polymerase that consumes nicotinamide adenine dinucleotide and adenosine triphosphate (ATP). These perturbations lead to apoptotic cell death.

Fludarabine phosphate represents the fluorinated derivative of adenine arabinoside (ara-A). This compound was known to retain cytotoxic action against leukemias and was resistant to degradation by adenosine deaminase. Solubility was poor, however, unless the 5'-monophosphate derivative was used; hence, fludarabine monophosphate is the 5'-monophosphate form of F-ara-A. Similar to the mechanism of action of cytarabine or ara-A, fludarabine phosphate requires phosphorylation by deoxycytidine kinase to the active triphosphate metabolite F-ara-ATP. Again, this triphosphate derivative inhibits ribonucleotide reductase, resulting in nucleotide pool imbalances, which prevent DNA repair and ultimately cause apoptosis.

2-CdA represents another chemical modification of deoxyadenosine, which renders the drug resistant to adenosine deaminase. After activation by deoxycytidine kinase, the triphosphate derivative similarly inhibits ribonucleotide reductase and accumulates intracellularly, perturbing the deoxyribonucleotide pool balance, resulting in DNA damage and cell death.

Enzymes such as cytoplasmic 5'-nucleotidase catalyze the degradation of the active triphosphate derivatives discussed earlier. Cells with relatively greater levels of the activation enzymes versus degradation enzymes were identified as likely clinical targets. Lymphoid disorders make good targets for these agents because they contain high levels of deoxycytidine kinase and low levels of 5'-nucleotidase and depend on polymerase- α for DNA repair. Because it was known that T-lymphoblastoid cell lines were most sensitive to these drugs, it was thought that T-lymphocyte disorders would be sensitive in vivo to these agents.

TABLE 85.7

Response Rates Observed in Clinical Trials With Purine Antimetabolite Agents

Drug	Overall Response Rate (%)	Reference
DCF	66	119
DCF	100	120
DCF	54	121
DCF	66	122
Fludarabine	18	123
2-CdA	28	124
2-CdA	38	125
2-CdA	18	126
2-CdA	100	127

2-CdA, 2-chlorodeoxyadenosine; DCF, 2'-deoxycytosine.

A number of studies treating patients with MF/SS have been performed with these drugs. Table 85.7 shows the results in these studies. Four studies used DCF as a single agent at doses ranging from 3.75 to 10 mg/m² daily for three doses every 21–28 days. Twenty five patients with MF/SS were included in these studies; overall, three CRs (12%) and 12 PRs (48%) were documented. The fourth study represents the largest phase II experience reported for the treatment of MF/SS and other CTCLs. Twenty-seven eligible patients were treated for 3 consecutive days at 3.75 mg/m²/day. Essentially, 80% of the doses were delivered at 3.75 or 5.0 mg/m²/day. Twenty one of 24 response-evaluable patients had SS (14 patients), tumor-stage MF (six patients), or large-cell transformation of MF (one patient). Patients had failed a median of three prior treatments before enrollment. The overall RR for patients with MF/SS was 66% (five CRs and nine PRs). Most responses were short lived because the median duration of response in patients with tumor-stage disease was 2 months (range, 1–2 months) and the median duration of response in erythrodermic disease was 3.5 months (no range given, but two patients had responses of at least 17 months).

The use of fludarabine for the treatment of MF/SS has also been assessed in a single, large phase II trial by Von Hoff et al. They treated 33 patients who were good-risk disease (i.e., no prior systemic therapy) or poor-risk disease (i.e., prior systemic therapy) with fludarabine alone at doses of 25 and 18 mg/m² for the two groups, respectively. One complete response and five PRs were obtained for an overall RR of 18%.

2-CdA has been evaluated as a single agent for the treatment of MF/SS in 21 patients who had failed at least one prior therapy. There were three CRs and three PRs (overall RR of 29%). The median duration of response in this heavily pretreated group, however, was only 4 months. Three other groups have also reported results in small numbers of MF patients. A total of 21 patients were reported when the studies are pooled. Seven patients achieved responses, giving an overall ORR of 33%, remarkably similar to results from the prior large, single-institution study.

The similarity in mechanism of action of these compounds would suggest that toxicity associated with the various compounds would be similar. This has definitely not been the case, however. There are distinct differences in the spectrum of acute and chronic toxicities with these agents. DCF and fludarabine are associated with higher rates of nausea or vomiting and alopecia than commonly associated with 2-CdA. The most significant toxicities with DCF and fludarabine, however, are neurotoxicity and immunosuppression. Approximately 15% of patients developed sepsis, and 10% developed an opportunistic infection, such as disseminated toxoplasmosis, cytomegalovirus infection, *Pneumocystis carinii* pneumonia, atypical mycobacterial infection, and fungemia in studies. Another 15% developed severe neurotoxicity in the form of confusion, motor weakness, paresthesias, and CNS demyelination. Treatment with 2-CdA is extremely well tolerated initially but may result in somewhat greater

myelosuppression than the other agents. This myelosuppression may even be more significant when the agent is used to treat T-lymphocyte disorders compared with B-cell diseases. In the study by Betticher et al, significant reductions in neutrophils and lymphocyte counts occurred in 46% and 41% of patients, respectively. In a study of 2-CdA, we reduced the days of therapy delivered by continuous infusion to 5 days from the usual 7 because of a perception that the toxicity, primarily prolonged thrombocytopenia, was unacceptable. These results suggest that patients treated with these agents should be carefully evaluated for infectious complications, especially opportunistic infections, and that prophylactic antibiotic therapy should be considered during and after therapy if significant immunosuppression is documented. In addition, one should carefully consider the value of continuing to administer cycles of therapy if there is no evidence of further improvement in clinical response, because of the risk for suddenly developing prolonged cytopenias that may limit future therapeutic approaches. In general it is not apparent that one purine antimetabolite is dramatically superior from these studies, although DCF has a slightly higher overall RR. It has been observed repeatedly in these studies that occasional patients with SS may have striking and durable responses to treatment, but ideally other agents emerging may allow for higher RRs with less toxicity in this population.

A relatively new class of antineoplastic agents, the proteasome inhibitors, also have activity in CTCL. *In vitro* activity of bortezomib has been demonstrated against CTCL cell lines, thought to be due to a decrease in NF κ B expression observed, and this reduction resulted in marked increase in spontaneous apoptosis. These data formed the rationale for performing a clinical trial. Zinzani et al reported a small phase II trial of 10 evaluable patients with stage IV or greater MF. In this limited sample, there was one CR and six PR observed, with a range of response durations of 7–14 months at the time of the report. Toxicity was as expected, with nearly 20% of patients experiencing grade 3 neutropenia and thrombocytopenia. Additional studies are ongoing with this agent in combination with other agents for histologically aggressive T-cell lymphomas.

Combination chemotherapy has often been employed for MF/SS patients with advanced disease at presentation or with progression. Usually alkylating agents are used, in combination with doxorubicin or vinca alkaloids. Response rates of 80%–100% have been achieved, with longer durations of remission than observed with single-agent therapy. There have been no trials comparing different aggressive combination regimens. High RRs with perhaps less toxicity have been observed in treating other NHLs using infusional combination regimens such as EPOCH (etoposide, prednisone, vincristine [Oncovin], cyclophosphamide, and hydroxydaunomycin). A trial in CTCL suggested comparable activity to a bolus schedule, with greater risk for febrile neutropenia and bacteremia associated with indwelling catheters required for the infusion.

It is our philosophy that this disease behaves similarly to other low-grade lymphomas (e.g., B-cell type), with periods of remission becoming shorter with subsequent therapeutic interventions. However, as noted, advanced-stage MF is associated with a relatively short median life expectancy. Patients with significant nodal involvement or extensive skin disease (T4 in particular) have median life expectancies of 30–55 months. A driving force in the development of treatments for this disease is the goal of altering the natural history for this group of poor-prognosis patients, or for delaying the development of poor-prognosis disease. There is no clinical trial of any modality that has demonstrated a survival benefit compared with a control group. Kaye et al demonstrated more than a decade ago that combination chemotherapy (and total-skin electron beam radiation therapy) did not provide a more favorable survival or even clinically significant delays in time to recurrence for patients, compared with standard palliative, less aggressive therapies. New drugs or approaches are still being developed with the goal of altering the disease state in poor-prognosis patients.

Because of the pressing need to identify new strategies to provide more durable remissions or even curative therapy for advanced

CTCL, new drugs continue to be tested. On the basis of the clinical evidence of possible activity in early-phase testing, several drugs have been evaluated. In a phase II trial of 44 patients with relapsed MF or PTCL (unspecified), a dose of gemcitabine was administered at 1200 mg/m² over 30 minutes for 3 weeks every 28 days. There were five (11%) CRs and 26 (59%) PRs (overall RR, 70.5%). The median duration of response ranged from 15 months for CRs to 10 months for those patients with PR. There appeared to be no difference in response type between patients with MF and PTCL. In a second trial at the MD Anderson Cancer Center with gemcitabine administered similarly but at a dose of 1000 mg/m², investigators documented a 68% overall RR (17 of 25), with two patients developing a CR. Toxicity included myelosuppression in the majority of patients and development of a hemolytic uremic syndrome in two older adult patients. Most recently, gemcitabine was studied as a first-line systemic treatment in 27 patients with stage T3 or T4 MF/SS. The overall RR was 70% (19 of 27), with six CRs. The median time to progression was 10 months. Toxicity was generally mild.

The camptothecins are a family of compounds that inhibit topoisomerase I, an enzyme required for unwinding strands of DNA for transcription and replication. In early-phase studies it was recognized that the administration of 9-aminocamptothecin (9-AC) by continuous infusion was required to maintain a drug concentration above a threshold level, which coupled with duration of exposure was important to ensure adequate inhibition of the target enzyme. In these studies at appropriate concentrations, activity was identified in NHLs, and it was therefore evaluated in MF/SS. We undertook a trial of intravenous 9-AC in patients with MF/SS. The trial was prematurely closed after 12 patients received 30 cycles. There were two PRs (17%) in a heavily pretreated population of patients; however, six of the 12 patients (50%) developed indwelling catheter infections, and three patients died 4–8 weeks after the last dose of 9-AC. The toxicity was deemed too excessive to justify this dose, route, and schedule of administration. This study nicely demonstrates the hazards of chemotherapy in this patient population, including the underlying risk for infection and the relative contraindication to indwelling catheters (hence a bias toward agents administered as short infusions through peripheral catheters, or oral agents, and the importance of prophylactic antibiotics if excessive invasive procedures are anticipated).

Another drug empirically tested for the treatment of MF/SS is pegylated doxorubicin based on the historic activity of doxorubicin against NHLs. The process of encapsulating the doxorubicin in pegylated liposomes creates stable, long circulating carriers of the drug that result in greater tumor cell uptake versus normal cell uptake. This may reduce normal cardiotoxicity and myelosuppression. The drug is approved for use against Kaposi sarcoma but has been evaluated in a small group of patients with MF in Europe. Six patients in this pilot study received pegylated liposomal doxorubicin at 20 mg/m² every 4 weeks. Four patients achieved a CR and one other patient achieved a PR. The overall RR was 83%. The median duration of response was not reported. Grade 3 adverse events were few and included one patient with lymphopenia and two with anemia. No other severe adverse effects were noted. A larger retrospective multicenter report of this agent administered intravenously at 20–40 mg/m² every 2–3 weeks in 34 patients has also been conducted. Overall, 15 patients achieved a CR and 15 achieved a PR (RR of 88%), with EFS of 12 months. Toxicity was similarly manageable.

The ability to biopsy skin lesions for studies of tumor cells in MF/SS has resulted in this disease being a favorable setting for the evaluation of candidate therapeutic agents and exploration of rational therapeutic development. These studies have allowed investigators to test new drugs at appropriate dosages with a correct schedule of administration, and to generate, prove, or refute hypotheses regarding mechanism of action or resistance. A number of studies of such agents have been completed and may lead to further drug testing in search of enhanced therapeutic activity in MF or perhaps achieve cure of MF.

An example of such an achievement has been the work with temozolomide for the treatment of MF/SS. This agent is an oral imidazotetrazine that has activity in solid tumors, such as brain tumors and melanoma. It has been determined that mechanisms of resistance to this agent include expression of high levels of the scavenger protein O⁶-alkylguanine-DNA alkyltransferase (AGT) in tumor cells. This protein is implicated in the recognition and repair of alkylator-induced DNA damage introduced by chloroethylnitrosourea (e.g., bis-chloroethylnitrosourea [BCNU]) or methylating agents (temozolomide). The presence of the AGT protein imparts resistance by removing toxic lesions formed at the O⁶ position of guanine. Chloroethylnitrosourea cross-links are prevented from forming by the removal of the chloroethyl lesion from the O⁶ position before rearrangement or by reaction with the intermediate, 1,O⁶-ethanoguanine, to form a cross-link between DNA and the repair protein. The AGT protein is inactivated in the process. Studies evaluating AGT levels in patients with brain tumors receiving BCNU therapy support the role of AGT in resistance to chloroethylating and methylating agents. Retrospective and prospective human studies have demonstrated a correlation between AGT concentration and clinical outcome after treatment with BCNU.

Because of the unique sensitivity of MF to topical BCNU, we were interested in exploring levels of AGT in a variety of patients with various stages of MF/SS. Patients with patch or plaque lesions expressed low levels of the AGT protein compared with a number of controls with reactive dermatitis, and the level of AGT increased correlating with the stage of MF/SS (i.e., patients with malignant lymphocytes harvested from peripheral blood or involved lymph nodes had higher levels of AGT than those with patch or plaque lesions). Given these data, we initiated a prospective trial of temozolomide in relapsed patients with MF/SS, correlating response to levels of AGT and other known resistance proteins (such as the family DNA mismatch repair proteins).

Twenty-six patients with relapsed heavily pretreated stage IB–IVB disease were evaluated. The overall RR was 27%, with two complete responders. Median disease-free survival was 4 months. We hypothesized that the optimal phenotype that would predict for good response to therapy would be low levels of AGT combined with normal levels of several DNA mismatch repair proteins. Interestingly, hypermethylation of these DNA repair proteins has been reported to result in silencing of the genes and to correlate with lack of the proteins as assessed by immunohistochemical techniques in patients with MF. This hypermethylation may be more prevalent in more advanced tumor lesions and suggests that a propensity for mutations may precede clinical progression. It also suggests that patients might benefit from treatment with a demethylating agent in combination with temozolomide. Unfortunately, in the trial above, pretreatment levels of O⁶-methylguanine-DNA methyltransferase (MGMT) and the mismatch repair genes mutL homolog 1 (*MLH1*)/mutS homolog 2 (*MSH2*) were not predictive of response to temozolomide.

Role of Stem Cell Transplantation

The natural evolution of the use of chemotherapy for this disease has been to use dose-intensified approaches with hematopoietic reconstitution with autologous or allogeneic bone marrow or stem cells. There are few reports in the literature of such treatment programs in well-designed prospective clinical trials.

Given the propensity of Sézary cells to be detectable despite a lack of clinical evidence even in early-stage disease if sophisticated molecular techniques are used, it is likely that reinfusion of neoplastic cells may occur with autologous bone marrow transplantation. The lack of dramatic benefit in low-grade B-cell lymphomas for autologous bone marrow transplantation similarly suggests that this approach will not benefit patients. We had a very limited experience with autologous bone marrow and SCT at our center and abandoned it, because of rapid progression of disease, in favor of aSCT.

aSCT has been presumed to be curative in small percentages of patients with low-grade B-cell lymphomas, and this approach has

now been investigated in the small subset of young MF/SS patients with HLA-identical siblings or HLA-matched unrelated donors who have poor-prognosis disease and have demonstrated relapse or resistance to IFNs, chemotherapy, and topical therapies. In an early study, a single patient treated with cyclophosphamide and total body irradiation was reported to achieve CR after aSCT, but relapse occurred by day 70, necessitating additional therapy. The patient remained in CR and was alive at least 6 years after the transplantation. In light of this, we and others have begun to explore this approach in patients with MF/SS who are young and have matched donors available. We have used as grafts marrow-derived stem cells enriched with peripheral blood-derived stem cells or peripheral blood stem cells only. We believe that in appropriate patients this approach should continue to be explored; older patients may benefit from strategies involving the use of RIC regimens that involve less myeloablative preparative regimens and rely on the effects of the donor marrow to create a GvL effect for disease control. Molina et al reported promising data using ASCT for patients with refractory MF/SS. Each of the seven patients treated had failed a median of seven therapies. Although one patient received a myeloablative conditioning regimen, five received a RIC regimen consisting of fludarabine and melphalan. Each of the patients achieved a clinical remission and resolution of molecular and cytogenetic evidence of the disease. After a median follow-up of 56 months, six of the eight patients were alive and free of evidence of lymphoma. The other two patients died of transplant-related complications. This small study provided the impetus to further develop ASCT strategies for the treatment of advanced CTCL refractory to standard therapies at many centers.

A metaanalysis from reports before 2008 of 20 allogeneic and 19 ASCTs was reported by Wu et al and includes some of the patients described here. The majority of patients in both groups received myeloablative chemotherapy and total-skin electron beam as preparative regimens, with the remainder in the aSCT group receiving RIC regimens. In the ASCT group EFS was only 20% at 1 year and 0% at 5 years, statistically significantly less the 65% and 60%, respectively, in the aSCT group. Overall survival was also significantly better in the ASCT group, confirming our impressions regarding the limitations of ASCT for this disease.

Since this metaanalysis was published, two larger single-institution or multiinstitution reports have been published. A European group reported the outcomes on 60 patients with MF/SS (36 of 24) who received either a matched related donor (mRD) or matched unrelated donor (mUD; 45 of 15) ASCT. Survival at 3 years was 54%. A multivariate analysis suggested that recipients of mRD ASCT had better progression-free and overall survival than patients receiving mUD ASCT transplants, and reduced-intensity transplants had less NRM without increased relapse of disease.

A single-institution trial in the United States reported the outcome of 19 patients treated with total-skin electron beam and nonmyeloablative ASCT in advanced MF/SS. The complete RR was 58%. Relapse was sometimes treated with reduced immunosuppression or donor lymphocyte infusions. With a median follow-up of 19 months, the median overall survival had not been reached.

Other Established Treatments for CTCL

Extracorporeal Photopheresis

An adaptation of the use of psoralen with UVA called *extracorporeal photopheresis* has been described by Edelson et al. Patients ingest 0.6 mg/kg of oral 8-MOP before a treatment. The treatment consists of routine leukapheresis with isolation of the mononuclear cell fraction. The cells are then exposed to UVA ex vivo within a special chamber inside the pheresis device. In the initial report, Edelson et al documented an 88.5% loss of lymphocyte viability compared with control patients treated with the drug alone. Overall, 64% of patients responded to therapy, with the best results in those with generalized erythroderma and, presumably, higher circulating Sézary cell levels. The mechanism is not thought to be directly cytotoxic, but rather to

induce a host immune response to the reinfused altered Sézary cells, possibly through activation of circulating dendritic cells. This theory would explain the findings of some investigators that patients without leukemic involvement do poorly with such therapy. This treatment modality has resulted in the best results in SS patients with erythroderma of short duration and with adequate CD8⁺ blood counts.

Several other groups have reported their experiences with photopheresis. When the data are analyzed on an intent-to-treat basis, overall RRs of 36%–52% were observed. Only 12%–18% achieved CR. These investigators attempted to wean patients from therapy as clearing of lesions was documented. Ultimately, most responders developed recurrent disease. Many trials are underway combining extracorporeal photopheresis with other active modalities.

Toxicity is mild and includes occasional nausea, erythematous flares, and temperature elevations. Patients may develop hypotension during leukapheresis, which usually responds to saline infusions.

Interferons

IFN- α is an active agent for the treatment of MF. Dosages and routes of administration have differed among studies. Initially, high-dose IFN was used, with maximum doses of 36–50 million International Units (IU). Bunn et al and Olsen et al independently demonstrated complete RRs of 10%–27% in heavily pretreated patients. The duration of response was only 5.5 months. Later trials of untreated patients with doses of 3–18 million IU given subcutaneously daily have demonstrated RRs of 80%–92%. From all these studies, it appears that a reasonable and tolerable single-agent dose is 12 million IU/m² administered subcutaneously daily. We recommend starting at 3 million IU and gradually increasing as treatment is tolerated by the patient.

In a single trial, the results of treatment of 16 refractory CTCL patients with IFN- γ were reported. Five patients experienced PRs (RR, 31%) with a median duration of 10 months (range, 3–32+ months).

Side effects of all IFNs are dose dependent. Most common adverse effects are constitutional symptoms, consisting of fever, chills, myalgias, malaise, and anorexia. Rarely, cytopenias, elevations of liver function test results, renal dysfunction, cardiac dysfunction, or changes in mental status can be seen. Patients need to be monitored closely while on IFN.

A retrospective analysis of a CTCL database, including 198 MF/SS patients undergoing systemic therapies, revealed a median time to next treatment for single- or multiagent chemotherapy of 3.9 months (95% CI, 3.2–5.1), compared with 8.7 months for IFN- α (95% CI, 6.0–18.0, $p < .00001$). This study suggests that the use of conventional chemotherapy regimens should be delayed until other options are exhausted.

Retinoids

Vitamin A and its natural and synthetic analogues are known as *retinoids*. These compounds have diverse biologic effects, influencing differentiation and proliferation of a number of structures during development. In addition, some compounds have been shown to influence immune function. Clinically, a number of approved formulations have demonstrated efficacy in MF and SS.

Many of the trials of retinoids for MF/SS were performed decades ago with limited patient numbers. Treatment with isotretinoin (13-*cis*-retinoic acid), a nonaromatic retinoid, has been associated with clinical benefit in a number of trials. Overall objective responses have been described in 33 of 56 patients treated in three clinical trials. A monoaromatic retinoid compound, etretinate, did not achieve similar results when tested as monotherapy for MF in several trials but did show efficacy in a trial for the treatment of parapsoriasis en plaques. A polyaromatic retinoid demonstrated efficacy in a small trial. Objective responses were observed in three of six patients (one CR and two PRs).

Vitamin A Derivatives Not Approved for CTCL

There has been a resurgence of interest in retinoids for the treatment of hematologic malignancies with the approval of all-*trans* retinoic acid (ATRA) for acute promyelocytic leukemia. ATRA has been studied in 33 patients with relapsed MF who had not had prior exposure to oral retinoids. Patients received 45 mg/m² daily in two divided doses for up to 2 years. In 29 evaluable patients, five responses were observed (one CR, four PRs) for an ORR of 17% with a median duration of response of 4.5 months. Another seven patients (24%) had stable disease. The most common toxicities included headache (37%) and mucous membrane dryness (80%). Only one patient experienced severe elevation of lipid levels. ATRA works through binding to specific retinoic acid receptors (RARs; RAR family α , β , and γ), which then bind to retinoic acid response elements located upstream of gene promoters, providing transcriptional control of proteins.

Approved Vitamin A Derivatives for CTCL

A second family of receptors, the retinoid X family of receptors (RXR), has been identified. Bexarotene is a synthetic retinoid that selectively binds this family of receptors. Unfortunately, as is the case with the retinoids that bind the RAR family of receptors, the expression of which genes that are altered to achieve the clinical benefits observed remains unknown. This compound has been tested in separate trials of early- and advanced-stage patients. At the 300 mg/m² dosage daily (dose recommended by the FDA), 54% of the 94 advanced-stage patients in an open-label phase II study responded to therapy (2% CRs). The median duration of response was 299 days. The early disease trial showed similar RRs. The toxicity spectrum is somewhat different from the RAR-specific retinoids, including more frequent severe elevations of lipid levels (although rarely associated with pancreatitis), hypothyroidism, and less frequent headaches and dry mucous membranes. The compound can also be used topically. A phase I/II trial of the topical bexarotene demonstrated a 63% RR (21% clinical CRs) in primarily early-stage patients with lesional application. Toxicity was mostly local irritation with erythema.

The favorable toxicity profile has led to a number of combination modality trials using retinoids. Some of these small trials have combined retinoids with IFN- α and have reported RRs of 40%–50%. Combinations of retinoids with PUVA have been suggested to result in clinical benefit in less time with less exposure to ultraviolet radiation. These experiences have been generally limited and often uncontrolled, making definitive conclusions impossible. Larger randomized trials are needed to determine if routine use of such combinations should be undertaken outside of an investigational trial.

Monoclonal Antibodies

Targeted therapy has become a reality for the treatment of many types of cancer, including MF/SS. Although the most common approach has been with the use of antibodies that target antigens expressed by the tumor cells (e.g., rituximab), another class of compounds known as *recombinant fusion proteins* has been developed, the prototype being DD, for the treatment of CTCL.

Approved Monoclonal Antibodies for Cutaneous T-Cell Lymphoma

DD is a single-chain protein in which the receptor-binding domain of native diphtheria toxin is replaced by the sequences encoding the IL-2 gene (CD25). Once this molecule binds to the high-affinity IL-2 receptor, the fusion toxin is internalized by receptor-mediated endocytosis and is proteolytically cleaved within endosomes to liberate the free ADP-ribosyl transferase activity of diphtheria toxin into the cytosol, where it then inhibits protein synthesis.

