Infusion reactions (chills, fever, and dyspnea) have been observed with carfilzomib. Therefore, it is recommended that dexamethasone (4 mg PO or IV) be administered prior to each dose during cycle 1 and prior to the first of the higher doses during cycle 2. Carfilzomib has been associated with pulmonary complications, renal toxicity, and cardiac events (including congestive heart failure and cardiac arrest) in 7% of treated patients. Chest pain and acute congestive heart failure may have been related to prehydration with normal saline. Ixazomib may cause transient rash. Marizomib has been reported to cause reversible CNS toxicities (hallucinations, loss of coordination). The toxicities of the newer agents will ultimately be important in determining whether these drugs are suitable for first-line use.

Targeting Apoptosis Signaling in Hematologic Malignancies

The processes of cell division and cell death are tightly coupled so that a net increase in cell numbers does not occur. Alterations in the expression or function of the genes controlling cell division and cell death can upset this delicate balance and are hallmarks of cancer. Although conventional anticancer drugs cause cell cycle perturbation

or DNA damage, they do not directly interact with the intracellular machinery involved in apoptosis. Tumor selectivity of conventional agents is largely caused by the increased sensitivity to apoptosis of tumor cells after DNA damage or cell cycle perturbation. Novel therapeutic agents or strategies that target critical regulators or effectors of apoptosis are under development and clinical testing, and these agents or strategies have the potential to exert selective cytotoxicity against cancer cells.

Caspases are the “executioners” for apoptosis. They are proteases that exist as inactive zymogens and are activated by proteolytic cleavage of their proforms in response to a variety of death stimuli. This processing occurs at conserved aspartic acid residues, thus generating the enzymatically active caspases. Caspase activation is organized as a cascade, with an upstream initiator and downstream effector caspase. Upstream initiator caspases contain large prodomains that interact with specific proteins involved in triggering the cascade. The downstream caspases, which function as the ultimate effectors of apoptosis, possess small prodomains and are activated predominantly by proteolytic cleavage by upstream caspases. The irreversible cleavage of specific protein death substrates by the downstream effector caspases directly or indirectly accounts for the biochemical and morphologic changes that are recognized as apoptosis.

At least three pathways of caspase activation leading to apoptosis have been identified (Fig. 57.9): (1) the receptor-initiated apoptosis pathway, where the TNF family of cytokine receptors activate initiator caspases such as caspase 8; (2) the mitochondria-initiated apoptosis pathway, where cyt c and other prodeath effectors are released from mitochondria into the cytosol that results in activation of caspase 9; and (3) a pathway of caspase activation, which involves a serine protease, granzyme B, that directly cleaves and activates several caspases, including procaspase 3.

Proapoptotic Targets of Anticancer Agents

Most cancer cells have active antiapoptotic pathways that prevent cell death in response to growth, checkpoint, DNA damage, and

metabolic stimuli. A number of current anticancer agents in development target these pathways and are designed to be effective alone or in combination with other agents that disrupt the cell cycle, DNA synthesis, invoke DNA damage, and so on.

Death Receptor–Initiated Apoptotic Signaling

Several TNF family receptors are known to transduce signals that result in apoptosis. These include TNFRSF1A (also known as CD120a and previously designated tumor necrosis factor receptor-1 [TNFR1]), TNFRSF6 (also known as CD95, APO-1, or FAS), TNFRSF25 (also designated TRAMP and known as DR3 or APO3), TNFRSF10A (also known as DR4 or TRAIL-R1), and TNFRSF10B (also known as DR5 or TRAIL-R2). These receptors, also called *death receptors*, are characterized by the presence of a death domain within their cytoplasmic region, and have been shown to trigger apoptosis upon binding to their cognate ligands or specific agonist antibody. The activating ligands for these death receptors are structurally related molecules that also belong to the TNF gene superfamily such as TNFSF6 (also known as Fas ligand), TNF, and TRAIL.

Ligation of death receptors produces receptor trimerization and formation of a death-inducing signaling complex (DISC). This is composed of TNFRSF6, Fas (TNFRSF6)-associated via death domain (FADD), and procaspase 8, an apical signaling complex that mediates receptor-induced apoptosis. FADD binds directly to FasR, TNFRSF10A, or TNFRSF10B and indirectly to TNFRSF1A via TNFRSF1A-associated via death domain protein (TRADD). FADD is essential for cell death signaling from all three receptors. FADD interacts through its C-terminal death domain to cross-link TNFRSF6, TNFRSF10A, or TNFRSF10B receptors and recruits procaspase 8 and procaspase 10, or TRADD, through its N-terminal death effector domain (DED) to the DISC (see Fig. 57.9). Oligomerization of caspase 8 within the DISC results in a high local concentration of the zymogen. The induced proximity under these crowded conditions generates low levels of intrinsic proteolytic activity of caspase 8, enough to allow the various proenzymatic molecules

Fig. 57.9 SCHEMATIC REPRESENTATION OF APOPTOTIC PATHWAYS.

to mutually cleave each other. Processing of caspase 8 removes the DED-containing prodomain, thus releasing the activated protease into the cytosol, where it can cleave and activate other downstream procaspases. In certain types of cells (type I), enough caspase 8 is activated by the activation of the death receptor to cause apoptosis. In other cell types, such as hepatocytes (type II), a sufficient level of caspase 8 activation is not achieved and the apoptotic signal is amplified by the mitochondrial pathway. The active caspase 8 cleaves the cytosolic p22 Bid into a BH3-only domain-containing, proapoptotic, truncated p15 tBid fragment, which translocates to the mitochondria and triggers the release of cyt c into the cytosol. Cleavage by caspase 8 has been shown to cause exposure of a glycine residue on p15 Bid that is myristoylated, thereby targeting p15 Bid to the mitochondria. Thus, N-myristoylation acts as an activating switch that enhances tBid-induced release of cyt c and apoptosis. The ability to cleave Bid may not be limited to caspase 8. Other caspases, such as caspase 3, as well as other proteases, such as granzyme B and lysosomal proteases, have been shown to activate Bid. This indicates that Bid probably serves to amplify the caspase cascade rather than to initiate it (see Fig. 57.9).

Fas ligation has also been shown to initiate an alternative pathway leading to apoptosis, involving activation of JNK/SAPK. After ligation, Fas recruits an adaptor protein called Daxx that interacts with the apoptosis signal-regulating kinase 1 (ASK1), activating the transcription factors AP-1 and ATF-2. After activation, ASK-1 launches a phosphorylation cascade that culminates in the activation of JNK. Activated JNK phosphorylates substrates such as c-Jun, p53, and a pro-death Bcl-2 member Bim. This, in turn, has been shown to trigger mitochondrial or death receptor-initiated apoptotic signaling.

Mitochondria-Initiated Apoptotic Signaling

Mitochondria sequester a potent cocktail of proapoptotic proteins. These proteins promote apoptosis by activating caspases (e.g., by cyt c), by inducing DNA fragmentation (e.g., by endonuclease G or apoptosis-inducing factor [AIF]), or by neutralizing cytosolic inhibitors of apoptosis (IAPs; e.g., by SMAC or Omi/HtrA2). On induction of apoptosis, unlike other proapoptotic proteins, mitochondrial AIF translocates to the nucleus to induce DNA fragmentation and apoptosis. Cyt c is a well-known component of the mitochondrial electron transfer chain. Cyt c is released from the mitochondria during apoptosis. After release into the cytosol, cyt c binds to apoptosis-activating factor (Apaf-1), a cytosolic adapter protein that contains a caspase recruitment domain (CARD), a nucleotide-binding domain, and multiple WD-40 repeats. Binding of cyt c to Apaf-1 increases its affinity for dATP or ATP by approximately 10-fold. It also triggers the oligomerization of Apaf-1 into a multimeric Apaf-1–cyt c complex, also called the *apoptosome*. This exposes the CARD domain of Apaf-1, which recruits several molecules of procaspase 9, inducing their autoactivation. Only the caspase 9 bound to the apoptosome is able to efficiently cleave and activate a downstream executioner caspase, caspase 3.

SMAC/DIABLO is a 25-kDa mitochondrial protein that is released by mitochondria into the cytosol during apoptosis. SMAC contains a mitochondria-targeting sequence at its N-terminus. This sequence is removed on import into the mitochondria, generating the mature SMAC protein. In the mitochondria-initiated and common effector pathways of apoptosis, the processing and proteolytic activity of caspase 9 followed by caspases 3 and 7 are inhibited by the IAP family of proteins. IAP family members include XIAP, cIAP1, cIAP2, and survivin. All IAPs contain at least one baculovirus repeat (BIR) domain, although some contain three. Another region, the RING domain, has ubiquitin ligase activity and promotes the self-degradation of IAPs through proteasomes in response to some apoptotic stimuli. Furthermore, during Fas death receptor-mediated apoptosis, XIAP is cleaved by activated caspase 3 into the N-terminal BIR1 and 2 and BIR3-RING finger fragments. The BIR3 domain binds and sequesters the monomeric and inactive caspase 9, thereby

inhibiting its activation. Overexpression of XIAP inhibits anticancer drug (including ara-C)–induced caspase activity and apoptosis. In contrast, downregulation of XIAP sensitizes cancer cells to apoptosis induced by chemotherapeutic drugs. The antiapoptotic activity of NF κ B has also been shown to be mediated by the induction of IAPs. The first four amino acids of the mature SMAC, Ala-Val-Pro-Ile (AVPI), bind to the BIR domain of IAP proteins. The four amino acids (AVPI) of SMAC that bind to the BIR3 domain of XIAP are similar to the XIAP-binding sequence of active caspase 9. In addition, SMAC has been shown to form a stable complex with the BIR2 domain of XIAP. SMAC binds to the linker-BIR2 domain and presumably disrupts its inhibition of the active caspase 3 and caspase 7 by steric hindrance. On induction of apoptosis, another mitochondrial protein, Omi/HtrA2 (a serine protease), is released from mitochondria and can induce caspase-independent cell death. Additionally, like SMAC, the mature Omi protein contains a conserved IAP-binding motif (AVPS) at its N-terminus. Omi complexes with XIAP at high stoichiometry and promotes apoptosis by neutralizing the caspase-inhibitory effect of XIAP. Recently, Omi has also been shown to process XIAP and promote its proteasomal degradation.

The Bcl-2 family of proteins is divided into three subfamilies. Members of the subfamily that include Bcl-2, Bcl-x_L, and Mcl-1 inhibit apoptosis (see Fig. 57.9). The Bax subfamily members that promote apoptosis, including Bax and Bak, share with Bcl-2 three of the four Bcl-2 homology domains, BH1–BH3. A C-terminus hydrophobic tail is responsible for the localization of these proteins to the outer membranes of the mitochondria and ER. The third BH3-only subfamily of proteins that includes Bid, Bim, and Bad also promotes apoptosis by binding and inactivating prosurvival Bcl-2 family members. The prosurvival Bcl-2 family members, to a variable degree, are bound to the membranes of the mitochondria, the ER, and the nuclear envelope. In the event of an apoptotic stimulus, BH3-only proteins require Bax and Bak to trigger mitochondrial apoptotic signaling. For example, the exposed BH3 domain of tBid oligomerizes with Bak and Bax, causing their mitochondrial membrane insertion and cyt c release. In response to apoptotic stimuli, Bax and Bak undergo conformational change and form membrane-associated homo-oligomers, disrupting the outer membrane of the mitochondria and ER and releasing the pro-death molecules into the cytosol. Besides tBid, Humanin peptide has been shown to activate Bax. Bcl-2 can block these events involving Bax activation by titrating tBid or Bim and/or heterodimerization with Bax and preventing mitochondrial permeabilization.

Induction of P53^{wt} in cells triggers apoptosis by transcriptional activation of prodeath effectors, including Bax, Noxa, Puma, Apaf-1, and DR5, and by transcriptional repression of Bcl-2 and IAPs. p53-dependent apoptosis has also been shown to occur in the absence of any gene transcription or translation. In response to apoptotic stimulus such as irradiation, p53 translocates to the mitochondria, where it directly induces permeabilization of the outer membrane by forming complexes with the protective Bcl-2, resulting in the release of cyt c into the cytosol. The E2F transcription factor, normally restrained by the Rb tumor suppressor to inhibit cell proliferation, has been shown to induce apoptosis through p53-dependent and p53-independent mechanisms. These mechanisms include transcriptional activation of ARF (the alternate reading frame product of the INK4a/ARF tumor suppressor locus) or p73 (a member of the p53 family), repression of Mcl-1, and inducing the levels of caspase proenzymes.

Selective Antiapoptotic Agents or Strategies

BCL2 Family of Proteins as Targets for Anticancer Drug Design

The antiapoptotic protein BCL2 was originally identified during the process of the discovery of the t(14;18) in human follicular lymphoma. Overexpression of BCL2 has been reported in both hematologic and solid malignancies and to mediate resistance to

traditional chemotherapeutic agents, radiation, and other antitumor treatments.

Bcl-2 Antisense

Liposomal antisense Bcl-2 oligonucleotide (Bcl-ASODN) has been created and shown to cause apoptosis of many types of cancer and leukemia cells. Bcl-2-ASODN also sensitized tumor cells in vitro and in vivo to chemotherapeutic drugs. The most promising agent to target Bcl-2 is Genasense (oblimersen sodium; G3139), an 18-mer phosphorothioate oligodeoxynucleotide antisense compound. Clinical studies suggest safety and efficacy in solid and hematologic malignancies. In a phase III trial, 241 patients were randomly assigned to receive oblimersen 3 mg/kg/day as a 7-day continuous infusion in addition to fludarabine–cyclophosphamide versus fludarabine–cyclophosphamide. This study met its primary objective by demonstrating a significantly superior CR or nodular partial remission (CR/nPR; 17% vs. 7%; $p = .025$); however, no significant differences in ORRs as well as TTP were found. However, at 5-year follow-up a significant improvement in survival was noted, with a hazard ratio of 0.6 for those treated with oblimersen. Results of another phase III study were reported in which the addition of oblimersen to high-dose dexamethasone did not improve OS or TTP in myeloma patients.

BH3 Peptide/Mimetics or Bcl-2/Bcl-XL Small-Molecule Antagonists

Another strategy to create Bcl-2 inhibitors has focused on developing small molecules that mimic the action of the endogenous Bcl-2-binding death agonists. Compounds that mimic the BH3-only class of death agonists such as Bad inhibit the survival proteins Bcl-2 and Bcl-x_L but do not appear to have independent proapoptotic activity. Two classes of novel small-molecule cell-permeable inhibitors of the Bcl-x_L-BH3 domain (BH3I) have been identified. Studies have demonstrated that BH3Is induce apoptosis by preventing BH3 domain-mediated interaction between proapoptotic and antiapoptotic members of the Bcl-2 family. Two natural products have been suggested to antagonize the antiapoptotic function of Bcl-2 or Bcl-x_L. Tetrocarcin A was reported to inhibit mitochondrial functions of Bcl-2 and suppress its antiapoptotic activity. In another report, Antimycin-A was shown to mimic activity of BH3 peptides and selectively induce apoptosis in cell lines overexpressing Bcl-x_L. Certain green tea catechins and black tea theaflavins were identified as potent inhibitors (K_i in the nanomolar range) of the antiapoptotic Bcl-2 family of proteins. On the basis of the high-resolution three-dimensional structure of the target receptor, small organic molecules that bind to this interface have been designed. ABT-737 is a BH3 mimetic that binds to Bcl-2, Bcl-x_L, and Bcl-w with high affinity ($K_i < 1$ nM) but not to Mcl-1. Preclinical data demonstrate cytotoxic activity in B lymphoid tumor cell lines, human follicular lymphoma, myeloma, and CLL cells, as well as synergism with other chemotherapeutic agents. Also, ABT-737 effectively kills AML blast, progenitor, and stem cells without disturbing normal hematopoietic cell development. However, the clinical utility of ABT-737 is limited, as it undergoes rapid metabolism and is not orally bioavailable. Targeted modifications of ABT-737 led to synthesis of navitoclax (ABT-263), an orally bioavailable BH3 mimetic. In the initial phase I trial¹² more than half of patients had a decrease in their lymphocytosis, with 35% achieving partial remission. The main toxicity was dose-dependent thrombocytopenia, which occurred early in the treatment cycle (days 2–5 of a 21-day cycle). Neutropenia occurred at higher dose levels. Other adverse events included gastrointestinal side effects and fatigue. The remarkable activity of this agent in early trials validated Bcl-2 as a target for the treatment of CLL. The clinical development of navitoclax was suspended because of thrombocytopenia; which is an off-target effect due to inhibition of Bcl-XL.

Venetoclax (Abt-199) was subsequently developed to replace navitoclax as a highly selective, orally available small-molecule Bcl-2 family protein inhibitor that binds with high affinity ($K_i < 0.10$ nM) to Bcl-2 and with lower affinity to other Bcl-2 family proteins Bcl-XL and Bcl-w (>480-fold and >2000-fold lower affinity than to Bcl-2, respectively). Thrombocytopenia is less frequent with venetoclax due

to its lower affinity to Bcl-XL. Early clinical experience with venetoclax is very promising, with remarkable efficacy in a patient population with relapsed or refractory CLL with high ORR (75%–79%) and impressive CR rates (22%–29%) and clearance of MRD even in the high-risk subsets of patients with the adverse-risk del(17p) chromosomal abnormality associated with p53 mutation/dysfunction, an unmutated immunoglobulin heavy chain gene (IGHV), and those with disease refractory to fludarabine in a phase I trial. The early clinical trials of venetoclax were suspended initially because all patients treated developed tumor lysis syndrome (TLS), which led to two deaths. That led to modification of the clinical protocol with a gradual dose escalation of venetoclax on a 2–3-weekly basis up to the target dose of 400 mg daily with stringent monitoring and aggressive prophylaxis and management of TLS. Although laboratory evidence of TLS remain highly prevalent in patients with CLL treated with venetoclax, no deaths due to TLS have been observed after adoption of these modifications. ORR rates as high as 61% have been reported in a mixed cohort of patients with relapsed NHL in combination with bendamustine and rituximab with no added toxicity. The responses were few in patients with relapsed DLBCL; however, responses (37.5%) were seen in patients with indolent lymphomas. A phase III clinical trial is in progress in patients with relapsed/refractory CLL comparing venetoclax and rituximab to bendamustine and rituximab. Venetoclax has received approval for relapsed/refractory CLL with del(17p) based on impressive clinical activity. However, the risk of TLS may be prohibitive to limit its use to clinicians with expertise in management of hematological malignancies and TLS.

Cyclin-Dependent Kinase Inhibitors

Orderly progression through the cell cycle is regulated by the coordinated expression of a variety of genes and proteins, and effected by the interactions between cyclins, CDKs 1–9 and endogenous CDK inhibitors (e.g., p21^{CIP1}, p27^{KIP1}, and p57^{KIP2}; see Fig. 57.1). CDK1, in association with cyclins A and B, is involved in G₂M progression; CDK2, CDK4, and CDK6, in association with cyclins A, D, and E, are involved in G₁S progression. Activation of CDKs results in phosphorylation of the pRb, which leads to its dissociation from the E2F transcription factor. Once freed, E2F triggers the transcription of diverse genes involved in cell cycle progression (thymidylate synthase and dihydrofolate reductase, among numerous others). Endogenous small-molecule CDK inhibitors such as P21^{CIP1} and P27^{KIP1} bind stoichiometrically to CDKs and inhibit their activity. CDK activity can also be regulated through inhibitory or activating phosphorylation. Interference with the activation of CDKs results in dephosphorylation of pRb, leading in turn to binding and inactivation of E2F and inhibition of cell cycle progression.

Cell cycle dysregulation is a cardinal characteristic of cancer. A classic example of this phenomenon is the association of increased expression of cyclin D₁ in MCL. Regulation of the cell cycle has been found to be closely related to apoptosis, and disruption of normal cell cycle transit has been shown to be a potent cell death stimulus. A corollary of this observation is that agents that interfere with the cell cycle, in addition to blocking cell cycle progression, can be potent inducers of programmed cell death. Cell cycle inhibitors can be subdivided into several categories. For example, they can act directly, as in the case of CDK inhibitors, or indirectly, as in the case of HDIs, compounds that block cell cycle progression by inducing endogenous cell cycle inhibitors such as P21^{CIP1}. The latter agents are discussed later in this chapter. CDK inhibitors can also be classified as specific (i.e., directed against a particular CDK, such as CDK2) or those that nonspecifically inhibit most CDKs (e.g., flavopiridol).

Flavopiridol

Flavopiridol (L86-8275) is a semisynthetic flavonoid derived from the Indian plant *rohitukine*. It was the first CDK inhibitor to enter

clinical trials in humans. Flavopiridol binds to the ATP-binding site of CDKs, resulting in reversible, competitive enzyme inhibition at concentrations of less than 100 nM. As noted earlier, flavopiridol is a relatively nonspecific CDK inhibitor and inhibits all CDKs, although it is less effective against CDK7. Flavopiridol induces G₁S or G₂M arrest, presumably a consequence of inhibition of CDK1 and CDK2. Flavopiridol may also act to block cell cycle progression by downregulating cyclin D₁ levels, inhibiting the CDK-activating complex (CDK7), or both.

In addition to blocking cell cycle progression, flavopiridol has been shown to be a potent inducer of apoptosis in malignant hematopoietic cells (e.g., acute and chronic leukemia) at low concentrations (e.g., <100 nM). Moreover, flavopiridol has shown activity against MM cells *in vitro*.

The proapoptotic actions of flavopiridol have been attributed to its capacity to inhibit the positive transcription elongation factor- β (PTEF- β), cyclin T/CDK9 complex by inhibiting phosphorylation of the C-terminal domain of RNA polymerase II. This leads to downregulation of several antiapoptotic proteins, including BIRC4, P₂₁^{CIP1}, and, in the case of MM cells, Mcl-1. Flavopiridol has also recently been shown to block the antiapoptotic actions of the IAP family member survivin.

In clinical studies, flavopiridol was initially administered as a 72-hour continuous infusion every 2 weeks, with a maximally tolerated dose of 40 mg/m². Steady-state plasma levels in excess of those necessary to inhibit CDKs and induce apoptosis in leukemia cells (e.g., 350 nM) were achieved. Dose-limiting toxicities were fatigue, diarrhea, nausea, and myelosuppression. However, the occurrence of thromboembolic phenomena and the general lack of single-agent activity have limited enthusiasm for administering flavopiridol by this schedule. Flavopiridol has also been administered as a daily IV bolus for 1, 3, or 5 days every 3 weeks with manageable toxicity, and other schedules are being examined, including a hybrid schedule with half the dose administered as an IV bolus and the other half as a more prolonged infusion. When administered as a daily bolus infusion for 3 days every 3 weeks, flavopiridol exhibited modest activity in patients with MCL. A novel pharmacologically directed schedule of flavopiridol has been developed in which half of the dose (e.g., 30 mg/m²) is administered as a 30-minute bolus-loading infusion and 30 mg/m² as a 4-hour infusion. In a phase I study, objective response rates of 45% were obtained with this schedule in patients with progressive CLL, including some with high-risk disease.¹³ Because of the rapidity of response, particularly in patients with high white blood cell counts, aggressive measures designed to avoid TLS (e.g., hydration, alkalinization of the urine, administration of rasburicase) are advisable. Efforts are now underway to use this novel flavopiridol schedule in combination with other agents and in other hematologic malignancies.

Because of limited single-agent activity, combination regimens involving flavopiridol are being explored in hematologic malignancies. On the basis of preclinical evidence of synergism with the antimetabolite ara-C, a regimen combining flavopiridol on a daily IV bolus schedule followed by high-dose ara-C has been initiated in patients with AML and has shown some activity. In a phase II study, flavopiridol was administered as a 1-hour bolus infusion of 50 mg/m² daily for 3 days before administration of high-dose ara-C (day 6) and mitoxantrone (day 9). CR rates of 67% were obtained in patients with high-risk AML and more than half were durable. More recently, evidence of synergism between flavopiridol and other signal transduction modulators has become the focus of considerable attention. For example, the observation that flavopiridol interacts synergistically with imatinib mesylate against CML cells, including some that are imatinib mesylate resistant, has prompted the initiation of a phase I trial of flavopiridol and imatinib mesylate in patients with progressive BCR-ABL⁺ hematologic malignancies. Four out of 21 patients responded. Evidence that flavopiridol interacts synergistically with HDAC and proteasome inhibitors in human leukemia cells has appeared, and clinical trials combining flavopiridol with the HDI vorinostat or the proteasome inhibitor bortezomib in patients with refractory AML/MDS and MM/indolent NHL are currently underway.

SNS032

SNS032 is a small-molecule CDK inhibitor discovered through high-throughput screening that is primarily active against CDK2. In preclinical studies, SNS032 has shown potent antiproliferative activity against ovarian and breast cancer cells *in vitro*. As is the case with other CDK inhibitors, SNS032 induces cell cycle arrest, pRb dephosphorylation, and, under some circumstances, apoptosis in CLL and myeloma cell lines. At least in some tumor cell lines, however, CDK2 may be dispensable for cell cycle progression. In CLL cells, SNS-032 was cytotoxic *in vitro* in untreated and refractory cell lines. RNA synthesis was suppressed after treatment, with evidence of CDK 2 and 7 inhibition.¹⁴

Several phase I trials of SNS032 have been initiated. SNS032 has been administered as either a 24-hour or 1-hour infusion every 3 weeks. Dose levels of 4–59 mg/m² have proven to be tolerable; the maximum tolerated dose for either of these schedules has not been reached. Toxicities have been mild and include rash, nausea and vomiting, diarrhea, and fatigue. In a clinical trial in patients with CLL (19 patients) and myeloma (18 patients), CDK7 and -9 inhibition was observed, but responses as a single agent were modest.

Hypomethylating Agents

Promoter methylation within CpG islands regulates gene expression in all cells. Disruption of normal gene expression profiles accompanies malignant transformation, giving rise to complex patterns of gene expression. As a consequence, promoters of many genes have an altered pattern of methylation, resulting in either gene activation or gene repression. The link between these concepts and the interest in agents that alter promoter methylation began with the realization that azacitidine, an agent used sparingly for treating myeloid leukemias, had efficacy when given at low doses either IV or SC for extended periods of time, and that in these cases, altered gene expression accompanied responses. Both azacitidine and 5-aza-2'-deoxycytidine (decitabine) act by irreversible inhibition of the DNA methyltransferases responsible for methylation of the cytidine in CpG islands and are thus S-phase-specific agents. Wijermans et al^{14a} first described that a related compound, 5-aza-2'-deoxycytidine, was effective when given as a continuous infusion to elderly patients with high-risk MDS, with a 54% response rate. The mechanism of action included both a direct change in promoter methylation and independent changes, with up to 70% genome-wide demethylation, suggesting either that genes with altered expression either up- or downregulated a second set of genes through altered pathways such as induction of WAFp21, p15, and p16, or in a more direct fashion through altered transcription factor expression. More recent studies have identified activity of these agents in both AML and CML. Most often, PRs or short-lived CRs are seen in AML, with CRs more common in MDS. Recent studies also describe a number of extended therapy regimens. Kantarjian et al^{14b} reported a comparison of 20 mg/m² decitabine IV for 5 days with 20 mg/m² SC daily for 5 days and 10 mg/m² IV for 10 days. The 5-day IV dose schedule was judged superior on the basis of clinical outcome with 39% CR, a higher proportion of reactivation of p15, and achievement of a hypomethylation state as well as clinical tolerance. Azacitidine has been given after allogeneic stem cell transplantation, at lower doses, as a "maintenance" regimen, to prevent relapse. De Lima et al^{14c} established the MTD of azacitidine after transplant as 32 mg/m² for 5 days. Posttransplant azacitidine may also augment graft-versus-leukemia effect and attenuate GVHD after transplant through expansion of T-regulatory cells. An oral formulation of azacitidine is currently in clinical development which would permit convenient and prolonged exposure to the drug, which may translate into better outcomes. It was recently shown that pretreatment with azacitidine, followed by R-CHOP chemotherapy, can restore chemosensitivity in DLBCL cells *in vitro* and in clinical samples from patients with DLBCL. The combination between azacitidine and R-CHOP was feasible, safe, and associated with a higher ORR compared with historic controls treated with R-CHOP alone. Azacitidine "priming" decreased SMAD1 methylation, and

increased SMAD1 mRNA, in DLBCL cells obtained from patients. SMAD1 is the major downstream effector of TGF- β . TGF- β exerts an antiproliferative effect in most NHL, and loss of antiproliferative response to TGF- β has been demonstrated in the majority of NHLs. SMAD1 hypomethylation has been associated with an abundance of SMAD1 mRNA and restoration of chemosensitivity in DLBCL cells after azacitidine “priming.”

Histone Deacetylase Inhibitors

Histone acetyl transferases (HATs) control gene expression through the modification of chromatin structure through acetylation of chromatin-bound histones. Regulation of acetylation is through histone deacetylation. Without the ability to fine tune histone binding to chromatin regions, gene expression is perturbed. Inhibition of this process by a group of agents termed *histone deacetylation inhibitors* alters gene expression in both normal and malignant cells. Often the result is differentiation of malignant cells or induction of apoptosis. Given the long history of the use of differentiating agents in leukemias, for APL (retinoids), low-dose ara-C and azacytidine, it is not surprising that newer HDIs have undergone extensive evaluation in leukemias.

Posttranslational Histone and Nonhistone Protein Modifications and Gene Transcription

Nucleosomes are regularly repeating, structural units of chromatin, which are essential in packaging eukaryotic DNA. Each unit is composed of 146 base pairs of DNA tightly wrapped around a core histone octamer. Each histone octamer consists of two units each of histones H2A, H2B, H3, and H4, and each nucleosome in turn is connected to its neighbor by a short segment of linker DNA approximately 10–80 base pairs in length. Histone H1 binds and stabilizes linker DNA. Each core histone has an N-terminal tail, which is lysine rich and positively charged. Specific amino acid residues at the N-terminal undergo a variety of enzymatic posttranslational modifications. Modifications can also occur within the globular domain of histones that make extensive contacts with DNA. *Histone code* is the name given to the combination of biochemical modifications affecting different histone residues that specify chromatin function. However, it has been suggested that various postsynthesis histone modifications be considered an epigenomic alphabet. Each modification is a letter, and the combination of modifications at a specified genomic region is a word that may have different functional meanings depending on the context.

HATs and HDACs are two classes of enzymes that mediate the acetylation and deacetylation, respectively, at evolutionarily-conserved N-terminal lysine residues. Acetylated histones are negatively charged and do not bind as tightly to negatively charged DNA, thereby facilitating gene transcription. In contrast, deacetylated histones bind closely to DNA, preventing transcription. Acetylation status of chromatin and hence gene transcription is dictated by balanced activity of HATs and HDACs. Acetylation of core histone bases has also been implicated in chromatin assembly, DNA repair, and replication timing of specific genomic regions. Cross-talk also exists between acetylation and ubiquitination. Thus, HDACs can decrease the half-lives of substrates by exposing the lysine residue for ubiquitination. Other crucial functions affected by the delicate balance between HATs and HDACs include activation of the apoptotic program via interaction between Ku70 and Bax; protein localization (nuclear vs. cytoplasm); and DNA binding of transcription factors such as p53, E2F1, GATA1, RelA, YY1, and hormone receptors. There is a growing list of nonhistone proteins that are modulated by HATs or HDACs. These include hypoxia-inducible factor-1 α (HIF-1 α), β -catenin, α -tubulin, Ku70, importin- α 7, cortactin, and, most recently, HSP90. HATs and HDACs can be classified into subfamilies according to the presence of highly conserved structural motifs. Please refer to [Table 57.5](#) for details.

Aberrant Histone Acetyl Transferase and Histone Deacetylase Activity in Hematologic Malignancies

Aberrant activity of HATs and HDACs resulting in aberrant gene transcription is a hallmark of many cancers, including many hematologic malignancies. Several chromosomal translocations in leukemia that produce chimeric fusion oncoproteins have been shown to recruit HDACs to promoters and repress genes involved in cell cycle growth inhibition and differentiation. For example, PML-RAR α in APL and AML1-ETO generated by t(8;21) translocation in AML recruit HDACs to their target genes, resulting in chromatin modification and repression of genes, leading to blocked differentiation and inhibition of apoptosis. HDACs have also been found in complexes with proteins that regulate cell cycle checkpoints such as Rb and its family members. Resistance to chemotherapy can occur because of increased levels of thioredoxin, a thiol reductase, and decreased levels of thioredoxin-binding protein (TBP-2) in many cancers; HDIs can reverse this phenomenon. These effects create a strong rationale for developing inhibitors of HDAC activity that would correct transcriptional deregulation of genes involved in cell cycle regulation and apoptosis as cancer therapeutic agents.

TABLE 57.5 Human Histone Deacetylases

Characteristics	Class I	Class IIa	Class IIb	Class III
Members	HDAC1, 2, 3, 8, 11	HDAC4, 5, 7, 9	HDAC6, 10	SIRT1, 2, 3, 4, 5, 6, 7
Localization	Nuclear	Nucleocytoplasmic	Nucleocytoplasmic	Nuclear/cytoplasmic/mitochondrial
Substrates	Histones p53 (HDAC1) NF κ B (HDAC3)	Histones HSP90	Histone Tubulin HSP90?	Histones Tubulin (SIRT2) p53 (SIRT1) TAF(I)68 (SIRT1)
Binding site inhibitors	Zn ²⁺ TSA SAHA/LAQ824 Depsiptide Trapoxin Butyrate VPA	Zn ²⁺ TSA SAHA/LAQ824 Trapoxin Butyrate VPA	Zn ²⁺ TSA SAHA/LAQ824 Tubacin	NAD ⁺ Nicotinamide

HDAC, Histone deacetylase; NAD, nicotinamide adenine dinucleotide; NF κ B, nuclear factor kappa-B; SAHA, suberoylanilide hydroxamic acid; TSA, trichostatin A; VPA, valproic acid.

Mechanisms of Anticancer Activity of Histone Deacetylase Inhibitors

Treatment with HDIs modulates expression of 2%–10% of a selective, but variable, subset of genes in various cell types with as many genes upregulated as are downregulated. Normal cells are more resistant than cancer cells to the effects of HDIs. HDI-induced cell cycle arrest and apoptosis is usually correlated with upregulation of p21, p27, and p16, and attenuation of cyclin A and D levels, leading to decreased activity of CDK4 and CDK2. Induction of GADD45 α and - β and upregulation of TGF- β , which inhibits c-Myc, may also contribute to the cell cycle arrest in G1 or G2. Promoter regions of p21 and the telomerase catalytic unit telomerase mutation in the reverse transcriptase (TERT) have been shown to contain SP1 sites that bind HDAC-recruiting transcription complexes. HDIs also activate the mitochondrial apoptotic pathway by transcriptional activation of apoptotic proteins such as TBP-2, Bad, Bim, Bid, BAK, Bax, and caspases 3 and 9, and repression of antiapoptotic proteins such as thioredoxin, bcl-2, XIAP, and Mcl-1. HDIs have also been shown to upregulate Fas and the Apo-2L/TRAIL receptors DR4 and DR5, downregulate c-FLIP, and enhance Apo-2L/TRAIL-induced DISC and apoptosis.

Treatment of leukemias with HDI alone or in combination with other agents such as all-trans retinoic acid has been shown to overcome the inhibition of differentiation caused by chimeric fusion oncoproteins such as PML-RAR α , PLZF-RAR α , or AML-ETO. HDIs have also been shown to induce the expression of gelsolin, an actin-binding protein involved in morphologic and cytostructural changes associated with differentiation. Several HDIs have been shown to induce acetylation of HSP90 and inhibit its chaperone association with important prosurvival client proteins such as AKT and c-Raf. This directs these client proteins to polyubiquitylation and proteasomal degradation, thus contributing to the lowering of the threshold for apoptosis in cancer cells. Inhibition of HDAC6 results in marked accumulation of ubiquitinated proteins (inhibition of the aggresome), via acetylation of α -tubulin, which in turn results in increased cellular stress and cytotoxicity.

HDIs may also act by exerting antiangiogenic and immune modulatory effects via downregulation of HIF-1 α and epidermal growth factor. HDIs also affect cancer cell migration, invasion, and metastasis by altering expression of extracellular matrix proteins and metastasis genes in favor of reduced cell invasion.

Two reports have provided potential insights into biomarkers for response to HDIs. The first demonstrated that enhanced JAK/STAT signaling negatively affected HDI-induced death of CTCL cells, and constitutive accumulation of STAT1 in the nucleus and high levels of phosphorylated STAT3 correlated with a lack of response to vorinostat in clinical trials. The second approach incorporated a sophisticated loss-of-function genetic screen that identified human RAD23 homolog B (HR23B) as important for HDI-induced apoptosis. Subsequent studies showed a correlation between HR23B expression and clinical response to vorinostat, and the interaction between HSP90 and HDAC6 was identified as being the crucial functional effector mechanism delineating relative sensitivity to HDI-induced apoptosis through regulated HR23B expression. Whether there is any functional interplay between JAK/STAT signaling and HR23B remains uncertain. Moreover, as HR23B expression can regulate sensitivity to HDIs that are very weak inhibitors of HDAC6 (e.g., apicidin, romidepsin), it is unlikely that direct effects on the HDAC6/HSP90 functional interaction account for the mechanistic role of HR23B in regulating HDI-induced apoptosis.

How or why tumor cells are more sensitive to HDI-induced apoptosis compared with matched, normal cells remains an intriguing and largely unanswered question. Previous studies indicated that tumor cells treated with HDI preferentially accumulate reactive oxygen species (ROS) compared with treated normal cells, concomitant with enhanced expression of the reducing molecule thioredoxin in normal but not tumor cells. Recently, we utilized donor-matched normal and transformed cells treated with vorinostat to identify a

tumor cell-selective, proapoptotic gene expression signature containing effectors of the intrinsic apoptotic pathway that conferred tumor cell-selective apoptosis mediated by vorinostat and romidepsin. It is not clear why matched tumor and normal cells selectively regulate a subset of genes that confer tumor cell-selective, HDI-mediated apoptosis. It is tempting to speculate that the cancer epigenome is altered in such a way as to predispose to altered expression of apoptotic genes in response to the transformation process, but definitive mechanistic evidence remains to be obtained.

Classes of Histone Deacetylase Inhibitors

Several structurally diverse classes of naturally occurring and synthetic compounds have been investigated for their ability to inhibit HDAC activity (Table 57.6). These include short-chain fatty acids (e.g., valproic acid [VPA]), hydroxamic acid derivatives (e.g., vorinostat, panobinostat), synthetic benzamides (e.g., entinostat), and cyclic tetrapeptides (e.g., romidepsin). All of these have undergone clinical evaluation.

Short-Chain Fatty Acid Histone Deacetylase Inhibitors

Sodium butyrate, a well-studied member of this class of compounds, induces in vitro growth arrest and differentiation of human leukemia cells at millimolar concentrations. Its clinical development has been hampered by its short half-life and difficulty in achieving millimolar levels in vivo. Phenylbutyrate, another derivative of butyric acid, is able to induce in vitro growth arrest and differentiation of leukemia cells at clinically achievable submillimolar concentrations. Importantly, at these levels, phenylbutyrate is able to synergize with retinoids in inducing cell cycle arrest, differentiation, and apoptosis of myeloid leukemia cells, and with ara-C in myeloid leukemias. VPA, a well-tolerated antiepileptic, was shown to be as effective as an HDI at levels ranging between 0.5 and 2.5 mM.

Two phase I trials have examined the therapeutic effects of phenylbutyrate in patients with AML and MDS. No responses were noted in either study, with neurotoxicity being the dose-limiting toxicity. Several studies have used VPA as monotherapy or in combination with other agents in hematologic malignancies. As monotherapy in MDS, response rates have been as high as 16% using the IWG criteria. Neurotoxicity has been the major side effect. Other side effects of VPA include thrombocytopenia, weight gain, asthenia, and rarely hepatic failure and pancreatitis. Given the low response rate, emphasis has shifted to newer HDIs.

Vorinostat and Other Hydroxamic Acid Derivative Histone Deacetylase Inhibitors

Members of this class are some of the most potent HDIs. They contain a functional group that interacts with the critical zinc atom at the base of the catalytic pocket of the class I and II HDACs. These HDIs also possess a hydrophobic cap and an aliphatic side chain that interacts with the edge and fits into the hydrophobic catalytic pocket, respectively, of the HDACs. Members of this class inhibit both class I and II HDACs. Vorinostat (SAHA, Zolinza) is a second-generation polar-planar compound that induces in vitro growth arrest, differentiation, or apoptosis of a variety of cancer, leukemia, and MM cells by restoring function of aberrantly silenced genes, among other effects. In phase I studies, vorinostat was administered IV to patients with solid tumors or hematologic malignancies daily $\times$ 3 or daily $\times$ 5 for up to 3 weeks. The maximum tolerated dose of vorinostat in patients with hematologic malignancies was 300 mg/m² daily $\times$ 5 for 3 weeks; thrombocytopenia and leukopenia were the notable toxicities, but induced no significant responses as a single agent in refractory AML. In sequential treatments in vitro, a schedule-dependent synergy was seen with other agents used to treat AML, but in some instances, antagonistic activity was observed. In a phase II study of vorinostat combined with gemtuzumab ozogamicin as induction therapy for elderly AML patients, a CR rate of more than 20% was observed. In a phase I trial of relapsed AML, vorinostat with idarubicin induced a 17% response rate with modification of histone acetylation patterns.

TABLE 57.6**Histone Deacetylase Inhibitors^a**

Name	Type of Compound	Cell Culture (Activity)	Animal Tumor Models	Clinical Trial
Butyrates	Short-chain fatty acids	Yes (μM)	Yes	Phase I/II
Valproic acid	Short-chain fatty acid	Yes	Yes	Phase I/II
Trichostatin A	Hydroxamic acid	Yes (nM)	Yes	—
Pyroxamide	Hydroxamic acid derivative	Yes (nM)	Yes	Phase I
Oxamflatin	Hydroxamic acid derivative	Yes (μM)	Yes	—
SAHA	Hydroxamic acid derivative	Yes (nM)	Yes	Phase I/II
TPX-HA analog (CHAP)	Hydroxamic acid derivative	Yes (nM)	Yes	—
LAQ824	Hydroxamic acid derivative	Yes (nM)	Yes	Phase I
MS-275	Benzamide derivative	Yes (μM)	Yes	—
CI-994 (<i>N</i> -acetyl dinaline)	Benzamide derivative	Yes	Yes	Phase I
Depsipeptide (FR901228, FK-228)	Cyclic tetrapeptides	Yes (nM)	Yes	Phase I/II
Trapoxin	Cyclic tetrapeptides	Yes (nM)	—	—
Apicidin	Cyclic tetrapeptides	Yes (nM)	Yes	—

^aActivity reported as “Yes” indicates that the compound has been shown to inhibit histone deacetylase (HDAC) activity, that is, growth of transformed cells in culture and in vivo tumor growth in animal studies. (—) indicates no data reported. CI-994 is reported to inhibit histone deacetylation but does not directly inhibit HDAC. SAHA, Suberoylanilide hydroxamic acid.

More impressive responses have been seen in patients with lymphoma. Specifically, treatment of patients with progressive, persistent, or recurrent T-cell cutaneous lymphoma showed strong evidence of significant responses, resulting in rapid FDA approval (see [Chapter 85](#)). In the pivotal study, 74 patients with stage IB and higher T-cell cutaneous lymphoma who had failed two systemic therapies were treated with vorinostat at a dose of 400 mg PO once daily. Sixty one patients (82%) had stage IIB or higher CTCL and 30 patients (41%) had Sézary syndrome. The objective response rate was 30% based on a standardized scoring system, and the median time to tumor progression was 202 days. In these studies, the common toxicities were diarrhea (52%), fatigue (52%), nausea (41%), and anorexia (24%). Although the definitive mechanism of action of this high degree of response is not known, a recent review outlines the current hypotheses. Furthermore, highly significant synergy has been observed in preclinical models combining vorinostat with bortezomib.

Progress with other lymphomas has been more complex. Thirty nine patients with advanced hematologic malignancies were enrolled in a trial composed of two cohorts examining IV and PO formulations of vorinostat. Up to 70% of patients had DLBCL. The median numbers of prior treatments were seven and five in the IV and PO cohorts, respectively. A substantial number of patients had undergone a prior stem cell transplant. Most patients tolerated vorinostat well. Responses were seen in about 15% of patients.

In patients with refractory follicular lymphoma, NHL, or MCL, ORRs of 47% were seen, and responses were observed in two of nine patients with marginal zone lymphoma. The duration of response was longer than 1 year. The largest recent study, by the Southwest Oncology Group (SWOG) in NHL, showed a very low response rate as a single agent, which resulted in combination therapy studies. A number of such studies are underway, but none to date has generated significant results showing combined agent clinical synergy.

Belinostat is another hydroxamic acid HDI that was recently FDA approved for the treatment of relapsed and refractory peripheral T-cell lymphoma (PTCL) based on a multicenter, single-arm BELIEF trial of 120 evaluable patients with PTCL that was refractory or had relapsed after prior treatment. Among patients with histologically confirmed PTCL ($n = 120$), the ORR was 25.8%. Similar to other two FDA-approved HDIs, belinostat was also tested in phase I and II clinical trials for both solid and hematological cancers.

Panobinostat is a second-generation hydroxamic acid-based hybrid polar HDI tested both in in vitro and in vivo tumor models, and in clinical trials. Panobinostat induces apoptosis in a

dose-dependent manner on human CML blast crisis K562 cells and acute leukemia MV4-11 cells with the activating length mutation of *FLT-3*. Exposure to panobinostat is associated with hyperacetylation of H3, H4, and Hsp90; increase in p21; and induction of cell cycle G1 phase accumulation.

Fifteen patients with a median age of 63 years and refractory AML, ALL, or MDS received IV panobinostat in a phase I trial at the following dose levels (mg/m²): 4.8, 7.2, 9.0, 11.5, and 14.0. Grade III QTc prolongation was observed in four patients at the 14.0 mg/m² level and in one patient at the 11.5 mg/m² level. QTc prolongation was asymptomatic and reversible on drug discontinuation. Other toxicities included nausea, diarrhea, vomiting, hypokalemia, and thrombocytopenia. Eight out of 11 patients with peripheral blasts had transient reductions in blast counts, which increased shortly after drug discontinuation. Panobinostat has also been shown to be highly effective in CTCL¹⁵ but not more effective than vorinostat. However, unlike vorinostat, single-agent activity has been seen, with response rates of almost 40% in refractory Hodgkin lymphoma. Even more impressive have been recent results in Hodgkin lymphoma patients relapsing after autologous transplantation, in which overall responses of greater than 70% and objective and durable responses were seen in 27% in a large cohort of 129 patients.¹⁶ Recently, the use of panobinostat has been approved in combination with bortezomib and dexamethasone in patients with relapsed and refractory MM.¹⁷ Many other hydroxamic acid derivative-based HDIs have entered preclinical or clinical studies as anticancer agents with promising results, including abexinostat, pracinostat, resminostat, givinostat, panobinostat, and CUDC-101.