In early phase I studies with DD, the RR of CTCL patients who demonstrated at least 20% expression of the IL-2 receptor was 30%. A phase III study comparing various dose levels of DD demonstrated a similar RR, but there was significant toxicity that led to a high dropout rate (constitutional symptoms, infusional reactions such as

hypotension, chest pain or dyspnea, and a vascular leak syndrome). Based on this trial the drug was approved for the treatment of relapsed/refractory CD25-expressing CTCL.

Recently, two dose levels of DD were compared with placebo in patients with stage IA–III disease. This clinical trial is one of the larger studies conducted in MF/SS to date and provides interesting information because it is one of the few to include a placebo control arm. Overall, 144 patients were enrolled, all with 20% or higher expression of CD25 on a skin biopsy specimen and randomized in a 1:1:1 fashion to either 18 µg/kg DD, 9 µg/kg DD, or the placebo, with the primary endpoint being overall RR. The RRs were 49.1%, 37.85%, and 15.9%, respectively, and both DD dose arms were statistically superior to the placebo. PFS (median >2 years) in the DD arms was also superior compared with placebo (median 4 months). Moderately severe and severe adverse events were both greater in the DD arms than placebo, but there was no dose effect with regard to safety.

Because of the toxicity spectrum of DD, we limit the use of this agent to patients who have failed several systemic agents (often bexarotene and IFN) previously and have more threatening disease such as the presence of skin tumors or nodal involvement. It is important to note that the pivotal trials did not allow concomitant use of corticosteroids to prevent nausea and infusion reactions. Subsequently, a retrospective case review of patients pretreated with corticosteroids suggested a more favorable toxicity profile and a RR of nearly 60%. The nature of the trial limited the conclusions to be drawn but suggested that aggressive pretreatment with steroids made this drug easier to administer to patients with advanced relapsed MF. However, this drug is currently not available. A newer version of the drug has been developed with improved manufacturing characteristics, but is only now entering clinical trials to determine if these changes have altered clinical activity.

Approved Targeted Agents for Cancer But Not for Cutaneous T-Cell Lymphoma

Targeted therapies against unique tumor antigens continue to be tested, such as the recombinant DNA-derived humanized monoclonal antibody alemtuzumab. This antibody is directed against CD52, which is present on the surface of normal and malignant B and T cells, and presumably works through antibody-dependent cellular cytotoxicity and activation of complement-dependent cytotoxicity, but may also induce apoptosis without complement activation. A number of trials of this agent in various stages of MF/SS have been reported. The initial phase II study using alemtuzumab in 50 patients with low-grade NHL, including eight patients with MF, demonstrated a 50% RR in MF (four of eight patients, two CR). In a phase II multicenter study of 22 patients with advanced MF ($n = 15$) and SS ($n = 7$) refractory to PUVA, radiotherapy, or systemic chemotherapy, intravenous treatment with 30 mg alemtuzumab three times a week for 12 weeks resulted in an ORR of 55%, with 32% of patients in CR and 23% in PR. Higher RRs were demonstrated in patients with erythroderma and those with fewer previous treatment regimens. Both patients with tumor-stage disease had progressive disease on alemtuzumab. Kennedy et al studied the efficacy of alemtuzumab in CTCL patients (stage IIB–IV) and demonstrated a PR in three (38%), with infectious complications in seven of eight patients. Two of the responders had SS, and these findings support our perspective that alemtuzumab may be most helpful in patients with erythrodermic MF and SS. We then conducted a trial in 19 heavily pretreated patients with erythrodermic MF or frank SS. In this trial the patients received a variety of subcutaneous, intravenous, or both routes of administration. The overall RR was 84% (47% CR and 37% PR). Median PFS was 6 months, but median overall survival was 41 months despite the advanced-stage disease and extensive prior therapy. We did not experience the dramatic infectious or cardiac events some investigators have reported, likely because of the routine inclusion of prophylactic antiviral, antifungal, and antipneumocystis agents. A multicenter retrospective analysis of 39 patients with advanced MF ($n = 6$) or SS ($n = 23$) indicated that the SS patients experienced a higher RR and longer median time to progression, an observation

that could be explained by findings from another study suggesting that alemtuzumab depletes all T cells in the blood but only the central memory T cells of the skin.

Another target of therapy for MF/SS is CD30. As noted earlier, this antigen is expressed in a variety of malignancies, including advanced HL, ALCL, and often the lesions of tumor-stage or transformed MF (tMF). As previously discussed, brentuximab vedotin (SGN-35) is an antibody to CD30 conjugated via a highly stable protease-cleavable linker to a derivative of auristatin E (monomethyl auristatin E), which inhibits microtubules and induces apoptosis in target cells. It has been approved for the treatment of relapsed HL and systemic ALCL that express CD30. There are now efforts underway to determine its efficacy in primary cutaneous ALCL and MF. Several preliminary studies have been reported. Investigators at Stanford led a trial of this molecule in MF/SS with all levels of expression of CD30. At the time of the preliminary report, 15 patients with MF/SS (13 stage IIB–IV MF/SS, nine with large-cell transformation) were included. Seven of the patients had less than 10% CD30 expression, seven had 10%–50% expression, and one had more than 50% expression by immunohistochemical analysis. An objective response was observed in 60% of the patients and in all cohorts by expression level of CD30. Toxicity was generally mild, including fatigue, peripheral neuropathy, rash, and infusion reactions. Two patients with pretreatment expression of CD30 developed antigen loss during treatment. In a phase II trial, in which SGN-35 was administered at 1.8 mg/kg every 3 weeks for up to eight cycles to 19 heavily pretreated MF/SS patients with variable CD30 expression, an ORR of 68% and median EFS of 27 weeks were reported. In another phase II trial involving 48 relapsed/refractory CD30⁺ CTCL patients (including patients with PC-ALCL, LyP, and MF) who received SGN-35, a 71% ORR was reported (100% ORR among the PC-ALCL and LyP patients). Neither of these studies demonstrated a correlation between response to SGN-35 and degree of CD30 expression, and response was noted even among cases with minimal expression of CD30. AEs observed in both studies included peripheral neuropathy, rash, diarrhea, and fatigue. Currently, patients with relapsed CD30⁺ MF or PC-ALCL are being enrolled in a multicenter, open-label phase III trial, which compares BV to physician's choice of either bexarotene or methotrexate ([ClinicalTrials.gov](https://clinicaltrials.gov/ct2/show/study?term=NCT01578499) identifier: NCT01578499).

Investigational Approaches

Because of the chronic relapsing nature of MF, new therapies with different mechanisms of action are needed to circumvent tumor resistance. A variety of such approaches are under investigation. These include the use of existing or newly developed retinoid compounds or combinations of retinoids with other agents. Other combination modalities under study include retinoids, IFNs, and chemotherapy or radiation therapy, and total-skin electron beam radiotherapy followed by photopheresis or chemotherapy. Given the lack of benefits of combination chemotherapy and radiotherapy previously, the role of such approaches should remain investigational. Another less toxic combination approach has been the simultaneous administration of IFN and phototherapy. An overall RR of 92% has been observed with this combination in all stages of patients, many of whom had been previously treated with other therapies.

Another approach to the therapy of this disease has involved new drugs to exploit the biologic characteristics of these neoplastic cells. For example, Notch signaling has been shown to be dysregulated in a variety of T-lymphocyte neoplasms. It has also been shown that Notch1 is expressed in tumor cells in many advanced-stage patients with MF/SS. There are specific inhibitors of Notch signaling that induce apoptosis in MF/SS cell lines, and this is an elegant example of how these molecular breakthroughs could be exploited to develop new approaches to the treatment of this disease. Other examples of recent or ongoing efforts to target aberrant molecular pathways in CTCL include clinical trials involving the use of PI3K inhibition and selective inhibition of nuclear export ([ClinicalTrials.gov](https://clinicaltrials.gov/ct2/show/study?term=NCT01578499) identifier: NCT01578499).

NCT02314247). Direct targeting of surface receptors of the neoplastic cells with monoclonal antibodies continues to represent a common investigative approach, with a number of new molecules described later.

Anti-CCR4 Monoclonal Antibody

As already discussed, KW-0761 (mogamulizumab) is a humanized defucosylated anti-CCR4 monoclonal antibody that has been approved in Japan for the treatment of ATL. CCR4, often expressed by CTCL cells, contributes to the skin-homing ability of the CTCL cells. Defucosylation of the Fc region of the agent allows for a greater binding affinity to the Fc γ receptor of effector cells, resulting in antibody-dependent cell-mediated cytotoxicity (ADCC). Among 21 MF and 17 SS patients in a phase I/II multicenter study, KW-0761 0.1 mg/kg, 0.3 mg/kg or 1 mg/kg administered weekly resulted in an overall RR of 37% in the total intention-to-treat population. Interestingly, when measured by immunohistochemistry on skin biopsy samples and flow cytometric analysis of peripheral blood, CCR4 expression did not correlate with response to therapy. Ishii et al observed that the degree of KW-0761-mediated ADCC against ATL cells was determined primarily by the number of effector NK cells present rather than by the amount of CCR4 present on the ATL surface. These observations may support the study of NK cell quantification as a biomarker of efficacy of KW-0761 and may support the study of the combination of KW-0761 with an NK cell-enhancing immunomodulatory drug such as lenalidomide. KW-0761 was also evaluated in a multicenter phase II study of 37 relapsed PTCL or CTCL ($n = 8$) patients who received the drug weekly at 1.0 mg/kg for 8 weeks. Overall, there was a 35% RR and a median PFS of 3 months, and among the eight CTCL patients, three had a PR, four had stable disease (SD), and one progressed. AEs consisted of cytopenias, pyrexia, and skin disorders. A phase III multicenter trial is currently enrolling relapsed/refractory CTCL patients for randomization to KW-0761 or vorinostat ([ClinicalTrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT01728805) identifier: NCT01728805).

Anti-CD3 ϵ Immunotoxin

Resimmune (A-dmDT390-bisFv[UCHT1]) is a recombinant anti-CD3 ϵ immunotoxin that is composed of the catalytic and translocation domains of diphtheria toxin fused to two antihuman CD3 ϵ Fv fragments. In a phase I study the agent was administered to 25 CTCL patients, most of whom had been previously treated, at doses ranging from 2.5 to 11.25 μ g/kg intravenously twice daily for 4 consecutive days. Nine patients (36%) experienced a response, four of which were complete (16%). The durations of the CRs were 72+, 72+, 60+, and 38+ months. Some patients in this study slowly converted from PR to CR even after receiving treatment. Patients with a lower tumor burden were more likely to respond. AEs were mild to moderate and included fevers, chills, hypotension, hypoalbuminemia, edema, hypophosphatemia, viral reactivation, and transaminitis. The phase II portion of this study is actively enrolling patients.

Anti-KIR3DL2 Therapy

As already mentioned, KIR3DL2 (CD158k) represents a unique cell surface target among the malignant CD4 $^+$ T cells from SS patients and tMF patients. KIR3DL2, which belongs to the inhibitory KIR family and is normally detectable on a minor subset of NK cells and on a rare subset of CD3 $^+$ CD8 $^+$ circulating T cells, has ligand specificity for HLA-A3 and HLA-A11 through a peptide-specific interaction and for HLA-B27 homodimer through peptide-independent recognition. CpG oligodeoxynucleotides have been shown to act as a ligand to KIR3DL2 on NK cells as well as on Sézary cells, resulting in downmodulation of KIR3DL2 from the cell surface and induction of cytokine release. Among malignant CD4 $^+$ cells of SS and tMF,

KIR3DL2 acts as an inhibitory coreceptor by its ability to downmodulate CD3-dependent early signaling events and may be responsible for maintaining a high circulating malignant cell burden by preventing activation-induced cell death.

In support of the clinical investigation of the humanized anti-KIR3DL2 antibody, IPH4102, as a treatment for SS and tMF, Marie-Cardine et al demonstrated a correlation between KIR3DL2 expression and TCR-V β clonality on circulating CD4 $^+$ T cells from 32 SS patients (Spearman $r = 0.6609$, $p < .0001$). Among blood samples from 35 healthy volunteers, CD4 $^+$ KIR3DL2 $^+$ T cells comprised 1.4%. Among six SS patient samples, costaining with IPH4102 bound to R-Phycoerythrin and anti-TCR-VB antibody showed consistent and homogeneous staining of the Sézary cells. A small population of TCR-negative cells stained positive for IPH4102, reflecting the normal NK cell population. ADCC and antibody-dependent PMN-mediated cytotoxicity, using allogeneic NK cells, were demonstrated using an SS cell line treated with IPH4102. Complement-dependent cytotoxicity, however, was not observed. In vivo antitumor efficacy was demonstrated in patient-derived xenograft murine models with solid and disseminated disease, with tumor reduction and improvement in survival demonstrated. Furthermore, IPH4102 showed in vitro ADCC among patient samples when using autologous NK cells. Lastly, despite that NK cells express KIR3DL2, the NK cells were spared from the cytotoxic effects of IPH4102 in this study, whereas alemtuzumab led to the elimination of NK cells. Altogether, this series of experiments demonstrate that Sézary cells are sensitive to ADCC mediated by IPH4102 through KIR3DL2 targeting at their surface; circulating NK cells of SS patients are functional and able to mediate potent IPH4102-directed ADCC; and IPH4102 antitumor activity is selectively targeted against KIR3DL2-expressing tumor cells and spares NK effectors. IPH4102 has received orphan drug designation by the European Commission for the treatment of CTCL, and a phase I trial is expected to start in the near future.

Anti-PD-1/PD-L1 Therapy

Given the established role of multiple forms of immunotherapy, such as IFN, extracorporeal photopheresis, and aSCT, in the treatment of CTCL, and the mounting supportive preclinical data, the investigation of the use of anti-PD-1/PDL1 therapy for CTCL is warranted. Conceptually, checkpoint blockade therapy differs from more traditional forms of immunotherapy, such as IFN- α and high-dose IL-2, by blocking the inhibitory controls (i.e., PD-1) of T cells rather than inducing brief periods of immunostimulation. This approach may overcome immunosuppression and thereby lead to more durable control of disease and improved survival. High expression of PD-1 has been noted among CD4 $^+$ T cells from SS patients, compared with the cells of early-stage MF patients and healthy donors in multiple studies. In vitro antibody blockade of PD-1 and PD-L1 from peripheral blood mononuclear cells of CTCL patients resulted in increased production of IFN- γ , a cytokine associated with Th1 antitumor immunity. The cytolytic activity of PD-L1-specific T cells against PD-L1-positive human CTCL cells and the lack of activity against PD-L1-negative human CTCL cells have also been demonstrated, but the use of PD-L1 as a predictive biomarker of response has not been validated. In immunophenotyping studies of freshly isolated malignant CD4 $^+$ T cells and tumor-infiltrating CD8 $^+$ T cells from CTCL patients, both cell lines displayed enhanced expression of PD-1 and other immune checkpoint proteins, consistent with immune exhaustion and suggestive that checkpoint blockade therapy may be beneficial in these patients. Recently presented data regarding the relationship between the mutational burden of some malignancies and response to anti-PD-1 antibody therapy support the investigation of mutational burden, directly assessed by sequencing or indirectly assessed by mismatch repair status, as a predictive marker to anti-PD-1/PD-L1 therapy in CTCL. In a phase I study of anti-PD-1 antibody nivolumab to treat hematologic malignancies, PRs were observed in two of 13 MF patients, while some others experienced

stable disease. Currently, a phase II study is enrolling relapsed/refractory MF/SS patients to receive the anti-PD-1 antibody pembrolizumab ([ClinicalTrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT02243579) identifier NCT02243579).

FUTURE DIRECTIONS

Knowledge of the unique cytokine milieu associated with these neoplastic T cells has led to trials testing cytokines that may inhibit the growth of these cells, such as IL-12 or IL-2. Vaccine approaches may be practical.

Significant amounts of basic and practical research have been performed in an attempt to control this disease, and future treatment approaches will likely depend on further understanding of the molecular and genetic bases of these disorders. We hope that one of the strategies under development or study will lead to treatments that can control the disease and symptomatic effects, or even cure this neoplasm in the majority of afflicted patients.

PLASMA CELL NEOPLASMS

Nikhil C. Munshi and Sundar Jagannath

Multiple myeloma (MM) is a malignancy involving terminally differentiated plasma cells. It includes a spectrum of plasma cell disorders ranging from monoclonal gammopathy of unknown significance (MGUS), a relatively benign condition to smoldering multiple myeloma (SMM), as well as the symptomatic malignant disorder MM, and its more aggressive form, plasma cell leukemia with circulating myeloma cells in the blood (Table 86.1). Various other plasma cell disorders belong to the same group of conditions, including Castleman disease, heavy chain disease, and Waldenström macroglobulinemia. MM is characterized by the presence of clonal plasma cells and production in the majority of cases of a monoclonal immunoglobulin (Ig) and/or its fragment with subsequent involvement or effects on organ function. Because there are five classes of immunoglobulins, the dysfunctional plasma cells can produce any one of the five immunoglobulin subtypes, including IgG, IgA, IgM, IgD, and IgE. Infrequently, heavy-chain components of the immunoglobulin are not produced by the myeloma cells, and the disease manifests as production and secretion of κ or λ light chains only. Very rarely, myeloma fails to produce a significant amount of protein and manifests as a nonsecretory MM. With the availability of a high-sensitivity, free light-chain assay, the frequency of true nonsecretory MM has significantly decreased.

EPIDEMIOLOGY

MM accounts for 1.8% of all malignancies and is the second most common hematologic malignancy. The prevalence of MM was around 95,688 in 2013, and it was estimated that 30,330 men and women (11,400 men and 9120 women) would be diagnosed with and 12,650 men and women would die as a result of myeloma in 2016. It is a disease involving a relatively older population with a median age at diagnosis of 69 years and median age at death of 74 years (Fig. 86.1A). Less than 5% of patients at diagnosis are younger than age 40 years. Myeloma is more frequent in men than in women and in African American than in white persons in the United States (Fig. 86.1B). The incidence of MM in African American males is approximately 15.7 per 100,000 per year as compared with 11.5 per 100,000 per year in African American females. The corresponding incidence rates are 7.7 and 4.5 per 100,000 in white males and females, respectively. A recent survey of MGUS in the US population showed a significantly higher prevalence of MGUS in African Americans (3.7%) as compared with white (2.3%) ($p = .001$) or Hispanic (1.8%) populations. Although the Asian population has a lower incidence of myeloma than their white counterparts, ethnic groups such as Hawaiians, female Hispanics, female American Indians from New Mexico, and Alaskan natives experience higher incidence rates than those of the US white population from the same geographic regions. Although there has been an increase in the incidence of MM, it is primarily attributed to better detection and surveillance of the disease as well as the overall aging of the population worldwide. Moreover, there has been an improvement in the overall survival (OS) of patients with MM from 3 to 7 years and longer.

HISTORICAL ASPECTS

The first published clinical description of a patient with myeloma was by Dr. Henry Bence Jones in 1850. He described a patient,

Thomas Alexander McBean, who presented with symptoms of fatigue, diffuse bone pain, and urinary frequency. Urinalysis showed a urinary protein with a peculiar heat property (now called *Bence Jones proteins*). The disease was given the name *multiple myeloma* by Rustizky in 1873 following his observation of multiple bone lesions in a similar patient. A larger review of this disease by Kahler in 1889 led to its being called *Kahler disease*, especially in Europe. Subsequently, investigative advances defined the disease further with descriptions of plasma cell and x-ray abnormalities in 1900 by Wright, of bone marrow aspiration in 1929, of electrophoresis in 1937, and of immunoelectrophoresis identifying the heavy and light chains in 1953, confirming the monoclonality of immunoglobulins in this disease. In recent years, recurrent chromosomal translocations have defined subgroups of patients with myeloma, and gene expression profiling and proteomic studies are providing a greater molecular understanding of the disease. Similarly, the influence of bone marrow microenvironment on myeloma cell growth and survival has been explored and led to the identification of novel therapeutic targets. The first randomized study in myeloma compared urethane with placebo and indicated that the survival of patients receiving urethane was inferior to that observed with a placebo. Progress in myeloma therapy started with first successful use of a chemotherapeutic agent in myeloma with racemic mixture of D- and L-phenylalanine mustards (sarcosine) in 1958 by Blokhin and colleagues; use of melphalan in 1962 by Bergsagel and colleagues; use of high doses of glucocorticoids in 1967; and subsequently use of melphalan in combination with prednisone (MP), which is used even today. With the use of high-dose therapy (HDT) with melphalan by McElwain and Powles in 1983, complete remissions (CRs) were achieved in a proportion of patients, and the identification of novel agents such as thalidomide and its immunomodulatory analogue lenalidomide and pomalidomide, as well as the proteasome inhibitor bortezomib and carfilzomib during the last 15 years targeting both myeloma cells and the bone marrow microenvironment, has further improved responses and OS.

PATHOBIOLOGY

MM, as with a number of other malignancies, remains a disease that is initiated and sustained by genomic changes that promote uncontrolled proliferative advantages to the tumor cells. Myeloma represents the classic multistep transformation process with an initial premalignant stage, MGUS, demonstrating a number of recurrent cytogenetic abnormalities as well as gene expression changes (Table 86.2). It is well documented that all MM develops from MGUS, suggesting that the initial event required for transformation to MGUS provides the first step in a multistep process.¹

Cytogenetics

MM is characterized by a significant molecular and genomic heterogeneity affecting tumor clones. Karyotypes in MM are usually complex, with both number and structural chromosomal abnormalities observed² (see Chapter 56). Although chromosomal abnormalities using conventional cytogenetics in newly diagnosed patients are detected in only 30% to 50% of patients, owing to the low proliferative activity of MM cells, in advanced stages when cells usually have a higher proliferative index, a greater number of abnormalities are

TABLE 86.1**Diagnostic Criteria for Multiple Myeloma, Myeloma Variants, and Monoclonal Gammopathy of Unknown Significance****Monoclonal Gammopathy of Undetermined Significance (MGUS) or Monoclonal Gammopathy, Unattributed/Unassociated (MG[u])**

M protein in serum <30 g/L
 Bone marrow clonal plasma cells <10%
 No evidence of other B-cell proliferative disorders
 No myeloma-related organ or tissue impairment (no end-organ damage, including bone lesions)

Asymptomatic Myeloma (Smoldering Myeloma)

M protein in serum >30 g/L and/or
 Bone marrow clonal plasma cell ≥10% to 60%
 No related organ or tissue impairment (no end-organ damage, including bone lesions) or symptoms

Symptomatic Multiple Myeloma (MM)

M protein in serum and/or urine^a
 Bone marrow (clonal) plasma cells^a or plasmacytoma
 Related organ or tissue impairment (end-organ damage, including bone lesions)

Solitary Plasmacytoma of Bone

No M protein in serum and/or urine^b
 Single area of bone destruction caused by clonal plasma cells
 Bone marrow not consistent with MM
 Normal skeletal survey (and MRI of spine and pelvis if done)
 No related organ or tissue impairment (no end-organ damage other than solitary bone lesion)^b

Nonsecretory Myeloma

No M protein in serum and/or urine with immunofixation
 Bone marrow clonal plasmacytosis ≥10% or plasmacytoma
 Related organ or tissue impairment (end-organ damage, including bone lesions)

Extramedullary Plasmacytoma

No M protein in serum and/or urine^c
 Extramedullary tumor of clonal plasma cells
 Normal bone marrow
 Normal skeletal survey
 No related organ or tissue impairment (end-organ damage including bone lesions)

Multiple Solitary Plasmacytomas (Recurrent or Not)

No M protein in serum and/or urine^d
 More than one localized area of bone destruction or extramedullary tumor of clonal plasma cells that may be recurrent
 Normal bone marrow
 Normal skeletal survey and MRI of spine and pelvis if done
 No related organ or tissue impairment (no end-organ damage other than the localized bone lesions)

Myeloma-Related Organ or Tissue Impairment (End-Organ Damage)

Calcium levels increased: serum calcium >0–25 mmol/L above the upper limit of normal or >2–75 mmol/L
 Renal insufficiency: creatinine >173 mmol/L
 Anemia: Hemoglobin 2 g/dL below the lower limit of normal or hemoglobin <10 g/dL
 Bone lesions: Lytic lesions or osteoporosis with compression fractures (MRI or CT may clarify)
 Other: Symptomatic hyperviscosity, amyloidosis, recurrent bacterial infections (more than two episodes in 12 mo)

^aIf flow cytometry is performed, most plasma cells (>90%) will show a neoplastic phenotype.

^bA small M component may sometimes be present.

^cA small M component may sometimes be present.

^dA small M component may sometimes be present.

CT, Computed tomography; MRI, magnetic resonance imaging.