Synthetic Benzamide Derivative Histone Deacetylase Inhibitors

Benzamide-containing HDIs are another class of compounds that showed both in vitro and in vivo anticancer activities. Among them, mocetinostat (MGCD0103) and entinostat (MS-275) are two examples of benzamide derivatives that had been taken to clinical trials. Mocetinostat (MGCD0103), a benzamide derivative HDI, is selective for both Class I and Class IV HDACs. A phase I trial of mocetinostat in patients with leukemia or MDS showed the drug was safe and exhibited antileukemia activity in these patients. Three patients also achieved a complete bone marrow response (blasts ≤5%). A phase II clinical trial in patients with CLL also demonstrated efficacy with a manageable side effects profile. The safety and efficacy of this compound was tested in patients with relapsed classical Hodgkin lymphoma during a phase II clinical trial. Even though the treatment showed promising clinical

activity with manageable toxicity in patients with relapsed classical Hodgkin lymphoma, four patients died during the study, of which two may have been treatment-related deaths. As a result, this study has been terminated. Entinostat is another Class I selective HDI and is well tolerated either as a single agent or in combination with other drugs. A phase I trial tested entinostat in patients with refractory solid tumors and lymphomas. Prolonged disease stabilization was seen in some patients, and the drug was well tolerated and demonstrated antitumor activity.

Cyclic Tetrapeptide Histone Deacetylase Inhibitors

The principal members of this class of agents are depsipeptide (romidepsin). Romidepsin has recently been approved by the FDA as an IV agent for the treatment of patients with relapsed or refractory CTCL. It is a potent HDI that exerts *in vitro* antitumor effects at nanomolar levels against several cancer cell types. It also induces apoptosis of human acute leukemia and CLL cells. It is a natural product derived from *Chromobacterium violaceum*, a bacterium isolated from Japanese soil samples. Additionally, romidepsin was shown to exert antiangiogenic effects by modulating the expression of genes involved in angiogenesis. FDA approval for romidepsin in relapsed/refractory CTCL is based on two large phase II studies: a multi-institutional study based at the NCI in the United States (71 patients), and an international study (96 patients). The treatment schedule was identical across both studies and the ORR was 34% in both studies. Romidepsin also induced complete and durable responses in patients with relapsed or refractory PTCL across all major PTCL subtypes, regardless of the number or types of prior therapies, with an objective response rate of 25%, which led to the approval of single-agent romidepsin for the treatment of relapsed or refractory PTCL in the United States. Similarly, a phase II trial enrolling 47 patients with PTCL of various subtypes including PTCL not otherwise specified, angioimmunoblastic, ALK-negative anaplastic large-cell lymphoma, and enteropathy-associated T-cell lymphoma also showed an ORR of 38%. A phase I study of romidepsin in patients with CLL and AML at a dosage of 13 mg/m² IV on days 1, 8, and 15 of a 4-week cycle showed antitumor activity in several patients, although no CRs or PRs were observed. Response was greater in patients with CLL than AML. There were no life-threatening toxicities, but constitutional symptoms characteristic of HDAC inhibition were observed in the majority of patients.

Depsipeptide shows substantial activity against CTCL and it has been approved by the FDA for treatment of CTCL patients who have received at least one prior line of systemic therapy at a dose of 14 mg/m² IV over 4 hours on days 1, 8, and 15 of a 28-day cycle. Another phase II study of depsipeptide as a single agent has shown an encouraging 38% response rate in PTCL. In relapsed myeloma, no objective responses have been observed.

Toxicity of Histone Deacetylase Inhibitors in Clinical Trials

The most common grade 3 and 4 adverse events observed with the use of HDIs were thrombocytopenia, neutropenia, anemia, fatigue, and diarrhea. In some cases, HDI-induced thrombocytopenia can be rapidly reversible upon withdrawal of the drug. Nausea, vomiting, anorexia, constipation, and dehydration were also seen in patients receiving HDIs. Deaths have been reported in clinical studies involving HDIs. For example, when mocetinostat was tested in patients with relapsed Hodgkin lymphoma four patients died, of which two were treatment-related deaths. Similarly, deaths were also reported in clinical trials involving vorinostat, givinostat, and many other HDIs.

Combinations of Histone Deacetylase Inhibitors With Other Agents

With an increased understanding of the function of HDIs, rational combinations of chemotherapies and HDI inhibitors have been investigated. The acceptable toxicity profile associated with HDI

treatment permits a broad integration into currently approved chemotherapy regimens. A variety of HDIs synergistically enhance the growth inhibition and apoptosis of DNA-damaging agents and irradiation. This occurs, in part, through a HDI-mediated increase in chromatin accessibility and downregulation of DNA repair. A small phase I study examined the MTD of vorinostat with standard-dose CHOP chemotherapy in 14 patients with untreated PTCL. The MTD of vorinostat was 300 mg daily. The combination was tolerated, with diarrhea being the most common toxicity observed, and with a 2-year PFS and OS of 79/70% and 81/75% in the two dosing schedules tested, respectively. Synergy between HDI and proteasome inhibitors has been demonstrated in preclinical and clinical studies in myeloma. The most well-characterized model of synergy between proteasome inhibitors and HDIs are the dual inhibition of the proteasome and aggresome pathways. Targeting both the proteasome with bortezomib and the aggresome with HDAC6 inhibitors in tumor cells induces greater accumulation of polyubiquitinated proteins, resulting in increased cellular stress and apoptosis. More specifically, proteasome inhibition drives the formation of aggresomes, which are dependent on the interaction of HDAC6 with tubulin and dynein complex. Moreover, the proteasome inhibitor (bortezomib) and HDAC6 inhibitors (tubacin or panobinostat) lead to increased hyperacetylation of tubulin and generation of polyubiquitinated proteins, thus increasing cellular stress response (i.e., c-Jun N-terminal protein kinase activation) and leading to apoptosis, which is, in part, dependent on caspase activity. The addition of panobinostat to bortezomib improved PFS by about 3 months in a recent randomized phase III trial of 768 patients with relapsed/refractory myeloma that led to FDA approval. Clinical trials are ongoing to test the combinations of HDI with hypomethylating agents, mTOR inhibitors, and other proteasome inhibitors.

Denileukin Diftitox

Denileukin diftitox (DD) or DAB389IL-2 (Ontak) is a fusion protein in which the receptor binding domain of diphtheria toxin has been exchanged for that of the IL-2 molecule. Because of the specificity of the IL-2 domain, the DT-mediated cytotoxic activity will predominately affect cells that express the IL-2 receptor (IL-2R). The IL-2R is selectively expressed on activated T-lymphocytes, B cells, and NK cells. It has been shown that IL-2 fusion toxin is cytotoxic against *in vitro* T-cell lines. It has been estimated that approximately 50% of CTCL cases express the IL-2R (CD25), as demonstrated by immunohistochemical staining. DD was approved by the FDA for the treatment of relapsed or persistent, CD25⁺ CTCL based on demonstrated efficacy in a placebo-controlled multinational dose-ranging study that enrolled 144 patients with CD25⁺ stages Ia–III CTCL. Patients who had three or fewer prior therapies were randomly assigned to receive an IV infusion of either DD at 0.018 mg/kg or 0.009 mg/kg on days 1–5 of a 21-day cycle (maximum eight cycles) or saline placebo. The ORR for patients receiving the 0.018 mg/kg dose was 46%, with a median response duration of 220 days. The ORR for patients receiving the 0.009 mg/kg dose was 37%, with a median response duration of 277 days. Patients receiving the saline placebo had an ORR of 16% and median response duration of 81 days. Significant improvements of PFS at both doses of DD was noted (hazard ratio: 0.27 comparing 0.018 mg/kg vs. placebo, *p* = .0002; hazard ratio: 0.42 comparing the 0.009 mg/kg vs. placebo, *p* = .02). Treatment-emergent adverse events that occurred in at least 20% of patients in the 0.018 mg/kg group, and more frequently than in the placebo arm, were fever, nausea, rigors, fatigue, vomiting, headache, peripheral edema, diarrhea, anorexia, rash, and myalgia. Serious adverse events in patients receiving DD included infusion reactions, capillary leak syndrome, and loss of visual acuity, including loss of color vision. Laboratory abnormalities reported included hypoalbuminemia and hepatic transaminitis. Both beixarotene and alitretinoin were shown to increase the expression of CD25 in the CTCL cell line. Cells that were subsequently exposed to DD showed a 50%–70% decrease in protein synthesis. This observation

suggests that increases in expression of components of the IL-2R can be achieved by retinoids and rexinoids, which may enhance the cytotoxicity of DD. A phase I trial investigating the use of bexarotene in conjunction with DD in patients with relapsed or refractory CTCL was undertaken, and eight out of 12 treated patients showed a greater than 50% increase in CD25 expression after treatment with bexarotene. A phase II trial of DD demonstrated an ORR of 48% in relapsed/refractory PTCL (excluding CTCL) with median PFS of 6 months. Higher responses (61%) were seen in CD25⁺ tumors. In a phase II trial in patients with relapsed/refractory NHL, the ORR was 25%, with similar responses in CD25⁺ and CD25⁻ tumors. DD has also demonstrated promising activity in 30 patients with steroid-refractory acute GVHD, with 71% of patients responding with either complete (50%) or partial resolution (21%) of GVHD. Hepatic transaminase elevation was the dose-limiting toxicity.

Heat Shock Protein Inhibitors

Heat shock proteins (HSPs) are molecular chaperones that increase their expression in response to cellular stresses, including heat shock, nutrient deprivation, oxidative stresses, heavy metals, and alcohol exposure. They form multimolecular complexes with cellular proteins (called *clients*), regulating their correct folding, repair, degradation, and function. A number of multigene families of HSPs exist, and their individual products vary in cellular expression, function, and localization; they are classified according to their molecular weight (e.g., HSP90, HSP70, HSP27). Exceptions to this rule are the chaperones identified as glucose-regulated proteins (GRP94 and GRP75).

HSP90 is one such molecular chaperone that regulates the function and stability of more than 200 proteins, many essential for maintaining cell signaling and survival during stress states. The protective actions of HSP90 also allow cancer cells to escape the inherent toxicity of their environment, evade the effects of chemotherapy, and protect themselves from their own genetic instability. In humans, HSP90 consists of four genes, cytosolic HSP90 α and HSP90 β , GRP94, and HSP75/TNF-associated protein 1 (TRAP1). The monomer HSP90 consists of a conserved 25-kDa N-terminal and a 55-kDa C-terminal domain. The N-terminus contains a highly conserved ATP-binding domain. Dimerization of these nucleotide-binding domains is essential for chaperone actions, ATP binding and hydrolysis. Phosphorylation leads HSP90 to interact with co-chaperones such as HSP70 and p23 to form heteroprotein complexes, which are essential for interaction with protein clients, including protein kinases, transcription factors (e.g., steroid hormone receptor, retinoid receptors, and HIF-1 α), and other proteins with various functions (e.g., mutant *p53*, the catalytic subunit of telomerase hTERT, TNFR1, and Rb). HSP90 inhibition leads to misfolded client proteins that are involved in malignancy to be polyubiquitinated and degraded by proteasomes.

The first generation of HSP90 inhibitors, benzoquinone ansamycins (herbamycin A, geldanamycin, and tanespimycin) was observed to have some antineoplastic activity, but their clinical development was limited by difficulties in formulation, hepatotoxicity and unexpected deaths in clinical trials. Newer, nongeldanamycin agents have improved bioavailability and water solubility, and have been observed to have limited single-agent activity against hematologic malignancies. In phase I studies in lymphoid malignancies, the HSP90 inhibitor AUY922 had an overall response of 10%, and was associated with grade 3 fatigue, visual disturbances, and anemia. With data suggesting possible synergy with other antineoplastic agents, it is possible that HSP90 inhibitors may be used in combination strategies.

Protein Translation Inhibitors

The increased proliferation and cell survival of cancer cells imposes a requirement for increased levels of short-lived proteins involved in cell division and survival. As a result, protein translation is markedly

upregulated in cancer cells, making ribosomal function and protein synthesis a potential therapeutic target.

Protein translation is divided into three phases: initiation, elongation, and termination. As discussed in earlier sections of this chapter, mTOR inhibitors disrupt the initiation phase by preventing assembly of the eIF4F complex, responsible for ribosomal recruitment. Other agents aimed at impeding translation by directly targeting the function of eIF4F have not yet had successful clinical applications.

Omacetaxine

Omacetaxine mepesuccinate (homoharringtonine, HHT, synribo), is a semisynthetic, highly purified compound derived from a plant alkaloid discovered more than 40 years ago. Omacetaxine prevents peptide elongation by binding the A site in the peptidyl cleft of the large ribosomal subunit, thus blocking correct positioning of the amino-acid side chains of tRNAs. The clinical activity of omacetaxine has been correlated with its capacity to decrease translation of short-lived proteins such as c-Myc, MCL-1, and Cyclin D1. The initial clinical studies of omacetaxine in CML were done with IV administration, before the introduction of BCR-ABL inhibitors, and were focused on patients who had failed IFN- α . Interest decreased after approval of imatinib for CML, but subsequent studies focused on the use of SC omacetaxine in patients who developed resistance to TK inhibitors and those carrying the T315I mutation. The maximum tolerated dose was 1.25 mg/m² subcutaneously twice daily. Subsequent studies demonstrated omacetaxine was capable of achieving major cytogenetic response in 23% of chronic-phase CML patients carrying the T315I mutation. Omacetaxine dosing was 1.25 mg/m² twice daily for 14 days every 28 days until achievement of a hematologic response, after which maintenance was given at the same dose for 7 days every 28 days. Hematologic toxicity was frequent (neutropenia 44%, anemia 39%, and thrombocytopenia 76%), particularly in the initial stages of treatment, and was managed by reducing the number of days of drug administration. The most common nonhematologic toxicities were infections, diarrhea, nausea, and fever. Severe nonhematologic toxicities included infection (10%), fatigue (5%), and increased alanine aminotransferase (3%). Omacetaxine received FDA approval in 2012 for the treatment of CML patients who have failed two or more TKI treatments.

DRUG RESISTANCE TO CHEMOTHERAPEUTIC AGENTS OR MULTIDRUG RESISTANCE

Although many hematologic malignancies develop resistance to a specific class of chemotherapeutic agents, especially to targeted therapeutics, through the development of kinase region point mutations, emergence of resistance to multiple cytotoxic chemotherapeutic agents is also common among hematologic malignancies. The basis for resistance includes specific drug resistance mechanisms, overexpression of the ATP-binding cassette (ABC) transporters such as MDR-1 for drug efflux, and overexpression of antiapoptotic proteins. The Goldie-Coldman hypothesis predicts that drug-resistant tumor cell clones survive because of a favorable spontaneous mutation, which occurs in approximately one in a million cells. Because 1 g of tumor contains 1×10^9 cells, it becomes obvious that high tumor burden states contain cells with a tremendous number of mutations, which can contribute to drug resistance. This is the rationale for using combination chemotherapy at specific dose intervals to maximize dose intensity.

Drug-resistance mechanisms have been discovered and subsequently defined at the molecular level by investigators working in vitro with tumor cell lines selected in the presence of specific antitumor agents, by analysis of primary samples of untreated and treated hematologic malignancies, and through screening of tumor banks. Classes of resistance include acquired protein deficiency, loss of sensitivity to apoptotic signals, and age-related defects in the cellular pathways that normally lead to apoptosis.

P-Glycoprotein (ABC-B1 Transporter)

Structure and Function

The ABC superfamily of membrane transporters mediates the cross-membrane flux of xenobiotics, naturally occurring toxic compounds, drugs, peptides, and ions. The ABC family has a profound impact on homeostasis and is critically important to proliferation and differentiation signals in normal progenitor cells. It also mediates drug sensitivity. The terminology remains challenging because many earlier works referred to PGP and MRP, but the more recent consensus on the ABC superfamily has created a more simple approach going forward. PGP (ABC-B1 transporter) has been the subject of intense biochemical and clinical studies since it was first discovered in drug-resistant cell lines more than 20 years ago. The biochemistry of PGP has been reviewed in detail by several investigators. This phosphorylated glycoprotein has a molecular mass of approximately 170 kDa and is localized to the plasma membrane, where it functions as a drug efflux pump (Table 57.7). The ATP-dependent extrusion of antineoplastic agents confers a relative level of resistance to the cell that overexpresses PGP. Recently, the family of drug-transporting proteins has been more carefully characterized, leading to the use of the term *ATP-binding cassette transporters*. The observation of double-minute chromosomes and homogeneously staining regions in several MDR cell lines suggested that gene amplification is involved in PGP-mediated MDR. The human *MDR1* gene, which codes for PGP and is involved in antitumor drug resistance, and the human *MDR2* gene (the product of which is expressed by hepatocytes) are located very near each other on human chromosome 7q21.1. The human *MDR1*

gene has 28 exons and codes for a protein of 1280 amino acids. The PGP molecule has two homologous halves, each with a hydrophobic region containing six transmembrane domains and a hydrophilic region containing an ATP-binding site. *N*-linked glycosylation occurs on the extracellular side (Fig. 57.10). PGP is a member of the ABC superfamily, which includes, among more than 100 others, the MRP; the *pfmdr* pump in *Plasmodium falciparum*, which results in chloroquine resistance; STE6, the transporter of the “a” peptide mating factor in yeast; the cystic fibrosis transmembrane conductance regulator (CFTR); and the TAP-1 and TAP-2 proteins that transport antigenic peptides for association with class I molecules and surface antigen presentation. MRP has been demonstrated in several MDR mammalian cell lines and in human tumors (see later), but a recent study in human tumor cell lines has shown TAP overexpression associated with MRP, as well as drug resistance resulting from transfection of the *TAP* genes.

PGP has a broad specificity for hydrophobic compounds and can both reduce the influx of drugs into the cytosol and increase efflux from the cytosol. To accomplish the former, this “hydrophobic vacuum cleaner” must detect drugs and expel them while they are still in the plasma membrane. Drugs are thought to be effluxed from the cytosol through a single barrel of the PGP transporter, although an exact mechanism has been lacking. A recent study has used electron microscopy to generate an initial structure of PGP to 2.5-nm resolution. The structure was further refined by three-dimensional reconstructions from single-particle image analysis of detergent-solubilized PGP and by Fourier projection maps of small crystalline arrays of PGP. This demonstrates that PGP is monomeric, with the shape of a cylinder 10 nm in diameter with a maximum height (in the plane of the membrane) of 8 nm (see Fig. 57.10). Approximately half of

TABLE 57.7 Characteristics of Three Mechanisms of Multidrug Resistance That Result From Overexpression of PGP, Multidrug Resistance-Associated Protein, or Lung Resistance-Related Protein

	PGP	MRP	LRP

Fig. 57.10 STRUCTURE OF P-GLYCOPROTEIN DETERMINED BY ELECTRON MICROSCOPY. A computer graphic representation of the three-dimensional reconstruction is shown as a shaded surface representation of the structure. The *straight arrow* shows the putative ATP-binding domains. *P* represents the aqueous pore open at the extracellular face of the membrane. *TMD*, two thumbs, each of which probably corresponds to one of the two transmembrane domains. *NBD*, 3-nm lobes projecting from the structure at the cytoplasmic face of the membrane, probably corresponding to the two nucleotide-binding domains. (A) View perpendicular to the extracellular surface of the lipid bilayer; (B) side view of P-glycoprotein in which the approximate position of the lipid bilayer is indicated by the two horizontal *dashed lines*. *Arrow* indicates asymmetric opening providing access from the lipid phase to the aqueous core of the protein. (Reproduced with permission from Rosenberg ME, Callaghan R, Ford RC, et al: Structure of the multidrug resistance P-glycoprotein to 2.5 nm resolution determined by electron microscopy and image analysis. *J Biol Chem* 272:10685, 1997.)

the PGP molecule is within the membrane because the lipid bilayer is approximately 4 nm in depth. When viewed from the extracellular surface of the membrane, PGP is pteroidal with a large central pore 5 nm in diameter. This large aqueous chamber in the membrane that is open to the extracellular space is closed on the cytoplasmic side, presumably by the two 3-nM intracellular lobes (putative nucleotide-binding domains) and the hydrophilic cytoplasmic loops between the transmembrane domains. Thus, this large pore has a “gate” on the cytoplasmic side of the membrane that can regulate the transport of different-sized substrates.

Substrates of PGP include (see [Table 57.7](#)) anthracyclines (doxorubicin, daunorubicin, epirubicin, and idarubicin), anthracenediones (mitoxantrone), aminoacridines (amsacrine), taxanes (taxol and taxotere), epipodophyllotoxins (VP-16 and VM-26), vinca alkaloids (vincristine, vinblastine, and vinorelbine), bortezomib, and actinomycin D. Mitomycin C and one of the topoisomerase I inhibitors (topotecan) are both weak substrates for PGP. Several drugs reverse the resistance mediated by PGP overexpression and sensitize cells to the cytotoxic effects of antineoplastic agents. These drugs compete with antitumor agents for efflux from the cell, effectively increasing the intracellular concentration of the cytotoxic drug, and include immunosuppressants (cyclosporin A [CSA], FK 506, rapamycin, PSC 833), calcium channel blockers (verapamil, nifedipine), antiarrhythmics (quinidine), and other miscellaneous agents. Several of these MDR-modulating agents have been used in clinical trials in an effort to sensitize resistant tumor cells (see later).

Methods of Detection

Several monoclonal antibodies that recognize PGP and are commercially available for routine analyses have been described. Monoclonal antibodies C219 and JSB-1 recognize internal epitopes of PGP,

whereas antibodies MRK16 and UIC2 detect external antigens and are more suited for fluorescence-activated cell sorting analysis.

P-Glycoprotein Expression in Normal Human Tissue

High levels of expression of *MDR1*/PGP have been found in the epithelium of several human tissues with excretory function, suggesting that PGP is normally involved in transporting both exogenous toxic compounds and endogenous metabolites. These tissues include the adrenal cortex, renal proximal tubule epithelium, biliary hepatocytes, small and large intestinal mucosa, pancreas, and endothelial cells of the brain and testis. Normal human hematopoietic tissues with high levels of *MDR1*/PGP include CD34⁺ progenitor cells, CD56⁺ (NK) cells, and CD8⁺ (T-suppressor) cells. Lower levels of expression have also been observed in CD4⁺ (T-helper) cells, CD19⁺ B cells, and CD14⁺ cells (monocytes).

P-Glycoprotein Expression in Human Malignancies

Increased expression of PGP has been observed in several human tumors, especially those malignancies that arise in tissues that normally have high levels of PGP expression. An analysis of 61 human tumor cell lines (from leukemia, CNS tumors, melanoma, breast cancer, ovarian cancer, colon cancer, lung cancer, and kidney cancer) that were not selected for resistance to antitumor agents demonstrated co-expression of two or three of the MDR proteins (PGP, LRP, or MRP) in 64% of the cell lines. PGP and LRP were overexpressed in 3% of the tumors; MRP and LRP in 43%; and PGP, LRP, and MRP in 18%. The cell lines with the highest levels of drug resistance were found to overexpress all three proteins. Whether this is true in primary human tumors awaits further investigations.

Acute Myeloid Leukemia

An earlier meta-analysis of studies that examined the expression of *MDR1*/PGP in blasts of patients with AML found that 40% (105 out of 261 patients) who were PGP positive achieved a CR, but 81% (192 out of 238) of PGP-negative patients obtained a CR. An analysis of 96 untreated patients with AML showed that PGP expression predicted induction failure ($p < .0001$) and decreased OS ($p < .001$), as did unfavorable cytogenetics. PGP expression was not detected in patients with favorable cytogenetic abnormalities [$t(15;17)$, $inv(16)$, $t(8;21)$], was found in 29% of those samples with a normal karyotype, and was expressed in 62% of patients with an unfavorable cytogenetic abnormality. PGP was also detected in 63% of those with secondary AML compared with 25% of those with de novo disease. PGP analysis with the MRK16 antibody in 211 elderly patients (older than 55 years) with untreated AML again showed that PGP expression is significantly associated with a decreased CR rate and resistant disease. Patients in this report with de novo PGP-negative AML with favorable cytogenetics have a CR rate of 81% compared with 12% for those with secondary AML, which is PGP positive and has unfavorable cytogenetics. Clinical trials using the PGP substrate Valspodar (PSC833) acting as a competitive inhibitor did not show the dramatic benefit expected, especially in older patients with acute leukemias.

Impact of P-Glycoprotein in Other Hematologic Malignancies

The role of PGP in the drug resistance of NHL, myeloma, and ALL is ill defined. CLL is another chronic leukemia in which few PGP-related antineoplastic agents are used. However, a single study has shown a correlation between *MDR1* expression and survival, in which the 10 B-CLL patients who were *MDR1* positive had a median survival of 19 months compared with 46 months for the 17 patients who were *MDR1* negative ($p < .01$). Nonetheless, a recent study identified bortezomib as a substrate for PGP, raising the possibility that myeloma PGP levels affect clinical response. There have not been recent studies of the role of PGP in drug resistance in NHL in the past 5 years. With the newer kinase inhibitors, it has recently been noted that nilotinib and dasatinib are high-affinity substrates of ABCG2. These agents appear to inhibit the function of this transporter, but whether this will translate into clinical impact has not received prospective attention.

Clinical Studies With Modulators of P-Glycoprotein

The clinical trials that have used various modulators of PGP have been reviewed by several investigators. An early study in VAD-refractory MM resulted in short-lived PRs to VAD plus racemic verapamil in five out of 22 patients. Four of the five responders overexpressed PGP; however, cardiac side effects precluded further dose escalation of IV *R,S*-verapamil. Continuous IV infusion of CSA with VAD in VAD-resistant myeloma patients resulted in seven out of 15 responses, which were more common in those who overexpressed PGP. A randomized SWOG phase III study of VAD and PO verapamil in 120 patients with refractory myeloma demonstrated a 41% and 36% response in the VAD and VAD/verapamil arms, respectively, with median survival times of 10 and 13 months, respectively. Continuous-infusion CSA has been dose escalated in combination with daunorubicin and ara-C. Transient hyperbilirubinemia was seen in 62% of the patients; these same patients had increased serum daunorubicin levels and a higher response rate. A CR was seen in 26 out of 42 patients; however, the MDR phenotype was not found to influence the response. A study of PSC833 in patients with acute leukemia treated with cytarabine, daunorubicin, and etoposide showed a modest benefit in patients younger than 45 years of age, raising the potential of developing an effective strategy in patients older than 60 years of age in whom PGP expression in leukemic cells is more common. Zosuquidar, a PGP inhibitor, was tested for efficacy in a phase III trial by ECOG in 449

patients older than the age of 60 years. No benefit in response rate or survival was noted. Likewise, in a CALGB study, in adults with untreated leukemia younger than the age of 60 years, PSC833 also did not improve survival or response rates. Thus, the future role of modulation of PGP in leukemia management remains ill defined.

Multidrug Resistance-Associated Protein (ABC G2 Transporter)

Structure and Function

The MRP was first described in 1992 in the doxorubicin-selected small-cell lung cancer cell line, and its biochemical characteristics and biologic properties have been reviewed.¹⁸ It has now been classified within the larger context of ABC transporters, termed *ABC G2 transporters*. Because much of the literature uses the MRP nomenclature, we refer to this herein except for the studies using the ABC terminology. This *N*-glycosylated plasma membrane phosphoprotein has a molecular mass of 190 kDa (1531 amino acids) and is a member of the ABC transporter superfamily (see Table 57.7 and Fig. 57.11). This transporter has 18 transmembrane domains (12 in the amino end and six in the carboxyl end) and is coded on human chromosome 16p13.1.

The overexpression of MRP has been shown in vitro to result in different levels of drug resistance to several classes of antineoplastic agents, represented by actinomycin D, chlorambucil, melphalan, cisplatin (CDDP), daunomycin, doxorubicin, epirubicin, teniposide (VM-26), etoposide (VP-16), and vincristine. Low levels of resistance have also been reported for taxol, vinblastine, and colchicine. In addition to antitumoral agents, MRPs (and its isoforms) are capable of transporting heavy metals (arsenicals, cadmium, and antimonials) as well as glutathione conjugates and cysteinyl leukotriene. Compounds reported to modulate MRP-mediated drug resistance in vitro include the calcium channel blocker verapamil nocardipine; the

Fig. 57.11 MODELS OF MULTIDRUG-RESISTANCE PROTEIN MEMBRANE TOPOLOGY. Multidrug-resistance protein (MRP) possesses features common to all members of the ATP-binding cassette transporter superfamily in that each half of the protein is predicted to consist of several transmembrane domains followed by a cytosolic nucleotide-binding domain (MBD). The first model (A) is based on computer-assisted hydropathy analyses of the human MRP amino acid sequence and predicts that MRP is composed of 12 transmembrane domains (solid bars), eight of which are within the NH_2 -proximal half of the protein. The second model (B), based on a comparison of human and murine MRP with other ATP-binding cassette transporters, suggests that there are up to four additional transmembrane domains in the NH_2 -proximal half of the protein. (Adapted from Loe DW, Deley RG, Cole SPC: *Biology of the multidrug resistance-associated protein, MRP*. Eur J Cancer 32A:945, 1996.)

protein kinase C inhibitor GF109203X; the cyclosporin analog PSC833; the TKI genistein; the gyrase-inhibiting antibiotic difloxacin; and amiodarone VX-710. Amiodarone VX-710, a nonmacrocyclic ligand of the FK506-binding protein FKBP12 and a potent modulator of PGP-mediated MDR, has been found to restore sensitivity of MRP-expressing HL60/ADR cells to the cytotoxic action of doxorubicin, VP-16, and vincristine. Other investigational agents include danusertib, a potent pan-aurora and ABL kinase inhibitor being developed for CML. The nonsteroidal antiinflammatory drug indomethacin has also been shown to significantly increase the sensitivity of HL60/ADR cells to doxorubicin and vincristine, and may be a specific inhibitor of MRP.¹⁹

Multidrug-Resistance Protein Expression in Hematologic Malignancies

The expression of MRP mRNA or the level of MRP protein has been assessed in 148 patients with hematopoietic malignancies. MRP mRNA expression was found to be significantly increased in 84% of patients with CLL and in 30% of those with AML. The vast majority of patients with ALL, CML, MM, hairy cell leukemia, and NHL were found to have low levels of MRP mRNA expression. MRP protein was assayed using the monoclonal antibody MRPr1, and the results were generally similar with increased expression in most patients with CLL. A study of 40 patients with refractory lymphoma and 16 with newly diagnosed lymphoma suggests a limited role for MRP mRNA expression in drug resistance in NHL because 15 paired samples in the refractory group showed no difference in MRP expression pre- and post-EPOCH treatment. In addition, the untreated patients had MRP mRNA levels that were no different from the pre- or post-EPOCH patient levels. A study of 49 patients with AML and 29 with ALL demonstrated significantly higher expression of MRP in ALL ($p < .007$) and in secondary AML ($p < .016$), but not in de novo AML. Combining overexpression of ABC G2 and FLT3-ITD, an Italian group identified that in adult AML patients, overexpression of ABC G2 was detected in 83 (50%) and FLT3-ITD in 47 (28%) patients. Although the response rate was not affected, the duration of remission was much shorter when these proteins were overexpressed. In a small study of 14 patients with relapsed AML, relapse was associated with a twofold increase in blast MRP mRNA relative to 29 patients with newly diagnosed AML ($p < .01$). Paired relative samples (obtained at diagnosis and at relapse) from 13 AML and four ALL patients showed a twofold increase in 80% of the patients at relapse, suggesting that the expression of the MRP transporter at relapse may be involved in drug resistance. Because purine nucleoside antimetabolites may be exported by ABC G2, as noted earlier, it is of note that clofarabine is also a substrate, but its function is mediated inversely by levels of deoxycytidine kinase. Also of note is the finding that drug treatment can demethylate and thus activate the ABC G2 exporter, thereby increasing its protective tumor impact.

The larger family of transporters, the ABC group that includes ABC G2 and ABC B1, are overexpressed in leukemic cells and in many malignant stem cells. In fact, in addition to CD44, high levels of ABC transporters assist in the characterization and isolation of the transplantable subpopulation of malignant stem cells. Brendel and coworkers found that both imatinib and nilotinib used to block the ABL kinase in CML were effectively blocking the ABC transporter in CML cells. This suggested both that these agents might function in part by blocking expression of an important leukemic stem cell protein, and that they would sensitize CML cells to other agents transported by the ABC system.

DNA Repair Pathway Mechanisms of Drug Resistance

O⁶-Alkylguanine-DNA Alkyltransferase

As noted previously, the nitrosoureas and methylating agents are cytotoxic largely because of formation of DNA adducts at the O⁶

position of guanine. The most efficient means of protection from the cytotoxicity of adducts at the O⁶ position of guanine is rapid repair by the O⁶-alkylguanine-DNA alkyltransferase (AGT or MGMT). This protein serves as the stoichiometric acceptor protein for O⁶-alkylguanine DNA monoadducts, transferring the alkyl group from DNA to the active site of the protein, inactivating the protein, and restoring DNA to normal. However, the N¹G–N³C DNA cross-link that follows chloroethylation is not a substrate for AGT. There is a striking correlation between drug resistance and alkyltransferase activity. Of interest, high levels of AGT are found in many leukemias, but low AGT is observed in normal human CD34 cells, perhaps explaining why nitrosoureas are not used in leukemia management and why nitrosoureas are effective myeloablative agents used in high-dose chemotherapy regimens. A novel inhibitor of AGT, O⁶-benzylguanine (BG) has been used to sensitize human tumors to BCNU. Studies indicate activity of the combination of BG and BCNU in myeloma and in cutaneous lymphomas. Therapeutic benefit from the methylating and alkylating agent cloretazine appears to be related to lower levels of AGT. Likewise, temozolomide has some therapeutic efficacy in leukemia in a manner inversely related to AGT levels in the tumor cells. A study in five pediatric patients pointed out that response to temozolomide was greater in those with MGMT promoter methylation and no evidence of MMR. This has been tested in a prospective phase II trial of older patients with leukemia. Temozolomide was given in a dosing schedule dependent on MGMT promoter methylation status, with a shorter course of therapy in those with low MGMT expression in the leukemic cells. The ORR in elderly leukemia patients who would otherwise not be candidates for treatment was about 40%, with a median duration of about 29–35 weeks.

Mismatch Repair

The spectrum of drug resistance and sensitivity to methylating agents does not end with AGT. Evidence suggests that methylating agent-induced cell death involves an aborted effort at MMR. Karran and others,²⁰ in mammalian systems, have shown that the replicative DNA polymerase and the repair polymerase pauses at O⁶-mG and preferentially inserts a thymine (T) at the site. The O⁶-mG:T base pair is recognized by the MMR system, which initiates (see later). In human cells, the MMR complex consists of at least six proteins involved in the recognition and repair of mismatch lesions: HMLH1, hMSH2, hMSH3, hPMS1, hPMS2, and GTBP (GT-binding protein, also called *MSH6*), all of which appear to be homologs of MMR proteins found in *Escherichia coli* and in yeast. After binding recognition, an endonuclease removes a patch of approximately 100–1000 bp containing the T mismatch, DNA polymerase- δ or - γ fills in the patch, with reinsertion of a T opposite the O⁶-mG, and a DNA ligase closes the strand break. Because the O⁶-mG:T is reformed, cytotoxicity ensues as a result of repetitive efforts at DNA repair and induction of chromosomal breakage, rearrangements, energy depletion, and apoptosis. Drug resistance based on mutation or loss of expression of an MMR protein, owing to mutation within one of the gene coding regions, or promoter methylation leading to loss of gene expression, has been noted in solid tumors and in leukemias and lymphomas. The mutator phenotype was originally described in cells with acquired resistance to methyl nitrosourea, methylmethanesulfonate, or *N*-methyl-*N*-nitroso-*N*-nitrosoguanidine, which were tolerant to G→A point mutations according to the inability to repair O⁶-mG and are cross-resistant to 6-TG used in childhood leukemia maintenance regimens, which form the 6-TG:T mismatch.

Major Molecular Response Mutations and Methylating Agent Resistance

MMR defects in humans were initially described in hereditary nonpolyposis colon cancer, which comprises approximately 15% of all colon cancer, lymphomas, and relapsing acute leukemias. The genetic defect results in a high rate of spontaneous mutations within microsatellite DNA, resulting in the RER phenotype arising as the expansion or contraction of mono-, di-, or tri-nucleotide repeats within the microsatellites. Tumor cells defective in MMR are

remarkably resistant to temozolomide regardless of AGT activity or its inhibition by BG, confirming the importance of MMR in sensitivity to methylating agents. Of interest, MMR mutant cells are also two- to threefold resistant to cisplatin, perhaps because the cisplatin DNA adduct is bound by the MMR complex, slowing its recognition and repair by the nucleotide repair pathway and increasing its cytotoxicity. Such MMR-deficient cells also exhibit microsatellite instability, a measure of genomic instability and the propensity to develop further mutations during therapy, leading to subclones of resistant cells. Loss of PMS2 has been identified in a family of childhood lymphomas. Microsatellite instability is seen in acute leukemias and in T-cell leukemias, suggesting both that these malignancies have lost MMR function and that they are more prone to drug resistance and acquisition of additional mutations that give rise to further drug resistance. Evidence of microsatellite instability and loss of MMR is present in some leukemias but is much more common in treatment-related leukemias, again providing a mechanism of drug resistance.

Base Excision Repair

Methylating agents such as procarbazine and temozolomide form large numbers of N³-A and N⁷-G adducts in addition to O⁶-mG (with TMZ, the relative amounts are 72 N⁷mG:8 O⁶mG:5 N³mA). Thus, under normal circumstances, cells process many more N⁷mG and N³mA lesions than O⁶mG lesions, even though the latter appear much more cytotoxic except in MMR-defective cells. Repair of N³-A and N⁷-G adducts through BER is efficient and normally leads to cell survival rather than cell death. Adducts are recognized by the methylpurine glycosylase with removal of the base, generating an abasic (or AP) site. The AP site is then cleaved by the class II hydrolytic endonuclease (or AP endonuclease) generating a single-strand break with a 5' PO₄, which becomes the substrate for DNA polymerase-β, and to a lesser extent, polymerases-δ and -γ, followed by DNA ligase (reviewed by Sancar²¹). Other compounds induce nucleotide pool imbalance, leading to misincorporation of bases that become substrates for BER. These compounds include folate antagonists such as methotrexate, 5-FU, and, to a lesser extent, nucleoside analogs such as fludarabine. Misincorporation of uracil after 5-FU inhibition of thymidilate synthase also leads to BER. Compounds to disrupt BER, such as TRC102, are now being developed and may lead to combination therapy for hematologic malignancies. An initial phase I trial with TRC102 has been completed with pemetrexed, and a second trial with temozolomide continues. A third trial using the combination of fludarabine and TRC102 in patients with CLL has found remarkable efficacy in the first cohorts after relapsing from fludarabine (unpublished).

Drug Resistance to Antimetabolites

Although overlap exists, antimetabolites can be classified into nucleoside analogs that are incorporated into RNA or DNA (or both) and agents that inhibit de novo purine and pyrimidine biosynthetic pathways. Mechanisms of resistance to these agents fall into several broad categories. For example, many antimetabolites are prodrugs in that they must be converted intracellularly into active nucleotide forms to exert their cytotoxic actions. Consequently, events that interfere with cellular accumulation of drug or nucleotide formation will reduce activity. Examples include decreased transport of methotrexate or decreased nucleotide formation of ara-C and 6-TG by reductions in activity of deoxycytidine kinase or hypoxanthine-guanine phosphoribosyltransferase, respectively. Alternatively, enhanced drug catabolism reduces cytotoxicity. Examples include the deamination of ara-C (to inactive ara-U) by CDD or catabolism of 6-TG by thiopurine methyltransferase. A third mechanism of resistance stems from the presence of increased intracellular levels of a competing metabolite (e.g., dCTP in the case of ara-C, or hypoxanthine or guanine in the case of 6-TG). Fourth, alterations in the level of activity of a target enzyme or the presence of a mutant form that is a poor target of inhibition will also confer resistance. Examples include increased

activity or a mutant form of DHFR (in the case of methotrexate), an altered DNA polymerase-α (in the case of ara-C), or increased activity of ribonucleotide reductase (through overexpression of either subunit). Finally, cytokinetic factors represent a common theme in the case of most (but not all) antimetabolites, in that a reduction in the S-phase fraction generally leads to reduced drug sensitivity. Note that these resistance mechanisms are agent specific and are distinct from the more general modes of resistance (e.g., increased expression of BCL2) associated with defects in the distal cell death pathway.

Mechanisms of Resistance to Signaling Inhibitors

The introduction of signaling inhibitors to the therapeutic armamentarium represents a significant advance in the treatment of hematologic malignancies. As discussed in the previous sections, these agents can inhibit with relative selectivity cellular signaling pathways essential for the survival of neoplastic cells. However, development of resistance has been observed in vitro and in clinical practice, and appears to be the rule rather than an exception with these agents. The mechanisms of resistance related to drug influx/efflux also can affect sensitivity to targeted agents. In addition, several other mechanisms have been described for signaling inhibitors, including genetic alterations, changes in protein expression, and activation of alternative pathways.

Genetic Modifications Leading to Resistance to Signaling Inhibitors

Cancer cells treated with kinase inhibitors tend to acquire genetic modifications that overcome the inhibitory effects of these agents.

Point mutations are the most common mechanism of resistance to TK inhibitors. The development of resistance against a specific inhibitor can be the result of a preexisting cancer cell subpopulation carrying the mutation; once exposure to the drug occurs and sensitive cells die, this cell population experiences selective advantage. On the other hand, cell line studies have been able to induce the emergence of resistance to specific signaling inhibitors, suggesting that the genomic instability experienced by neoplastic cells facilitates emergence of new mutations that may affect drug sensitivity.

Mutations that confer resistance to a kinase inhibitor commonly affect the affinity of the drug for the kinase domain without affecting its catalytic activity. Other mutations affect the conformation of the kinase, making it less available to the inhibitor, and others decrease the affinity of the kinase for ATP, affecting the efficacy of ATP-competitive inhibitors.

Genetic amplifications are common in cancer cells. Many signaling inhibitors target pathways that present amplification of one of its components. Further increases in gene amplification can affect the drug-target balance in favor of the latter. Gene amplifications resulting in increases in target may be overcome by increasing the inhibitor dose, as it is done in clinical practice with imatinib; however, this is limited by the higher potential for adverse events.

Genetic modifications that don't involve the target can also result in resistance. This can occur when mutations or amplifications result in increased activity or expression of signaling molecules located downstream or parallel to the point of inhibition. These "escape" mechanisms may be taken into consideration when designing combination strategies for treatment with multiple targeted agents.

FUTURE DIRECTIONS

The treatment of hematologic malignancies has seen significant progress over the last decades. The continuing expansion of the therapeutic armamentarium with the addition of target-based therapies presents clinicians and researchers with several challenges. The first problem is one of choice; with several agents identified as effective for

a single malignancy, an evidence-based choice will be more difficult to make in the absence of head-to-head comparison in clinical trials. In addition, a major question remains whether the newer signaling inhibitors, “third-wave” agents, and newer immunotherapies only achieve disease control and potentially prolong survival, without definitive disease eradication and cure. It is possible that the former objective is sufficient for approaching normal lifespan in certain disorders, particularly those of indolent nature affecting patients of more advanced age. However, aggressive disorders that represent a life-threatening condition when relapsed would be better treated with curative intent. Strategies for aggressive, resistant, or relapsed disease will likely require inclusion of multiple agents of different generations and mechanisms of action. Current clinical trials are exploring the use of combinations of signaling inhibitors or anti-apoptotic agents with “traditional” chemotherapeutic agents. These combinations, along with the addition of monoclonal antibody and antibody–drug conjugate-based therapies as well as future strategies may achieve sufficient disease control to achieve disease eradication and cure in a larger number of patients. Researchers and clinicians will need to also take into account the cost of these therapies and their impact on quality of life, particularly as several target-based agents have been demonstrated to have activity as maintenance therapies. The long-term effects of many of these agents are still unknown. Future clinical trial design and planning should include answers to these questions: potential for cure versus disease control, rational use strategies, and identification of the most effective and least toxic therapeutic approaches for each disease.

Certainly future considerations include the incorporation of genetic and genomic information into the clinic, as well as other markers of abnormalities of the “signalome” of a specific hematologic malignancy. Application of these diagnostic strategies to a specific patient will allow for individual tailoring of the treatment strategy, both based on the characteristics of the tumor and the individual capacity to tolerate and metabolize drugs. Extensive validation studies will be necessary to understand the true value of these tests in the management of patients with hematologic malignancies.

CLINICAL PHARMACOLOGY OF ALKYLATING AGENTS

MECHLORETHAMINE (MUSTARGEN)

Chemistry: Mechlorethamine, also called *nitrogen mustard*, is a water-soluble and alcohol-soluble analog of sulfur mustard gas. It is a bifunctional chloroethylating agent that alkylates DNA, RNA, and protein.

Absorption, Fate, and Excretion: The parent compound is highly reactive and has a biologic half-life of approximately 15 minutes. The principal route of degradation is spontaneous hydrolysis, but some enzymatic demethylation also occurs.

Preparation and Administration: Mechlorethamine is supplied in vials of 10 mg with 100 mg of sodium chloride and is reconstituted with 10 mL of sterile water to yield a 1-mg/mL solution, ideally prepared immediately before use. However, the manufacturer considers the drug expired 1 hour after reconstitution. The drug is injected over a few minutes through tubing as a freely running intravenous (IV) infusion. For topical application (e.g., in mycosis fungoides), 10 mg of drug is dissolved in 60 mL of tap water. Alternatively, a 10 mg% ointment has been used by dissolving the drug in 95% ethyl alcohol and petrolatum (Aquaphor). Mechlorethamine is a powerful vesicant. In the event of extravasation, vigorous irrigation followed by 0.25% sodium thiosulfate injection at the site of extravasation should be attempted. Ice packs may be placed for 6–12 hours to minimize the local reaction.