TABLE 86.2**Recurrent Cytogenetic Changes in Myeloma**

Common Cytogenetic Alterations		
Chromosomal Abnormality	Patients (%)	Genes Involved
Hyperdiploidy	50–60	Unclear
Hypodiploidy	20	Unclear
Pseudodiploidy	15	Unclear
del(17p)	8	p53
t(4;14)	15	<i>FGFR3</i> , <i>MMSET</i>
t(11;14)	20	Cyclin D1
t(14;16)	3	<i>c-MAF</i>
t(14;20)	1	<i>MAFB</i>
t(6p25 or 6p21;14)	1	<i>IRF4</i> or <i>CCND3</i>
t(8;14)	5	<i>c-Myc</i>
t(9;14)	<1%	<i>PAX5</i>
del(13 or 13q)	50%	Unclear
Recently Identified Alterations		
1q+	35%	
1p–	30%	
5q+	50%	
12p–	10%	

identified. Importantly, using fluorescence in situ hybridization (FISH) as well as flow cytometry–based DNA aneuploidy analysis, genomic alterations are observed in over 90% of the patients with MM. These results suggest that the normal cytogenetics observed in the majority of the patients is derived from normal cellular components of the bone marrow and not from the cells belonging to the myeloma clone. Although detection of karyotypic changes in MGUS and SMM is extremely low, again owing to very low frequency of proliferating cells in these indolent conditions, with the use of FISH, up to 50% of the patients with MGUS and SMM have genomic alterations.

The most prominent cytogenetic abnormality identified is hyperdiploidy and recurrent translocations involving 14q32 region, which contains the *IgH* gene, the λ light chain region on chromosome 22, or the κ light-chain genes on chromosome 2, suggesting that these abnormalities may be an early important event in the development of plasma cell disorders. *IgH* translocation has been confirmed using FISH analysis in approximately 47% of patients with MGUS and over 70% of patients with MM, the λ light chain region in 17% of patients with MM, and the κ light-chain genes in a very small number of patients. The frequency of various common translocations in MM is provided in Table 86.2.

Hyperdiploidy

Almost half of patients with MM have a hyperdiploid karyotype (>46 chromosomes), whereas less than one-fourth of the patients have a hypodiploid karyotype (<46 chromosomes). Hyperdiploid MM is a relatively homogeneous group, with a median quartile of 54 chromosomes involving nonrandom gains. Interestingly, trisomies mostly involve odd-numbered chromosomes: 3, 5, 7, 9, 11, 15, 19, and 21. The structural abnormalities observed in MM are not exclusive for nonhyperdiploid MM, because they are also observed in hyperdiploid patients along with the hyperdiploid changes. Of note, most (if not all) of the human myeloma cell lines are derived from patients with the nonhyperdiploid genomic changes, which may reflect the difference in proliferative potential between these two categories. Hyperdiploidy has been reported to be associated with a better prognosis based upon retrospective analyses. This has been confirmed more

Fig. 86.1 (A) Multiple myeloma (MM) average annual age- and gender-specific incidence per 100,000 in the United States in 2009. (B) MM average annual race-specific incidence per 100,000 in the United States in 2009. Increase in incidence is noted with advancing age; the incidence is greater in males than in females; and a higher incidence is observed in African American than in white populations.

recently using an interphase FISH approach to define ploidy. However, a study by the International Myeloma Foundation (IFM) showed that hyperdiploidy was not an independent prognostic factor; rather, it was associated with a lower incidence of other independent poor risk features, such as $\text{del}(13)$, $\text{t}(4;14)$, and $\text{del}(17p)$.³

Translocations Involving 14q32

Chromosomal region 14q32 has been identified as a recurrent site of translocations in myeloma. Unlike mantle cell lymphoma, where the IgH breakpoint is near the site targeted by VDJ recombination, the breakpoint on 14q32 in MM is located within the IgH or the switch region. In all, over 25 different chromosomal regions have been involved in translocations involving 14q32 region; the major translocation partners are 4p16, 6p21, 11q13, 16q23, and 20q11. The $\text{t}(11;14)(q13;q32)$ translocation is present in approximately 20% of patients with myeloma and involves the cyclin D1 gene⁴ (Table 86.2). Although this translocation leads to upregulation of cyclin D1, its role in oncogenesis is unknown. Despite known molecular functions of cyclin D1 in the cell-cycle and cellular proliferation, the $\text{t}(11;14)$ myelomas have a low proliferative index, appearing morphologically as small mature plasma cells or lymphoplasmacytic cells expressing CD20. Initial studies suggested a better survival outcome in patients

with this translocation; however, larger studies have failed to confirm this observation.

The $\text{t}(4;14)(p16;q32)$ is a cryptic translocation not easily detectable by conventional karyotyping. It leads to a unique dysregulation of two genes located at the 4p16 region; the gene for fibroblast growth factor receptor 3 (FGFR3) located on the telomeric side of the breakpoint and MM SET domain gene (MMSET) located on the centromeric side (Table 86.2). The translocation leads to the molecular activation of FGFR3 gene transcription. FGFR3 is one of the four high-affinity tyrosine kinase receptors for FGF and mediates signaling, resulting in signal transducer and activator of transcription 3 (STAT3) phosphorylation and activation of the mitogen-activated protein kinase (MAPK) pathway (Table 86.2). It is not expressed in normal plasma cells and is shown to have oncogenic potential in both *in vitro* and *in vivo* studies. Interestingly, about one-third of the patients with $\text{t}(4;14)$ do not overexpress FGFR3. The translocation also generates a novel chimeric IGH-MMSET gene by disrupting the MMSET gene within its first intron. MMSET plays a crucial role in chromatin remodeling as well as in transformation in MM.

Several studies have confirmed that a poor prognosis is associated with the $\text{t}(4;14)$; however, some of the newer therapies, such as bortezomib, are able to overcome the poor outcomes associated with $\text{t}(4;14)$. It is interesting to note that genetic studies using FISH have identified the presence of $\text{del}(13)$ in at least 85% of the patients with

t(4;14). The reasons for this strong association are so far unknown. Both FGFR3 and MMSET are potential therapeutic targets, and several tyrosine kinase inhibitors are currently being tested in order to inhibit FGFR3 function.

The t(14;16)(q32;q23) involves the *c-MAF* gene located at the 16q23 breakpoint. c-Maf is a basic zipper transcription factor that positively regulates cyclin D2 and ITGB7 (Table 86.2). Although this translocation is reported in only 5% of patients with MM, it is observed in 25% of MM cell lines, suggesting its role in cell proliferation as well as its association with aggressive behavior of the disease. t(14;16) is considered to be associated with poor prognosis. The other translocation partner of 14q32 is 20q11, observed in less than 5% patients. It dysregulates *MAFB* expression, another basic transcription factor belonging to the MAF family, and it has as yet unclear molecular consequences. It is also considered to be associated with a poor outcome; however, studies have been very small because of its infrequent occurrence.

Although c-Myc is increasingly being considered to play a role in myeloma pathobiology, t(8;14) translocations involving c-Myc are rare, unlike Burkitt lymphoma, where it is considered a classic feature. Almost 20% of patients with 14q32 translocation have other partners with unclear clinical or molecular significance.

Deletion 17p

Loss of the short arm of chromosome 17 [del(17p)] has been described in about 10% of patients with early-stage MM. The deletion involves the major part of the short arm of chromosome 17 with consequent loss of a number of genes, including *p53* (Table 86.2). However, *p53* abnormalities represent an important late event, mostly acquired during evolution and associated with progression to an aggressive form of the disease. A study of *p53* gene mutations in 52 patients with myeloma showed that 7 of 52 patients had *p53* abnormalities, all with an advanced, clinically aggressive acute/leukemic stage of MM. Patients presenting with del(17p) have a poor prognosis, despite the use of novel agent combinations or HDT and transplant. Mutations of the *TP53* gene are uncommon events in myeloma, especially at diagnosis.³

Deletion 13q14

Deletion of chromosome 13 or part of its long arm is detected in approximately 15% to 20% of the patients by conventional cytogenetics and by interphase FISH in 50% of the patients. Interestingly, del(13q) is also detected in 50% of patients with MGUS by FISH, predominantly in a small subpopulation of cells, indicating that it is a secondary genetic event occurring after initial clonal expansion. Although the retinoblastoma gene is present in the deleted region, the exact molecular consequence of del(13q) has not yet been ascertained. A number of studies, especially with conventional agents as well as HDT, have identified del(13q) to be a poor prognostic feature in myeloma; however, recent studies have identified that there is an association between del(13q) and t(4;14), and in absence of t(4;14), del(13q) by itself is not associated with a poor prognosis, especially with the use of novel agents.³ However, del(13q) detected by conventional cytogenetics is still considered a poor prognostic feature. Interestingly, del(13q) is also common in chronic lymphocytic leukemia but does not confer an adverse prognosis.

Abnormalities of the 1q Region

Recent studies have reported the biologic role and prognostic implications of a gain of 1q. In fact, this is one of the most frequently reported cytogenetic abnormalities in MM, being described in about one-third of the patients. This abnormality has also been reported in a number of other hematologic and solid tumors. A gain of the 1q21 chromosomal region or overexpression of the *CKS1B* gene located in

this region is associated with a poor outcome; however, further studies are required in order to ascertain the clear prognostic impact of 1q gains. A number of important genes in addition to *CKS1B* are located in this region, including the interleukin 6 (IL-6) receptor.³

GENOMICS

Expression Profiling

Several investigators have performed expression profiling of CD138⁺ myeloma cells using high-density microarrays in order to better understand the pathobiology of myeloma, develop prognostic models, identify new targets for drug development, and develop personalized medicine approaches. These studies have identified sequential genetic changes from normal plasma cells to plasma cells from patients with MGUS and MM, and they have provided clues to the molecular basis for malignant transformation and potential therapeutic targets.

Expression profiling in combination with cytogenetic changes has been used to classify myeloma in order both to identify phenotypic and molecular subgroups as well as to develop a prognostic scoring system. The molecular classification compared profiles from MM cells with those from MGUS representing an initial indolent form of the disease and MM cell lines representing cells with a more aggressive phenotype. A later, more detailed classification identified different subgroups, based mainly on cyclin D gene expression and on the different 14q32 translocations. This molecular classification, refined in 2006, identified seven subclasses of myeloma. In this model, the first class was defined by the translocation t(4;14) and was identified by overexpression of the MMSET and/or FGFR3 genes. The second class was related to the translocation t(14;16) or t(14;20) and was defined by upregulation of one of the MAF genes. Cases with CCND1 or CCND3 upregulation [owing to the translocations t(11;14) or t(6;14)] clustered in two different classes, CD1 (class 3) and CD2 (class 4). The CD2 group was characterized by CD20 expression. The fifth group was characterized by hyperdiploidy. The last two groups were characterized by a low incidence of bone disease, according to low Dickkopf-related protein 1 (DKK1) expression, whereas the last group was characterized by increased expression of genes involved in proliferation. This molecular classification has been further modified by the Dutch-Belgian Hemato-Oncology Group (HOVON) group. This analysis did not confirm the “low bone disease” group, but three other subgroups were identified: one group characterized by overexpression of cancer testis antigen genes, another group defined by overexpression of positive regulators of the nuclear factor- κ B (NF κ B) pathway, and a third subgroup enriched for “myeloid” genes (unclear significance).⁵ Various prognostic signatures have also been developed using these expression profile data to identify high-risk disease. RNA sequencing is now replacing microarray-based expression profiling, providing additional genomic correlates including transcriptome modifiers and splicing.

Copy Number Alteration

DNA-based high-throughput techniques such as array comparative genomic hybridization (CGH) and high-density single-nucleotide polymorphism (SNP) arrays have identified recurrent copy number alterations (CNAs). These studies have identified significant molecular heterogeneity (Fig. 86.2).⁶ CNAs have been observed in 98% of 192 newly diagnosed patients with MM. Two distinct groups were observed. One group of patients showed a hyperdiploid phenotype with gains of chromosomes 3, 5, 7, 9, 11, 15, 18, 19, and 21 and/or loss of chromosomes 13, 22, and X (in female cases). The second group is characterized by gain or loss of subchromosomal region. These include deletion of 1p, 6q, 8p, 12p, 14q, 16p, 16q, and 20p as well as amplification of 1q and 6p. The genomic heterogeneity observed within the hyperdiploid group is driven by the presence of either gain of copies of chromosome 1q and/or chromosome 11, chromosome 13 loss, or chromosome 5 gain. Subclasses of

Fig. 86.2 UNSUPERVISED HIERARCHIC CLUSTERING OF SINGLE-NUCLEOTIDE POLYMORPHISM (SNP) ARRAY-BASED DATA IN 192 PATIENT SAMPLES. Each column represents a patient, and SNPs are arranged from 1p(tel) to Xq(tel) from *top* to *bottom* so that copy number changes are depicted from *top* to *bottom* for each chromosome. *Red* suggests gain of copy number, and *blue* suggests loss of copy number (*upper*). (A) Recurrence of copy number abnormalities (CNAs) across 192 patients with multiple myeloma (MM) in chromosomal order. *Red* or *blue* bars denote gain or loss of chromosome material (*lower*). The figure identifies recurrent areas of gains and losses in MM with identification of genomic subgroups and potential therapeutic targets. (Adapted from Avet-Loiseau H, Li C, Magrangeas F, et al: Prognostic significance of copy-number alterations in multiple myeloma. *J Clin Oncol* 27:4585, 2009.)

hyperdiploid patients with MM and their correlation with gene expression profiles provide a basis for identifying therapeutically targetable genes. The molecular basis of this genomic heterogeneity may stem from uncontrolled recombination activity that may drive continued acquisition of genomic changes.

To identify genetic events underlying the genesis and progression of MM, a high-resolution analysis of recurrent CNAs using array CGH and expression profiles was prepared from a collection of MM cell lines and outcome-annotated clinical specimens.⁷ Attesting to the molecular heterogeneity of MM, distinct genomic subtypes along with 87 discrete minimal common regions within recurrent and highly focal CNAs were identified. The genes residing in these regions provide a genomic framework to understand the biology of MM as well as to identify potential therapeutic targets.

Transcriptome Modifiers

Alternate splicing is an important posttranslational modification that allows production of multiple protein isoforms, and over 90% of human genes undergo alternative splicing. The spliced isoform frequency varies between tissues, and these protein isoforms may have related, distinct, or even opposing functions. Changes in alternative splicing have been reported in myeloma cells compared with normal

plasma cells, and these changes have been correlated with an effect on overall clinical outcome.

MicroRNAs (miRNAs or miRs) are a class of small noncoding RNAs that cleave specific targeted transcripts inhibiting translational of specific genes. Differences in the expression patterns of miRNAs have been observed between MM and MGUS. For example, miR-32, and miR-17-92, are overexpressed only in MM, whereas miR-21, miR-106b-25, and miR-181a/b show similar expression patterns in both MM and MGUS but are highly expressed compared with normal plasma cells, providing a possible clue to events underlying progression from MGUS to MM. miRs 15a/16 are present on chromosome 13, and their downregulation is described in a subset of MM. Although this does not strictly correlate with chromosome 13 deletion, which is observed in almost half of the patients with MM, a potential effect of these miRs on MM cell proliferation has been described. A similar attempt at correlating observed cytogenetic changes and their effects on miR expression has identified overexpression of miR-let-7e, miR-125-5p, and miR-99b in patients with t(4;14) translocation and miR-1 and miR-133a in patients with t(14;16) MM. A causal relationship between changes in these miR expression patterns and their effects on target genes and eventual phenotypic changes in MM still needs to be established.⁸ As in gene expression profiling, miRNA expression profiling also identifies subgroups with different clinical outcomes, highlighting a significant role of miRNAs in determining MM biology and its possible role as a therapeutic target. An integrated analysis of mRNA and miR profiling has been used to identify regulatory networks that combine miRNA-mRNA pairs that may drive the behavior of tumor cells. One such network combines p53-MDM2 expression with the downregulation of miR-192, miR-194, and miR-215 in a subset of patients with MM. Such analyses might explain some of the observed genomic changes in myelomagenesis and its progression. Further studies have reported a role for miR-21, miR-29, and miR-34a in supporting myeloma cell and survival, suggesting their potential as novel therapeutic targets. Efforts to combine various genomic changes to develop an integrated oncogenomic model are being pursued. A recent study has described feedforward loops integrating miRNA, transcription factor, and gene. One such dysregulated circuit in MM includes c-Myc/miR-23b/Sp1, which has potential for therapeutic targeting.

Epigenomic Alterations

The importance of epigenetic regulation in MM was established by the finding that a lysine methyltransferase (MMSET) was rearranged and activated in poor prognosis t(4;14)-associated MM. Additional studies in MM have begun to further describe epigenomic events, including DNA methylation, histone modifications, and other aberrations of chromatin, that affect MM proliferation and survival. This area of research has gained added importance with approval of the first histone deacetylase (HDAC) inhibitor for the treatment of MM.

A genome-wide methylation profile has identified hypomethylation as a characteristic that distinguishes nonmalignant from malignant plasma cells.⁹ Different methylation patterns have been observed in MGUS and MM cells, explaining their distinct gene expression patterns and the behavior of myeloma cells. Similarly, the differential or downregulated expression of genes involved in cell-cell signaling and cell adhesion by plasma cell leukemia cells has been attributed to remethylation of the family of genes. The downregulated expression of adhesion genes might explain the independence of plasma cell leukemia cells from interactions with bone marrow stromal cells (BMSCs), leading to their release into the circulation. Epigenetic changes modulating myeloma cell growth and survival genes have also been reported. For example, methylation of p16, a negative cell-cycle regulator, is reported as an early event in MGUS. p16 methylation, however, has not been shown to be predictive of OS in a larger cohort study. A recent study combining DNA methylation and gene expression profiling identified hypermethylated *GPX3*, *RBP1*, *SPARC*, and *TGFBI* genes to be associated with significantly shorter OS, independent of other high-risk features.

Chromatin regulators have become an important target in understanding myeloma biology and as potential therapeutic targets. Bromodomain-containing protein 4 (BRD4) is a widely expressed transcriptional coactivator and has been identified as a regulatory factor for c-Myc expression in myeloma. JQ1, an inhibitor of BRD4, induces antiproliferative effects associated with cell-cycle arrest and cellular senescence. Although the prognostic impact of epigenomic changes has still not been studied in detail, it has already provided various therapeutic targets, including HDAC inhibitors or enhancer of zeste homolog 2 (EZH2) inhibitor.

Sequencing

The availability of next-generation sequencing (NGS) has revealed a complex and evolving genomic structure in myeloma. Three large independent studies ($n = 733$ patients) have described the mutational landscape in myeloma (Table 86.3). These studies failed to identify a universal driver mutation, but they revealed recurrent lower-frequency mutations in KRAS, NRAS, FAM46C, DIS3, BRAF, and TP53. Mutations in NRAS, KRAS, and BRAF all affect the MAPK pathway, with overall perturbation of this pathway occurring in around half of the patients. Specific mutations (ataxia telangiectasia mutated [ATM], ataxia telangiectasia and Rad3-related protein [ATR], TP53, CCND1), their mutational load, and copy number abnormalities have been used as markers of prognosis in myeloma.

NGS studies have confirmed that at the time of diagnosis, patients have a number of coexistent clones. Some mutations are in all the cells (clonal), whereas others are in a subset of cells (subclonal). Importantly, the clonal and subclonal content changes and evolves over time. Using sequential samples from the same patient, four distinct patterns of clonal evolution have been observed (linear, branching, no change, and differential clonal response) (Fig. 86.3). This information can now be exploited in the clinic. Because the genomic characteristics continue to evolve in a patient, repeated reassessment over time may be required.

Besides prognostication, the mutational profile is beginning to be used to guide therapy and to develop a personalized medicine approach. The presence of NRAS mutations has been reported to be associated with a poor response to bortezomib, whereas interferon regulatory factor 4 (*IRF4*) mutations are associated with a better outcome following immunomodulatory drug (IMiD) therapy. Mitogen-activated protein kinase kinase (MEK) inhibitors for the MAPK pathway, BRAF inhibitor for B-RAF mutations, ATR/ATM inhibitors, and CCND1 inhibitors are some examples of adapted strategies that can now be considered in patients with specific mutations. Vemurafenib was effective in a patient with myeloma with V600E BRAF mutation. Similarly, a larger study of a MEK inhibitor, trametinib, in RAS-mutated/MAPK pathway-activated relapsed refractory myeloma has shown encouraging efficacy. NGS data is also being used to accurately evaluate responses to treatment targeting minimal residual disease (MRD).

MICROENVIRONMENT AND SIGNALING

Myeloma cells interact with BMSCs, leading to both local cytokine production and both cytokine-mediated and adhesion-mediated signaling changes. The adhesion of the MM cell to the BMSC is mediated by the interaction of the adhesion molecules expressed by myeloma cells (Table 86.3) with BMSCs and extracellular matrix proteins. Adhesion and associated signaling changes affect the migration and localization of the myeloma cells in the bone marrow. Moreover, proliferative/antiapoptotic signaling cascades activated within MM cells as a result of these interactions include phosphatidylinositol 3-kinase (PI3K)/Akt, Ras/Raf/MAPK, MEK/extracellular signal-related kinase (ERK), Janus kinase 2 (JAK2)/STAT3, and NFκB. These pathways lead to MM cell growth, survival, and development of drug resistance (Fig. 86.4).¹⁰ For example, syndecan-1, a cell surface transmembrane heparan sulfate proteoglycan present on MM cells, interacts with type I collagen and regulates the growth of MM cells; it also mediates increased osteoclast (OC) activity. Elevated

TABLE 86.3 Recurrent Mutated Genes in Multiple Myeloma

Gene	Function/Pathway	Prevalence in Bolli et al ($n = 67$ Patients)	Prevalence in Lohr et al ($n = 203$ Patients)
<i>NRAS</i>	MAP kinase pathway	25% (17/67)	20% (40/203)

Two-dimensional density plots show the clustering of the fraction of tumor cells carrying each mutation (*black dots*) at each time point (*x* = early sample, *y* = late sample; increasing intensity of *red* indicates the location of a high posterior probability of a cluster). *Right*: Phylograms representing the clonal composition of the tumor at each time point, where the length of each branch is proportional to the size of the clone (i.e., the number of variants) and the width to its clonality (i.e., the proportion of cells bearing each variant).

Fig. 86.4 INTERACTION AND ADHESION OF MULTIPLE MYELOMA (MM) CELLS TO BONE MARROW (BM) STROMAL CELLS (BMSCs) LEADS TO ADHESION- AND CYTOKINE-MEDIATED SIGNALING. Binding of MM cells to BMSCs induces the activation of p42/p44 mitogen-activated protein kinase (MAPK) and nuclear factor- κ B (NF κ B) in BMSCs. The activation of NF κ B upregulates adhesion molecules on BMSCs. Cytokines secreted through this interaction, including interleukin 6 (IL-6), tumor necrosis factor- α (TNF- α), and vascular endothelial growth factor (VEGF), activate the main signaling pathways (p42/p44 MAPK, Janus kinase [JAK]/signal transducer and activator of transcription 3 [STAT3] and/or phosphatidylinositol 3-kinase [PI3K]/AKT) and their downstream targets, which triggers MM cell growth, survival, and migration. The RAS/RAF/mitogen-activated protein kinase kinase (MEK)/MAPK pathway mediates proliferation of MM cells. JAK/STAT3, along with upregulation of B cell lymphoma extra large (BCL-XL) and myeloid cell leukemia-1 (MCL1), mediates survival. PI3K/AKT, through downstream activation of BAD and NF κ B and/or inactivation of caspase-9, mediates antiapoptosis. NF κ B and forkhead in rhabdomyosarcoma (FKHR) modulate cyclin D and KIP1, thereby regulating cell-cycle progression. Signaling through PI3K induces downstream protein kinase C (PKC) activity and MM cell migration. *APRIL*, A proliferation-inducing ligand; *BAFF-R*, B cell-activating factor receptor; *BSF-3*, B-cell stimulating factor 3; *ERK*, Extracellular signal-related kinase; *FGFR3*, fibroblast growth factor receptor 3; *GSK-3 β* , glycogen synthase kinase 3 β ; *IAP*, inhibitor of apoptosis protein; *ICAM-1*, intercellular adhesion molecule 1; *IGF-1*, insulin-like growth factor 1; *IL*, interleukin; *LFA-1*, lymphocyte function-associated antigen 1; *mTOR*, mammalian target of rapamycin; *MUC-1*, mucin 1; *SDF-1 α* , stromal cell-derived factor 1 α ; *TNF- α* , tumor-necrosis factor- α ; *VCAM-1*, vascular cell adhesion molecule 1; *VEGF*, vascular endothelial growth factor; *VLA-4*, very late antigen 4. levels of syndecan-1 shed into serum correlate with increased tumor mass, decreased matrix metalloproteinase-9 activity in serum, and a poor prognosis.