Toxic Effects: Myelosuppression is the dose-limiting systemic side effect. This worsens with each additive cycle. Severe nausea and vomiting, infertility, alopecia, and pain at the site of injection, which can sometimes spread to involve the venous system (tracking), are also common. Occasionally, a macular papular rash is observed, but this does not appear to be allergic in nature and does not contraindicate continuation of therapy. Infertility is common but may be reversible. Infrequent adverse effects include alopecia, anorexia, weakness, and diarrhea. The drug has also been shown to induce chromosomal abnormalities and may contribute to the development of secondary leukemias, as seen in patients treated with this agent as part of the MOPP (mechlorethamine, vincristine [Oncovin], procarbazine, prednisone) regimen.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: Mechlorethamine is incorporated in many chemotherapy combinations used in the treatment of Hodgkin lymphoma (MOPP and MOPP/ABV [Adriamycin, bleomycin, and vinblastine] hybrid) and in some non-Hodgkin lymphomas (NHLs; prednisone, etoposide, methotrexate, doxorubicin [Adriamycin], cyclophosphamide, Leucovorin [PROMACE]/MOPP). However, its use has largely been supplanted by other agents.

Cyclophosphamide (Cytoxan)

Chemistry: Cyclophosphamide is a cyclic phosphamide ester of mechlorethamine. After being metabolically activated, it alkylates DNA, forming cross-links.

Absorption, Fate, and Excretion: The drug is relatively well absorbed orally, with approximately 75% oral bioavailability. The

parent compound is not active. The drug is metabolized by the hepatic cytochrome P450 (CYP) system, which ultimately generates at least two active compounds, phosphoramidate mustard and acrolein. The latter appears to be responsible for cyclophosphamide's bladder toxicities. The plasma half-life of cyclophosphamide varies from 4 to 6.5 hours. Approximately 15% of the drug is excreted unchanged in the urine. Dose reduction should be considered in patients with severe renal failure.

Preparation and Administration: Cyclophosphamide is supplied as 25- and 50-mg tablets and as a powder for parenteral administration in 100-, 200-, and 500-mg and 1- and 2-g vials. It is dissolved by adding 5 mL of preservative-free sterile water for every 100 mg of drug. Cyclophosphamide is chemically stable for 24 hours at room temperature and for 6 days if refrigerated.

Toxic Effects: Bone marrow suppression is the major side effect. The myeloid series is primarily affected, although thrombocytopenia also occurs at high doses and alopecia is common. Nausea and vomiting can be severe and are usually delayed, occurring 6–8 hours after administration. Hemorrhagic cystitis occurs in 10% of patients receiving nontransplant doses and is apparently caused by the formation of the urotoxin acrolein. Because of this potential side effect, patients should be well hydrated. Mesna disulfide (sodium 2-mercaptoethanesulfonate disulfide) has also been used on a weight-equivalent basis to ameliorate cyclophosphamide-induced bladder toxicity. Other potential toxic effects include stomatitis, skin and nail hyperpigmentation, interstitial pulmonary fibrosis, and the syndrome of inappropriate secretion of antidiuretic hormone. Rare episodes of acute congestive heart failure have been reported. After bone marrow transplant doses, hemorrhagic cystitis is common, and cardiac toxicity (cardiomyopathy) may be seen. Late sequelae include bladder fibrosis (more common with daily [oral] therapy), bladder cancer, leukemogenesis, and infertility.

Potential Drug Interactions: Corticosteroids may increase P450 enzyme-induced metabolism and is often avoided in high-dose therapy. When combined with doxorubicin, it may increase cardiac toxicity. This may be prevented by amifostine. In animal studies, conflicting results were reported when the P450 enzyme inducer phenobarbital was given with cyclophosphamide. Most investigators, however, have observed a reduction in the amounts of active metabolites. Conversely, when cimetidine (but not ranitidine) was administered in leukemia-bearing mice before treatment with cyclophosphamide, a significant prolongation of their survival and higher plasma concentrations of alkylating metabolites were observed. Although one should remain alert for these potential drug interactions, none has been demonstrated in humans. Cyclophosphamide reduces serum pseudocholinesterase levels, which may prolong the neuromuscular blocking effects if given simultaneously. Caution must be exercised when administering high doses of these two drugs to critically ill patients. Life-threatening hyponatremia may develop when used in conjunction with indomethacin, although the precise incidence is unknown.

Therapeutic Indications in Hematology: Cyclophosphamide is a key drug in the treatment of lymphomas and myeloma. It is incorporated in many chemotherapy regimens, including CHOP, MACOP-B, PROMACE/CYTABOM, CVP, and VMCP (see [Chapters 81](#) and [85](#) for details). In addition, cyclophosphamide is the drug

most commonly used in preparatory regimens for bone marrow transplantation. It is also used in solid tumors and as an immunosuppressant in nonmalignant conditions such as glomerulonephritis and systemic lupus erythematosus.

Ifosfamide (Ifex)

Chemistry: Ifosfamide is an oxazaphosphine nitrogen mustard that differs from cyclophosphamide by the placement of chloroethyl groups.

Absorption, Fate, and Excretion: As in the case of cyclophosphamide, the parent compound is inactive and is metabolized by the CYP system in the liver. The metabolism of ifosfamide is influenced by the dose and schedule of administration. When administered as a single bolus, 60% is eliminated into the urine, 53% as unchanged inactive drug. When administered daily for 5 consecutive days, 56% is excreted into the urine, 15% as the inactive parent compound. The half-life is 7 hours when administered daily for 5 consecutive days and 15 hours when given as a single bolus dose. There is poor penetration across the blood–brain barrier. Its longer half-life and slower metabolic activation allow higher doses to be given.

Preparation and Administration: The drug is provided in 1-g vials and should be reconstituted in sterile water or bacteriostatic water to a final concentration of 50 mg/mL. Ifosfamide can be diluted further in 5% dextrose, normal saline, or Ringer solution for injection to achieve concentrations of between 0.6 and 20 mg/mL. The solution should be infused over 30 minutes. To prevent hemorrhagic cystitis, patients must receive Mesna disulfide for protection against urotoxicity and must be kept well hydrated (2 L/day). Mesna is a thiol compound that is rapidly oxidized to dimesna in vivo. Mesna and dimesna are filtered by the glomeruli, reabsorbed in the proximal tubule, and finally secreted back into the tubular lumen of the kidney. In the tubules, approximately one-third of the filtered dimesna is readily converted back to Mesna. The free sulfhydryl group of this compound reacts with the urotoxic metabolite acrolein produced by both ifosfamide and cyclophosphamide (see Fig. 57.7). This reaction creates a nontoxic acrolein–Mesna thioether that is safely eliminated in the urine. Mesna has also been shown to inhibit the degradation of ifosfamide or cyclophosphamide to acrolein.

Mesna has been given in combination with ifosfamide in different doses and schedules. One recommended schedule uses IV bolus injection in a dosage equal to 20% of the ifosfamide dose (on a milligram-to-milligram basis) at the time of ifosfamide administration and 4 and 8 hours after each dose of ifosfamide. Mesna has also been given by continuous infusion with excellent results. The two agents may be mixed together in the same IV solution; however, Mesna is not compatible with cisplatin.

Toxic Effects: With the use of Mesna to protect against urotoxicity, myelosuppression—especially leukopenia and, to a lesser extent, thrombocytopenia—is the dose-limiting side effect. Renal tubular acidosis can occur. CNS effects, observed in approximately 10% of patients treated, include somnolence, confusion, depressive psychosis, and hallucinations. Less commonly, dizziness, disorientation, and cranial nerve dysfunction occur. Nausea and vomiting are common. Low serum albumin and elevated serum creatinine may enhance CNS toxicity. As with cyclophosphamide, such side effects as alopecia, leukemogenesis, and infertility also occur. Cardiac toxicity is rare.

Potential Drug Interactions: Because ifosfamide is also metabolized by the P450 system, physicians should remain alert for the same type of potential drug interactions that have been reported with cyclophosphamide. A recent report advises close monitoring of warfarin anticoagulant control in patients receiving ifosfamide/Mesna.

Therapeutic Indications in Hematology: Ifosfamide was recently approved for treatment of patients with refractory testicular

cancer. In hematologic malignancies, its major indication is in the treatment of refractory lymphomas.

Melphalan (Melphalan)

Chemistry: Melphalan is synthesized from nitrogen mustard and phenylalanine. It is a bifunctional chloroethylating agent that forms DNA cross-links.

Absorption, Fate, and Excretion: The oral bioavailability of melphalan is quite variable, 20%–50% of the drug being excreted in the stool. Some patients show virtually no oral absorption. This fact is particularly pertinent in the treatment of patients with myeloma, in whom a lack of response to melphalan may simply be caused by poor oral absorption. Melphalan has a half-life of approximately 90 minutes. It is extensively metabolized, with only approximately 10%–15% of an administered dose excreted unchanged in the urine.

Preparation and Administration: Melphalan is commercially available in 2-mg tablets and in IV formulation for high-dose therapy.

Toxic Effects: The dose-limiting toxicity is myelosuppression, manifested by leukopenia and thrombocytopenia, and generally occurring 2–3 weeks after therapy. Recovery may take 6 weeks, however, in patients who have been heavily pretreated with chemotherapy drugs, radiotherapy, or both. Nausea, vomiting, and alopecia are uncommon side effects and are usually mild. Occasionally, amenorrhea and azoospermia, pulmonary fibrosis, dermatitis, and secondary malignancies (e.g., leukemia) occur, especially in patients receiving the drug over the long term. At cumulative doses of less than 600 mg, the incidence of second hematologic malignancy is probably less than 2% but may be greater than 15% at higher doses. Higher doses used in transplant patients result in gastrointestinal toxicity that is dose limiting. At these doses, the syndrome of inappropriate secretion of antidiuretic hormone, pneumonitis, and hepatic venoocclusive disease have been observed.

Potential Drug Interactions: Administration of high-dose IV melphalan with cyclosporine increases the risk of cyclosporine nephrotoxicity.

Therapeutic Indications: The major use of melphalan is for the treatment of multiple myeloma (MM), either as a single agent or in combination with other alkylating agents and prednisone (e.g., the MP and VMCP regimens). The IV formulation has been approved for isolated limb perfusion in melanoma. It is used in high-dose protocols for myeloma and solid tumors at doses of 140–200 mg/m².

Chlorambucil

Chemistry: Chlorambucil is an aromatic derivative of mechlorethamine.

Absorption, Fate, and Excretion: Chlorambucil is well absorbed after oral administration. It is extensively metabolized in the liver to its major metabolite, phenylacetic acid mustard (PAAM), which also has bifunctional alkylating activity. The half-lives of chlorambucil and PAAM are 1.5 and 2.5 hours, respectively; less than 1% of either chlorambucil or PAAM is excreted in the urine.

Preparation and Administration: Chlorambucil is commercially available as 2-mg tablets.

Toxic Effects: Treatment is usually well tolerated, with myelosuppression the dose-limiting toxic effect. Patients on a daily oral schedule should have biweekly complete blood counts. Nausea and vomiting are uncommon, but mild alopecia and skin rashes occasionally occur. As with the other alkylating agents, azoospermia (especially above a cumulative dose of 400 mg), amenorrhea, and secondary

leukemia are potential risks of prolonged therapy. Rare cases of pulmonary fibrosis have also been reported.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: The major uses are in the treatment of Waldenström macroglobulinemia, low-grade lymphomas, chronic lymphocytic leukemia (CLL), and Hodgkin lymphoma. Except for CLL, chlorambucil has been supplanted by newer agents.

Busulfan (Myleran)

Chemistry: Busulfan is an alkylsulfonate bifunctional alkylating agent not chemically related to mechlorethamine. It forms DNA intrastrand and interstrand cross-links.

Absorption, Fate, and Excretion: Busulfan is well absorbed after oral administration. When given by the IV route, greater than 90% is cleared from the plasma after 3 minutes. The drug is extensively metabolized to inactive compounds that are excreted renally. The major metabolite is methane sulfonic acid, although more than 10 other not fully identified metabolites exist. Virtually no intact busulfan is found in the urine. The biologic half-life of busulfan is approximately 2.5 hours.

Preparation and Administration: The drug is commercially available as 2-mg tablets.

Toxic Effects: Although at low doses the major effect of busulfan is on the granulocytic series, at high doses all three hematologic series are affected. Compared with the other alkylating agents, its nadir of myelosuppression may be relatively late, in a range of 11–30 days. Hematologic recovery is also prolonged and may take approximately 54 days. A relatively common side effect is an Addisonian-like syndrome characterized by skin hyperpigmentation and weakness but without abnormalities in adrenal function. Cumulative pulmonary toxicity has been well described and consists of a mixed alveolar and interstitial pneumonitis. As with the other alkylating agents, infertility and leukemogenesis can occur. Nausea and vomiting are rare. At high doses, it is associated with hepatic venoocclusive disease in up to 19% of patients. Seizures may also occur and are controlled by diphenylhydantoin.

Potential Drug Interactions: A metabolic interaction may take place between busulfan and various anticonvulsant medications; however, further description of the specific effects is awaited.

Therapeutic Indications in Hematology: Busulfan is used mainly in the treatment of chronic myeloid leukemia. More recently, high-dose busulfan has been incorporated into preparatory regimens for bone marrow transplantation. Blood level monitoring with adjustment for higher dose levels improved therapeutic outcome and reduced toxicity.

Carmustine (BCNU)

Chemistry: Carmustine, also called BCNU (1,3[bis]-2-chloroethyl-nitrosourea), decomposes spontaneously into a chloroethyl hydroxide that can alkylate the DNA and into an isocyanide molecule, which may produce carbamylation of proteins. Cytotoxicity is caused by DNA cross-links.

Absorption, Fate, and Excretion: IV-administered carmustine is rapidly metabolized, with a half-life of 70 minutes. Approximately 30%–80% of metabolites are eliminated in the urine within 24 hours. The drug, its metabolites, or both readily cross the blood–brain barrier, resulting in cerebrospinal fluid concentrations within the range of 15%–70% of plasma levels. Peak serum levels vary widely in patients treated at 200–600 mg IMF.

Preparation and Administration: Carmustine is commercially available in 100-mg vials as a white lyophilized powder. The drug is reconstituted with 3 mL of absolute alcohol provided by the manufacturer and 27 mL of sterile water, and can be further diluted with normal saline or 5% dextrose in water. It should be used immediately after reconstitution and can be infused over 1–2 hours.

Carmustine is chemically stable for 3 hours at room temperature and for 24 hours when refrigerated.

Toxic Effects: Myelosuppression is the dose-limiting toxic effect and tends to increase with successive cycles of therapy. Leukopenia and thrombocytopenia are characteristically delayed and reach their maximum between the third and sixth weeks after drug administration. Nausea and vomiting can be severe. Abnormal liver function test results may be found, but the abnormalities are usually mild and reversible. Two rare but serious toxic effects include cumulative pulmonary or interstitial pneumonitis progressing to fibrosis and progressive renal damage, which are dose related. Secondary leukemias can also occur 5–10 years after treatment. Patients who receive greater than 1100 mg/m² are at increased risk of pulmonary fibrosis. Carmustine is not a vesicant, but rapid infusion often produces a burning sensation at the injection site.

Potential Drug Interactions: Cimetidine may enhance the myelosuppressive effect of carmustine. Carmustine may decrease the pharmacologic effects of phenytoin. In rats with intracerebrally implanted tumors, pretreatment with phenobarbital eliminated the antitumor activity of carmustine. The reduction in carmustine antitumor activity correlated with increased carmustine metabolism, which is apparently the result of hepatic microsomal enzyme induction.

Therapeutic Indications in Hematology: Carmustine in combination with other cytotoxic agents may be used in the initial treatment of Hodgkin lymphoma (BCVPP regimen) and multiple myeloma (VBAP regimen). In high-dose therapy, it appears in BEP for relapsed lymphomas.

Lomustine (CCNU)

Chemistry: Lomustine, also called CCNU, is a nitrosourea derivative with chloroethyl and cyclohexyl side chains.

Absorption, Fate, and Excretion: The drug is rapidly absorbed from the gastrointestinal tract and is rapidly and completely metabolized. Its active metabolites have prolonged plasma half-lives, within a range of 16–48 hours. Approximately 50% of an administered dose is detectable (as metabolites) in the urine within 24 hours, and 75% is detectable within 4 days. Active metabolites cross the blood–brain barrier and can be detected in significant concentrations in the cerebrospinal fluid.

Preparation and Administration: The drug is commercially available in 10-, 40-, and 100-mg capsules.

Toxic Effects: The toxicity profile of lomustine is similar to that of carmustine. Because lomustine can produce vomiting and the drug is given orally, special attention should be directed to emesis control. If the patient vomits soon after ingestion, the vomitus should be inspected for the presence of intact capsules. The drug should be given again if capsules are identified with certainty. Secondary leukemias are reported 3–10 years after use.

Potential Drug Interactions: These are similar to those of carmustine.

Therapeutic Indications in Hematology: Lomustine is occasionally used as second-line treatment for patients with Hodgkin lymphoma and NHL and for childhood gliomas.

Streptozocin (Zanosar)

Chemistry: Streptozocin is a naturally occurring nitrosourea derived from *Streptomyces acromogenes*. The drug is a glucosamine-1-methyl-nitrosourea, which, unlike the other nitrosoureas, methylates DNA and is cytotoxic owing to induced mismatch repair.

Absorption, Fate, and Excretion: After IV administration, the drug is rapidly metabolized, with no intact drug detectable in the plasma after 3 hours. Its half-life is 40 hours. Within the first 24 hours after administration, approximately 10% of the parent compound is excreted in the urine.

Preparation and Administration: The drug is commercially available in 1-g vials and is reconstituted with either 9.5 mL of normal saline or 5% dextrose in water for injection to form a 100-mg/mL solution. IV infusion of the drug over 30–45 minutes usually prevents discomfort at the injection site. Patients should be kept well hydrated to preclude renal tubular toxicity.

Toxic Effects: Although nausea and vomiting have been considered by some investigators to be the limiting toxic effects, in most phase I trials nephrotoxicity was the principal dose-limiting effect. Nausea and vomiting are severe and require aggressive antiemetic support. Streptozocin may also aggravate duodenal ulcers. Renal toxicity frequently occurs and includes mild proteinuria, glycosuria, hypophosphatemia, renal tubular acidosis, and occasionally irreversible azotemia. Although the myelosuppressive effect of streptozocin is mild, it can potentiate the bone marrow suppression of other cytotoxic drugs. Slight increases in hepatic enzymes can also occur. Occasionally, patients (primarily those with insulinomas) may experience transient alterations in glucose metabolism.

Potential Drug Interactions: Streptozocin can potentiate the hyperglycemic effect of glucocorticosteroids. Phenytoin therapy decreases the cytotoxic effect of streptozocin on the pancreatic β -cells, leading to potential interference with its therapeutic effect in patients with pancreatic islet cell tumors. Streptozocin is a potent renal toxin, and every effort should be made to avoid concomitant administration of other nephrotoxins.

Therapeutic Indications in Hematology: Streptozocin has been used in the initial treatment of Hodgkin lymphoma and, less commonly, in NHLs.

Dacarbazine

Chemistry: Dacarbazine is also called DTIC [5-(3,3-dimethyl-1-triazeno)imidazole-4-carboxamide]. After undergoing metabolic activation by microsomal enzymes in the liver, it acts primarily as an alkylating agent.

Absorption, Fate, and Excretion: After IV administration, the drug is extensively metabolized. Activated DTIC has an elimination half-life of 5–7 hours. Approximately 40%–50% of the parent drug is found in the urine within the first 24 hours after administration.

Preparation and Administration: DTIC is commercially available in 100- and 200-mg vials, which must be protected from light and stored at a temperature of 2–8°C. The drug is reconstituted with normal saline or sterile water to produce a 10-mg/mL solution. It can be administered as a slow IV push or by infusion over 15–30 minutes.

Toxic Effects: Myelosuppression, primarily represented by leukopenia, is the dose-limiting toxic effect. Use of the drug leads to considerable problems with emesis and requires aggressive antiemetic support. A flulike syndrome consisting of fever, malaise, and myalgias may occur. Direct sunlight during the first 2 days after drug administration may result in facial flushing, facial paresthesias, and light-headedness. Hepatotoxicity and diarrhea have also been reported.

Pain along the injection site can occur if the drug is rapidly infused but can usually be lessened by prolonging the infusion rate. Secondary leukemias are reported between 3 and 10 years after use.

Potential Drug Interactions: DTIC activation may be enhanced by phenytoin or phenobarbital, although the clinical significance of this potential interaction remains uncertain. There may be a potential (as yet poorly characterized) drug interaction with levodopa, whereby the response to levodopa is diminished.

Therapeutic Indications in Hematology: DTIC is used primarily in the treatment of Hodgkin lymphoma as part of the ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, and DTIC) regimen and for melanoma.

Procarbazine

Chemistry and Mechanism of Action: Procarbazine is a substituted hydrazine derivative with a chemical structure similar to that of the monoamine oxidase inhibitors (MAOIs). Accordingly, procarbazine exhibits weak MAOI effects. Procarbazine itself is inert and must undergo metabolic activation to generate cytotoxic reactants, the mode of action of which is not clear. They may inhibit transmethylation of methyl groups of methionine into tRNA or may also directly damage DNA. Hydrogen peroxide, formed during the autooxidation of procarbazine, may attack protein sulfhydryl groups contained in residual proteins tightly bound to DNA.

Absorption, Fate, and Excretion: Procarbazine is rapidly and completely absorbed by the oral route, with peak plasma levels occurring within 60 minutes. It penetrates well into the cerebrospinal fluid. The drug is readily metabolized in the liver and has a plasma half-life of 10 minutes after IV injection. The major sites of elimination are the kidneys, where approximately 70% of the drug is excreted as *N*-isopropylterephthalamic acid and less than 5% is excreted unchanged.

Preparation and Administration: Procarbazine is commercially available as 50-mg capsules.

Toxic Effects: The usual dose-limiting toxic effect is myelosuppression. Occasionally, nausea and vomiting may be dose limiting, although tolerance to those effects may develop during continued administration. Other less common side effects include paresthesias, headache, dizziness, depression, apprehension, insomnia, nightmares, hallucinations, drowsiness, ataxia, foot drop, decreased reflexes, tremors, coma, confusion, convulsions, skin rash, alopecia, myalgia, and arthralgia. Procarbazine may possibly be leukemogenic.

Potential Drug Interactions: Combination chemotherapy that includes procarbazine may result in a decrease in digoxin plasma levels. Because procarbazine is a weak MAOI, hypertensive reactions could theoretically occur after concurrent ingestion of sympathomimetics, levodopa, tricyclic antidepressants, or foods with high tyramine content (e.g., dark beer, yogurt, cheeses, and red wines). However, such reactions have not been reported. Concomitant use of narcotics or other strong sedatives may result in exaggerated depressant effects, leading to coma and possibly death. Procarbazine also interacts with alcohol, causing a disulfiram-like reaction.

Therapeutic Indications in Hematology: Procarbazine is often used in combination with other cytotoxic agents in the treatment of Hodgkin lymphoma (MOPP and MOPP derivatives) and to a lesser extent in the treatment of NHL (PROMACE-MOPP).

Temozolomide

Chemistry and Mechanism of Action: Temozolomide is not active but undergoes rapid nonenzymatic conversion at physiologic pH to the reactive compound monomethyl 5-triazino imidazole

carboxamide (MTIC), which is also the active methyl group-donating metabolite of DTIC. Unlike DTIC, formation of MTIC from temozolomide does not require metabolic activation (liver); thus there is much more consistent conversion from temozolomide to the methyl-donating MTIC. The cytotoxicity of MTIC is thought to be primarily caused by alkylation of DNA. Alkylation (methylation) occurs mainly at the O⁶ and N⁷ positions of guanine. Cytotoxicity results from processing of these lesions by methylguanine methyl-transferase, mismatch repair, and base excision repair.

Absorption, Fate, and Excretion: Temozolomide is rapidly and completely absorbed after oral administration; peak plasma concentrations occur in 1 hour. Food reduces the rate and extent of temozolomide absorption.

Temozolomide exhibits a mean elimination half-life of 1.8 hours and exhibits linear kinetics over the therapeutic dosing range. Temozolomide is spontaneously hydrolyzed at physiologic pH to the active species, MTIC and to temozolomide acid metabolite. MTIC is further hydrolyzed to 5-amino-imidazole-4-carboxamide (AIC), which is known to be an intermediate in purine and nucleic acid biosynthesis and to methylhydrazine, which is believed to be the active alkylating species. Approximately 38% of the administered temozolomide total radioactive dose is recovered over 7 days; 37.7% in urine and 0.8% in feces. The majority of the recovery of radioactivity in urine is as unchanged temozolomide (5.6%), AIC (12%), temozolomide acid metabolite (2.3%), and unidentified polar metabolite(s) (17%). Overall clearance of temozolomide is approximately 5.5 L/hour/m².

Preparation and Administration: Temozolomide is given orally with each capsule containing either 5, 20, 100, 140, 180, or 250 mg of temozolomide. The inactive ingredients for TEMODAR capsules are lactose anhydrous, colloidal silicon dioxide, sodium starch glycolate, tartaric acid, and stearic acid.

Toxic Effects: Bone marrow depression, including neutropenia, lymphopenia, anemia, and thrombocytopenia, occurs frequently with temozolomide. Mild transaminase elevations of up to 40% of patients and hyperbilirubinemia of up to 19% are seen. Mild-to-moderate headache is among the most commonly reported adverse effects along with moderate nausea and vomiting, although these may be secondary to the use of antiemetics.

Drug Interactions: None described.

Therapeutic Indications in Hematology: Temozolomide may have some activity in both acute myeloid leukemia (AML) and acute lymphocytic leukemia (ALL), but the correct dose is presently unknown. Temozolomide has no activity in NHL.

Bendamustine

Chemistry and Mechanism of Action: Bendamustine is a bifunctional alkylating agent (mechlorethamine analogue). Its structure is characterized by a nitrogen mustard group linked to a benzimidazole nucleus, which forms covalent bonds with electron-rich nucleophilic moieties, resulting in interstrand DNA cross-links. Bendamustine is active against both quiescent and dividing cells.

Absorption, Fate, and Excretion: Although absorbed well orally, bendamustine is only administered intravenously. It is highly protein bound, averaging approximately 95%. The half-life of bendamustine is approximately 40 minutes. Bendamustine is primarily metabolized in the liver via hydrolysis, and little is excreted in urine unchanged, but the pharmacokinetics in patients with significant renal failure are unknown.

Preparation and Administration: Bendamustine is available for IV use in single-use vials containing either 25 mg or 100 mg of bendamustine HCl. Sterile water for injection is added to each vial to obtain a 5-mg/mL solution. The lyophilized powder should completely dissolve in 5 minutes. After being diluted with either 0.9% sodium chloride injection, US Pharmacopeia (USP), or 2.5% dextrose/0.45% sodium chloride injection, USP, the final admixture is stable for 24 hours when stored refrigerated or for 3 hours when stored at room temperature.

Toxic Effects: Bendamustine frequently causes anemia, severe neutropenia, and thrombocytopenia. Infusion reactions presenting as fever, chills, pruritus, and rash have been seen. Antihistamines, antipyretics, and corticosteroids have been effective in preventing these reactions. Tumor lysis syndrome has been seen with the first dose of bendamustine, so appropriate precautions should be taken. Local reactions are seen with extravasation, and care should be taken when administering the drug in a peripheral site. Headache, nausea, and vomiting, as well as skin reactions including rash, toxic skin reactions, and bullous exanthema, have occurred with bendamustine. AML has been reported in patients after use of bendamustine HCl.

Drug Interactions: Although their clinical significance is unknown, ciprofloxacin, fluvoxamine, and omeprazole may increase bendamustine levels and decrease levels of active minor metabolites.

Therapeutic Indications in Hematology: Bendamustine has been effective in treating chronic lymphoid leukemia, MM, Hodgkin lymphoma, NHL, and indolent B-cell lymphomas.

APPENDIX

57.2

CLINICAL PHARMACOLOGY OF ANTIMICROTUBULE AGENTS

Vincristine (Oncovin) and Vinblastine (Velban)

Chemistry and Mechanism of Action: Both vincristine and vinblastine are asymmetric dimeric compounds that bind to the protein tubulin at a site distinct from that for the taxanes. At low concentrations vincristine and vinblastine inhibit microtubule dynamics. At higher concentrations they disrupt microtubules that constitute the mitotic spindle, resulting in metaphase arrest. They are relatively M-phase specific. Owing to their lipophilicity, vinca alkaloids are rapidly taken into cells and achieve several-hundred-fold higher intracellular than extracellular concentrations. Whereas overexpression of the multidrug resistance transporters P-glycoprotein (PGP) or multidrug resistance protein can reduce the intracellular accumulation, alterations in the α - or β -tubulins can affect drug-target interaction for vinca alkaloids.

Absorption, Fate, and Excretion: After IV injection, both drugs are rapidly distributed to the body tissues, especially the red blood cells and platelets. Their elimination follows a triphasic pattern. The elimination half-lives are as follows α , less than 5 minutes; β , 50–155 minutes; and γ , 20–85 hours. Both vinca alkaloids are primarily eliminated through the liver into the bile and feces, making patients with obstructive liver disease more susceptible to toxic effects. A 50% reduction in the dose is recommended for serum bilirubin concentrations of 1.5–3.5 mg/dL. Dose modification for renal dysfunction is not indicated. After brief IV bolus administration, peak plasma vincristine concentrations of 100–400 nM are achieved, which decline to less than 10 nM in 2–4 hours. Continuous infusion doses of 1.0 mg/m²/day produce vincristine plasma concentrations ranging from 1 to 10 nM.

Preparation and Administration: Vincristine is commercially available in 1-, 2-, and 5-mg vials. Each milliliter contains 1 mg of vincristine sulfate, 100 mg of mannitol, 1.3 mg of methylparaben, and 0.2 mg of propylparaben. Vincristine is a powerful vesicant that should be administered only IV into a freely running infusion of normal saline or dextrose solution. If the drug is given by continuous infusion, it must be infused through a central IV line. In case of extravasation, infusion should be discontinued and any residual drug aspirated through the line. The manufacturer also recommends infiltrating the area with 1–2 mL of hyaluronidase, 150 U/mL, and then applying warm compresses for 72 hours to facilitate dispersion of the drug. Vinblastine is commercially available as a lyophilized powder and a 1-mg/mL solution in 10-mg vials. The lyophilized drug is reconstituted by adding sodium chloride for injection (which may be preserved with either phenol or benzyl alcohol) to the 10-mg vial. Administration of vinblastine should follow the same guidelines described for vincristine.

Toxic Effects: Vincristine's dose-limiting toxic effect is neurotoxicity, which appears to be related to its relative polarity. Peripheral neurotoxicity usually manifests as sensory impairment, decreased deep-tendon reflexes, and paresthesias. Less commonly, severe painful dysesthesias, ataxia, foot drop, and cranial nerve palsy (e.g., affecting the extraocular and laryngeal muscles) can occur. Autonomic neurotoxicities include constipation, abdominal cramps, and ileus, which may be prevented by use of mild laxatives. Alopecia occurs frequently, but myelosuppressive effects are minimal. Rare side effects include inappropriate secretion of antidiuretic hormone and ischemic cardiac toxicity. Vinblastine's dose-limiting toxic effect is myelosuppression,

with leukopenia more pronounced than thrombocytopenia. Anemia is uncommon. Neurotoxicity can also occur but is significantly less common than with vincristine. Vinblastine is also a vesicant.

Potential Drug Interactions: Both vinca alkaloids have been reported to increase the accumulation of methotrexate and etoposide in tumor cells. Acute shortness of breath and bronchospasm can occur when vincristine or vinblastine is given in conjunction with mitomycin C. Because asparaginase may impair the hepatic clearance of vincristine, it is preferable to administer the vincristine 12–24 hours before L-asparaginase. Vincristine may decrease the absorption and plasma levels of orally administered drugs such as digoxin. Dilantin may increase the cytotoxicity of vincristine in multidrug-resistant tumor cells; however, this remains to be demonstrated in the clinic. When concurrently administered, erythromycin may increase the toxicity of vinca alkaloids, especially vinblastine.

Therapeutic Indications in Hematology: The vinca alkaloids are among the most important drugs in the treatment of hematologic malignancies. They have a broad spectrum of activity and are often incorporated into many chemotherapy regimens used in the treatment of ALL, Hodgkin lymphoma, NHL, CLL, and MM.

Vinorelbine (Navelbine)

Chemistry and Mechanism of Action: Vinorelbine is a semi-synthetic derivative of vinblastine (5'-nor-hydrovinblastine) with an eight-member catharanthine ring. Similar to other vinca alkaloids, it also binds to tubulin, inhibits microtubule assembly, and produces a mitotic arrest of cells. These occur at concentrations that relatively spare axonal microtubules, which may reduce neurotoxicity.

Absorption, Fate, and Excretion: Short (6–10 minutes) IV infusions of 30 mg/m² produce peak plasma concentrations approximately 1.0 μ g/mL with a triphase decay. Rapid α (<5 minutes) and β (49–168 minutes) half-lives result in a rapid decline in the plasma concentration in the first hour posttreatment followed by a prolonged terminal half-life of 18–49 hours, reflecting slow efflux from the peripheral compartment. The volume of distribution at steady state is 20–75.6 L/kg. The drug is extensively bound to platelets, lymphocytes, and plasma proteins. The major site of metabolism is the liver, with 33%–80% of the drug excretion in feces and approximately 20% in urine.

Preparation and Administration: Vinorelbine is available for injection in single use as 10 mg/mL in 1- or 5-mL vials without preservatives. The calculated dose is diluted to 1.5–3.5 mg/mL for a slow injection (6–10 minutes) by a syringe with 5% dextrose or 0.9% saline, or between 0.5 or 2.0 mg/mL in an IV bag. Because vinorelbine is a strong vesicant, it should be administered through a freely flowing IV access avoiding all extravasation.

Toxic Effects: Vinorelbine shares many of the principal toxicities of vinblastine. Myelosuppression is dose limiting but not cumulative, with nadirs occurring 7–10 days after administration.

Anemia and thrombocytopenia occur infrequently. Because of lower affinity for axonal versus spindle microtubules, neurotoxicity is less prominent with vinorelbine. Mild-to-moderate peripheral neuropathy and constipation occur in approximately 30% of patients, and the incidence of neuropathy increases with the duration of

treatment. Mild-to-moderate nausea and vomiting is seen in 33% of patients. Stomatitis and diarrhea are less frequent. Transient elevations of transaminases have been reported. Among the miscellaneous side effects noted are chest pain with or without electrocardiographic changes (6%, most with underlying cardiac disease), as well as bronchospasm and dyspnea (5%). Alopecia is seen in 10% of patients.

Therapeutic Indications in Hematology: Objective responses have been observed in approximately 33% of patients with Hodgkin lymphoma or NHL.

Paclitaxel (Taxol) and Docetaxel (Taxotere)

Chemistry and Mechanism of Action: Both paclitaxel and docetaxel are complex diterpene alkaloid esters consisting of a taxane system linked to an oxetane ring and a C-13 side chain that is necessary for their cytotoxic effects in mammalian cells. After binding to the N-terminal 31 amino acids of the β -tubulin subunit in the tubulin oligomers or polymers, these taxanes kinetically stabilize microtubule dynamics at plus ends. They also decrease the lag time and shift the equilibrium toward tubulin polymerization into microtubule bundles. The disequilibrium of tubulin–microtubule polymerization results in mitotic arrest and apoptosis of cells. Taxane-induced mitotic arrest is associated with phosphorylation of B-cell lymphoma (BCL2) protein and increased intracellular levels of free BAX protein, which promote apoptosis. Compared with paclitaxel, docetaxel demonstrates 1.9-fold greater affinity for tubulin binding sites and greater potency in mediating BCL2 phosphorylation.

Absorption, Fate, and Excretion: Taxanes generally are administered by IV infusion lasting over 3, 24, or 96 hours (paclitaxel) or 1 hour (docetaxel). Depending on the dose and schedule, peak plasma concentrations of paclitaxel range between 0.05 and 15.0 mM. Its steady-state volume of distribution ranges between 48 and 182 L/m², with rapid uptake in almost all tissues except the CNS and 98% plasma protein binding. Plasma decay for paclitaxel is biphasic, with α and β half-lives of 0.34 and 5.8 hours, respectively. Saturable distribution and elimination appear to be responsible for paclitaxel's nonlinear pharmacokinetics. This means that paclitaxel dose escalation in shorter schedules may result in disproportionate increases in area under the concentration–time curve and peak plasma concentration. It is metabolized to 6-hydroxy paclitaxel by the CYP3A isoform of the PU₅₀ mixed-function oxidases in the hepatic microsomes. Total fecal and urinary excretion of paclitaxel and its metabolites is approximately 70% and 10%, respectively. Although dose modification is not necessary for renal insufficiency, a 50% reduction in dose is recommended even for moderate hyperbilirubinemia or significant elevations in hepatocellular enzymes. When administered as a 1-hour IV infusion, docetaxel has linear pharmacokinetics that fit a three-compartment model. Similar to paclitaxel, docetaxel also has a high clearance rate (0.36 L/hour), a steady-state volume of distribution (67.3 L/m²), and a terminal half-life of 12 hours. Docetaxel also has high protein binding (97%) and extensive tissue distribution. The drug or its metabolites also have high fecal (80%) and low urinary elimination (5%). Metabolism of docetaxel also primarily occurs in hepatic microsomal P450 mixed-function oxidases, CYP3A, CYP2B, and CYP1A.

Preparation and Administration: Paclitaxel is available as a 30-mg/5 mL single-dose vial in polyoxyethylated castor oil (Cremophor EL) 50% and dehydrated alcohol, USP 50%. The contents of the vial must be diluted before use. Docetaxel for injection is available as a concentrate in polysorbate 80 in two vial contents (23.6 mg/0.59 mL or 94.4 mg/2.36 mL) along with the appropriate diluent (1.83 or 7.33 mL) in separate vials. Adding diluent that is 13% (w/w) ethanol in water for injection to the concentrate produces a final premix concentration of 10 mg docetaxel/mL. The required amount of premix is transferred by a calibrated syringe into 0.9% saline or 5% dextrose to produce a final concentration of 0.3 or 0.9 mg/mL. The IV infusion is administered over 1 hour.

Toxic Effects: Hypersensitivity reaction (HSR) was noted in up to 30% of patients in the early phase I studies. HSR occurs early in the first or second infusion and may be caused by vehicle Cremophor EL or paclitaxel itself. HSR consists of dyspnea, bronchospasm, urticaria, and hypotension. Most HSRs regress completely after stopping the infusion and treatment with antihistamines, fluids, and vasopressors. Prolonged infusions (>3 hours) and premedication (dexamethasone 20 mg PO, 12 and 6 hours before treatment, diphenhydramine 50 mg, and ranitidine 150 mg IV 30 minutes before treatment) have reduced the incidence of major HSRs to less than 3%. Patients with a history of HSR may be rechallenged with paclitaxel at a markedly slower infusion rate, 20 mg dexamethasone IV every 6 hours for four doses before treatment. Although not formulated in Cremophor EL, HSRs can occur in up to 25% of patients receiving docetaxel. Most HSRs are minor, consisting of flushing, chest tightness, and low back pain. Premedication with dexamethasone 8 mg PO twice daily for 3 days starting 1 day before treatment with docetaxel considerably reduces the incidence of HSRs and fluid retention. Neutropenia is the main toxicity of paclitaxel and docetaxel, but it is not cumulative. With higher doses of paclitaxel (250 mg/m² over 24 hours), this can be ameliorated with subsequent administration of granulocyte colony-stimulating factor. Severe thrombocytopenia and anemia are rare. Symmetric, distal, peripheral sensory neuropathy is usually seen with higher doses or multiple doses of paclitaxel. This often limits chronic use of paclitaxel. Diffuse areflexia and neuronopathy are less commonly seen. Higher doses can also cause motor and autonomic neuropathy as well as myalgias, especially in patients with preexisting neuropathy or when paclitaxel is used with cisplatin. Severe peripheral neuropathy or myalgias are less common after repetitive docetaxel at 100 mg/m². Cardiac rhythm abnormalities, especially bradyarrhythmias and (rarely) heart blocks, have been reported secondary to paclitaxel treatment. A direct causal link between paclitaxel and myocardial ischemic episodes and tachyarrhythmias has not been established. Although noted, a direct link has also not been established between the occurrence of cardiac conductance abnormalities or ischemia and docetaxel treatment. Nausea, vomiting, diarrhea, and stomatitis are uncommon and generally mild to moderate. Alopecia is universal with both drugs. Skin toxicity is more severe and common with docetaxel. It is characterized by an erythematous pruritic maculopapular rash affecting the forearms and hands. Onychodystrophy with discoloration, ridging, and brittleness of fingernails also occurs. Docetaxel can cause cumulative fluid retention, resulting in peripheral edema, third-space fluid collection, and weight gain, which usually resolves slowly after stopping docetaxel. Concurrent treatment with dexamethasone, as noted earlier, delays the onset and decreases the incidence of these side effects.

Potential Drug Interaction: When paclitaxel infusion (24 hours) is administered after cisplatin, there is a 33% reduction in the clearance rate of paclitaxel. This produces suboptimal antitumor cytotoxicity and more profound neutropenia. Hence, the sequence of paclitaxel followed by cisplatin is commonly recommended. The use of carboplatin after paclitaxel has been reported to cause less thrombocytopenia than carboplatin alone. Mucositis is more pronounced when paclitaxel is used before doxorubicin, a sequence that reduces the clearance of doxorubicin. Hematologic toxicity is more prominent with the sequence of cyclophosphamide followed by paclitaxel compared with the reverse sequence of administration. Anticonvulsants such as phenytoin and phenobarbital induce the metabolism of paclitaxel and docetaxel by the P450 mixed-function oxidases. Conversely, *in vitro* studies have shown that inhibitors of the P450 system can interfere with the metabolism of both drugs. These inhibitors include erythromycin, testosterone, ketoconazole, and fluconazole.

Therapeutic Indications in Hematology: Both paclitaxel and docetaxel have significant activity against previously treated patients with NHL. Paclitaxel is also very active against HIV-associated Kaposi sarcoma.

APPENDIX

57.3

CLINICAL PHARMACOLOGY OF ANTIMETABOLITES

Cytosine Arabinoside

Chemistry and Mechanism of Action: Cytosine arabinoside (1'- β -D-arabinofuranosylcytosine; ara-C) is a nucleoside analog that differs from its naturally occurring counterpart (2'-deoxycytidine) by virtue of the presence of a hydroxyl group in the 2'- β configuration. The altered reactivity of the resulting arabinosyl sugar moiety confers on ara-C its cytotoxic activity. Ara-C enters the cell by a facilitated nucleoside diffusion mechanism and is converted to its nucleoside monophosphate form, ara-CMP, by the pyrimidine salvage pathway enzyme, deoxycytidine kinase. This represents the rate-limiting step in ara-C metabolism. Ara-C may also be catabolized intracellularly to an inactive form, ara-U, by the enzyme cytidine deaminase (CDD). Ara-C is ultimately converted to its lethal triphosphate derivative, ara-CTP, by a mono- and diphosphate kinase. Ara-CTP is an inhibitor of DNA polymerases α , β , and γ , and is also incorporated into replicating DNA strands, leading to inhibition of chain initiation and elongation and premature chain termination. The extent of incorporation of ara-C into DNA closely correlates with lethality in leukemic cells. Although ara-C is generally thought of as a prototypical S-phase-specific agent, its ability to interfere with DNA repair polymerases (e.g., β and γ) as well as lipid biosynthetic enzymes may account for lethal effects in noncycling cells.

Absorption, Fate, and Excretion: After IV administration, ara-C is rapidly deaminated to an inactive form, ara-U, by CDD. This enzyme is present in the plasma, liver, and kidney but is present at very low levels in the CNS. The initial plasma half-life of ara-C has been estimated to be 10–12 minutes. Approximately 90% of the administered ara-C dose is excreted by the kidneys as ara-U or other inactive metabolites. The terminal half-life of ara-C is approximately 2–3 hours. CNS ara-C levels after a 2-hour infusion approximate 50% of plasma concentrations. Steady-state plasma concentrations after standard-dose therapy (e.g., 100–200 mg/m²/day as a continuous infusion) approximate between 10⁻⁷ and 10⁻⁶ M. When ara-C is given as a high-dose bolus infusion (e.g., 1–3 g/m² over 1–3 hours), plasma levels as high as 100 μ M can be achieved.

Preparation and Administration: Ara-C is provided as a sterile, lyophilized powder for reconstitution in vials containing 100 mg, 200 mg, 1 g, or 2 g of material. The powder is reconstituted with sterile bacteriostatic water for injection with benzyl alcohol (0.945%) added as a preservative. When reconstituted in this way, solutions are stable for up to 48 hours under controlled temperatures (e.g., between 15°C and 30°C or 60°F and 86°F). Material reconstituted without preservative should be used immediately. For intrathecal injection, ara-C should be reconstituted in a diluent that does not contain preservative (e.g., preservative-free 0.9% sodium chloride, USP) and used immediately.

Toxic Effects: Ara-C is primarily toxic to rapidly dividing tissues; consequently, myelosuppression and gastrointestinal toxicity represent the major side effects of this agent. Patients receiving ara-C regularly experience leukopenia, anemia, and thrombocytopenia, with nadirs appearing 7–14 days after drug administration. Gastrointestinal toxicity includes nausea and vomiting, abdominal pain, mucositis, and a chemical hepatitis characterized by elevation of liver function enzymes. The latter is generally reversible. Patients receiving ara-C as a high-dose infusion (e.g., 1–3 g/m² repeated every 12 hours for a total of 6–12 doses) experience standard toxicities and several unique

ones. These include alopecia, an exfoliative dermatitis, a chemical conjunctivitis (generally ameliorated by the prophylactic administration of a steroid or saline ophthalmic solution), a respiratory distress-like syndrome (characterized by the appearance of rales, abnormal radiography findings, and pulmonary insufficiency), and cerebellar toxicity. The latter, which is characterized by nystagmus, ataxia, and other cerebellar signs, may be irreversible, and its appearance mandates discontinuation of therapy. Intrathecal administration of ara-C has been rarely associated with the toxicities described later for methotrexate.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: Ara-C represents a mainstay in the treatment of AML (e.g., as part of the “7 and 3” regimen, in which it is given in conjunction with daunorubicin). It is also incorporated into some induction regimens for ALL. High-dose ara-C (HIDAC), either alone or in combination with anthracycline antibiotics, is frequently used in the treatment of refractory or relapsed AML or ALL. High-dose ara-C has also been used in some salvage regimens for NHL (e.g., ESHAP). Chronic low-dose ara-C has been used in the treatment of patients with myelodysplastic syndrome (MDS).