There are various cellular components that constitute the bone marrow milieu, including OCs, osteoblasts (OBs), endothelial cells, and immune cells, each contributing distinctly to the overall effect of the microenvironment. For example, the cross-talk between tumor cells and components of the bone marrow comprised of OCs and OBs help propagate not only the development of osteolytic lesions but also survival and proliferation of MM cells. Several cytokines and signaling pathways have been identified as important mediators in the disruption of the OC–OB axis.¹¹ Impaired osteoblastogenesis

resulting from the release of WNT inhibitors such as DKK1 have been studied, and a neutralizing DKK1 antibody has been shown to suppress tumor-induced bone resorption and MM growth in vivo. Restoring normal bone homeostasis by disrupting this cross-talk represents a potential strategy to create a hostile niche for tumor growth. Similarly, endothelial cell proliferation and increased angiogenesis play a prominent role in MM. Compared with normal bone marrow, increased bone marrow microvessel density (MVD) has been observed in MGUS and MM. There is a stage-related increase in bone marrow MVD that is also correlated with prognosis. Both vascular endothelial growth factor (VEGF) and hepatocyte growth factor (HGF) have been reported to be angiogenic factors expressed

by MM cells. These results also suggest angiogenesis as a potential therapeutic target and explain in part the efficacy of thalidomide and lenalidomide.

Activation of NF κ B has been observed in MM cells, especially following their interaction with BMSCs. A number of abnormalities contributing to the dysregulation of NF κ B and constitutive activation of the noncanonical NF κ B pathway have been described.¹⁰ The NF κ B pathway can be activated either by deletion of NF κ B inhibitors (such as TRAF3 or CYLD) or by activation of NF κ B activators (such as NF κ B-inducing kinase [NIK] or CD40). Inactivating mutations of TRAF3 and/or elevated expression of NIK by genomic alterations or protein stabilization have been described and may explain mechanisms whereby MM cells achieve autonomy from the bone marrow microenvironment.

CYTOKINES

Myeloma cell growth, survival, antiapoptosis, and drug resistance are in part mediated by a number of cytokines produced by MM cells as well as BMSCs. In fact, the production of cytokines is significantly modulated by MM–BMSC interactions and includes IL-6, insulin-like growth factor 1 (IGF-1), VEGF, tumor necrosis factor- α (TNF- α), transforming growth factor- β (TGF- β), IL-17, IL-21, C-X-C motif chemokine 12 ligand (CXCL-12), and others.¹⁰

Interleukin 6

IL-6 is one of the most important cytokines mediating both growth and survival of MM cells. IL-6 plays an important role in the terminal differentiation and also the proliferation of normal plasmablasts. The IL-6 receptor is composed of an α chain (gp80) and a signal-transducing β chain (gp130), which are expressed by MM cells. IL-6 binding to its receptor activates Ras/RAF/MEK/ERK, JAK/STAT, and PI3K/AKT signaling pathways, mediating growth, survival, and drug resistance. The major source of IL-6 production is the bone marrow stroma, with myeloma cells contributing to a lesser extent. IL-6 production is induced by MM–BMSC interactions as well as by other cytokines, including TNF- α and VEGF, present within the bone marrow milieu. IL-6 acts mainly in a paracrine fashion but also has, to some extent, autocrine activity. IL-6 has a number of other activities, including being responsible for a number of symptoms observed in patients, induces anemia and thrombocytosis, induces regulatory T cells (Tregs) as well as T helper 17 (Th17) cells with associated immunosuppression, and mediates enhanced bone resorption by OCs. Additionally, IL-6 promotes thrombosis without affecting fibrinolysis. It induces a prothrombotic state by increasing the expression of fibrinogen, factor VIII, and von Willebrand factor; increases the production of platelets; and activates endothelial cells. Importantly, it confers resistance to antitumor agents especially dexamethasone. Myeloma cells shed IL-6R α and soluble IL-6R, which can transduce the response of myeloma cells to IL-6. High serum levels of IL-6 as well as IL-6R are predictive of a poor prognosis. Both IL-6 and IL-6R are thus therapeutic targets, and antibodies targeting them are in advanced stages of clinical development.

Insulin-Like Growth Factor 1

IGF-1, similar to IL-6, is a mitogenic factor secreted by myeloma cells and mediates growth and survival of myeloma cells through activation of the PI3K and MAPK signaling pathways. IGF-1 receptor is expressed by myeloma cells, and binding of IGF-1 to its receptor activates both signaling pathways. IGF-1 also mediates adhesion and migration of myeloma cells via β_1 -integrin and upregulates FLIP, XIAP, and A1/Bfl1, thereby further enhancing tumor cell growth and survival. A number of IGF-binding proteins have been described that modulate IGF-1 activity. These molecular and signaling changes collectively lead to induction of drug resistance, especially to

dexamethasone and to a greater extent than that observed with IL-6. These results have provided evidence for IGF-1 as an important therapeutic target.

Vascular Endothelial Growth Factor

VEGF is produced predominantly by myeloma cells, and its expression is enhanced by MM–BMSC interaction as well as by IL-6 and CD40 activation. It has only modest proliferative effects on myeloma cells, but it is the major factor affecting myeloma cell migration as well as angiogenesis. VEGF mediates part of its activity via Flt-1 phosphorylation and downstream activation of MEK and protein kinase C α (PKC α) signaling. Although these data suggest VEGF as a potential target, specific anti-VEGF therapeutics have not yet yielded significant clinical responses in myeloma.

Transforming Growth Factor- β

TGF- β does not have a direct effect on myeloma cells, but it has a number of activities that indirectly affect the clinical presentation of patients with myeloma. It is produced by MM cells and induces secretion of IL-6 by BMSCs. Importantly, it induces immunosuppression characteristic of myeloma and may also affect normal plasma cell development and function, thereby contributing to suppressed background immunoglobulin production in myeloma. It is also a major cytokine that affects Th cell development, especially Tregs and Th17 cells.

Interleukin 17 and Proinflammatory Cytokines

Elevated levels of Th17 cells, along with increased levels of serum IL-17 and associated proinflammatory cytokines IL-21, IL-22, and IL-23, are observed in patients with myeloma. IL-17 has multiple effects in myeloma, including induction of myeloma cell growth; suppression of immune function, especially in association with IL-22; and induction of bone disease by increasing OC number and function. IL-17 also induces IL-6 production by BMSCs, thereby augmenting its myeloma growth-inducing effects. IL-17 triggers phosphorylation of JAK1, STAT3, and ERK1/2. TNF- α upregulates expression of both IL-21 and of IL-21 receptor (IL-21R), and IL-21 induces proliferation and inhibits apoptosis of myeloma cells independent of IL-6 signaling.

Other Cytokines and Chemokines

Tumor Necrosis Factor- α

TNF- α is primarily a mediator of inflammation. It is produced by myeloma cells and has no significant direct effect on myeloma cells. However, it induces IL-6 production by BMSCs. Antibodies specifically targeting TNF- α have not shown clinical activity. CXCL-12 (SDF-1) is expressed by BMSCs, and its receptor CXCR4 is expressed by myeloma cells. It induces only a minimal proliferative effect; however, it plays a more important role in mediating migration. HGF, through its receptor c-Met expressed on the majority of myeloma cells, promotes cell invasion, migration, and proliferation. It also induces differentiation and proliferation of OCs and increases bone resorption in patients with myeloma.

IMMUNE ENVIRONMENT

Significant immune dysfunction is observed in patients with MM involving both T-cell and B-cell function as well as abnormalities in dendritic cell (DC), natural killer (NK) cell, and natural killer T (NKT) cell activity.^{12–14} Researchers in a recent study described the

importance of antigen-driven selection in the pathogenesis of MGUS. Those researchers investigated the increased association of MGUS in patients with Gaucher disease and showed that the clonal immunoglobulin in patients with Gaucher disease was reactive against lysoglucosylceramide, which is markedly elevated in these patients. Additionally, 33% of patients with sporadic MGUS also have clonal immunoglobulins specific for the lysolipids and lysophosphatidylcholine. These data were confirmed in mouse models of Gaucher disease–associated MGUS. Furthermore, these investigators also identified a novel type II NKT cell–mediated pathway for glucosphingolipid-mediated dysregulation of humoral immunity to account for the increased risk of B-cell malignancies observed in Gaucher disease.

T Cells

Significant phenotypic and functional aberrations in both CD4⁺ and CD8⁺ T cells have been observed in patients with both MGUS and MM. In MM, impaired action of virus-specific CD8⁺ cells, particularly against influenza and Epstein-Barr virus, has been reported. Hyperactive T cells associated with impaired T-cell receptor (TCR) signaling and increased sensitivity to costimulatory signals have been reported. In fact, further abnormalities of the TCR variable β -chain repertoire have been observed following chemotherapy in patients with MM. Reductions in CD4⁺ T-cell numbers and CD4⁺/CD8⁺ T-cell ratio are observed in the peripheral blood of patients with MM. Persistent proliferative activity of both CD4⁺ and CD8⁺ T cells has been observed in both patients with MGUS and patients with MM. This activity plays a possible role in controlling tumor cell growth and survival. Overall hyperactivity, clonal expansion, and homeostatic proliferation of T-cell activity has been observed. Moreover, CD4⁺ and CD8⁺ T cells from the bone marrow of patients with MGUS are able to mount a stronger immune response against autologous MGUS plasma cells than T cells from the bone marrow of patients with MM, suggesting the role of the immune system in controlling plasma cell growth in MGUS and loss of immune surveillance in MM. Although bone marrow T cells are dysfunctional in MM, these cells can be stimulated in vitro, leading to restored function. Tregs, the CD4⁺/CD25⁺ Th cells, specifically express forkhead box protein Foxp3 and actively suppress inappropriate immune responses, maintaining immune homeostasis. In MM, Tregs are lower in number and are dysfunctional, mediated by elevated IL-6, soluble IL-6R, and TGF- β levels. Another report suggests that, following short exposure to IL-2, purified Tregs from patients with MM are able to induce suppressive activity in vivo and in vitro. Lenalidomide, granulocyte colony-stimulating factor (G-CSF), and allogeneic stem cell transplant may directly or indirectly affect Tregs and may account for some of the observed variations in Treg number and function in patients with MM. Th17 cells specifically express the retinoic acid–related orphan receptor- γ t and produce IL-17, which provides protection against certain bacterial, fungal, and viral infections. Development of Th17 cells is also determined by TGF- β and IL-6, which are upregulated in MM. In myeloma, an increased number of Th17 cells have been reported, which is associated with increased serum levels of IL-17 and other proinflammatory cytokines, such as IL-21, IL-22, and IL-23. These data support the hypothesis that myeloma cell growth suppresses immune function and induces osteoclastogenesis, supporting bone disease in MM. These effects make Th17 cells an important therapeutic target in MM. $\gamma\delta$ T cells possess a distinct TCR and represent a small subset of T cells that is involved in generating an antimyeloma response. $\gamma\delta$ T cells are considered a bridge between innate and adaptive immunity and are able to kill major histocompatibility complex class I chain–related protein A (MICA)-positive MM cells via the NKG2D (an NK cell–triggering receptor) pathway. Interestingly, MICA expression is significantly higher in plasma cells from patients with MGUS. Bisphosphonates have been shown to activate $\gamma\delta$ T cells, which may in part explain their weak antimyeloma activity. As in other malignancies, expression of PD-1 is increased in T cells from patients with active myeloma. Moreover, myeloma cells

express programmed death ligand 1 (PDL-1) at variable levels, along with plasmacytoid dendritic cells (pDCs) and myeloid-derived suppressor cells. These results partly explain the lack of antimyeloma immune response and provide a rationale for targeting this pathway using checkpoint inhibitors.

Significant B-cell and plasma cell dysfunction is observed in MM as represented by suppressed uninvolved immunoglobulins. For example, patients with IgA myeloma have suppression of serum IgG and IgM levels. This is not considered to be mediated by high levels of monoclonal paraprotein, because suppressed immunoglobulins have also been observed in patients with nonsecretory disease. An explanation for this observation remains elusive; however, suppressed uninvolved immunoglobulins predispose patients to infectious complication because they reduce the patient's ability to generate a specific humoral immune response to infections and/or vaccinations. For example, in a study of the serologic responses to vaccinations against influenza, *Streptococcus pneumoniae*, and *Haemophilus influenzae* in 52 patients with MM, researchers reported that only 19% developed protective antibody titer levels against influenza, 39% against *S. pneumoniae* (39%), and 41% against *H. influenzae* type b. These observations suggest the necessity to define suitable immunization protocols for patients with MM and the need to study the humoral and cellular responses following vaccination in terms of clinical efficacy, magnitude, and duration of response. Both B- and T-cell immune function are also affected by the therapeutic agents themselves with a further increase in the risk of infectious complications, such as the increased risk of herpes zoster virus infection following bortezomib treatment or bacterial infections following dexamethasone use. Recovery of uninvolved immunoglobulins to normal levels following effective therapy has been associated with both improved survival and protection from infectious complications.

Alteration in NK cell number has been observed in MM and is correlated with disease burden; for example, high numbers of NK cells have been observed in patients with a low tumor burden. NK cells are considered to have a potential therapeutic role, and the immunomodulatory drugs (thalidomide, lenalidomide, and pomalidomide) enhance NK cell–mediated cytotoxicity against MM cells. Invariant NKT cells, which constitute an innate lymphocyte lineage with potential for a potent antitumor immune response through the production of Th1 cytokines, are functionally defective in MM; however, these cells can be cultured in vitro with restored function, suggesting the possibility of their adoptive transfer as a potential therapeutic strategy in MM.

DCs are important antigen-presenting cells that generate effective immune responses, including antitumor responses. DC dysfunction partly mediated by cytokines such as VEGF, IL-10, and TGF- β has been reported in MM. However, it is possible to improve the defective DC function by in vitro generation. A number of studies have used DC-based vaccination strategies, including vaccinations with DCs pulsed with the idiotype protein. DCs pulsed with MM antigen-directed peptides or MM cell lysate, and fusion of MM cells with DCs has been reported to lead to an antimyeloma immune responses following vaccination. Increased numbers and function of pDCs have been reported in the bone marrow microenvironment, which mediates the immune deficiency characteristic of MM and promotes MM cell growth, survival, and drug resistance. pDCs are resistant to novel therapies; however, they are being targeted using specific agents, including anti-IL-3R antibody and Toll-like receptors with CpG oligodeoxynucleotides, to both restore pDC immune function and abrogate pDC-induced MM cell growth.

CLINICAL MANIFESTATIONS

Patients with MM present with a number of signs and symptoms that are related to either marrow infiltration by plasma cells or manifestations of end-organ damage leading to renal dysfunction, bone lesions, and/or immunoparesis (Table 86.4). However, in up to 20% of the patients, MM may present with asymptomatic disease diagnosed on

TABLE 86.4 Clinical Features of Multiple Myeloma

Bone Destruction	Marrow Infiltration
Pain	Anemia
Fractures	Bleeding tendency
Cord compression	Reduced Globulins
Radicular pain	Recurrent infections
Hypercalcemia	Pneumonia
Polyuria, polydipsia	Cryoglobulins
Nausea, vomiting	Raynaud's phenomenon
Renal Failure	Acrocyanosis
Nausea, vomiting	Hyperviscosity
Malaise, weakness	Shortness of breath
Amyloidosis	Transient ischemic attacks
Peripheral neuropathy	Deep vein thrombosis
Dependent edema	Retinal hemorrhage
Organomegaly	Epistaxis

the basis of routine blood work. The symptoms may also be related either to deposition of paraproteins in various organs as either light chain or amyloid deposits or to cytokines such as IL-6 or VEGF produced by the myeloma cells and/or the BMSCs. Owing to improvement in routine blood work and availability of sensitive tests, the clinical presentation in myeloma has changed over the last 25 years. Overall, patients are more frequently being diagnosed with asymptomatic disease rather than on the basis of presenting symptoms. For example, patients present less often with bone pain, pathologic fractures, renal failure, or hyperviscosity. Various clinical features of myeloma are summarized in Table 86.4.

Bone Disease

Almost two-thirds of patients with MM present with bone pain as their main symptom. The mechanism of bone involvement is multifactorial, including direct bone destruction by the unbalanced hyperactivity of OCs and suppression of osteoblastic activity. This is further accentuated by the cytokine milieu generated in the bone marrow microenvironment by interaction between myeloma cells and BMSCs, which includes IL-6, IL-1 β , TNF- α , and macrophage inflammatory protein 1 α .¹¹ A member of the TNF family, receptor activator of nuclear factor- κ B ligand (RANKL), also plays an important role in OC growth and differentiation via its receptor located on OCs. RANKL is secreted by stromal cells and OBs and induces differentiation and maturation of OC progenitors. Osteoprotegerin (OPG) acts as a decoy receptor for RANKL and plays a significant role in the development of bone disease in myeloma. In myeloma, the soluble syndecan produced by myeloma cells occupies and sequesters OPG, leading to excess RANKL activity, which induces OC differentiation and proliferation with the development of lytic bone lesions. Importantly, myeloma cells also secrete DKK-1, which has OB inhibitory activity, leading to suppression of new bone formation and further contributing to bone disease in myeloma.¹⁵ Thus DKK-1 has become an important therapeutic target to improve bone anabolic effects. These factors together lead to osteoporosis and lytic bone lesions. Additionally, direct infiltration of bone by myeloma cells also causes bone destruction. Overall, one observes pain that is aggravated on movement and also collapse of vertebrae leading to a decrease in height as well as symptoms of nerve compression. Besides pain, involvement of extremity and/or spine leads to lack of mobility and associated problems, including predisposition to thrombotic events.

Hypercalcemia

Hypercalcemia is observed in approximately 25% to 30% of patients with myeloma and is usually a manifestation of higher disease burden.

Its occurrence is related to bone involvement as well as production of various cytokines that lead to increased bone resorption and calcium release. Hypercalcemia manifests as mental status changes, lethargy, nausea and vomiting, and constipation. In extreme cases, a patient can also develop seizure activity. A normal serum calcium level in the presence of high paraprotein and/or low albumen level may require calculation or measurement of ionized calcium levels to assess true and effective serum calcium levels. Hypercalcemia can also induce renal failure caused by dehydration, and it is to be considered a hematologic emergency meriting prompt intervention.

Renal Failure

Renal insufficiency is a frequent and serious complication of myeloma that has a multifactorial etiology.¹⁶ The most common and reversible cause of renal failure is light chain tubular cast deposition and/or light chain deposition disease (commonly associated with κ light chains). Similarly, proteins can be deposited as amyloid, predominantly involving λ light chains (specifically λ light chain subtype 6) with development of kidney failure. Amyloidosis is quite often associated with nephrotic syndrome range proteinuria. The proteinuria observed in patients with amyloid is more nonspecific, which differs from conditions with light chain cast nephropathy with predominantly excess of light chain excretion in the urine. Another common cause is hypercalcemia leading to osmotic diuresis and prerenal dysfunction associated with volume depletion. Additional mechanisms of renal failure in myeloma include renal calcium deposition with interstitial nephritis, use of nonsteroidal antiinflammatory drugs for pain control, hyperuricemia, intravenous contrast dye use for imaging purposes, chemotherapy-induced nephrotoxicity, and use of bisphosphonates. The development of light chain deposition disease has been reported to be associated with Tamm-Horsfall protein, which promotes heterotypic aggregation of light chains with deposition in the kidneys. Patients with renal failure are quite asymptomatic. However, when symptoms are present, they are predominately malaise, weakness, nausea, or vomiting.

Anemia

Anemia is another presenting symptom of myeloma and is symptomatically associated with fatigue and shortness of breath. The anemia usually is normochromic and normocytic and has a number of etiologic factors, including inadequate erythropoietin production caused by renal dysfunction, erythropoietin unresponsiveness predominately caused by various cytokines produced by MM cells, dilution resulting from a significantly increased immunoglobulin level, and bone marrow infiltrative processes.¹⁷ Part of the development of anemia may also be related to high IL-6 levels. In patients who have had a number of treatments, quite often anemia is related to repeated rounds of chemotherapy. Erythropoietin administration therefore is an important supportive measure for the symptomatic treatment of anemia in myeloma. In one study, improvement in hemoglobin was observed in 60% of treated patients, and responses were observed in those with low erythropoietin levels compared with normal or high levels (72% vs. 20%).

Neurologic Symptoms

Patients with MM present with a number of neurologic symptoms related either to direct involvement of the nervous system or the impact of cytokines and/or paraproteins on the nervous system. The most common abnormality is compression of the spinal cord and/or nerve roots giving rise to pain as well as various degrees of neurologic dysfunction, including paraplegia with loss of bladder and bowel control. Cord compression is considered a neurologic emergency requiring prompt intervention, which might allow complete recovery of function. In this setting, urgent MRI followed by radiotherapeutic

and/or surgical intervention is warranted. Peripheral neuropathy is another common manifestation observed in almost one-third of the newly diagnosed patients if analyzed using sophisticated and sensitive methods. Peripheral neuropathy also can develop as a result of use of a number of therapeutic agents, such as thalidomide, bortezomib, and vincristine. Moreover, POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes) includes a prominent sensory neuropathy associated with sclerotic myeloma. Paraneoplastic central nervous system (CNS) manifestations have been reported occasionally in myeloma and are considered to be related to clonal immunoglobulin targeting various CNS cells and/or structure. The polyneuropathy in myeloma is due to multiple factors, including amyloid deposits, infiltrative processes with other protein deposits, metabolic causes related to hypercalcemia and/or hyperviscosity, immune processes, or cytokines effects. IgM-related neuropathy is well described in which a myelin-associated globulin (MAG) has been described in 50% of the patients. Presence of MAG provides diagnostic clues as well as a parameter to follow therapy. Traditionally, meningeal involvement has been described very rarely in myeloma; however, with prolonged survival with novel agents, it is being seen more frequently. This type of complication is usually observed with high-risk disease. Finally, intracranial plasmacytomas involving brain parenchyma, either from the skull or from the skull base, has been reported in advanced cases.

Hyperviscosity

Hyperviscosity is less frequent in myeloma than in Waldenström macroglobulinemia, where higher-molecular-weight IgM molecules frequently cause an increase in viscosity. In general, hyperviscosity in IgG myeloma is extremely uncommon. For hyperviscosity to develop, generally an IgG more than 10 g/dL, IgA more than 7 g/dL, and IgM more than 5 g/dL are required to cause symptomatology. Occasionally, certain physicochemical characteristics of immunoglobulin may lead to self-aggregating properties and induce viscosity even at a lower level. This has been reported with IgG3, which is more frequently associated with hyperviscosity than various other IgG myelomas. The commonly observed symptoms are related to circulatory decline of vital organ function, leading to complaints of headache, visual symptoms, shortness of breath, bleeding complications such as nosebleeds, and eventually mental status changes. The confirmation of viscosity can be obtained by measuring viscosity, which may exceed 4.0 centipoise (cP); however, symptoms at lower levels of viscosity have been observed. Therapy is instituted more on the basis of symptomatology than on absolute measured levels of viscosity and requires prompt institution of plasmapheresis with quick resolution of symptoms.

Infections

Infection is one of the most important causes of morbidity and a common cause of mortality in myeloma. Owing to compromised T- and B-cell function, patients with myeloma are at a significant high risk of developing recurrent bacterial as well as viral and fungal infections. As described earlier, various factors lead to inability of patients with myeloma to mount a humoral immune response.¹⁸ The patients are susceptible to polysaccharide-encapsulated organisms as well as enteric gram-negative bacilli. Further susceptibility to infections also stems from a number of therapeutic interventions, especially corticosteroids. For example, fungal infection, most commonly oral thrush, is observed following high-dose dexamethasone-based therapy, whereas herpes zoster viral infection is observed frequently following bortezomib-based therapy. In both cases, prophylactic antibiotics or antivirals are indicated. A number of cases of therapy-induced activation of *Mycobacterium tuberculosis* in developing countries have been reported. The risk of infection is highest during the first 2 months of initiation of therapy, when both myeloma-related immunosuppression and therapy-related immunosuppression increase the

predisposition to infectious complication. Prompt diagnosis of infectious complications and quick institution of therapy, or preferably initial prophylactic measures, prevents major complications.

Coagulation Disorders

Both bone marrow suppression with cytopenias and coagulation abnormalities are observed in myeloma. Myeloma might be associated with both bleeding problems and thrombotic events. The coagulation abnormalities are related to high levels of a paraprotein that interferes with the normal coagulation pathways as well as platelet dysfunction caused by either decreased numbers and/or function. The coagulation abnormalities include an acquired deficiency of factor VIII. A hypercoagulable state is observed in 15% of patients with IgG myeloma and one-third of patients with IgA myeloma, and it is related to hyperviscosity, acquired activated protein C resistance, lupus-like anticoagulants with thromboembolic complications, acquired deficiency of protein S, and a therapy-related hypercoagulable state associated specifically with immunomodulatory agents such as thalidomide and lenalidomide. In the absence of prophylactic measures, such immunomodulatory agents have been reported to cause deep vein thrombosis (DVT) in 10% to 20% of patients, in whom the thrombotic risk increases with associated use of dexamethasone, other chemotherapeutic agents, and/or previous history of DVT or immobility.

Thrombocytosis is more frequently associated with myeloma than thrombocytopenia, driven mainly by the high levels of IL-6, which drives growth and maturation of megakaryocytes. Rarely, extensive bone marrow infiltration by myeloma cells, and more commonly repeated cycles of chemotherapy, leads to thrombocytopenia during the advanced stages of the disease.