Methotrexate

Chemistry and Mechanism of Action: Methotrexate (*N*-[4-[(2,4-diamino-6-pteridinyl)methyl]methylamino]benzoyl]-L-glutamic acid) represents a member of a class of compounds referred to as *antifolates*. Methotrexate is a potent inhibitor of dihydrofolate reductase, an enzyme responsible for the reduction of dihydrofolates to tetrahydrofolates. The latter are required in 1-carbon transfer reactions involved in de novo purine and pyrimidine biosynthesis, including conversion of deoxyuridylate (dUMP) to thymidylate (dTMP) by thymidylate synthase. As in the case of most antimetabolites, methotrexate is primarily active against S-phase cells. Methotrexate is transported across cell membranes by an energy-dependent, temperature-sensitive concentrative process involving folate-binding proteins, after which it is polyglutamylated by the enzyme folylpolyglutamyl synthetase. Polyglutamylation of methotrexate enhances its intracellular retention and in some studies has been shown to correlate with the sensitivity of leukemic cells to this agent. The mechanism by which methotrexate kills cells may stem from interference with DNA synthesis (leading to a “thymine-less death”) secondary to DHFR inhibition, disruption of purine biosynthesis, or a combination of these actions. The lethal actions of methotrexate may be reversed by reduced folates such as 5-formyltetrahydrofolate (leucovorin). The possibility that tumor cells may exhibit impaired transport of such reduced folates serves as the basis for strategies involving administration of high-dose methotrexate in conjunction with leucovorin rescue.

Absorption, Fate, and Excretion: In adults, oral absorption is dose dependent, with mean bioavailability approximating 60% at doses of 30 mg/m² or less. At higher doses (e.g., ≥ 80 mg/m²), bioavailability is less. Peak plasma concentrations occur 1–2 hours after oral administration. Methotrexate bioavailability approximates 100% for parenteral routes of administration; with these routes, peak plasma methotrexate levels are achieved within 30–60 minutes after administration. For each route, the steady-state volume of

distribution ranges from 40% to 80% of body weight. Methotrexate tends to accumulate in third-space fluids (e.g., ascites or pleural effusions) and can result in prolonged release and accompanying toxicity. Consequently, it is generally not advisable for patients with fluid accumulations to receive methotrexate. Methotrexate competes with reduced folates for transport across cell membranes; however, at high doses (e.g., $\geq 100 \text{ mg/m}^2$), passive diffusion is the primary mechanism through which intracellular accumulation occurs. Methotrexate is approximately 50% protein bound and does not penetrate the CNS barrier when administered orally or parenterally at conventional doses. However, when given by the intrathecal route, high CNS levels are achieved. Administration of high-dose methotrexate with leucovorin rescue can also result in therapeutic CNS levels.

The primary route of excretion is renal, with 80%–90% of the drug appearing unchanged in the urine within 24 hours after IV administration. The terminal half-life of methotrexate is 4–10 hours for patients receiving low-dose therapy and 8–15 hours for those receiving high-dose therapy. Because of the primary renal rate of excretion and the possibility of nephrotoxicity, methotrexate should be withheld or administered at reduced doses in patients with impaired renal function. Patients receiving high-dose methotrexate therapy should be hydrated and their urine alkalinized before administration to reduce the risks of toxicity.

Preparation and Administration: Methotrexate is available in multiple formulations: (1) tablets, containing 2.5 mg methotrexate and inactive ingredients (lactose, magnesium stearate, and pregelatinized starch); (2) methotrexate sodium injection, available in vials of 25, 50, and 250 mg, containing benzyl alcohol as a preservative, sodium chloride, and water for injection (preservative-containing solutions should not be used for intrathecal or high-dose administration); (3) methotrexate sodium injection without preservative, which can be used for IV, intraarterial, intrathecal, and high-dose administration; and (4) lyophilized powder, which is provided in 20-mg vials and is reconstituted with preservative-free sodium chloride or 5% dextrose in water to a final concentration not exceeding 25 mg/mL.

For intrathecal administration, solutions of 1–1.5 mg/mL should be prepared using preservative-free 0.9% sodium chloride as the diluent. For high-dose therapy, leucovorin rescue is required to prevent significant toxicity. Leucovorin is administered 12–24 hours after methotrexate at a dose of between 15 and 25 mg IV, intramuscularly (IM), or PO every 6 hours until the methotrexate dose declines to levels of less than $5 \times 10^{-7} \text{ M}$.

For patients receiving intermediate or high-dose methotrexate (e.g., $\geq 500 \text{ mg/m}^2$), serum methotrexate and creatinine levels should be monitored at 24-hour intervals. If, after 48 hours serum methotrexate levels are greater than $5 \times 10^{-7} \text{ M}$ but less than $1 \times 10^{-6} \text{ M}$, leucovorin is continued at a dose of 25 mg/m² every 6 hours for eight doses until methotrexate levels decline to below $5 \times 10^{-7} \text{ M}$. If levels are greater than $1 \times 10^{-6} \text{ M}$ but less than $2 \times 10^{-6} \text{ M}$ at 48 hours, the dose of leucovorin is increased to 100 mg/m² every 6 hours for eight doses. For methotrexate levels $\geq 2 \times 10^{-6} \text{ M}$ at 48 hours, the dose of leucovorin is 200 mg/m² every 6 hours for eight doses.

Toxic Effects: Methotrexate primarily exhibits its toxic effects toward proliferating tissues. Consequently, dose-limiting toxicities include bone marrow suppression (leukopenia, thrombocytopenia, anemia), mucositis, and diarrhea. High-dose therapy is occasionally accompanied by transient elevations in liver function test results, but chronic low-dose therapy is more often associated with hepatic fibrosis. Standard-dose therapy is rarely associated with nephrotoxicity, but acute renal failure can be seen with high-dose therapy secondary deposition of 7-OH-methotrexate in the renal tubules. The risk of methotrexate nephrotoxicity is significantly reduced by ensuring adequate hydration and alkalinization of the urine. Other reported toxicities include a maculopapular rash and an idiosyncratic pulmonary toxicity characterized by cough, fever, dyspnea, hypoxia, and interstitial infiltrates.

A necrotizing leukoencephalopathy has been reported in patients receiving methotrexate who have had prior cranial irradiation. Intrathecal methotrexate has been associated with several toxicities, including (1) chemical arachnoiditis; (2) motor paralysis accompanied by cranial nerve dysfunction, seizures, and coma; and (3) chronic demyelinating syndrome. Each of these may be exacerbated by prior craniospinal irradiation.

Potential Drug Interactions: Methotrexate exhibits many potential drug interactions that are related to plasma protein binding. For example, many compounds are known to displace methotrexate from serum albumin, potentially increasing its bioavailability. These agents include sulfonamides, salicylates, tetracyclines, chloramphenicol, and phenytoin. However, the clinical implications of such interactions are not clear. Nonsteroidal antiinflammatory drugs should not be administered in conjunction with methotrexate when the latter is given at intermediate or high doses owing to the potential for elevation and prolongation of methotrexate plasma concentrations. Penicillins can reduce renal clearance of methotrexate and should be used with caution in this setting. Probenecid may also reduce renal transport of methotrexate. Administration of methotrexate can also reduce the clearance of theophyllines, and concomitant use of these agents requires careful monitoring. Increases in methotrexate toxicity have been observed in some patients receiving trimethoprim-sulfamethoxazole, possibly as a consequence of enhanced antifolate effects. Administration of folates in vitamin preparations may reduce the efficacy of methotrexate by bypassing dihydrofolate reductase inhibition. Methotrexate may increase the toxicity (and potentially the activity) of various antineoplastic agents in a schedule-dependent manner (e.g., when given before 5-fluorouracil).

Therapeutic Indications in Hematology: Methotrexate is widely used in the treatment of ALL, particularly in the maintenance phase. Methotrexate is frequently administered intrathecally in patients with CNS leukemia and prophylactically in certain patients with ALL. It also represents a component of various multidrug regimens used in the treatment of NHL (e.g., M-BACOD, PROMACE-CYTABOM).

Hydroxyurea

Chemistry and Mechanism of Action: Hydroxyurea is an inhibitor of the ribonucleotide reductase system that catalyzes the rate-limiting step in the de novo biosynthesis of purine and pyrimidine deoxyribonucleotides, that is, the conversion of ribonucleotide diphosphates to their deoxyribonucleoside diphosphate derivatives. Ribonucleotide reductase consists of two subunits: a binding and allosteric effector component and an iron-binding catalytic component. Hydroxyurea binds to and inactivates the catalytic subunit of the enzyme. Similar to most antimetabolites, hydroxyurea is an S-phase-specific agent and blocks cells in the G₁S phase of the cell cycle. Exposure of cells to hydroxyurea leads to a depletion of deoxyribonucleotide triphosphate (dNTP) pools, the extent of which correlates with DNA synthesis inhibition and cell death. Two consequences of hydroxyurea administration include potentiation of the metabolism or cytotoxicity of nucleoside analogs (e.g., ara-C) as a result of dNTP pool depletion and elimination of amplified genes present extrasomally in double-minute chromosomes.

Absorption, Fate, and Excretion: Hydroxyurea is generally administered PO, although IV regimens are currently being investigated. The drug is readily absorbed from the gastrointestinal tract, with peak plasma levels as high as 2.0 mM occurring approximately 2 hours after oral administration. Serum concentrations decline to undetectable levels after 24 hours. The drug is primarily excreted via the renal route, with 75%–80% of the drug appearing in the urine 12 hours later. The drug penetrates the cerebrospinal fluid, although it has not been established that therapeutic levels are achieved after standard oral administration.

Preparation and Administration: Hydroxyurea is provided as 500-mg capsules. The drug is stored at room temperature in tightly capped containers and protected from heat.

Toxic Effects: The most common adverse reactions include myelosuppression (leukopenia, thrombocytopenia, anemia), gastrointestinal symptoms (e.g., nausea and vomiting, stomatitis, anorexia, appetite disturbances), and dermatologic toxicity (e.g., rashes, skin ulcerations, facial erythema). Rarer toxicities, generally seen at high doses include neurologic disturbances, such as drowsiness, dizziness, headache, and convulsions; altered renal function; and alopecia. The mutagenic potential of hydroxyurea is unknown, and the drug should be avoided when possible in pregnant women.

Potential Drug Interactions: As noted earlier, hydroxyurea may increase the toxicity of certain nucleoside analogs. Hydroxyurea may also serve as a radiosensitizing agent; consequently, patients receiving concurrent radiation therapy may experience enhanced toxicity.

Therapeutic Indications in Hematology: Hydroxyurea has also been successfully used in the treatment of Philadelphia chromosome negative myeloproliferative neoplasms, including myelofibrosis, polycythemia vera, and essential thrombocythemia. Its leukemogenic potential is uncertain, however, and it should be used with caution, particularly in younger patients. Hydroxyurea has also been shown to reduce the incidence of painful crises in individuals with sickle cell anemia in a subset of patients, a phenomenon that may result from increases in red blood cell fetal hemoglobin levels.

Fludarabine

Chemistry and Mechanism of Action: Fludarabine phosphate is a fluorinated derivative of the nucleotide analog ara-A, which is resistant to deamination by the degradative enzyme CDD. It is converted intracellularly to its triphosphate derivative, which inhibits ribonucleotide reductase, as well as DNA polymerase- α and DNA primase. Fluoro-ara-ATP is also incorporated into DNA, a process that appears to be essential for the induction of apoptosis in leukemic cells. Fludarabine is toxic to S-phase cells, but its ability to interfere with DNA repair may contribute to lethality in their noncycling counterparts.

Absorption, Fate, and Excretion: After IV injection, fludarabine phosphate is rapidly deaminated (i.e., within minutes) in the plasma to its nucleoside derivative, 2'-fluoro-ara-A, which is then converted intracellularly to its nucleotide form, 2'-fluoro-ara-AMP by the pyrimidine salvage pathway enzyme, deoxycytidine kinase. The half-life of 2'-fluoro-ara-A is approximately 10 hours; the primary mode of elimination is renal, with 25% of the total dose appearing in the urine as unchanged 2'-fluoro-ara-A. Total body clearance of fludarabine is inversely correlated with serum creatinine.

Preparation and Administration: Fludarabine is supplied as a sterile powder in 50-mg vials containing 50 mg of mannitol and sodium hydroxide to adjust the pH to 7.7. Material is reconstituted in 2 mL of sterile water to yield a 25-mg/mL solution for injection. The material may be stored at 4°C (40°F); because the reconstituted solution contains no antimicrobial preservative, the drug should be administered within 8 hours of formulation.

Toxic Effects: The most common dose-limiting toxicity is myelosuppression (neutropenia, thrombocytopenia, and anemia). Other toxicities include fever, chills, infection, nausea, and vomiting. Rarer toxicities include malaise, fatigue, anorexia, and weakness. Patients with CLL receiving fludarabine have experienced serious opportunistic infections and tumor lysis syndrome. The most serious toxicity of fludarabine when administered at high doses (>40 mg/m²/day for 5 days) is irreversible neurotoxicity, including cortical blindness, necrotizing leukoencephalopathy, and death. This phenomenon has

rarely, if ever, been seen in patients receiving conventional doses (e.g., 25 mg/m²/day for 5 days). Rare reports of interstitial pneumonitis have appeared.

Potential Drug Interactions: Fludarabine has been shown to potentiate the intracellular metabolism and activity of ara-C, although the toxicity of this combination may also be enhanced. No other interactions have been reported.

Therapeutic Indications in Hematology: Fludarabine has shown marked activity in both untreated CLL and in disease refractory to standard alkylating agent therapy. Fludarabine has also shown activity as a single agent, and particularly in combination with others (e.g., mitoxantrone, Cytosan) in indolent NHL.

2'-Chlorodeoxyadenosine

Chemistry and Mechanism of Action: 2'-Chlorodeoxyadenosine (CdA; cladribine) is a derivative of deoxyadenosine that differs from its parent compound by the presence of a chlorine moiety at the 2'-position of the purine ring. It is transported intracellularly by facilitated nucleoside diffusion and phosphorylated by the pyrimidine salvage pathway enzyme deoxycytidine kinase. CdA is relatively resistant to deamination by CDD. CdA is readily converted to its triphosphate derivative, 2'-chlorodeoxyadenosine-5'-triphosphate, particularly in cells of lymphoid origin, and is incorporated into tumor cell DNA by DNA polymerase- α . CdATP is also an effective inhibitor of ribonucleotide reductase, which may contribute to lethal effects. CdA induces cell death (apoptosis) in both cycling and noncycling cells, possibly by promoting DNA fragmentation and by depleting cells of ATP or NAD, or both.

Absorption, Fate, and Excretion: Relatively little pharmacokinetic information concerning CdA is available. The drug is most commonly administered as a 7-day continuous infusion or as a 2-hour infusion over 5 days. The bioavailability of CdA after subcutaneous (SC) administration approximates that of the IV route but is less than that after oral administration. Renal excretion appears to be the major route of elimination. When given as a 2-hour infusion, CdA has a relatively long terminal half-life (e.g., $\approx$ 6 hours), and plasma concentrations after such a schedule may approximate those associated with the continuous infusion. Cerebrospinal fluid levels are approximately 25% of plasma concentrations.

Preparation and Administration: For daily infusions, CdA is diluted under sterile conditions in bags containing 500 mL of 0.9% sodium chloride injection, USP. The use of 5% dextrose solutions is not recommended because of enhanced degradation of the drug. For preparation of longer infusions (e.g., 7 days) the use of bacteriostatic sodium chloride injection, USP, is recommended. After being prepared, solutions of CdA should be refrigerated at a temperature between 4°C (40°F) and 8°C (47°F) for no more than 8 hours before administration.

Toxic Effects: The major toxicity of CdA is myelosuppression, which is primarily observed after intermittent rather than continuous infusion. Other toxicities include fever, generally beginning several days after initiation of therapy, and increased susceptibility to opportunistic infections. Rare side effects include nausea and hepatic and renal toxicity.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: CdA has shown significant activity in CLL and hairy cell leukemia. However, response rates in the former disorder appear to be somewhat less than those obtained with fludarabine; moreover, patients who have progressed on fludarabine therapy infrequently respond to CdA. Other diseases in which CdA has shown activity include NHL and Waldenström macroglobulinemia.

2'-Deoxycoformycin

Chemistry and Mechanism of Action: 2'-Deoxycoformycin (pentostatin; DCF) is an adenosine analog that is a highly effective inhibitor of the purine biosynthetic enzyme adenosine deaminase (ADA). It is transported across cell membranes by facilitated nucleoside diffusion, where it binds tightly to ADA. Inhibition of ADA results in accumulation of deoxyadenosine metabolites, most notably dATP. dATP exerts its toxic effects through inhibition of ribonucleotide reductase and induction of global imbalances in dNTP pools. These result in interference with DNA synthesis and repair. 2'-Deoxycoformycin is particularly toxic to certain lymphoid cells with low levels of ADA activity. It is also toxic to both cycling and resting cells; the mechanism underlying its cytotoxicity toward quiescent cells is unknown.

Absorption, Fate, and Excretion: After IV injection of 2'-deoxycoformycin, the plasma clearance follows a biphasic pattern, with a terminal elimination half-life of 3–15 hours. Protein binding is limited. The drug is only partially metabolized, with approximately 60%–80% of the drug appearing unchanged in the urine after 24 hours. The total-body clearance of 2'-deoxycoformycin correlates well with creatinine clearance. Patients with impaired renal function may require reductions in the 2'-deoxycoformycin dose.

Preparation and Administration: 2'-Deoxycoformycin is unstable when reconstituted in solutions of pH less than 5.0. Consequently, it is customarily reconstituted in normal saline. 2'-Deoxycoformycin is provided in vials containing 10 mg of drug, 50 mg of mannitol, and sodium hydroxide to adjust the pH to less than 7.0. It is administered as an IV infusion over 20–30 minutes. Hydration is recommended before and after 2'-deoxycoformycin administration.

Toxic Effects: The major toxicities of 2'-deoxycoformycin include myelosuppression, nausea and vomiting, immunosuppression, acute renal failure, keratoconjunctivitis, fever, and elevations of liver function enzymes. At high doses, neurologic toxicity, including somnolence, seizures, and coma, have been reported, although these are seen infrequently in patients receiving standard dose therapy. When administered at such doses (e.g., 4 mg/m² biweekly), side effects are relatively minor.

Potential Drug Interactions: 2'-Deoxycoformycin may augment the toxicity of ara-A as a consequence of inhibition of ADA.

Therapeutic Indications in Hematology: 2'-Deoxycoformycin is primarily used in the treatment of hairy cell leukemia, in which response rates of up to 90% have been reported, even in patients refractory to other therapy, including interferon- α (IFN- α). Activity has also been reported in other lymphoid malignancies, such as T-cell lymphoma, CLL, prolymphocytic leukemia, and Waldenström macroglobulinemia, although its precise role in the treatment of these disorders remains to be fully evaluated.

6-Thioguanine

Chemistry and Mechanism of Action: Thioguanine (6-TG) is a guanine analog in which the 6'-hydroxyl group is replaced by a sulfhydryl group. It interferes with de novo purine biosynthesis at multiple levels. After transport across the cell membrane by facilitated diffusion, 6-TG competes with hypoxanthine and guanine for phosphorylation by hypoxanthine-guanine phosphoribosyltransferase and is converted to its nucleotide form, 6-thioguanilic acid (TGMP), which accumulates within cells. TGMP inhibits several purine biosynthetic enzymes, including glutamine-5-phosphoribosylpyrophosphate aminotransferase and IMP dehydrogenase. 6-TG nucleotides are also incorporated in DNA and RNA, where they function as fraudulent bases. It is presently unknown which of these actions (interference with purine interconversions, blockade of de novo purine biosynthesis, or nucleic acid incorporation) is primarily

responsible for 6-TG cytotoxicity, although DNA incorporation appears to play a significant role. 6-TG is considered to be an S-phase-specific agent.

Absorption, Fate, and Excretion: After oral administration, the bioavailability of 6-TG is variable, ranging from 14% to 46% of the administered dose (mean: 30%). Peak plasma levels are achieved 8 hours after administration and decline slowly thereafter. The average plasma disappearance of 6-TG is approximately 80 minutes, with a range of 25–240 minutes. Relatively little unchanged material appears in the urine; the major excreted product is the methylated derivative 2-amino-6-methyl thiopurine. CNS penetrance after parenteral administration is minimal.

Preparation and Administration: 6-TG is available in tablet form for oral administration. Each tablet contains 40 mg of 6-TG and inactive ingredients, including gum acacia, lactose, magnesium stearate, potato starch, and stearic acid. IV preparations are available only in experimental settings.

Toxic Effects: The major dose-limiting toxicity of 6-TG is myelosuppression. Other less common toxicities include gastrointestinal disturbances (nausea and vomiting, anorexia, diarrhea), jaundice, and elevated liver function test results.

Potential Drug Interactions: In contrast to 6-MP, the metabolism of 6-TG is not modified by allopurinol; consequently, dose adjustments do not have to be made when these agents are administered concurrently.

Therapeutic Indications in Hematology: The primary indication for 6-TG is in the treatment of AML, generally in conjunction with other agents (e.g., daunorubicin and ara-C). However, it has not been firmly established that addition of 6-TG to such regimens improves therapeutic efficacy. 6-TG also has activity in chronic myeloid leukemia, although it has been supplanted by other agents (e.g., hydroxyurea, IFN- α in this disorder).

6-Mercaptopurine

Chemistry and Mechanism of Action: 6-Mercaptopurine (1,7-dihydro-6H-purine 6-thione monohydrate; 6-MP; purinethol) is an analog of the purine bases adenine and hypoxanthine. It is both an antineoplastic and immunosuppressive agent. Similar to 6-TG, 6-MP and its metabolites act at multiple levels to interfere with purine biosynthesis and interconversions. It competes with hypoxanthine and guanine for hypoxanthine-guanine phosphoribosyltransferase, and after conversion to thioinosinic acid (TIMP), blocks conversion of IMP to xanthylic acid and IMP to AMP. Both TIMP and another metabolite, 6-methylthioinosinate (MTIMP), inhibit glutamine-5-phosphoribosylpyrophosphate aminotransferase. 6-MP is also incorporated into RNA and DNA, thereby functioning as a fraudulent base. It is unknown which of these actions is primarily responsible for the lethal actions of 6-MP, although available evidence points to DNA incorporation as a prime determinant of cytotoxicity.

Fate, Absorption, and Excretion: After oral administration, the bioavailability of 6-MP is highly variable, presumably because of interpatient differences in gastrointestinal absorption, which averages 50% of the administered dose. Extensive catabolism by hepatic xanthine oxidase also contributes to drug elimination. Approximately 50% of the administered 6-MP or its metabolites are recovered in the urine. The volume of distribution generally exceeds the total body water. After IV administration, the plasma disappearance half-life was 47 minutes in adults. Plasma protein binding is modest (approximately 19%), and CNS penetrance is minimal.

Preparation and Administration: 6-MP is supplied as tablets for oral administration. Each tablet contains 50 mg of 6-MP and the

inactive ingredients corn and potato starch, lactose, magnesium stearate, and stearic acid. An IV preparation containing 500 mg of 6-MP per vial is available for investigational use.