Amyloidosis

Monoclonal proteins, specifically light chains, can be deposited in various organs as an insoluble fibrillar protein, amyloid, affecting organ dysfunction (see [Chapter 88](#)). Around 20% of patients with light-chain (AL) amyloidosis also have a concurrent diagnosis of MM, and all patients with AL amyloid have clonal light-chain production. Although clinically overt amyloidosis is observed less frequently in MM, intense investigation to identify amyloid deposits using fat pad biopsies, concurrent staining of bone marrow with Sudan black, and obtaining rectal biopsies can identify some level of amyloid deposit in almost one-third of patients. Patients with amyloid deposits can present with a number of features primarily related to organ damage, including renal and cardiac dysfunction and symptoms suggesting carpal tunnel syndrome. Classic presentations of advance amyloid include cutaneous fragility around the eyelids, with raccoon eyes and macroglossia. Patients with advanced amyloid with myeloma have a poor overall outcome; however, therapeutic intervention currently remains the same in patients with myeloma with amyloidosis.

LABORATORY MANIFESTATIONS

Investigations to Detect Clonality

Protein Electrophoresis

Serum protein electrophoresis is performed to quantitate the monoclonal proteins present in myeloma ([Table 86.5](#)).¹⁹ In 70% of the patients, the monoclonal protein is IgG; in 20%, it is IgA; and in 5% to 10% of patients, it is light chains only. Less than 1% patients have a monoclonal protein that is IgD, IgE, or IgM or truly a non-secretory myeloma. The identification of the exact type of paraprotein in both serum and urine requires immunofixation ([Fig. 86.5](#)). This should be performed at the time of initial diagnosis, and it needs to

 Serum free light chain and ratio

Evaluation for Clonal Plasma Cells

Bone marrow aspirate and biopsy for
 Histology
 Clonality by immunostaining or flow cytometry by κ/λ staining
 Fine-needle aspiration of plasmacytoma if indicated

Evaluation for End-Organ Damage

Hemogram to detect anemia
 Chemistry panel for renal function and calcium
 Radiologic evaluation: skeletal survey
 PET-CT or MRI as indicated for bone lesions or extramedullary disease

Evaluation for Risk Stratification

β_2 -Microglobulin and serum albumin for ISS stage
 Cytogenetics and fluorescence in situ hybridization on bone marrow sample
 LDH
 C-reactive protein

Other Investigations for Selected Patients

Abdominal fat pad or rectal biopsy for amyloid
 Solitary lytic lesion biopsy
 Serum viscosity if IgM component or high IgA levels or serum M component >7 g/dL
 Immunofixation for IgD or IgE in select cases

CT, Computed tomography; Ig, immunoglobulin; ISS, International Staging System; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging; PET, positron emission tomography.

be repeated to confirm achievement of a complete response. Patients who produce intact immunoglobulins can also produce excess light chain, giving a picture that is associated with both heavy and light chains; for example, a patient can have an IgG κ and a κ light-chain myeloma. Associated with the presence of a monoclonal protein, the uninvolved immunoglobulins are suppressed. For example, patients with IgG myeloma will have suppressed IgA and IgM. In a setting where all three immunoglobulins are suppressed, one should suspect either light-chain disease and/or the possibility of IgD or IgE MM. Very rarely, a biclonal or triclinal pattern of immunoglobulins is observed, more often with the same light chain but rarely with a different heterotypic light chain. This may suggest truly separate clones, especially with separate light chains. Quantitation of Bence Jones proteins in urine is still important, both for diagnosis of myeloma and for follow-up. It is important to note that a free light-chain measurement in the urine is not informative. Those patients with only a monoclonal protein in the urine require frequent 24-hour Bence Jones protein measurements during follow-up. Therapeutically, patients with each of the various types of immunoglobulins are treated with a similar type of therapy; however, patients with IgA myeloma appear to have an inferior survival. The immunoglobulin isotype remains constant in a given patient over the natural history of the disease; however, occasionally, a patient producing one immunoglobulin at the time of diagnosis, at relapse, or with advanced disease may present with only the same light chain as initially observed with the original immunoglobulin (light chain escape) or occasionally may become nonsecretory. Both the changes are reflective of the change in plasma cells to a more aggressive or undifferentiated form. As a result of the observed light-chain escape, patients without initial Bence Jones proteins initially detected in the urine will require periodic 24-hour urine Bence Jones protein measurements during follow-up.

The unique sequences that are observed with the idiotype protein (CDR3) have been used as a marker that specifically identifies a tumor cell clone and have been applied to a polymerase chain reaction–based methodology to detect MRD with high sensitivity. Early studies using such molecular methods for detecting MRD have

Fig. 86.5 REPRESENTATIVE PATTERNS OF SERUM ELECTROPHORESIS AND IMMUNOFIXATION. In each figure, the *upper panels* represent immunofixation patterns, the *middle panels* are the densitometric tracings of the gels, and the *lower panels* are agarose gels of urine sample (*left*) and serum (*right*). (A) Normal pattern of serum and urine protein on electrophoresis. Because there are many different immunoglobulins in the serum, their differing mobilities in an electric field produce a broad peak. (B) In monoclonal gammopathies, the predominance of a product of a single cell produces a sharp peak. The immunofixation identifies the type of immunoglobulin, such as κ light chain in urine and IgG κ in serum. (C) In patients with light chain–only disease, a clonal band is observed only in urine, with no clear peak in serum, such as γ light chain in urine with no distinct immunofixation positivity in serum. (Courtesy Dr. Neal I. Lindeman; used with permission.)

identified those patients who achieve complete molecular remissions that are associated with improved overall outcome.

Serum Free Light Chains

This test measures serum light chains that are not associated with heavy chains. The presence of serum free light chains provides an additional marker and measurement of plasma cell proliferation, and its quantitation has been used to determine protein levels in a number of patients who were previously considered oligosecretory or nonsecretory. For example, 80% of patients with previously diagnosed nonsecretory myeloma have measurable serum free light chains. Routine use of serum free light chain measurements is indicated for diagnosis, response evaluation, and prognosis. As shown in patients with MGUS and SMM, serum free light chain ratio allows for identification of those patients with increased likelihood of progression to symptomatic myeloma. The measurement of serum free light chain does not replace the measurement of Bence Jones proteins in 24-hour urine collection.

A recently developed heavy/light chain assay allows identification and quantification of the different light chain types belonging to each immunoglobulin class (e.g., IgA κ and IgA λ) and allows calculation of ratios of monoclonal/polyclonal immunoglobulins (heavy/light chain ratio). In one study, heavy/light chain assays allowed quantification of monoclonal proteins not accurately measurable by SPEP or nephelometry, and the heavy/light chain ratio indicated the presence of disease in 8 of 31 patients who achieved CR and in sequential studies indicated evolving relapse in three patients before immunofixation became positive. The assay requires further validation before wider clinical use.

Bone Marrow Examination

Except for patients with solitary plasmacytoma, the presence of clonal plasma cells (>5%) is usually observed in all plasma cell disorders, and malignant plasma cells can be distinguished from normal plasma cells by monoclonal antibody staining and flow cytometry (Table 86.6).²⁰ Clonal plasma cell populations comprising 10% or greater of the nucleated cells within a bone marrow aspirate or biopsy (whichever is higher if both are done) is required to differentiate MGUS from SMM and for MM (Table 86.1). The quantitation of plasma cells should be performed with at least a 200-cell count, and confirmation of clonality is essential for diagnosis, which can be done either by immunostaining using κ/λ staining or by flow cytometry (Table 86.6 and Fig. 86.6). In the absence of clear bone marrow involvement, a biopsy-proven soft tissue or bony plasmacytoma is

also adequate for diagnosis (Fig. 86.7). Cytogenetic and FISH studies should be performed on bone marrow samples at the time of diagnosis, and if initially confirmed as low-risk disease, then they should be repeated on bone marrow performed at the time of relapse. Although important for prognostication, cytogenetic or FISH study-identified abnormalities are not adequate for differentiating MM from MGUS or SMM. A seven-color flow cytometry panel is now also used with bone marrow samples to detect MRD.

Investigation to Detect End-Organ Damage

The diagnosis of a plasma cell disorder is based on the presence of a monoclonal protein and clonal plasma cells. However, the diagnosis

Fig. 86.7 MORPHOLOGIC SPECTRUM OF NEOPLASTIC PLASMA CELLS IN MULTIPLE MYELOMA. There is significant morphologic heterogeneity in the plasma cells, as seen on bone marrow aspirate (A–E) and biopsy (F and G). The plasma cells can sometimes be fairly normal appearing (A and F); they can be “lymphocyte-like” and difficult to distinguish from lymphoplasmacytic lymphoma (B and G); they frequently can exhibit cytologic atypia with prominent nucleoli and nuclear to cytoplasmic dyssynchrony (C and H); they can exhibit anaplastic features (D and I); and they can show “blastic” features (E and J). Myeloma can also evolve into leukemic phase (K) and can be associated with osteosclerosis (M), as sometimes seen in association with POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes).

of MGUS/SMM, which currently does not require therapeutic intervention, and active symptomatic MM, which needs treatment, is based on the detection of end-organ damage, which includes bone lesions, anemia, renal dysfunction, and hypercalcemia. The details of the diagnostic criteria are listed in [Tables 86.7](#) and [86.8](#).²⁰

Radiographic Evaluation

The standard evaluation of bone lesions in myeloma is by a skeletal survey that includes plain x-rays of the entire skeleton. The presence of characteristic lytic lesions is considered diagnostic for myeloma ([Fig. 86.8](#)). Rarely, in POEMS, bone lesions are osteosclerotic. The bone lesions do not always resolve following effective therapy. Because of the absence or suppression of osteoblastic activity, the bone scan is diagnostically not a useful investigative tool in myeloma. Almost all patients with myeloma have osteoporosis as a result of unbalanced osteoclastic activity. Bone mineral density (BMD) measurement by dual-energy x-ray absorptiometry helps identify osteoporosis and is considered a useful investigation. However, it is not uniformly used, because all patients with myeloma are known to have osteoporosis, and now all patients receive bisphosphonates, making the measurement of BMD irrelevant in therapeutic decision making. Details of various imaging modalities and their role in myeloma diagnostics are described in [Table 86.9](#).

Magnetic resonance imaging (MRI), computed tomography (CT), and positron emission tomography (PET) are increasingly being used for patients with MM. An MRI scan allows assessment of the degree of bone marrow involvement and involvement of the spinal cord. One-third of the patients have generalized hyperintensity on MRI of the skeleton, another one-third have predominantly focal lesions within the background of a low level of bone marrow involvement, and the remaining one-third have a mixed picture with focal

TABLE 86.9

Imaging Modalities for Disease Assessment in Myeloma

	Use	Sensitivity/Specificity	False-Negatives	False-Positives
Bone scan	For diagnostic screening, except for multiple myeloma	Varies	Pure osteolytic lesions	- Trauma - Inflammation - Benign tumor - Healing
X-ray	- Can clarify nonspecific findings on bone scan - Assesses risk of fracture - Possible follow-up of tumor response, but evidence of response takes considerable time to appear	Low sensitivity	- Low disease burden - Osteopenia	- Trauma - Inflammation - Benign tumor - Healing
CT	- For anatomic detail in axial skeleton - Possible follow-up of tumor response, but role is still undefined	High sensitivity	Low disease burden	- Trauma - Inflammation - Benign tumor - Healing
MRI	- Detection of spinal cord compression - Can help distinguish benign from malignant vertebral compression fracture - Possible follow-up of tumor response, but role is still undefined	High sensitivity and specificity	Lesion only in cortex	Edema
PET scan	- May eventually become first-line screening test for bone metastases - Possible follow-up of tumor response, but role is still undefined	High specificity	Lesion only in cortex	After chemotherapy
Bone density	- Measure osteoporosis - Response to bisphosphonates	High specificity and sensitivity		Age-related Osteoporosis

CT, Computed tomography; MRI, magnetic resonance imaging; PET, positron emission tomography.

lesions within the background of generalized involvement of the bone marrow. MRI is indicated in all patients with a suspected diagnosis of a solitary plasmacytoma and is indicated in SMM to identify any occult bone marrow involvement. Identification of multiple lesions not observed on a skeletal survey allows prediction of progression and early intervention.

In symptomatic myeloma, MRI is considered a routine evaluation to detect unsuspected focal lesions, to assess the extent of involvement of the bone marrow especially in the spine and pelvis, and to explore the possibility of cord compression. MRI is an important tool in patients with nonsecretory myeloma and becomes a critical method to evaluate response. Normalization of MRI findings after achieving

CR is a good prognostic feature and is being considered as one of the methods to better define a CR.

CT has been used to evaluate focal lesions in order to perform fine-needle biopsies for cytologic analysis. CT scans provide a better picture of the bone component and can also be used to judge the integrity of the bone. PET along with CT can be used to define extramedullary disease (EMD) as well as medullary lesions, and they complement MRI for follow-up of patients with nonsecretory myeloma (Fig. 86.9). Conversion of PET positivity to negativity has prognostic significance. In one prospective study of 192 patients, the presence at baseline of at least three focal lesions (FLs) detected by PET-CT, a standardized uptake value (SUV) >4.2 , and EMD adversely

4/2010

10/2011 CR

Fig. 86.9 POSITRON EMISSION TOMOGRAPHIC/COMPUTED TOMOGRAPHIC SCANS SHOWING MULTIPLE FLUORODEOXYGLUCOSE-AVID LESIONS IN SKELETON (*UPPER PANEL*), ALONG WITH THEIR RESOLUTION ON ACHIEVING COMPLETE REMISSION (*LOWER PANEL*).

affected the 4-year estimate of progression-free survival (PFS) (≥ 3 FLs, 50%; SUV >4.2 , 43%; presence of EMD, 28%). An SUV >4.2 and EMD was also correlated with a shorter OS (4-year OS rates 77% and 66%, respectively). In this study, posttherapy persistence of PET positivity for lesions predicted a poor outcome as compared with those with a negative PET-CT (PFS 66% and OS 89%).

A prospective evaluation of MRI and PET-CT at diagnosis and before maintenance therapy was performed in a subgroup of 134 patients with MM in the IFM/DFCI 2009 trial. At diagnosis, MRI was positive in 127 (94.7%) of 134 patients and PET-CT was positive in 122 (91%) of 134 patients, respectively ($p = .33$). Few patients achieved a normal MRI after three cycles of VRD before maintenance. Normalization of the MRI following three cycles of VRD and before maintenance had no prognostic value for both PFS and OS. Normalization of PET-CT was more frequently observed: 45% following three cycles of VRD and 79% before maintenance. Importantly, normalization of PET-CT was associated with an improvement in PFS, and normalization before maintenance was a predictor for improved OS.

Renal Function

A serum creatinine >173 mmol/L is considered to represent end-organ damage. Because absolute creatinine values do not incorporate the patient's age, they may underrepresent the extent of renal dysfunction. There has been consideration of using the creatinine clearance as a more optimal diagnostic criterion. Because patients with myeloma are older and other comorbidities such as diabetes and hypertension can also affect renal function, it is necessary to establish the relationship between renal dysfunction and the plasma cell disorder; for example, the presence of Bence Jones proteinuria may be required to support such a relationship. In the absence of Bence Jones proteinuria, a renal biopsy may be necessary. This may be even more critical in patients who otherwise fit the criteria for MGUS or SMM but have renal dysfunction. A renal biopsy is not required for all patients, but only when one is uncertain about the cause of the renal dysfunction. A biopsy is not currently required to document light chain cast nephropathy if Bence Jones protein is present as the predominant urinary protein. Other causes of renal dysfunction should be considered before attributing renal dysfunction to MM.

Hemogram and Serum Calcium

A standard complete blood count is performed to detect anemia. The level of anemia considered diagnostic of myeloma is a hemoglobin 2 g/dL below the lower limit of normal or the patient's baseline level or hemoglobin <10 g/dL. It is always necessary to exclude other causes of anemia. Circulating plasma cells are frequently observed in patients with MM. A serum calcium level should be measured and corrected to the level of albumin, or in occasional cases, an ionized calcium level should be obtained.

Prognosis

Myeloma is a disease with a varied outcome, with 20% of patients having a survival of less than 2 years, whereas over 40% of patients have more than a 10-year survival. Therefore it is critically important to identify disease features that allow one to identify low- versus high-risk disease to better tailor therapeutic interventions. Moreover, such a risk stratification approach permits the physician to predict life expectancy and allows one to develop metrics by which to evaluate the results of clinical trials. Various prognostic variables have been identified, including tumor-burden related factors such as β_2 -microglobulin, more than three lytic bone lesions, hypercalcemia, and soluble IL-6 receptor; tumor biology-related factors such as cytogenetic/FISH-identified abnormalities, genomic changes, plasma cell labeling index, IgA myeloma, C-reactive protein, and lactate dehydrogenase (LDH); tumor microenvironment-related factors,

such as bone marrow MVD, serum soluble syndecan-1 levels, soluble CD16 levels, and bone marrow pDC numbers; patient-related factors, such as age, renal failure, albumin, and performance status; and treatment-related factors, such as achieving a CR or a very good partial response (VGPR) and the performance of tandem autologous transplants. Among these features, the International Staging System (ISS) uses serum albumin and β_2 -microglobulin levels, cytogenetic/FISH changes, and newer genomic correlates of outcome that have been validated in a number of studies and are considered standard predictive markers. A short list of investigations to be performed for risk stratification of patients with MM is provided in Table 86.10.²¹

INTERNATIONAL STAGING SYSTEM

The ISS described in Table 86.11 uses simple chemical tests (serum albumin and β_2 -microglobulin) to predict outcome.²² ISS staging is

Fig. 86.10 REVISED INTERNATIONAL STAGING SYSTEM (R-ISS) INCORPORATING ISS, FLUORESCENCE IN SITU HYBRIDIZATION, AND LACTATE DEHYDROGENASE PREDICTS BOTH EVENT-FREE SURVIVAL (*LEFT PANEL*) AND OVERALL SURVIVAL (OS; *RIGHT PANEL*). *NR*, Not reached; *PFS*, progression-free survival.

able to predict both event-free survival (EFS) and OS and is valid regardless of age, geographic region, study site, standard-dose therapy or HDT, method of albumin measurement, and use of novel agents. Although it is universally applicable, it does not include the genetic makeup of the myeloma cells and thus lacks an important biologic characteristic that drives the disease process.

Recent efforts have been made to combine multiple features to improve prognostication. Avet-Loiseau proposed a combination of β_2 -microglobulin levels and cytogenetics to predict outcomes. A revised ISS that combines ISS staging with cytogenetic abnormalities (Table 86.11, Fig. 86.10) has been created. Walker et al combined recurrent molecular adverse features with the ISS and proposed an ISS mutation score to identify a high-risk patient.

Cytogenetics/FISH

Using conventional cytogenetics, detection of any abnormality is predictive of an adverse outcome. Of course, the recurrent chromosomal changes $t(4;14)$ and $t(14;16)$, as well as loss of 13q34 and 17p13, identified using traditional cytogenetic methods are associated with a poor prognosis. Hyperdiploidy and $t(11;14)$ have been reported in some studies to predict a favorable outcome.

As described earlier, because of a low proliferative index, cytogenetic abnormalities are detected in only a small number of patients, and interphase FISH is used to detect specific genetic aberrations. Among these abnormalities, patients with $t(4;14)$ (15% of the patients) have a poor prognosis. In some early studies, the use of bortezomib and lenalidomide has been shown to at least partly overcome the poor risk associated with this abnormality. The $del(17p)$ observed in 8% to 10% of the patients remains a poor risk feature not overcome by novel therapies.³ Although the $p53$ gene resides in this region of the deletion, a clear biologic confirmation of its role is lacking. $p53$ mutations have been detected in only a very small number of patients. In patients without $t(4;14)$ or $del(17p)$, $del(13)$ is not considered to predict a poor outcome. Moreover, the presence of $del(13)$ is observed in patients with MGUS and SMM without clear correlation with clinical outcome. The findings raise questions about the role of $del(13)$ in myeloma progression and its use in predicting prognosis. A combination of a high-risk feature such as a 17p13 deletion may coexist with trisomies of several chromosomes, a good risk feature. In a recent study by the IFM, researchers reported that if patients have trisomy of 3 and 5 along with other poor-risk cytogenetics, their overall outcome may improve, whereas presence of trisomy 21 may further adversely affect the outcome. As shown in Table 86.2, newer additional chromosomal changes are being identified that are

predictive of clinical outcomes; gain of chromosome 1q and loss of 1p are considered to predict a poor outcome. Additional studies are needed to confirm their significance.

High-Throughput Genomic Studies

Additional analyses of genomic changes that drive the disease process have been performed using the high-throughput microarray profiling technique. CNAs have been studied using either SNP⁶ or CGH⁷ arrays, whereas expression of genes has been evaluated using expression profiling that covers the entire genome. These studies have been correlated to clinical outcomes.

The IFM-DFCI collaborative group has correlated CNA with survival outcomes in 192 newly diagnosed patients with MM who were uniformly treated. A univariate analysis identified amplifications of 1q and deletions of 1p, 12p, 14q, 16q, and 22q to be associated with a poor prognosis, whereas amplification of chromosomes 5, 9, 11, 15, and 19 was associated with a superior outcome. A multivariate analysis identified $amp(1q23.3)$, $amp(5q31.3)$, and $del(12p13.31)$ as the most significant independent adverse markers ($p < .0001$). This model has been further validated in an independent cohort of 273 patients, confirming the utility of SNP profiling for prognostication.⁶

Using gene expression, profiling a 70-gene model has been proposed by the UAMS group.²³ This signature identifies three groups of patients: those with high-, intermediate-, and low-risk disease. Similarly, a 15-gene model classifying patients into two risk groups has been proposed by the IFM group.²⁴ Interestingly, there are no common genes between the two models. This likely is due to the different treatments received by the patient groups, differences in the platform used, and more likely the redundancy and overlapping functions of the genes regulating various pathways. A larger-scale study incorporating various genomic correlates will be required in the future to identify and validate signatures that can identify risk categories and response to therapies.

Minimal Residual Disease

Achieving a complete response has traditionally been considered an important prognostic indicator, and previous studies have indicated that achieving a VGPR is associated with a superior survival outcome. However, because the majority of patients achieving CR relapse, it is clear that substantial residual disease persists, requiring better methods to measure MRD. The large amount of recent data has demonstrated that an MRD-negative status can be achieved in a large proportion

Fig. 86.11 KAPLAN-MEIER ESTIMATES OF PROGRESSION-FREE SURVIVAL (PFS; *LEFT*) AND OVERALL SURVIVAL (OS; *RIGHT*) IN PATIENTS ACHIEVING MINIMAL RESIDUAL DISEASE (MRD)-NEGATIVE VERSUS MRD-POSITIVE STATUS. To evaluate the impact of achieving MRD-negative status on PFS and OS, 14 studies ($n = 1273$ subjects) provided data on the impact of MRD on PFS, and 12 studies ($n = 1100$) provided data on OS.

of patients. Two important methods used to measure MRD are multicolor flow cytometry and NGS. The latter has sensitivity of 1 cell in 10^6 bone marrow cells, which is required for best demonstration of a superior outcome in those patients achieving conventional CR. These studies and a meta-analysis clearly suggest significant improvement in both EFS and OS (Fig. 86.11) in those patients achieving MRD-negative status. The evolving consensus is that achieving MRD-negative status should become the ultimate goal of all therapeutic interventions.

DIFFERENTIAL DIAGNOSIS

The diagnosis of MM is based largely on laboratory investigations. No single symptom or group of symptoms is pathognomonic of MM. A significant number of patients remain asymptomatic, and the diagnosis is usually delayed. Most frequently, in a relatively asymptomatic patient, investigations are carried out because of increased total protein levels, proteinuria, renal dysfunction, and/or bone pain. An older patient with any of these features or unexplained back pain, anemia, or recurrent infection should be screened for myeloma. Unexplained and marked elevation of an erythrocyte sedimentation rate also warrants investigation. The diagnosis is pursued in two steps: first, the detection of a monoclonal protein and monoclonal plasma cells, and second, identification of end-organ damage. This is essential to differentiate early-stage plasma cell disorders such as MGUS or SMM from active symptomatic myeloma (Table 86.1). Once a diagnosis of MM is suspected, the investigations detailed in Table 86.5 are to be carried out. Detection of a monoclonal protein includes electrophoresis of serum proteins as well as 24-hour urine collection and serum-free light chain measurements. Both serum protein electrophoresis and quantitative immunoglobulins are required, and an immunofixation is important at the time of diagnosis to identify the type of paraprotein present. The bone marrow is examined for the presence of clonal plasma cells, mainly by histology but also importantly by immunostaining or flow cytometry using κ/λ staining (Table 86.6). Determination and quantitation of clonal plasma cells are required to differentiate SMM from MGUS (Table 86.1). Detailed investigations for evidence of organ damage should be undertaken to look for bony lesions, renal dysfunction, anemia, and hypercalcemia. In patients where hyperviscosity is suspected, besides measuring serum viscosity, a fundoscopic examination is useful. Detailed diagnostic criteria are summarized in Table 86.1.²⁰

TREATMENT

Treatment of underlying plasma cell neoplasm is warranted when an organ or tissue function is compromised. The damage or functional impairment of an organ can be caused by the underlying plasma cell clone or the monoclonal protein. The acronym *CRAB* (hypercalcemia, renal impairment, anemia, and bone disease) is helpful in this regard. Symptomatic hyperviscosity, amyloidosis, monoclonal immunoglobulin deposition disease, recurrent bacterial infections (more than two major infections), and progressive peripheral neuropathy are also indications for the initiation of treatment. The constellation of polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and the skin changes in the setting of osteosclerotic myeloma (POEMS syndrome) may present a challenging diagnosis but is always an indication for treatment. In addition, the International Myeloma Working Group has defined the following events that warrant systemic therapy: (1) clonal bone marrow plasma cell percentage (aspirate or biopsy, whichever is higher) of 60% or above, (2) elevated serum free light chain 100 mg/L or greater associated with involved/uninvolved free light chain ratio ≤ 100 , and/or (3) more than one focal lesion visualized by MRI. One or more osteolytic lesions >1 cm in size identified by CT or PET-CT, as well as lytic lesion(s) noted on skeletal surveys, is an acceptable indication to initiate therapy. Osteoporosis and compression fracture alone in the absence of lytic lesions with the latest imaging techniques is not a myeloma-defining event.

MGUS and SMM

MGUS is characterized by serum paraprotein <3 g/dL; bone marrow plasmacytosis $<10\%$; and absence of amyloidosis, a solitary plasmacytoma, Waldenström macroglobulinemia, or a B-cell lymphoproliferative disorder (Table 86.1). Three distinct clinical subtypes of MGUS based on paraprotein have been described (non-IgM MGUS, IgM-MGUS, and light-chain MGUS). The diagnosis of MGUS is often incidental where a serum or urine protein electrophoresis and immunofixation are ordered as part of a battery of tests. The test may have been ordered for evaluation of elevated globulin in the serum, proteinuria, peripheral neuropathy, osteoporosis, immune disorders, or hypogammaglobulinemia.^{25,26} The rate of progression of non-IgM MGUS to MM is 1% per year. These patients can be further risk stratified on the basis of a serum M spike level less than 1.5 g/dL,

Fig. 86.12 KAPLAN-MEIER ESTIMATES OF LIKELIHOOD OF PROGRESSION TO MYELOMA FROM MONOCLONAL GAMMOPATHY OF UNKNOWN SIGNIFICANCE (MGUS) (A) OR SMOLDERING MULTIPLE MYELOMA (SMM) (B). Estimates are based on risk features identified in MGUS (M spike >1.5 g/dL, non-immunoglobulin G [non-IgG] paraprotein, and abnormal [Abn] free light-chain ratio [FLCR]) and in SMM (bone marrow [BM] with >10% plasma cells, M spike >3.0 g/dL, and Abn FLCR). RR, Relative risk.

IgG isotype, and normal serum free light chain ratio (Fig. 86.12). The presence of all these factors is associated with only a 2% chance of progression at 20 years after eliminating competing causes of death (low risk). If one of these factors is abnormal, patients will fall into the low intermediate-risk category, with 10% absolute risk of progression to myeloma at 20 years. Presence of two abnormal factors places the patients into the high intermediate-risk group; their absolute risk of progression to MM is 18% at 20 years. Finally, when all three risk factors are abnormal, the patient falls into a high-risk category with an absolute risk of progression of 27% at 20 years. IgM MGUS has a slightly higher rate of progression at 1.5% per year to Waldenström macroglobulinemia, chronic lymphocytic leukemia, AL amyloidosis and occasionally MM. MYD88 (L265P) is a recurrent mutation in Waldenström macroglobulinemia and is seen in 50% to 80% of cases of IgM MGUS. The presence of the MYD88 (L265P) is an independent predictor for progression to Waldenström macroglobulinemia or other lymphoproliferative disorder. The presence of both MYD88 mutation and serum M spike >1.5 g/dL at diagnosis identifies a subset of patients with a high risk for progression. Light chain MGUS is defined as Bence Jones proteinuria <0.5 g/24 hours and bone marrow <10% plasma cells; these patients have a 0.3% per year probability of progression to MM or light chain amyloidosis.

Non-IgM asymptomatic myeloma (smoldering myeloma) is characterized by bone marrow plasmacytosis 10% to 60% and/or serum paraprotein ≥ 3 g/dL but absence of myeloma-defining events or amyloidosis.²⁵ Asymptomatic myeloma is often diagnosed following a workup for an elevated total protein in the serum, proteinuria, or borderline anemia. It may also be discovered incidentally, like MGUS. It has been shown that every case of MM is preceded by detection of paraprotein by a minimum of 2 years or more. The rate of progression to MM is 10% per year for the first 5 years, 3% per year for the next 5 years, and 1% per year after 10 years. Because patients have no symptoms or related organ or tissue impairment, no treatment intervention is recommended. Several factors aid in categorizing patients into the different risk categories. Factors predictive of early progression include monoclonal spike ≥ 3 g/dL, bone marrow plasmacytosis $\geq 10\%$, and an abnormal free light chain ratio (>8 or <0.125). Presence of three or more of these factors identifies patients with a high risk for progression after a median of 2 years; presence of two of these variables identifies an intermediate-risk group with a median time to progression of 5 years; and presence of only one of these risk factors identifies a low-risk group with a median time to progression of 10 years. Other investigators have used other risk factors, such as aberrant plasma cell population $\geq 95\%$ by flow cytometry, reduction in uninvolved globulins, evolving myeloma, and abnormal MRI findings, to stratify patients into different risk categories. Immunoparesis is also observed in MGUS and SMM. In one study, suppression of uninvolved immunoglobulin was observed in 25% of patients with MGUS (18% had decreased levels of only one

Ig, and 7% had low levels of two Igs) and 52% of patients with SMM (22% with one Ig, and 30% with both chains). In this analysis, immunoparesis was one of the independent predictors with a significant impact on PFS in MGUS and SMM. Light chain SMM is defined by the presence of Bence Jones proteinuria of ≥ 0.5 g/24 hours and bone marrow plasmacytosis $\geq 10\%$. These patients have a rate of progression to MM of 5% per year for 5 years, 3% per year for the next 5 years, and 2% per year after 10 years. IgM SMM has a cumulative probability of progressing to Waldenström macroglobulinemia, amyloidosis, or lymphoma of 6% at 1 year, 39% after 3 years, and 59% at 5 years (12% per year).

This information has been helpful in designing clinical trials to try to delay the progression to symptomatic MM for patients in a high-risk category. A single randomized trial by a Spanish group showed that early intervention with lenalidomide and dexamethasone in a high-risk group delays the time to progression and prevents the occurrence of renal failure or lytic bone disease. Moreover, by preventing complications, the study showed a survival advantage for early intervention. However, treatment intervention outside clinical trials is still not recommended for patients with asymptomatic myeloma. No benefit has been shown for early intervention as compared with treatment after the patient has progressed to symptomatic myeloma. Early intervention with thalidomide in asymptomatic myeloma has been reported to delay progression to symptomatic myeloma but was associated with peripheral neuropathy, and a survival benefit has not been shown in a randomized clinical trial.

Solitary Plasmacytoma: Medullary and Extramedullary

A diagnosis of solitary plasmacytoma requires fulfillment of each of the following criteria: histologic confirmation of clonal plasma cells at a single site; a negative bone marrow with absence of a clonal plasmacytosis; no distant bone involvement; and no anemia, hypercalcemia, or renal impairment (Table 86.1). The solitary plasmacytoma could present as a single bony lesion (medullary) or in soft tissue outside the bone (extramedullary). A solitary plasmacytoma of the bone is 40% more common than an extramedullary soft tissue plasmacytoma. Solitary plasmacytoma of the bone is most commonly encountered in the axial skeleton (skull, spine, pelvis, ribs, and sternum), accounting for 80% of cases; upper and lower extremities account for 15% of cases. Extramedullary soft tissue plasmacytomas are often associated with the mucosal area of the upper aerodigestive passages (80%).

Solitary plasmacytomas are rather uncommon and account for 6% of plasma cell neoplasms. The incidence is 0.3 per 100,000 person-years in United States. Similarly to MM, the incidence of solitary plasmacytomas increases with age; however, the median age of diagnosis was 62 years for extramedullary plasmacytomas and 65

years for solitary bone plasmacytoma as compared with median age of onset at 71 years for MM in the National Cancer Institute Surveillance, Epidemiology, and End Results program (SEER) data. The incidence of solitary plasmacytoma increased by 10% in 1999–2004 relative to 1992–2008, whereas the incidence of MM declined by 3% during the same period.

Patients presenting with solitary plasmacytomas require a complete workup to confirm the diagnosis. They should undergo serum protein electrophoresis, serum immunofixation, serum free light chain assay, urine protein electrophoresis, urine immunofixation, a diagnostic bone marrow aspiration and biopsy with flow cytometry to detect clonal plasma cells, and detailed skeletal imaging that should include either PET-CT or a skeletal survey and MRI of the spine and pelvis. One-third of the patients may present with a detectable monoclonal paraprotein in the serum or urine or both. Persistence of the monoclonal paraprotein after local treatment is predictive of a recurrence of MM. Patients with less than 10% plasma cells in the bone marrow biopsy may be managed with therapies directed against the solitary lesion initially. However, these patients will also progress to MM over the subsequent years of follow-up.

Solitary plasmacytomas are generally treated with local radiation therapy at a dose of 40–50 Gy. Depending upon the location, small extramedullary soft tissue plasmacytomas may be treated with excision biopsy alone. Solitary plasmacytomas of the bone may require surgical intervention for stabilization followed by local radiation therapy.

The disease-free survival at 10 years is 63% for patients with solitary plasmacytomas. The disease-specific survival seems to plateau at about 80% for extramedullary plasmacytomas, compared with 50% for solitary bone plasmacytomas. Less than one-third of solitary extramedullary plasmacytoma patients died as a result of myeloma, as compared with 58% of the patients with solitary bone plasmacytomas. Progression to myeloma generally occurs within 5 years from initial diagnosis. Patients presenting with medullary plasmacytomas, patients with persistence of a monoclonal paraprotein after treatment for the solitary plasmacytoma, patients with detectable low levels of clonal plasma cells in the bone marrow, patients between 40 and 60 years of age, and patients of African American descent are at higher risk for progression to MM. These patients should be followed closely for the next 5 years.

Symptomatic Myeloma

Patients presenting with symptoms caused by the myeloma tumor mass, such as anemia, lytic bone disease, hypercalcemia, or renal impairment (CRAB), require systemic therapy. Myeloma-defining events that warrant systemic therapy include a clonal bone marrow plasma cell percentage (aspirate or biopsy, whichever is higher) 60% or above, elevated serum free light chain 100 mg/L or greater associated with involved/uninvolved free light chain ratio ≤ 100 , and/or more than one focal lesions on MRI studies. In addition, patients with a low tumor mass but with organ dysfunction caused by a paraprotein or immunodeficiency such as monoclonal immunoglobulin deposition disease or amyloidosis of an organ, progressive peripheral neuropathy, two or more serious infections (pneumonia, bacteremia) that require treatment. Related organ or tissue impairment also warrants initiation of systemic therapy.²⁰

Front-line therapy for MM is often predicated on whether the patient is eligible, willing, and able to proceed with HDT and stem cell transplant. The treatment given before stem cell harvest and transplant is called induction therapy followed by consolidation with HDT and stem cell rescue. Patients not embarking on HDT are started on initial therapy for 9–18 months. Both groups of patients may subsequently receive maintenance therapy.

Induction Regimen/Initial Treatment

Tremendous progress has been made in the treatment of MM, with improvement in life expectancy. The availability of new drugs has

paved the way for this improved outcome. This includes (1) traditional chemotherapy agents targeting the DNA, including melphalan, cyclophosphamide, doxorubicin, bendamustine, etoposide, and cisplatin; (2) immunomodulatory drugs thalidomide, lenalidomide, and pomalidomide; (3) proteasome inhibitors bortezomib, ixazomib, and carfilzomib; (4) the HDAC inhibitor panobinostat; and (5) monoclonal antibodies elotuzumab and daratumumab. There has been progress in understanding the biology of the disease. In every patient, there are multiple clones (three to five) at the time of diagnosis, as well as ongoing mutations during the course of the illness, and recurrences are caused by expansion of different clones (clonal tides) over time. Therefore combination therapy that includes drugs from different classes is likely to be more successful in eradicating the tumor. Achieving deep remission (CRs) predicts a better PFS. In addition, treatment should be tailored to tumor genetics, the age and frailty of the patient, comorbidities, and renal impairment.

TREATMENT OF NEWLY DIAGNOSED MYELOMA

Chemotherapy With Stem Cell-Sparing Agents

Patients considered for stem cell harvest are generally treated with combinations that are stem cell sparing. Before immunomodulatory agents and proteasome inhibitors became widely available, patients were treated with pulse dexamethasone alone or in combination with vincristine and adriamycin (VAD) and cyclophosphamide (CVAD or CVAMP; methylprednisolone substituted for dexamethasone). For more information, see box on [Treatment of Newly Diagnosed Multiple Myeloma](#).

Dexamethasone

Glucocorticoids induce apoptosis in myeloma cells. Glucocorticoids induce I κ B production, which then sequesters NF κ B, resulting in downregulation of IL-6 and other inflammatory cytokines. Dexamethasone 40 mg is administered in a pulsed fashion for 4 days, starting on days 1, 9, and 17 for the first cycle. Some researchers have used this dose and schedule every 35 days, whereas others have given dexamethasone on days 1–4, every other cycle, on a 28-day schedule. Results achieved with pulsed dexamethasone alone compare well with those of VAD chemotherapy, and MP, with equivalent response rates and OS. Single-agent dexamethasone is no longer advocated as a treatment for newly diagnosed MM. However, under selected clinical situations, the use of pulsed dexamethasone is helpful in specific situations, including severe spinal cord compromise, hypercalcemia, and acute renal failure caused by light chain nephropathy. While patients are on intensive dexamethasone, close monitoring for hyperglycemia and antibiotic and prophylaxis against bacterial, *Pneumocystis carinii* pneumonia, and fungal infections are recommended. Weight gain, mood swings, insomnia, fluid retention, proximal myopathy, and steroid-induced psychosis are known side effects. Cataracts, osteoporosis, and avascular necrosis of the hips are some of the long-term consequences of steroid exposure.

Vincristine, Adriamycin, and Dexamethasone

Infusional therapy with vincristine and doxorubicin (Adriamycin) with pulsed dexamethasone is an effective stem cell-sparing induction regimen. Vincristine and doxorubicin are administered by continuous infusion at doses of 0.4 mg/day and 9 mg/m²/day along with oral dexamethasone 40 mg/day for 4 days. Following six to nine cycles of VAD chemotherapy, the overall response rate (ORR) is 45% to 55%, and the CR rate is less than 5%. There are no differences in the median PFS (18 months) or OS (3 years) from those achieved with standard alkylating agent treatments (MP, VMCP/VBAP, VBMCP). However, if the induction therapy is followed by consolidation with high-dose melphalan and autologous stem cell transplant,

BOX 86.1 Treatment of Newly Diagnosed Multiple Myeloma

- Confirm patient has symptomatic myeloma. Patients with monoclonal gammopathy of unknown significance or smoldering multiple myeloma are not treated outside a clinical trial.
- Evaluate for risk stratification using International Staging System staging, fluorescence in situ hybridization/cytogenetic and biochemical testing to test renal function, and lactate dehydrogenase to develop long-term treatment plan as well as prognosis. Although initial treatment is not affected by risk category, a later consideration of more aggressive consolidation or use of allogeneic stem cell transplant in eligible patients can be considered in high-risk younger patients.
- Induction: Both transplant-eligible and transplant-ineligible patients can be treated with a triple-drug regimen (bortezomib and dexamethasone with lenalidomide [RVD], with thalidomide [VTD] or cyclophosphamide [VCD], OR other proteasome inhibitor (carfilzomib or ixazomib) in place of bortezomib, cyclophosphamide, thalidomide, dexamethasone [CTD]) for three to six cycles pretransplant or 9–12 months for transplant-ineligible patients. For transplant-ineligible patients, additional options include a two-drug regimen (dexamethasone with lenalidomide [RD], with bortezomib [VD] OR with thalidomide [TD]) OR melphalan-containing regimens, which include melphalan with prednisone (MP) in combination with any of the newer agents, MPT, MPV, or MPR.
- Selection of therapy should be influenced by patient characteristics.
 - Renal dysfunction: agents that can be considered for use are bortezomib, carfilzomib, cyclophosphamide, thalidomide, and dexamethasone (VCD or VTD)
 - Neuropathy: agents that can be considered for use are lenalidomide, carfilzomib, cyclophosphamide, and dexamethasone.
 - Older-age patients: consider dose or schedule attenuation.
 - Convenience: use of oral versus intravenous agent regimen.
- Transplant-eligible patients can undergo a single autologous transplant with melphalan, with a second autologous transplant being optional, depending upon the overall response or on protocol participation.
- Maintenance: Following transplant or optimal induction therapy (to best response), patients can receive maintenance with thalidomide, lenalidomide, or bortezomib. For high-risk patients only, both bortezomib and lenalidomide or a thalidomide combination may be used. Selection can be influenced on the basis of the induction regimen.
- Improving complete response rates is a key goal of current trials, but patients can live a long time with residual paraprotein.

substantial improvement in the PFS and OS has been observed. Hair loss and the need for catheter placement to administer these vesicant agents are important limitations and require acceptance by the patient. It is also possible to administer the daily dose of vincristine and adriamycin as an intravenous push without loss of efficacy or increased toxicity.

Chemotherapy With Alkylating Agents

Alkylating agents melphalan and cyclophosphamide were introduced in the management of MM in the early 1960s. Since the time of introduction, they have continued to play a vital role in the treatment of myeloma. MP has been the gold standard of treatment. All new combinations are benchmarked against MP. MP has been given in different doses and schedules for a minimum of 9–18 months. Other agents such as cyclophosphamide, carmustine (BCNU), vincristine, and/or Adriamycin, have been successfully combined with MP (e.g., VBMCP, VBAP). Combination therapies improved the response rate but did not change the OS outcomes. MP has a response rate of 50% to 60%, a PFS of 18 months, and an OS of 30–36 months.

In the 1960s, single-agent oral cyclophosphamide and oral melphalan were compared head to head in a randomized, double-blind

study and were noted to have equivalent antimyeloma activity. Cyclophosphamide is less stem cell toxic than melphalan. Cyclophosphamide in high doses (2 g/m² up to 6 g/m²) followed by filgrastim has been used for stem cell mobilization, whereas high doses of melphalan (200 mg/m²) are routinely used as the conditioning regimen in conjunction with an autologous stem cell transplant. There is a higher incidence of secondary leukemia associated with chronic melphalan therapy (up to 17% at 50 months), leading to abandonment of melphalan as maintenance therapy and limiting the exposure to 1 year or less.

Immunomodulatory Drugs

Currently, thalidomide, lenalidomide, and pomalidomide are the three IMiDs available for the treatment of MM. Recently, insights into the mechanism of action of IMiDs has been gained with the discovery of thalidomide-binding protein cereblon (CRBN). Human CRBN was originally identified as a candidate gene for an autosomal recessive form of mild mental retardation and is located on chromosome 3 at 3p26.2. CRBN is the substrate receptor of CUL4-RBX1-DDB1-CRBN also known as CRL4^{CRBN} E3 ubiquitin ligase. IMiDs bind CRBN and inhibit ubiquitination of endogenous CRL4^{CRBN} substrates, but unexpectedly IMiDs also repurpose the ligase to target new proteins for degradation. IMiDs induce degradation of the lymphoid transcription factors Ikaros (IKZF1) and Aiolos (IKZF3) and casein kinase 1α (CK1α). Degradation of Ikaros and Aiolos contributes to clinical efficacy in the treatment of MM, whereas degradation of CK1α is responsible for IMiD activity in 5q-associated myelodysplastic syndrome. Downregulation of Ikaros and Aiolos lead to specific and sequential downregulation of c-Myc followed by IRF4 and subsequent growth inhibition and apoptosis of myeloma cells. Drug resistance to IMiDs is associated with depletion of CRBN. Aiolos and Ikaros are transcriptional repressors of IL-2 in T cells. Thus IMiDs are able to increase the number of T cells and NK cells; there is polyfunctional T-cell activation with increased cytokine production by CD4 and CD8 T cells and reduction of the suppressive effects of Tregs on T-effector cells. There is increased expression of cytotoxic genes granzyme B and perforin by CD8 T cells and NK cells.

Thalidomide

An international, randomized phase III trial has shown that thalidomide with dexamethasone (TD) is superior to dexamethasone alone for ORR (63% vs. 46%) and PFS (14.9 months vs. 6.5 months). There was no difference in efficacy between TD versus VAD as a pretransplant induction regimen. TD had a slightly inferior survival outcome compared with MP as first-line therapy in elderly patients. Thalidomide does not overcome poor prognostic genetic features. TD is no longer considered optimal treatment for newly diagnosed patients with MM. Thalidomide is generally prescribed at 200 mg daily. No maximally tolerated dose (MTD) has been defined; doses as high as 800 mg daily has been used. Major side effects of thalidomide include irreversible peripheral neuropathy that develops after exposure for a period of 6 months or longer. Other serious side effects include DVT and pulmonary embolism when combined with dexamethasone but does require thromboprophylaxis for patients without additional risk factors for developing DVT. Prophylaxis with a low-dose aspirin (81–100 mg) daily is adequate. Other clinically significant side effects include severe constipation, severe bradycardia, and skin rash. Results with thalidomide combinations in relapsed and newly diagnosed patients are summarized in [Tables 86.12 and 86.13](#).

Thalidomide has been used in combination with other drugs in newly diagnosed patients with MM. Six large randomized clinical trials have been conducted combining melphalan and prednisone with or without thalidomide. Metaanalysis of these six large studies has shown MPT to be superior to MP alone: The ORR improved by 22% (59% vs. 37%); PFS improved by 5 months (20 months vs. 15

months); and OS by 6 months (39 months vs. 33 months) (Table 86.14). MPT is an acceptable front-line treatment for patients over the age of 65 years. Side effects were higher in the MPT arm; DVT occurred in 6% to 12% versus 1% to 4% of patients; peripheral neuropathy occurred in 6% to 23% of patients versus 0% to 5% of patients; and discontinuation of treatment occurred in 41% to 45% of patients versus 6% to 11% of patients compared with MP alone (Table 86.15).

Thalidomide, adriamycin, and dexamethasone (TAD) induction therapy followed by stem cell transplant and subsequent maintenance

with thalidomide was noted to be superior to VAD induction followed by transplant and interferon maintenance in a large randomized trial by the HOVON Group.

Oral Regimens

Cyclophosphamide, thalidomide, and dexamethasone (CTD) was compared with infusional CVAD chemotherapy for patients eligible for HDT in a large, multicenter, randomized phase III trial conducted

in the United Kingdom (MRC Myeloma IX Trial). The CTD regimen consisted of cyclophosphamide 500 mg weekly, thalidomide 100 mg daily, and dexamethasone 40 mg for 4 days every other week. The induction chemotherapy was given for a minimum of six cycles and up to nine cycles or until maximum response. The postinduction ORR was significantly higher with CTD versus CVAD (82.5% vs. 71.2%; $p < .0001$); likewise, CR rates were also higher with CTD (13% vs. 8.1%; $p = .0083$). This differential response was maintained following autologous stem cell transplant with regard to posttransplant CR (50% vs. 37.2%; $p = .00052$). With a median follow-up of 47 months, there was no difference in PFS or OS between the two groups. This establishes CTD as an acceptable induction therapy before transplant.

For elderly patients and patients otherwise ineligible for HDT, CTD was compared with MP. The dose of cyclophosphamide was 500 mg weekly, thalidomide 50 mg daily, and dexamethasone 20 mg for 4 days every other week. Both arms were oral regimens. CTD therapy was associated with a superior ORR (63.8% vs. 32.6%; $p < .0001$) and CR rate (13.1% vs. 2.4%) and VGPR (16.9% vs. 1.7%). After a median follow-up of 44 months, PFS and OS were similar between the groups. CTD was associated with higher rates of thromboembolic events, constipation, infection, and neuropathy. This study also illustrated that thalidomide was incapable

of improving the outcome of patients with unfavorable genetic markers.

Lenalidomide

Lenalidomide and dexamethasone are an effective combination therapy for the treatment of previously untreated symptomatic myeloma patients. A large, open-label, phase III randomized trial comparing lenalidomide plus high-dose dexamethasone or lenalidomide plus weekly dexamethasone conducted by the Eastern Cooperative Oncology Group established lenalidomide and dexamethasone as a simple oral regimen that could be used as an induction therapy before transplant or as a first-line therapy without a stem cell transplant. Administration of lenalidomide 25 mg daily for 3 weeks on and 1 week off, along with dexamethasone 40 mg in a pulsed fashion (days 1–4, 9–12, and 17–20) for the first four cycles only (high-dose dexamethasone arm), gave a higher response rate of 79% compared with weekly dexamethasone 40 mg (low-dose dexamethasone arm; 60%); however, the high-dose dexamethasone arm was associated with a higher incidence of infections and venous thromboembolism and an inferior 1-year survival rate (87%) compared with the low-dose dexamethasone arm (1-year survival rate of 96%). However, with longer follow-up, there was no survival difference between the two arms.

In a large, open-label, international randomized clinical trial, 1623 patients who were transplant ineligible were randomly assigned to lenalidomide and dexamethasone (RD) administered as 28-day cycles until disease progression occurred (535 patients), to the same combination of RD for 72 weeks (18 cycles; 541 patients), or to MPT for 72 weeks (547 patients). The median PFS rates were 25.5 months with continuous RD, 20.7 months with 18 cycles of RD, and 21.2 months with MPT (hazard ratios for the risk of progression or death 0.724 for continuous RD vs. MPT and 0.704 for continuous RD vs. 18 cycles of RD; $p < .001$ for both comparisons). OS rates at 4 years were 59% with continuous RD, 56% with 18 cycles of RD, and 51% with MPT.

A retrospective case-control study done at a single institution by researchers who compared lenalidomide-dexamethasone with thalidomide-dexamethasone revealed that lenalidomide-dexamethasone was better tolerated, with a higher ORR (80% vs. 61%), higher VGPR (34% vs. 12%), improved PFS (27 months vs. 17 months), and improved OS. Addition of clarithromycin to lenalidomide and low-dose dexamethasone resulted in an ORR of 90%, a VGPR rate of 74%, and a CR for 39% of patients.

Thus the combination of lenalidomide and dexamethasone is an excellent induction regimen as first-line therapy for newly diagnosed patients with MM. Results with lenalidomide combinations in relapsed and newly diagnosed patients are summarized in [Tables 86.16](#) and [86.17](#). Lenalidomide has also been combined with MP

with its continued use as maintenance, and as shown in Table 86.15, it provides a superior response and PFS to that of MP alone.

Bortezomib

Bortezomib, a boron-containing dipeptide, is the first proteasome inhibitor to be introduced for the treatment of MM. Bortezomib is a specific and reversible inhibitor of the 26S proteasome, binding to the chymotrypsin-like enzymatic site. The incomplete and transient inhibition of the proteasome results in apoptosis of myeloma cells by activation of both caspases 8 and 9 while sparing normal tissue. There is downregulation of NFκB in the myeloma cells, OCs, and the surrounding stromal cells. This results in decreased release of inflammatory cytokines such as IL-6 in the bone marrow milieu. Bortezomib not only arrests osteoclastic activity by reducing sRANKL and decreases CTX, and TRACP-5b but also induces OBs by decreasing serum DKK-1 as reflected by an increase in bone alkaline phosphatase and osteocalcin, regardless of treatment response.

Bortezomib as a single agent induces CR in 10% of patients and results in an ORR of 27% in newly diagnosed mm patients; bortezomib is not recommended as a monotherapy. Bortezomib and dexamethasone (B-D) is an excellent induction regimen with an ORR of 88% and CR+VGPR rate of 19% and one year survival of 87%. A randomized trial has shown B-D to be superior to VAD as an induction regimen with a higher CR rate (15% vs. 6%) and ORR (79% vs. 63%).²⁷ Following autologous stem cell transplant, there was a continued advantage for the B-D arm: CR/near-CR of 35% versus

18% and VGPR or better of 54% versus 37%. Median PFS was 36 months versus 30 months, and 3-year survival rates were 81% versus 77% with a median follow-up of 32 months. Results with bortezomib combination therapy including relapsed and newly diagnosed patients are summarized in Tables 86.7 and 86.8. Bortezomib has also been combined with melphalan and prednisone, and as shown in Table 86.15, after 5 years of follow-up, it provides ORR, CR, PFS, and OS superior to MP alone.

Combination of Three or Four Classes of Drugs

It is possible to combine drugs from different classes with nonoverlapping toxicities without compromising their dose to maximize their antitumor effect and eliminate potentially resistant clones to prolong remission duration. Generally, three-drug combinations have been shown to give the highest ORR and VGPR as compared with two-drug regimens (VCD, VRD, VTD).^{28,29} Fig. 86.13 summarizes the results with two-, three-, and four-drug regimens and suggests improved responses and a higher incidence of CR using a three-drug regimen (RVD, VCD) with apparently no clear benefit of adding a fourth agent as yet. Similar results are also depicted in Fig. 86.13 with MP-based regimens. In the Southwest Oncology Group trial, 525 patients were randomly allocated to bortezomib, lenalidomide, and dexamethasone (VRD; 242 patients) or to lenalidomide and dexamethasone (RD; 229 patients). Patients randomized to VRD received eight 3-weekly cycles, and patients assigned to RD received six 28-day cycles. Patients from both arms were subsequently maintained on RD until progression. Patients randomized to the three-drug combination

Fig. 86.14 COMPARATIVE TRIALS OF HIGH-DOSE THERAPY (HDT) WITH STANDARD-DOSE CHEMOTHERAPY (SDT). Intergroupe Francophone du Myélome (IFM-90; *left panel*) randomized trials with 200 patients randomized to SDT with VMCP-VBAP (vincristine, melphalan, cyclophosphamide, and prednisone and vincristine, carmustine, adriamycin, and prednisone) versus HDT with melphalan 140 mg/m² plus total body irradiation (800 cGy) and Medical Research Council (MRC-VII; *right panel*) trial with 401 patients randomized to SDT with doxorubicin, carmustine, cyclophosphamide, and melphalan or HDT with CVAD followed by melphalan 200 mg/m² and stem cell rescue. Significantly longer overall survival was noted with HDT in both studies. HD, High dose; OS, overall survival.

(VRD) had a better median PFS of 43 months than patients receiving two drugs (RD) with a median PFS of 30 months ($p = .0018$; HR, 0.712). Surprisingly, there was improvement in OS for the triplet regimen (VRD; median OS, 75 months) over the doublet regimen (RD; median OS, 64 months) with a hazard ratio of 0.7 and a p -value of .025.

High-Dose Therapy and Consolidation

Tim McElwain introduced high-dose intravenous melphalan for the treatment of MM in 1983. A dose-response effect for melphalan was quite evident in MM. In the 1980s and 1990s, HDT with stem cell support was increasingly used to treat younger patients (aged 65 years and under).

Source of Stem Cells

In the 1980s, bone marrow was harvested from the patient under general anesthesia. This approach has been completely supplanted by the use of peripheral blood stem/progenitor cells. Autologous bone marrow transplant was associated with delayed hematopoietic recovery by 1 week compared with mobilized blood stem cells, resulting in a higher transplant-related morbidity and mortality of 10% compared with 2% with peripheral blood progenitor cells. Stem cells can be mobilized with chemotherapy alone, chemotherapy and growth factor (G-CSF or granulocyte-macrophage colony-stimulating factor), or growth factors alone (G-CSF, G-CSF plus plerixafor). The degree of tumor cell contamination in the peripheral blood stem cell product has had no influence on transplant outcome. Ex vivo manipulations to eliminate tumor cells within the graft have not resulted in any improvement in the depth of response, PFS, or OS. It is preferable to use stem cell-sparing agents as induction therapy before stem cell harvest. Alkylating agent exposure and lenalidomide exposure should be limited to ensure adequate stem cell harvest and complete hematopoietic recovery posttransplant. It is preferable to collect stem cells after the achievement of best antitumor response to induction therapy to minimize tumor cell contamination.

AUTOLOGOUS STEM CELL TRANSPLANT

Single High-Dose Therapy With Stem Cell Transplant Rescue

Several prospective, randomized clinical trials were performed in the 1990s to define the role of HDT and stem cell transplant as a component of front-line therapy for patients with MM. In two studies (IFM 90³⁰ and MRC VII³¹), researchers reported the superiority of HDT and stem cell transplant with respect to response rate, PFS, and OS, which led to widespread use of HDT and stem cell transplant for patients up to the age of 65 years (Fig. 86.14).³² However, there were other studies that did not show a survival advantage but did show improvements in the response rate and PFS. One such clinical trial was conducted by the French myeloma auto-graft group in patients between the ages of 55 and 65 years (MAG 90). That study showed a higher response rate (CR + MRD 36% vs. 20%) and a trend for improved PFS (EFS, 25.3 vs. 18.7 months; $p = .07$) in favor of the HDT arm, but no difference in OS. Researchers in a Spanish trial gave induction therapy with VBMCP/VBAD for four cycles at five week intervals, and subsequently responding patients were randomized between HDT and continuation of standard chemotherapy for eight additional cycles of VBMCP/VBAD. Although the HDT arm had a higher CR rate, there was no difference in PFS or OS. Another trial conducted in the United States also allowed for induction therapy, followed by randomization of all patients to a single autotransplant versus continued VBMCP therapy for 1 year. This study did not show a difference in OS between the two arms. In this study, the patients in the standard treatment arm were allowed to receive HDT and stem cell transplant following relapse. Results of five large randomized trials comparing SDT with HDT are summarized in Table 86.18.

In another randomized phase III trial with patients under the age of 56 years, investigators evaluated the role of early versus late transplant (MAG 91). This study showed that there was no difference in OS. However, the investigators showed that early application of HDT resulted in prolonged PFS compared with the standard chemotherapy arm; the time without symptoms, additional treatment, and treatment toxicity were favorable when HDT was applied as part

of the initial therapy. This allowed for flexibility in the timing of transplant to suit the patient's clinical situation and preference.

A metaanalysis of primary data obtained from the three French studies (IFM 90, MAG 90, and MAG 91) showed no difference in the OS between standard therapy and HDT arms. Likewise, authors of another metaanalysis using data culled from nine randomized clinical trials reported in the literature showed no survival benefit for HDT and stem cell transplant. These data are in direct contrast to the metaanalysis using the Swedish Cancer Registry and SEER data with improvement in 5-year relative survival ratios for younger patients primarily due to the introduction of HDT and stem cell transplant in the 1990s.

On the presumption that therapy with a single alkylating agent at MTD may not be adequate for disease eradication, Barlogie pioneered a tandem transplant approach as part of his total therapy approach for the treatment of MM in 1989 (Total Therapy 1) and reported promising results without increased treatment-related morbidity or mortality. Single HDT resulted in a CR rate well under 25% in most trials. These investigators tried to improve the results by providing a second consecutive high-dose melphalan and stem cell transplant (tandem transplant).

There have been four large randomized clinical trials comparing the role of tandem autotransplant against a single episode of HDT and stem cell transplant (Table 86.19). All four studies showed improvement in the depth of response (VGPR) following a tandem

transplant, and three of the four studies showed improvement in PFS, but only one study showed an improvement in the OS. The French trial (IFM 94³³) showed the benefit of a second transplant only for patients not in VGPR or better after the first transplant. In the era of novel agents, a VGPR or better can be obtained before transplant, and therefore a second transplant is seldom used outside the setting of a clinical trial (Table 86.20).

In the era before introduction of novel agents, induction regimen had only a minimal role because CRs were uncommon (less than 5%) with high-dose dexamethasone or VAD chemotherapy. Thus HDT played a critical role in achieving favorable CR and VGPR rates and prolonged durability of unmaintained responses. The availability of novel agents has dramatically changed this paradigm. Novel agents have improved VGPR or better before stem cell transplant, allowing for posttransplant consolidation and maintenance. Whether novel agents can supplant HDT and stem cell transplant is an important question that has yet to be answered.

Induction Therapy With Novel Agents

Randomized clinical trials have shown that combined thalidomide and dexamethasone therapy is equivalent to VAD chemotherapy. The Dutch HOVON 50 trial researchers compared thalidomide during the induction phase and as maintenance following HDT and stem

**TABLE

^aP Value significant.

cell transplant. TAD chemotherapy was superior to VAD chemotherapy on the basis of overall response and quality of response before and after HDT and stem cell transplant. In addition, maintenance with thalidomide improved the PFS and resulted in a trend toward improved OS. Lenalidomide and dexamethasone have been shown to be useful as an induction regimen before transplant. However, no formal randomized clinical trial has been performed comparing this combination with conventional chemotherapy. Exposure to lenalidomide should be limited to four to six cycles because it compromises stem cell mobilization.

French Study IFM 2005-1

B-D was superior to VAD chemotherapy as an induction regimen. There was improvement in CR and VGPR before and after transplant, and there was a trend for prolonged PFS but no difference in the OS.²⁷ The lack of impact on PFS and OS is perhaps a result of limited bortezomib exposure to a maximum of four cycles during the induction phase.

Combining bortezomib with immunomodulatory drugs further improves the outcome before and after stem cell transplant. In a large randomized clinical trial of 480 patients conducted by the GIMEMA Italian Myeloma Network, VTD was shown to be superior to PD for induction therapy and for consolidation after tandem transplant. VTD induction therapy significantly improved the rate of complete or near-complete response before the transplant. This higher response rate continued following tandem transplant and was further augmented by two cycles of VTD consolidation as opposed to TD posttransplant. This increase in the depth of response has translated to a superior PFS. However, there was increased neuropathy encountered by the patients in the VTD arm. The French investigators reduced the dose intensity of VTD and confirmed in another randomized trial that four cycles of VTD were superior to four cycles of B-D as an induction regimen before transplant.³⁴ There was less neuropathy, owing to the adjustment of bortezomib and thalidomide doses. The Spanish group compared TD, VTD, and multiagent chemotherapy as induction therapy and showed that VTD was superior following transplant. The patients were further randomized to maintenance therapy with VP versus VT, with no difference in outcome observed. Results of two large studies of HDT with over 7 and 12 years of follow-up are shown in Fig. 86.15, suggesting a possibility of a tail in the survival curve with over 10% to 20% of patients remaining disease-free or alive after 10 years, suggesting a possibility for long-term survival in myeloma.

Allogeneic Stem Cell Transplantation

Allogeneic stem cell transplant offers a potential for cure for patients with MM that is mediated by a graft-versus-myeloma effect, tumor-free graft, and potential for donor lymphocyte infusion to combat

the residual or recurrent disease (Fig. 86.16). However, the role of allogeneic stem cell transplant in MM is limited. Patients are generally older (over 75% of the patients are over the age of 55 years), often presenting with comorbidities such as renal impairment, diastolic dysfunction of the heart, and restrictive lung disease. The underlying immunodeficiency associated with this disease is worsened by posttransplant immunosuppression, resulting in a high transplant-related mortality with standard myeloablative conditioning regimens. Relapse after allogeneic stem cell transplant contributes to the modest efficacy of this approach. Whereas it could be shown that there is a graft-versus-myeloma effect with sustained molecular remission, it has been difficult to induce graft-versus-myeloma effects while avoiding graft-versus-host disease (GVHD). There are no convincing survival data to support widespread use of allogeneic stem cell transplant outside a clinical trial.

There has been improvement in 6-month and 2-year survival rates since 1994 as compared with the prior era. This improvement reported by the European Bone Marrow Transplant Registry was attributed to better supportive care measures and patient selection. Reduced-intensity conditioning regimens, with reduction in immediate transplant-related mortality and stable engraftment, as well as use of peripheral blood progenitor cells from donors with their rapid engraftment kinetics, renewed interest in the use of allogeneic stem cell transplant for MM. Bensinger et al reported the long-term results of allogeneic transplant for MM at the Fred Hutchinson Cancer Research Center spanning 34 years. Among the 144 patients undergoing an ablative conditioning regimen, the 2-year nonrelapse transplant mortality was 55%; major causes of death included fungal and viral infections, acute respiratory distress syndrome, acute GVHD, and multiorgan failure. The 2-year non-transplant-related mortality was 18% among the recipients of nonablative conditioning regimens; the causes of death were mostly chronic GVHD and progressive disease. The 10-year OS was 15% for myeloablative regimens as compared with 35% for nonmyeloablative regimens. The incidence of acute GVHD was similar (65% ± 2%), but the incidence of extensive chronic GVHD was 27% for ablative regimens as compared with 67% for nonablative regimens (Table 86.21).

There have been several studies reported combining the tandem autologous transplant approach with “mini” allogeneic stem cell transplant. The Italian group reported superior outcomes for patients receiving an autograft-allograft protocol compared with patients receiving tandem autograft protocols.³⁵ After a median follow-up of 46 months, the median OS had not been reached for patients receiving auto-allotransplants as compared with 58 months for tandem autotransplants; the EFS rates were 43 and 33 months, respectively, for the two groups (Table 86.21). The French group subjected patients with high risk (β_2 -microglobulin >3 mg/L and chromosome 13 deletion) to tandem auto-transplants or auto-allotransplant on the basis of availability of human leukocyte antigen-compatible sibling donors. On an intention-to-treat basis, there was no difference in EFS or OS with a trend for better OS in patients treated with tandem autologous stem cell transplants. In a recently completed BMT-CTN

Fig. 86.15 MAINTENANCE THERAPY PROLONGS PROGRESSION-FREE SURVIVAL (PFS). Lenalidomide maintenance improves PFS after hematopoietic stem cell transplant (HSCT). (A) Intergrupee Francophone du Myélome (IFM) trial. (B) Cancer and Leukemia Group B (CALGB) trial. (C) Lenalidomide maintenance improves PFS following standard chemotherapy (melphalan, prednisone, and lenalidomide [MPR]) or after high-dose therapy. (D) Improved PFS following continuous lenalidomide and dexamethasone (Ld) until progression versus Ld for 18 months or melphalan, prednisone, and thalidomide for 18 months. *MPT*, melphalan, prednisone, and thalidomide; *Ld*, lenalidomide and weekly dexamethasone. (Data from Attal M, Lauwers-Cances, Marit G, et al: lenalidomide maintenance after stem cell transplantation for multiple myeloma. *N Engl J Med* 366:1782, 2012; McCarthy P, Owzar K, Hofmeister CC, et al: lenalidomide after stem cell transplantation for multiple myeloma. *N Engl J Med* 366:1770, 2012; Palumbo A, Cavallo F, Gay F, et al: Autologous transplantation and maintenance therapy in multiple myeloma. *N Engl J Med* 371:895, 2014; and Benboubker L, Dimopoulos MA, Dispenzieri A, et al: Lenalidomide and dexamethasone in transplant ineligible patients with myeloma. *N Engl J Med* 371:906, 2014.)

Fig. 86.16 CENTER FOR INTERNATIONAL BLOOD AND MARROW TRANSPLANT RESEARCH ANALYSIS OF MYELOMA TRANSPLANTS. Among 23,197 patients who received an autotransplant for multiple myeloma (MM) between 2000 and 2009, the 3-year probability of survival was $70\% \pm 1\%$. Allogeneic stem cell transplant for MM is reserved for patients with high-risk disease, and the majority of transplants were performed after an autologous hematopoietic cell transplant (HCT) with reduced-intensity or nonmyeloablative conditioning regimens. Among the 979 patients who received an allogeneic HCT between 2000 and 2009, the 3-year probabilities of survival were $51\% \pm 2\%$ for the 827 recipients of human leukocyte antigen (HLA)-matched sibling donor grafts and $26\% \pm 2\%$ for the 470 recipients of unrelated donor grafts. (From Pasquini MD, Wang Z: CIBMTR summary slides, 2010. Adapted from <http://www.cibmtr.org/>.)

trial in the United States, there was no difference in outcome between auto-/mini-allo transplant and tandem autologous transplant. In order to increase the effect of donor lymphocyte infusions against the tumor cells, vaccination strategies are currently being pursued.

Syngeneic Transplantation

Results of syngeneic transplant are superior to autologous transplant and allogeneic stem cell transplant. The results are better than autologous transplant because of lower relapse rates with twin transplant. This may be related to the lack of tumor cells in the graft and/or a graft-versus-myeloma effect without GVHD. The results of syngeneic transplant are also superior to allogeneic stem cell transplant on the basis of low transplant-related mortality and the absence of clinical GVHD. These conclusions were based on reports published by two large transplant registries (CIBMTR and EBMT).

Maintenance

Maintenance therapy is the use of ongoing low-intensity chemotherapy to eliminate or suppress MRD over a prolonged period.

Maintenance therapy is administered when the disease is in remission, at either undetectable or low levels. The purpose of maintenance therapy is to prolong remission duration and thereby life expectancy. Maintenance therapy improves the quality of response, supporting the notion that an additional antitumor response during the maintenance phase will be beneficial. Immunomodulatory molecules are well suited for maintenance therapy because they can be administered orally at low doses for a prolonged period.³⁶

The first two randomized trials published on thalidomide maintenance after autotransplant showed an improvement in PFS and OS. In the Total Therapy II trial, researchers randomized patients to thalidomide induction and a maintenance arm versus a no thalidomide arm; this study showed improvement in PFS and a delayed improvement in OS after 8 years of follow-up. In the HOVON 50 trial, patients were similarly randomized to thalidomide induction followed by thalidomide maintenance after transplant or VAD induction followed by interferon maintenance. This trial also showed improvement in PFS and OS for patients in the thalidomide arm. A meta-analysis of published results to date indicated a significant reduction of the risk for progression with thalidomide maintenance therapy. Outcome did not differ between trials that used thalidomide during the maintenance phase only and those that used thalidomide for both induction and maintenance treatment. The MRC IX trial

TABLE 86.22 Randomized Studies Comparing Maintenance Therapy in Myeloma

MPR, Melphalan-prednisone-lenalidomide; MPRR, melphalan-prednisone-lenalidomide followed by lenalidomide maintenance; NA, not available; OS, overall survival; PFS, progression-free survival; VP, bortezomib-prednisone; VT, bortezomib-thalidomide.

had an intensive therapy arm (stem cell transplant) and a nonintensive arm (no stem cell transplant); once the patients had completed the intensive or nonintensive treatment arm, they were randomized to receive thalidomide maintenance or no maintenance. There was improvement in PFS but no improvement in OS when the two groups were compared. Results of major randomized studies evaluating maintenance therapy are summarized in [Table 86.22](#).

There have been three large randomized trials exploring the role of lenalidomide as maintenance therapy. Two of these studies were maintenance therapy after autologous stem cell transplant (CALGB and IFM), and the third study was in elderly patients receiving MP. All three studies showed improvement in PFS by 18 months; only the CALGB study showed improvement in OS. There appears to be a slightly increased risk of occurrence of a second malignancy when lenalidomide is administered along with melphalan immediately after HDT with melphalan. Lenalidomide therapy is also unable to alter the poor prognosis attributed to adverse cytogenetics or FISH results.

Bortezomib has also been used in the maintenance setting. Generally, bortezomib maintenance has been restricted to clinical trials in which bortezomib was also used during the induction phase of the treatment. Bortezomib maintenance seemingly improved the outcome in patients with high-risk cytogenetics or FISH results. Bortezomib is given less frequently in the maintenance setting; different studies have used different schedules of administration.

RELAPSED DISEASE

Relapse is defined as reappearance of signs and symptoms of the disease or signs of increasing disease and/or end-organ dysfunction that are related to the underlying myeloma.³⁷ Patients presenting with a symptomatic relapse require treatment intervention. Patients with rapidly rising paraprotein, doubling of the paraprotein within a short interval, also require treatment. Patients with asymptomatic biochemical relapse do not require treatment. Generally, serum M spike greater than 1 g/dL, Bence Jones proteinuria greater than 500 mg per day, or serum free light chain level greater than 200 mg/L would be a minimum requirement to consider intervention with systemic therapy. Occasionally, myeloma cells may become dedifferentiated or anaplastic and may produce only light chain components (Bence Jones escape phenomenon) or no paraprotein at all. These patients generally tend to have a more aggressive clinical course. The development of compression fractures and fractures at a site of previous lytic lesion per se does not constitute progression of myeloma. Development of hypercalcemia, progressive anemia, and new or worsening kidney function would merit prompt treatment intervention.

Currently, relapsed and refractory disease is defined as having failed three or more lines of prior therapy with previous exposure to all four classes of drugs (cytotoxic agents, immunomodulatory agents,

proteasome inhibitors, and glucocorticoids) and progressing during the last line of therapy. These patients have a life expectancy less than 1 year.

There are several considerations in choosing the treatment for patients with relapsed myeloma.³⁷ These include disease-related factors such as slow, indolent, or single site of relapse or rapid and multiple sites of relapse. Patients with a single site of relapse may benefit from radiation treatment. Special considerations need to be given to patients presenting with extramedullary soft tissue plasmacytomas, CNS relapses, or plasma cell leukemia. Patients presenting with an elevated LDH, high β_2 -microglobulin, del(17p), and multiple copies of 1q generally have a poor prognosis. Patients presenting with advanced age, poor performance status, renal impairment, and poor hematologic reserve or concurrent myelodysplastic syndrome from prior therapy present a great challenge. The choice of treatment is also predicated on prior drug exposure, whether the relapse is on or off therapy, and ongoing toxicity from prior therapy. For more information, see box on [Treatment of Relapsed Multiple Myeloma](#).

Thalidomide

Thalidomide monotherapy was originally introduced for the treatment of advanced and refractory myeloma. In the initial phase II trial, thalidomide was administered at 200 mg daily with increments every 2 weeks up to 800 mg for 169 patients. A partial response or better was noted in 30% of patients with a 2-year EFS of 20% and OS of 48%. A phase III trial (OPTIMUM) compared dexamethasone with thalidomide monotherapy at 100 mg, 200 mg, and 400 mg daily doses. The median times to progression were 6, 7, 8, and 9.1 months, respectively. The response rates and the median survival were similar in all treatment groups. In a systematic review published by Glasma-cher, partial responses or better in 30% of relapsed patients with 1-year survival of 60% were reported. Thalidomide has been combined successfully with other conventional chemotherapy agents as well as proteasome inhibitors for improved response rates and better disease control. Thalidomide is especially useful when a patient presents with renal impairment and cytopenias. It is also useful for palliation when combined with oral cyclophosphamide and prednisone in patients with a poor performance status.

Lenalidomide

In two large phase III randomized trials (MM 009, MM 010), lenalidomide and dexamethasone was found to be superior to dexamethasone in patients with relapsed myeloma after one to three lines of prior therapy. Updated results with a median follow-up of 48 months showed an ORR of 61%, median time to progression of 13.4

BOX 86.2 Treatment of Relapsed Multiple Myeloma

- Ensure patient has had relapse requiring intervention. A negative immunofixation test becoming positive is not an indication to initiate salvage therapy. A clear clinical relapse occurs with new or increased evidence of end-organ damage, and a substantial or aggressive biochemical relapse is defined by criteria for progressive disease.
- Selection of treatment depends on prior therapy received
 - Lenalidomide based
 - Initial treatment with bortezomib/thalidomide.
 - Underlying peripheral neuropathy
 - Lenalidomide used with caution in patients with renal dysfunction with appropriate dose adjustment
 - Bortezomib based
 - Initial treatment with immunomodulatory agents
 - Renal dysfunction
 - Poor hematopoietic reserve
 - Long response (>12 mo) to prior bortezomib
 - Thalidomide based
 - Prior bortezomib/lenalidomide
 - Renal impairment
 - Poor hematopoietic reserve
 - Chemotherapy with or without novel agent combination
 - Progressed on novel agents
 - Rapid, aggressive relapse with high lactate dehydrogenase and/or extramedullary plasmacytomas
 - Salvage transplant
 - In transplant-eligible patients, transplant needs to be considered if stem cell transplant was deferred at initial therapy or patient had a long remission (>3 yr) after first transplant or has poor hematopoietic reserve and stem cells are being stored. Transplant may also be considered as a way to reestablish hematopoiesis in select cases.
- Special considerations
 - Rapid, or multiple sites, or extramedullary sites: chemotherapy with or without novel agent combination
 - Central nervous system relapse - radiation therapy for localized disease, intrathecal chemotherapy for positive cerebrospinal fluid cytology, along with systemic therapy as indicated
 - Poor performance status and hematopoietic reserve - oral therapy with low-dose daily cyclophosphamide, thalidomide, and prednisone
 - Prior drug exposure and associated toxicity: consider presence of neuropathy, cytopenias, and renal dysfunction to decide on agents, their schedule, and dose
- Clinical trials
 - Consider enrolling patient on a clinical trial with a new drug

months, duration of response of 16 months, and OS of 38 months. Patients who had received more than one line of prior therapy had an ORR of 57%, and time to progression was 10.6 months. A median PFS of 9.5 months and OS of 31 months were reported. Patients with moderate or severe renal impairment developed more severe thrombocytopenia, required more frequent dose modifications, and had inferior survival outcomes. Prior exposure to thalidomide did not preclude responses to lenalidomide; however, patients who had relapsed or progressed on thalidomide had a lower response rate (under 50%) and a shorter time to progression (7 months). Lenalidomide can easily be combined with conventional chemotherapy as well as bortezomib. Combination therapy results in a higher response rate and better disease control.

Bortezomib

In a large phase II trial (SUMMIT) conducted with patients with relapsed and refractory MM, bortezomib monotherapy had an impressive ORR of 28%, including 10% CR or near-CR. The median time to progression was 7 months, the duration of response was 12.7 months, and the median survival time was 17 months.

Among patients with relapsed myeloma following one to three lines of prior therapy, bortezomib monotherapy had an ORR of 43%, a median time to progression of 6.2 months, a duration of response of 8 months, and a median survival of 30 months. Bortezomib monotherapy is less effective in patients who have received more than one line of prior therapy. Bortezomib is also synergistic when used in combination with other drugs, including alkylating agents, anthracyclines, immunomodulatory drugs, and dexamethasone. These combinations generally produce higher ORRs in the range of 50% to 80%, with an increasing duration of response and OS. Bortezomib plus pegylated liposomal doxorubicin was shown to be superior to monotherapy in a large randomized trial with an improved time to progression (9.3 vs. 6.5 months) and OS. Bortezomib also was recently administered as a subcutaneous injection. In a randomized trial comparing subcutaneous with intravenous administration, identical 42% response ratios were observed. The subcutaneous routes, however, had an improved safety profile, each with a reduced incidence of peripheral neuropathy (38% vs. 53% any grade, $p = .044$; 6% vs. 16% grade 3 or worse, $p = .026$).³⁸

New Agents

Relapsed Myeloma

Several large phase II and phase III randomized clinical trials have been conducted in patients with relapsed myeloma. These studies have resulted in the approval of six new drugs for the treatment of relapsed myeloma since 2012, including three new drugs (panobinostat, ixazomib, and elotuzumab) for patients with one to three relapses and pomalidomide, carfilzomib, and daratumumab for those with more than three relapses or refractory myeloma (Tables 86.23, 86.24).

Carfilzomib is a selective and irreversible proteasome inhibitor of the chymotrypsin-like activity of the proteasome. It is administered intravenously. In a large, open-label, single-arm phase II study, 266 patients with relapsed myeloma progressing on the last therapy were treated with carfilzomib at 20 mg/m² during cycle 1 and thereafter at 27 mg/m² intravenously twice weekly for three of four weeks. Patients were refractory or intolerant to both bortezomib and lenalidomide. The ORR was 23.7% with a median duration of response of 7.8 months and a median OS of 15.6 months. Common adverse events included fatigue, anemia, and thrombocytopenia. A small proportion of patients (<5%) experienced grade 3 or 4 dyspnea, acute renal failure, and heart failure.

In the ENDEAVOR trial, dose-intense carfilzomib/dexamethasone (Kd) was more efficacious than bortezomib/dexamethasone (VD) with improvement in the ORR (77% vs. 63%) as well as doubling of CR rate (13% vs. 6%) and median PFS (18.7 months vs. 9.4 months). Because the median follow-up time was short (1 year), there was no survival advantage noted. Anemia, dyspnea, and cardiac failure were the most common grade 3/4 adverse events in the Kd group, whereas diarrhea and peripheral neuropathy were more common in the VD arm.

ASPIRE was a large, randomized phase III trial comparing carfilzomib, lenalidomide, and dexamethasone (KRd; 396 patients) with lenalidomide and dexamethasone (Rd; 396 patients) in patients with relapsed myeloma who had one to three prior treatments. PFS was significantly improved in the KRd arm compared with the Rd arm (26.3 months vs. 17.6 months; hazard ratio for progression or death, 0.69; $p = .0001$). The median OS was not reached in either group at the time of the interim analysis, but the 2-year OS survival rates were 73.3% in the KRd arm and 65.0% in the Rd arm (hazard ratio for death, 0.79; $p = .04$). The KRd arm had an ORR of 87.1% compared with 66.7% in the Rd arm ($p < .001$). There was an increased incidence of grade 3/4 adverse events such as hypokalemia, thrombocytopenia, hypertension, and cardiac failure in the KRd arm.

PANORAMA1 was a large, multicenter, international, randomized, placebo-controlled, double-blind phase III trial for patients with relapsed myeloma who had received between one and three regimens.

Ixazomib + RD	65	80%	20.5	20.6
CRD	792	85%	28.6	26.3

CRD, Lenalidomide-cyclophosphamide-dexamethasone; Dex, dexamethasone; DOR, duration of response; Elo, elotuzumab; Len, lenalidomide; ORR, overall response rate; PFS, progression-free survival; Pom, pomalidomide.

Patients were randomly assigned to receive panobinostat + BD (387 patients) or Placebo + BD (381 patients). The median PFS was 12 months for the panobinostat group and 8 months for the control group. The median follow-up was 6 months, and there was no difference in the OS at the time of publication of the results. There was an increased incidence of grade 3/4 adverse events such as thrombocytopenia, diarrhea, asthenia, or fatigue and peripheral neuropathy in the panobinostat arm.

TOURMALINE-MM1 was a phase III study comparing the oral proteasome inhibitors ixazomib, lenalidomide, and dexamethasone (IRd; 360 patients) with placebo, lenalidomide, and dexamethasone (Rd; 362 patients) in patients with relapsed/refractory myeloma who failed one to three regimens. After a median follow-up of 14.7 months, the IRd group had a PFS of 20.6 months compared with the placebo group, which had a PFS of 14.7 months (hazard ratio for disease progression or death in the ixazomib group, 0.74; $p = .01$).

The ORRs were 78% in the ixazomib group and 72% in the placebo group. The median OS has not been reached in either group after 23 months. Diarrhea, rash, and thrombocytopenia were the more common grade 3/4 adverse reactions associated with the IRd group compared with the placebo group.

Pomalidomide is a third-generation immunomodulatory molecule that is more potent than lenalidomide. In a multicenter, open-label, randomized phase II study, the efficacy and safety of pomalidomide with or without low-dose dexamethasone was studied in 221 patients who had relapsed myeloma after two or more lines of prior therapy and were progressing on the last therapy. The ORR was 33% for patients receiving pomalidomide and low-dose dexamethasone and 18% for patients receiving pomalidomide alone with median response durations of 8.3 and 10.7 months, median PFS rates of 4.2 and 2.7 months, and OS of 16.5 and 13.6 months, respectively. Refractoriness to lenalidomide or resistance to both lenalidomide and bortezomib did not affect the outcomes with pomalidomide and low-dose dexamethasone. Grade 3/4 neutropenia (41%), anemia (22%), and thrombocytopenia (19%), as well as pneumonia (22%), were the predominant adverse events encountered. An international, randomized, open-label phase III trial compared pomalidomide and low-dose dexamethasone with high-dose dexamethasone in patients with refractory myeloma after two lines of chemotherapy containing bortezomib and lenalidomide. A group of 302 patients was randomly assigned to receive pomalidomide and dexamethasone, and another group of 153 received high-dose dexamethasone alone. After a median follow-up of 10 months, the median PFS was 4 months for patients receiving pomalidomide and dexamethasone versus 1.9 months for high-dose dexamethasone alone. The most common grade 3/4 hematologic adverse events in the pomalidomide arm were neutropenia, anemia, and cytopenias. Nonhematologic adverse events (grade 3/4) included pneumonia and fatigue.

Elotuzumab is an immunostimulatory monoclonal antibody targeting signaling lymphocytic activation molecule F7 (SLAMF7). The drug showed activity in combination with lenalidomide and dexamethasone in a phase Ib-II study of patients with relapsed/refractory myeloma. Elotuzumab was further evaluated in an open-label, international, randomized, multicenter phase III trial known as the ELOQUENT-2 trial. The two arms of the trial consisted of elotuzumab, lenalidomide, and dexamethasone (ERd; 321 patients) and lenalidomide and dexamethasone (Rd; 325 patients). The rate of PFS

at 1 year (after a median follow-up of 24.5 months) in the ERd group was 68%, as compared with 57% in the Rd group. Moreover, at 2 years, there was a 41% PFS advantage in the ERd group compared with 27% in the Rd group. The median PFS was 19.4 months in the ERd group versus 14.9 months in the Rd group (hazard ratio for progression or death in the elotuzumab group, 0.70; $p < .001$). ORRs varied between the two groups: 79% in the ERd group and 66% in the Rd group. Prespecified interim analysis for OS indicated a strong trend ($p = .0257$) in favor of the ERd arm compared with the Rd arm with early separation sustained over time (43.7 months vs. 39.6 months, respectively; hazard ratio, 0.77). Of the patients in the ERd group, 10% had infusion reactions. Other grade 3/4 adverse events in the ERd arm were lymphocytopenia and fatigue.

Daratumumab is a human anti-CD38 IgGκ monoclonal antibody that has recently been approved for patients who have had more than three relapses or refractory myeloma. Daratumumab binds CD38-expressing malignant plasma cells with high affinity and induces tumor cell death through diverse mechanisms of action, which include complement-dependent cytotoxicity; antibody-dependent, cell-mediated cytotoxicity; antibody-dependent cellular phagocytosis; and induction of apoptosis. Moreover, daratumumab suppresses Tregs and the actor enzyme activity-driven suppression of T cells via the adenosine signaling pathway. The ORR was 29% among 106 patients treated with daratumumab at 16 mg/kg; the median response duration was 7.4 months, PFS was 3.7 months, and OS was 17.5 months. Daratumumab was well tolerated; fatigue and anemia were the most common adverse events.

The POLLUX trial was a phase III study comparing daratumumab, lenalidomide, and dexamethasone (DRd; 286 patients) with lenalidomide and dexamethasone (Rd; 283 patients) in patients with relapsed/refractory myeloma. After a median follow-up of 13.5 months, the estimated median PFS was not reached in the DRd group compared with 18 months in the lenalidomide and dexamethasone group.

Other promising targets, agents, and stages of their clinical development are listed in Table 86.25. The optimal treatment of a relapsed patient requires ensuring that the patient's relapse requires intervention. The approach to therapy is dictated by whether the patient had a prior transplant or is a transplant candidate, and the selection of a possible drug depends on the prior therapy received. Additional selection criteria should consider patient characteristics such as age, risk factors, existing comorbidities such as renal failure, previous toxicities such as neuropathy, and patient convenience. Improving CR rates is a key goal of current trials in relapsed patients as well.

Bisphosphonates

Aminobisphosphonates, pamidronate, and zoledronate have been investigated in patients with myeloma and bone disease and have been shown to reduce skeletal complications and bone pain. Researchers in a number of older randomized studies looked at their efficacy in patients with existing bone lesions and evaluated the development of new skeletal-related events. In this regard, pamidronate 90 mg and zoledronic acid 4 mg are equipotent in reducing bone-related problems in MM; the infusion time for zoledronic acid is 15 minutes as compared with 1 to 2 hours for pamidronate. In a recent large study, MRC IX, investigators evaluated the efficacy of zoledronic acid in a randomized comparison with clodronate. This study included 1960 patients and confirmed the efficacy and superiority of zoledronic acid in preventing new skeletal-related events in patients both with and without existing bone lesions (Table 86.26), and it provided evidence that its continued use beyond 2 years was beneficial³⁹; importantly, the study also suggested that zoledronic acid compared with clodronate, a first-generation bisphosphonate, improves OS, providing for the first time some evidence of its antimyeloma activity (Fig. 86.17).⁴⁰ A similar survival advantage has also been reported with pamidronate (21 vs. 14 months; $p = .041$) in patients receiving salvage chemotherapy and pamidronate versus chemotherapy alone. Pamidronate

administration alone has also been shown to produce responses or delays in disease progression in occasional patients. Bisphosphonates have multiple actions, including suppression of OC number and function, inhibition of IL-6 production by stromal cells, inhibition of farnesyl and geranyl-geranyl transferase activity, and immune effects via γ/δ T cells.

Two potential side effects of bisphosphonates have limited their very long-term use in the recent past; effects on renal function and development of osteonecrosis of the jaw (ONJ). ONJ is observed in patients with dental infections or procedures following its longer-term use. The frequency of these adverse events has been between 3% and 5%. In one study, 11 (3.8%) of 292 patients with MM developed ONJ. Patients receiving bisphosphonates require a thorough dental checkup before starting therapy and should have frequent dental follow-up with careful and conservative use of dental procedures. With these precautions, the frequency of ONJ has been reduced. Similarly, the measurement of renal function before each bisphosphonate dose and the adjustment of dose based on renal function also make use of bisphosphonates safer. A slower administration of bisphosphonates prevents or protects against the development of renal dysfunction. Most recently, the recommended duration of bisphosphonate has been 2 years, with reduction in frequency after that if patients enjoy a good remission. However, in the light of the recent MRC-IX study, this recommendation will require revision with the possible benefits of long-term use. Additional bone-directed targets and agents are in development that have the ability to further inhibit OC function (denosumab) and also to improve OB activity and with bone anabolic effects (DKK-1 - BHQ-880 and activin A -ACE-011). These agents are currently under clinical investigation in patients with MM.

FUTURE DIRECTIONS

Significant advances have occurred in the understanding of the pathobiology of MM, which have translated to development of novel therapeutics. Predictive in vitro and in vivo models have been developed to study growth and survival characteristics of MM cells in the context of the bone marrow microenvironment, but, more important, to preclinically evaluate efficacy of novel targeted agents. Similarly, there has been an explosion of genomic data covering various genomic correlates including expression profile, CNA, alternate splicing, miRNA, and now whole-genome and RNA sequencing with mutational analysis of expressed genes as well as noncoding regions. Understanding of mutational landscape, molecular drivers of the disease and patterns, and surrogates of genomic evolution are providing newer clues to the disease biology as well as novel therapeutic approaches. Evolving understanding of the epigenomic alterations that affect cell growth, survival, and development of drug resistance is providing clues for novel interventions. For example, there is already an HDAC inhibitor approved for therapy of relapsed myeloma. Moreover, MM cell proliferation is now considered to be dependent on the bromodomain and extraterminal (or "BET") domain family of bromodomain-containing proteins (BRD2, BRD3, and BRD4), which are novel therapeutic targets.

These model systems and improved understanding have led to new drug development, with 10 new agents approved for myeloma in the last 12 years and over 15 other novel agents in phase I or II studies. The genomic information is being integrated to develop more accurate risk stratification models and to develop personalized medicine to optimize response while avoiding toxicities. With these advances and use of combination of agents, there is a significant improvement in the achievement of CR, over 60% to 70% in some studies. This has led to validation of molecular MRD as an important new endpoint in myeloma with its incorporation into all clinical studies as well as exploration as an ultimate endpoint to achieve cure. Finally, because of these advances, the median survival of patients with MM has increased from 3 years to over 8–10 years, and in a number of individuals, it becomes a chronic disease with curative outcome predicted in a proportion of patients in the near future.

TABLE
86.25

Novel Targets in Myeloma, Agents, and Stages of Ongoing Clinical Trials

Target	Agent	Clinical Study Phase	Single Agent (S)/Combination (C)
Cell Surface Targets			
FGF, PDGF	(mAb) TKI258	I	S
CD38	mAb	I	S
CD40	SGN-40 (mAb)	I/II	S, C (lenalidomide)
	HCD122 (mAb)	I	S
CD56	huN901-DM1 (C-mAb)	I	S
CD138	BT062 (mAb-DM4)	I	S
RANKL	AMG162 (mAb)	I/II	S
MUC1	AR20.5 (mAb)	I/II	S
BAFFR	LY2127399 (mAb)	I/II	S
CD52	Alemtuzumab (mAb)	II	S
TRAIL	Apo2L/TRAIL (Apo2 ligand)	I	S
	Mapatumumab	I/II	S
IGF1/R	IGF1R CP-571 (mAb)	I	S
	EM164 (mAb)	I	S
IL6/R	CNT0328 (mAb)	II/III	S, C (bortezomib)
	Altizumab (mAb)	III	S
VEGF/R	Bevacizumab (mAb)	II	S
	SU5416	II	S
	Zactima (ZD6474)	II	S
DKK-1	BHQ-880	I/II	S
Activin A	ACC001	I/II	S
KIR	IPH101	I/II	S
CXCR3	AMD3100	II	C (bortezomib)
Intracytoplasmic and/or Nuclear Targets			
CDK	Alvocidib (NSC649890)	I	S
CDK and GSK3 AT7519M	I/II		S, C (bortezomib)
IKK	RTA402	I	S
Akt	Perofofosine	III	C (bortezomib)
HDAC	Panabinstat	III	C (bortezomib)
	Vorinostat	II/III	C (bortezomib)
	Romidopsin	II/III	C (bortezomib)
Farnesyltransferase inhibitor	Tipifarnib (R115777)	II	S, C (bortezomib)
HSP90	KOS953	II	C (bortezomib)
	AUY922	II	C (bortezomib)
	IP1504	I/II	C (bortezomib)
Proteasome	Carfilzomib	II/III	S, C (lenalidomide)
	NPI-0052	I	S
	MLN9708	I	S
Mitochondria	GCS-100	I/II	C
mTOR	CCI-779 II	II	C (bortezomib)
	RAD001	II	C (lenalidomide, bortezomib)
	INK128	II	S
PKC	Enzastaurin	I/II	S, C (bortezomib)
Telomerase	GRN163L	I/II	S, C (bortezomib)

BAFFR, B cell-activating factor receptor; CDK, cyclin-dependent kinase; CXCR3, C-X-C motif chemokine receptor 3; DKK-1, Dickkopf-related protein 1; FGF, Fibroblast growth factor; GSK3, glycogen synthase kinase 3; HDAC, histone deacetylase; HSP90, heat shock protein 90; IGF1/R, insulin-like growth factor 1 receptor; IKK, inhibitor of nuclear factor- κ B kinase; mAb, monoclonal antibody; IL6/R, interleukin-6 receptor; KIR, killer cell immunoglobulin-like receptor; mTOR, mammalian target of rapamycin; MUC1, mucin 1; PDGF, platelet-derived growth factor; PKC, protein kinase C; RANKL, receptor activator of nuclear factor- κ B ligand; TRAIL, tumor necrosis factor-related apoptosis-inducing ligand; VEGF/R, vascular endothelial growth factor receptor.

Data collected from National Cancer Institute clinical trials website, Multiple Myeloma Research Foundation website, and International Myeloma Foundation website.

TABLE
86.26

Cumulative Annual Incidence of First and Subsequent Skeletal-Related Events for the Intention-to-Treat Populations Randomized to Zoledronic Acid Versus Clodronate

	Skeletal-Related Events		Incidence (95% CI)		Overall Difference (95% CI) Between Clodronic Acid and Zoledronic Acid ^a	<i>p</i> -Value for Preceding 12 Mo ^b
	Clodronic Acid (<i>n</i> = 979)	Zoledronic Acid (<i>n</i> = 981)	Clodronic Acid (<i>n</i> = 979)	Zoledronic Acid (<i>n</i> = 981)		
12 mo	451 (46%)	333 (34%)	0.43 (0.38–0.48)	0.33 (0.28–0.37)	0.11 (0.04–0.18)	0.0002
24 mo	93 (9%)	54 (6%)	0.60 (0.53–0.66)	0.42 (0.36–0.48)	0.18 (0.09–0.26)	0.0024
36 mo	28 (3%)	16 (2%)	0.69 (0.61–0.78)	0.47 (0.40–0.53)	0.23 (0.12–0.33)	0.0089

Data are number (%), unless otherwise indicated.

^a*p* < .0001.

^bUnadjusted *p*-value for the comparison of incidence of skeletal-related events in zoledronic acid group versus clodronic acid group per 12 months (e.g., 24-month *p*-value is for incidence between 12 months and 24 months).

CI, Confidence interval.

Fig. 86.17 Time to first skeletal-related event overall (A), in patients with bone lesions at baseline (B), and in patients without bone lesions at baseline (C). Cox proportional hazards p -value. Kaplan-Meier analyses of OS with zoledronic acid (ZOL) versus Clodronate (CLO) in patients with or without bone disease or other SRE at baseline. (D) Patients with bone disease or other SRE at baseline. (E) Patients without bone disease or other SRE at baseline. The benefit appears to be predominantly in those with prior SREs. CI, Confidence interval; CLO, clodronate; HR, hazard ratio; OS, overall survival; SRE, skeletal-related event; ZOL, zoledronic acid. WALDENSTRÖM MACROGLOBULINEMIA/ LYMPHOPLASMACYTIC LYMPHOMA

Steven P. Treon, Jorge J. Castillo, Zachary R. Hunter, and Giampaolo Merlini

Waldenström macroglobulinemia (WM) is a lymphoid neoplasm resulting from the accumulation, predominantly in the marrow, of a clonal population of lymphocytes, lymphoplasmacytic cells, and plasma cells, which secrete a monoclonal immunoglobulin (Ig) M.¹ WM corresponds to lymphoplasmacytic lymphoma (LPL) as defined in the Revised European-American Lymphoma (REAL) and World Health Organization classification systems.^{2,3} Most cases of LPL are WM; less than 5% of cases are IgA-secreting, IgG-secreting, or nonsecreting LPL.

In 1944, Jan Waldenström, a Swedish physician-scientist, reported in *Acta Medica Scandinavica* three cases of a disease he presciently thought was related to myeloma but for the absence of bone involvement and the scarcity of plasma cells in the infiltrate of small lymphocytes. He noted the increase in plasma protein concentration, marked increased serum viscosity, exaggerated bleeding and retinal hemorrhages, and virtually every other feature of the disorder in his case descriptions. In collaboration with a colleague, he showed, using ultracentrifugation and electrophoresis, that the abundant abnormal protein had a molecular weight of approximately 1 million and was not an aggregate of smaller proteins. The disease, which he described with such thoroughness, was later named in his honor.

EPIDEMIOLOGY

The age-adjusted incidence rate of WM in the United States is 3.4 per 1 million among males and 1.7 per 1 million among females. It increases in incidence geometrically with age.^{4,5} The incidence rate is higher among Americans of European descent. Americans of African descent represent approximately 5% of all patients.