Toxic Effects: The major dose-limiting toxicity of 6-MP is myelosuppression. This is dose related and is manifested by leukopenia, thrombocytopenia, and anemia. The hematologic effects of 6-MP may be delayed, so it is important to withdraw the medication temporarily at the first sign of unusual hematologic toxicity. Individuals with an inherited disorder of thiopurine methyltransferase deficiency may be particularly susceptible to 6-MP-mediated hematopoietic suppression. Other toxicities include hepatotoxicity (elevated liver function test results, cholestasis, hepatic necrosis, ascites), nausea, vomiting, mucositis, fever, rash, and diarrhea. The hepatotoxicity, which occurs in 10%–40% of patients, requires close monitoring and discontinuation of therapy until recovery occurs. Patients receiving 6-MP uniformly experience immunosuppression.

Potential Drug Interactions: Allopurinol, an inhibitor of xanthine oxidase, significantly reduces the catabolism of 6-MP when the latter is given orally, leading to major increases in plasma concentrations. Allopurinol does not alter the pharmacokinetics of IV 6-MP, presumably because of the absence of first-pass metabolism of 6-MP when administered by this route. When administered in conjunction with allopurinol, the dose of 6-MP should be reduced by one-third to one-fourth. Increased toxicity has been reported in patients receiving concurrent 6-MP and trimethoprim-sulfamethoxazole. 6-MP may also modify the effects of warfarin.

Therapeutic Indications in Hematology: The major use for 6-MP is in the maintenance phase of treatment for ALL. 6-MP has also been used in the treatment of patients with immune thrombocytopenia purpura or autoimmune hemolytic anemia refractory to all other forms of therapy.

5'-Azacitidine

Chemistry and Mechanism of Action: 5'-Azacitidine is an analog of the nucleoside cytidine, differing from the parent compound by virtue of the presence of nitrogen at the 5' position of the heterocyclic ring. 5'-Azacitidine is transported across the cell membrane by facilitated nucleoside diffusion and is converted to its nucleotide monophosphate form, 5'-aza-CMP, by the pyrimidine salvage pathway enzyme uridine-cytidine kinase. 5'-Azacitidine is also a substrate for the degradative enzyme CDD. It is ultimately converted to its lethal derivative, 5'-aza-CTP, which is incorporated into RNA, and to a lesser extent, DNA. The lethal actions of 5'-azacitidine are believed to result from its ability to interfere with protein synthesis through disruption of RNA processing. The chemical instability of the 5'-azacitidine ring structure is also believed to contribute to the cytotoxicity of this compound.

Absorption, Fate, and Excretion: The drug distributes into a volume corresponding to the total body water after IV administration and is also well absorbed after SC injection.

It is extensively deaminated in the plasma and liver and displays minimal plasma binding. Peak plasma concentrations after IV injection approximate 1.0 mM. The initial half-life of 5'-azacitidine (or its metabolites) is approximately 4 hours, although the drug is rapidly converted to various derivatives within minutes of administration. There is minimal cerebrospinal fluid penetration.

Preparation and Administration: Azacitidine is available in 100-mg vials and can be administered both IV and SC. When given SC, it should be reconstituted with 4 mL of sterile water for injection. The diluents should be injected slowly into the vial. Vigorously shake or roll the vial until a uniform suspension is achieved. The suspension will be cloudy. The resulting suspension will contain azacitidine 25 mg/mL. Do not filter the suspension after reconstitution. Doing so could remove the active substance. Azacitidine reconstituted for

SC administration may be stored for up to 1 hour at 25°C (77°F) or for up to 8 hours between 2°C and 8°C (36°F and 46°F). To provide a homogeneous suspension, the contents of the dosing syringe must be resuspended immediately before administration. To resuspend, vigorously roll the syringe between the palms until a uniform, cloudy suspension is achieved. When given IV, reconstitute each vial with 10 mL of sterile water for injection. Vigorously shake or roll the vial until all solids are dissolved. Withdraw the required amount of solution to deliver the desired dose and inject into a 50–100-mL infusion bag of either 0.9% sodium chloride injection or lactated Ringer solution.

Toxic Effects: The major toxicity of 5'-azacitidine has been leukopenia and, to a lesser extent, thrombocytopenia. Nausea and vomiting, which are often refractory to standard antiemetic therapy, have also been encountered, most frequently in patients receiving bolus infusions. Gastrointestinal toxicity is ameliorated by administering 5'-azacitidine as a continuous infusion. Other potential side effects include diarrhea, fever, hepatotoxicity (most frequently in patients with preexisting hepatic disease), neuromuscular toxicity, rash, and hypotension.

Drug Interactions: None reported.

Therapeutic Indications in Hematology: 5'-Azacitidine is primarily used in the treatment of refractory AML, with response rates ranging from 17% to 30% when used as a single agent. 5'-Azacitidine has also yielded clinical responses in a subset of patients with the MDS when administered as a low-dose continuous infusion. In early trials, low-dose 5'-azacitidine increased fetal hemoglobin levels in some patients with sickle cell anemia and thalassemia; however, its mutagenic potential has limited the use of this agent in nonmalignant conditions.

Decitabine

Chemistry and Mechanism of Action: Decitabine is a synthetic nucleoside analog of 2'-deoxycytidine, a cytotoxic S-phase pyrimidine analogue that induces hypomethylation of DNA at concentrations that do not cause major suppression of DNA synthesis. It also causes cellular differentiation or apoptosis. This is accomplished by intracellular phosphorylation of decitabine to its triphosphate form, which is incorporated into DNA and blocks methylation of newly synthesized DNA by binding to DNA methyltransferase. Nonproliferating cells seem relatively insensitive to decitabine.

Absorption, Fate, and Excretion: Decitabine is widely distributed with less than 1% protein binding and is tolerated after SC injection. There is some CNS penetration after subcutaneous injection with cerebrospinal fluid concentrations in patients with meningeal leukemia that were approximately 20% of corresponding steady-state plasma levels. The mean half-life is 0.5–0.6 hours. The route of metabolism appears to be deamination by CDD, principally found in the liver but also in granulocytes, the intestinal epithelium, and whole blood.

Preparation and Administration: Decitabine is available in 50-mg vials, which are reconstituted with 10 mL of sterile water for injection (USP); upon reconstitution, each milliliter contains approximately 5.0 mg of decitabine at a pH of 6.7–7.3. Immediately after reconstitution, the solution should be further diluted with 0.9% sodium chloride injection, 5% dextrose injection, or lactated Ringer solution injection to a final drug concentration of 0.1–1.0 mg/mL. Unless used within 15 minutes of reconstitution, the diluted solution must be prepared using cold (2°–8°C) infusion fluids and stored at 2°–8°C (36°–46°F) for up to a maximum of 7 hours until administration.

Toxic Effects: The major toxicity of decitabine has been bone marrow suppression, including leukopenia, thrombocytopenia, and

anemia. Nausea and vomiting are mild. Other potential side effects include diarrhea, fever, and hepatotoxicity, including hyperbilirubinemia, transamination elevations, and electrolyte abnormalities.

Drug Interactions: None reported.

Therapeutic Indications in Hematology: Decitabine is indicated for treatment of patients with MDS, including previously treated and untreated, de novo, and secondary MDS. It has also been used as salvage therapy both alone and in combination for AML, chronic myeloid leukemia, and acute lymphoid leukemia.

Gemcitabine

Chemistry and Mechanism of Action: Gemcitabine (2',2'-difluorocytidine monohydrochloride) is a nucleoside analog that differs from 2'-deoxycytidine by virtue of the presence of fluorine atoms in the 2' α and 2' β positions of the cytidine ring. It is transported across the cell membrane by facilitated nucleoside diffusion, phosphorylated by deoxycytidine kinase, and ultimately converted to its lethal metabolites, dFdCDP and dFdCTP. The diphosphate form (dFdCDP) inhibits ribonucleotide reductase, leading to disruption of dNTP pools and resultant interference with DNA synthesis and repair. The triphosphate form (dFdCTP) competes with dCTP for incorporation into DNA. Reductions in dCTP pools (secondary to ribonucleotide reductase inhibition) result in self-potentialization of gemcitabine action. Incorporation of gemcitabine into DNA in S phase inhibits elongation of the replicating strand, leading to DNA chain termination. The lethal actions of gemcitabine in leukemia cells have been related to the induction of apoptosis and are not restricted to cells actively engaged in DNA synthesis. Gemcitabine has been shown to be considerably more potent in inducing apoptosis in cultured human leukemia cells than ara-C.

Absorption, Fate, and Excretion: In studies involving IV administered labeled gemcitabine, up to 98% of the drug was recovered in the urine after 1 week. The excreted dose was composed of a minor fraction (gemcitabine; <10%) and inactive metabolites (e.g., 2'-deoxy-2',2'-difluorouridine). Plasma protein binding was minimal. In studies involving both short and long gemcitabine infusions, the pharmacokinetics were found to be linear and best described by a two-compartment model. Plasma half-life and clearance are influenced both by age and gender. For short infusions, half-lives varied from 32 to 94 minutes; for longer infusions, half-lives varied from 245 to 638 minutes. The volume of distribution was approximately 50 L/m² for short infusions and 370 L/m² for long infusions.

Preparation and Administration: Vials of gemcitabine contain 200 mg or 1 g of the HCl derivative formulated with mannitol (200 mg or 1 g) and sodium acetate (12.5 mg or 62.5 mg) as a sterile lyophilized powder. HCl or NaOH has been used for pH adjustment.

Toxic Effects: The major dose-limiting toxicity of gemcitabine is myelosuppression, although anemia and thrombocytopenia have also been encountered. Other toxicities include nausea and vomiting, transient elevations in liver function test results, mild hematuria, proteinuria (and in rare cases, hemolytic uremic syndrome), fever, rash, dyspnea, edema, and a flulike syndrome. Other infrequent toxicities included alopecia, paresthesias, and bronchospasm.

Potential Interactions: Gemcitabine may function as a radiosensitizing agent and can increase the toxicity of ionizing radiation. No other interactions are known.

Indications in Hematology: The primary indication for gemcitabine is in the treatment of patients with pancreatic carcinoma. However, as an experimental agent, gemcitabine is being evaluated for the treatment of ALL and CLL.

Nelarabine, Arabinofuranosylguanine (Ara-G)

Chemistry and Mechanism of Action: Nelarabine is a prodrug of the deoxyguanosine analog 9'- β -D-arabinofuranosylguanine, also known as ara-G. Accumulation of a metabolite ara-GTP in leukemic blasts allows for incorporation into DNA, leading to inhibition of DNA synthesis and cell death.

Absorption, Fate, and Excretion: Nelarabine is demethylated by ADA to ara-G, then monophosphorylated by deoxyguanosine kinase and deoxycytidine kinase, and subsequently converted to the active 5'-triphosphate, ara-GTP. Nelarabine is only available in an IV formulation. Nelarabine and ara-G are both partially eliminated by the kidneys. Approximately 5%–10% of nelarabine is excreted by the kidneys compared with 20%–30% of ara-G. Nelarabine exhibits a half-life of 30 minutes, and ara-G, the active metabolite, has a half-life of 3 hours.

Preparation and Administration: Nelarabine for injection is supplied as a clear, colorless, sterile solution in glass vials. Each vial contains 250 mg of nelarabine (5 mg of nelarabine/mL) and sodium chloride (4.5 mg/mL) in 50 mL of water for injection, USP. Nelarabine is not diluted before administration. The dose is transferred into polyvinylchloride (PVC) infusion bags or glass containers and administered as a 2-hour infusion in adult patients or as a 1-hour infusion in pediatric patients.

Toxic Effects: Bone marrow suppression encompassing all cell lines causing anemia, leucopenia, thrombocytopenia, and neutropenia occurs in all patients. Neurologic complications of nelarabine include asthenia, altered mental states including severe somnolence, CNS effects including convulsions, and peripheral neuropathy ranging from numbness and paresthesias to motor weakness and paralysis. Demyelinating disease of the CNS may occur when combining nelarabine with other drugs that may have CNS toxicity. Nausea and vomiting are seen and antiemetics are necessary.

Drug Interactions: Pentostatin has been shown to be a strong inhibitor of ADA in vitro. Concurrent administration of nelarabine and pentostatin may result in reduced ADA-dependent conversion of nelarabine to its active moiety, thereby potentially decreasing nelarabine efficacy or altering nelarabine's adverse event profile. Therefore, concomitant administration of nelarabine and pentostatin is not recommended.

Therapeutic Indications in Hematology: Nelarabine is effective in T-cell ALL, T-cell lymphoma, and T-cell lymphoblastic lymphoma. The dosage in adults of nelarabine is 1500 mg/m² administered IV over 2 hours on days 1, 3, and 5 repeated every 21 days. The pediatric dosage of nelarabine is 650 mg/m² administered IV over 1 hour daily for 5 consecutive days repeated every 21 days. The proper number of cycles for adult and pediatric patients has not been determined.

Clofarabine

Chemistry and Mechanism of Action: Clofarabine is a purine nucleoside antimetabolite formulated in unbuffered normal saline with a pH range of 4.5–7.5. It inhibits DNA synthesis by decreasing cellular deoxynucleotide triphosphate pools by inhibiting ribonucleotide reductase, terminating DNA chain elongation, and inhibiting repair through incorporation into the DNA chain by competitive inhibition of DNA polymerases.

Absorption, Fate, and Excretion: Clofarabine is 47% bound to plasma proteins, primarily albumin. Clofarabine is phosphorylated intracellularly to the cytotoxic active form (clofarabine triphosphate) by deoxycytidine kinase. The terminal half-life is estimated to be 5.2 hours with the metabolite clofarabine triphosphate, yielding a half-life greater than 24 hours, and 49%–60% of the dose is excreted in

the urine unchanged. Systemic clearance and volume of distribution at steady state were estimated to be 28.8 L/hour/m² and 172 L/m², respectively.

Preparation and Administration: Clofarabine is supplied in a 20-mL, single-use vial that contains 20 mg of clofarabine in 20 mL of unbuffered normal saline at a concentration of 1 mg/mL. Clofarabine should be filtered through a sterile 0.2- μ m syringe filter and diluted with 5% dextrose injection, USP, or 0.9% sodium chloride injection, USP, before IV infusion to a final concentration between 0.15 and 0.4 mg/mL.

Toxic Effects: Bone marrow suppression encompassing all cell lines causing anemia, leucopenia, thrombocytopenia, and neutropenia occurs in all patients. A capillary leak syndrome, also known as *systemic inflammatory response syndrome* (SIRS), thought to be related to cytokine release leading to respiratory distress, hypotension, pleural effusions, pericardial effusions, and multiorgan failure may occur in

a small number of patients. Elevations of liver transaminases are seen and are transient (typically, less than 2 weeks' duration) and occurred within 1 week of clofarabine initiation. Elevations in bilirubin may also occur.

Drug Interactions: None described.

Therapeutic Indications in Hematology: Clofarabine is effective in treating ALL. The recommended pediatric dose is 52 mg/m² administered by IV infusion over 2 hours daily for 5 consecutive days. Treatment cycles are repeated after recovery or return to baseline organ function, approximately every 2–6 weeks. Clofarabine has been used in adults at a dosage of 40 mg/m² administered by IV infusion over 2 hours daily for 5 consecutive days. Clofarabine has also been used in combination with cytarabine. Because this drug is excreted to a major extent by the kidneys, extreme caution should be used in patients with renal dysfunction.

TOPOISOMERASE I INHIBITORS AND TOPOISOMERASE II INHIBITORS

TOPOISOMERASE II INHIBITORS

Etoposide (Vepesid), Etoposide Phosphate (Etopophos), Teniposide (Vumon)

Chemistry and Mechanism of Action: Etoposide (VP-16), etoposide phosphate, and teniposide (VM-26) are semisynthetic derivatives of epipodophyllotoxin. The mechanism of action of these drugs appears to be related to their ability to stabilize a topoisomerase II–DNA cleavable complex, which acts as a replication fork barrier and leads to the generation of irreversible DNA damage and cell death in proliferating cells.

Absorption, Fate, and Excretion: Etoposide has an oral bioavailability of 25%–75%. Its terminal half-life is 6–8 hours, with approximately 30%–40% excreted in the urine, two-thirds as unchanged drug. There is no accumulation with consecutive daily administration, but cytotoxicity has strict schedule dependency. Clinical studies suggest that in patients with a plasma creatinine level greater than 130 mol/L, the etoposide dose should be reduced by more than 25%.

Etoposide phosphate is rapidly and completely converted in vivo to VP-16 by the activity of phosphatase and has been shown to have the same pharmacokinetics as VP-16. Because of its increased water solubility, etoposide phosphate can be given IV in much less volume. In addition, the metabolic acidosis and hypotension seen with the infusion of VP-16 are not seen with this prodrug.

Teniposide has a multiphasic pattern of clearance from plasma with a terminal half-life of 9.5–21 hours. Unlike those of etoposide, metabolites of teniposide account for greater than 80% of the drug excreted in the urine. Similar to etoposide, there is significant interpatient and inpatient variation in clinical pharmacokinetics. There are currently no formal recommendations for dose modification in patients with renal insufficiency.

Preparation and Administration: Etoposide is commercially available as 50-mg capsules and in vials of 50 and 100 mg at a concentration of 20 mg/mL. When the drug is diluted with normal saline or 5% dextrose in water to a concentration of 0.2 or 0.4 mg/mL, it is stable for 96 or 48 hours, respectively. Etoposide must be administered slowly over more than 30 minutes to prevent hypotension.

Etoposide phosphate is available commercially as single-dose vials containing etoposide phosphate equivalent to 100 mg of etoposide. When it is diluted with water, 5% dextrose, or normal saline to a concentration of 10–20 mg/mL, it can be administered without dilution over 5–10 minutes. When reconstituted, etoposide phosphate is stable for 24 hours at room temperature or under refrigeration.

Teniposide is supplied in 50-mg vials for IV use only. The IV solution may be taken orally but is unpalatable. Currently, no oral preparation is available in the market; however, for investigational purposes, each 50-mg vial may be dissolved in 50–100 mL of syrup or juice. To achieve optimal absorption, a single oral dose of 60 mg/m², which may be repeated at 6-hour intervals, is advised. As with etoposide, rapid infusion can produce hypotension.

Toxic Side Effects: Myelosuppression, especially leukopenia, is the dose-limiting toxic effect of etoposide and teniposide. Nausea and

vomiting are usually mild and easily prevented with antiemetics. Rapid infusion of etoposide (<30 minutes) may cause hypotension. Anaphylactoid reactions (e.g., bronchospasm) occur in fewer than 2% of patients and may be related to the Cremophor vehicle. Alopecia occurs in approximately 20% of patients treated with etoposide. This side effect is more common with teniposide. When the drug is given in bone marrow transplantation doses, mucositis and diarrhea are prominent and may be dose limiting.

Potential Drug Interactions: Theoretically, any drug that increases the S-phase fraction will increase the cytotoxicity of epipodophyllotoxins and other topoisomerase inhibitors. Conversely, drugs that inhibit DNA synthesis antagonize the effect of etoposide and teniposide (e.g., 5-fluoro-2'-deoxyuridine given before etoposide in some human cancer cell lines decreases the cytotoxicity of the latter). More recent in vitro data suggest that synergistic cytotoxic effects are seen when VP-16 is given after a topoisomerase I inhibitor, which appears to upregulate the amount of topoisomerase II enzyme. Antagonistic effects have been reported when a topoisomerase II inhibitor is given before a topoisomerase I inhibitor. In hematology, etoposide and teniposide may inhibit intracellular ara-CTP formation leading to reduced ara-C cytotoxicity. Potentiation of teniposide activity has been seen with methotrexate and dipyridamoles. There is at least a twofold increase in the clearance of teniposide with concomitant administration of phenobarbital or phenytoin. Cyclosporine and other PGP antagonists (PSC 833) potentiate the cytotoxic effects of etoposide.

Therapeutic Indications: Etoposide is used in the treatment of NHL and as a second-line treatment for Hodgkin lymphoma. It is also incorporated in the preparatory regimens for bone marrow transplantation of refractory lymphomas (CBV) and acute leukemia. Teniposide has been approved as a front-line agent with combination chemotherapy for childhood ALL. Combination chemotherapy with teniposide has been used successfully in some cases of refractory adult ALL and acute monocytic leukemia, but the duration of remission is not significantly different from that with other standard salvage regimens. In NHL, teniposide has shown comparable activity to vincristine. Etoposide phosphate has been given in both standard-dose and high-dose (as a single agent) chemotherapy regimens and appears to have the same pharmacokinetics and antitumor activity as VP-16.

Daunorubicin

Chemistry and Mechanism of Action: Daunorubicin is an anthracycline that inhibits DNA topoisomerase II, acting as a poison at lower concentrations and a suppressor of cleavable complex formation at higher doses. Daunorubicin is also a DNA intercalator and generates reactive oxygen intermediates.

Absorption, Fate, and Excretion: After IV injection, daunorubicin undergoes rapid tissue uptake and concentration. It is rapidly metabolized in the liver, where approximately 25% of the drug concentrates and has a half-life of 20–50 hours. The principal metabolite is daunorubicinol, which also displays antineoplastic activity. Biliary excretion accounts for approximately 75% of the drug and metabolite elimination. Patients with significant hepatic dysfunction should receive an attenuated dose of daunorubicin.

Preparation and Administration: Daunorubicin is supplied with 100 mg of mannitol in 20-mg vials, from which it is reconstituted with 4 mL of sterile water for injection. The vial should be protected from sunlight. Daunorubicin is a powerful vesicant that should be administered into the tubing of a freely flowing IV infusion of either 5% dextrose in water or normal saline. In the event of extravasation, as much infiltrated drug as possible should be aspirated from the tissue, and cold compresses should be maintained on the site for several hours. Despite these measures, skin grafting may be necessary. Daunorubicin is not physically compatible with heparin, and the two drugs should not be co-administered in the same IV tubing. The patient should be informed that daunorubicin may impart a red color to the urine for up to 72 hours after administration.

Toxic Effects: Myelosuppression, predominantly leukopenia, is the dose-limiting toxic effect. Mucositis, nausea and vomiting, and alopecia are common. Facial flushing, conjunctivitis, and lacrimation may occur in rare cases. Erythematous streaking near the site of injection occurs as a benign local allergic reaction and should not be confused with extravasation. The drug can produce a severe local reaction (e.g., pneumonitis, esophagitis) in previously irradiated areas, even when both therapies are not administered concomitantly (radiation recall). Cardiac toxicity is a unique characteristic of the anthracycline antibiotics and can be acute or chronic. In the acute form, abnormal ECG changes such as ST-T wave elevation and arrhythmias may be seen. Transient reduction in the ejection fraction can also occur acutely and is often associated with pericarditis (pericarditis-myocarditis syndrome). The chronic form of anthracycline cardiac toxicity is related to the cumulative dose. The dose limit of doxorubicin is generally considered to be 450–500 mg/m², where the risk of clinical cardiotoxicity is between 1% and 10%. The corresponding cumulative dose limit for daunorubicin is 900–1000 mg/m². The cardiac toxicity is clinically characterized by congestive heart failure, usually refractory to medical therapy. Cardiac irradiation or the administration of cyclophosphamide may increase the risk of cardiotoxicity. The cardiotoxic effects appear to be related to the formation of free radicals and not to the inhibition of DNA topoisomerase II. The cardioprotective agent dexrazoxane (Zincard) is now available and recommended to be started at a doxorubicin cumulative dose greater than 350 mg/m².

Potential Drug Interactions: Daunorubicin is not physically compatible with heparin or dexamethasone. The drug interactions described for doxorubicin (description follows) probably occur with daunorubicin as well.

Therapeutic Indications in Hematology: Daunorubicin is used in combination with other drugs in the treatment of AML and ALL.

Doxorubicin (Adriamycin)

Chemistry and Mechanism of Action: Doxorubicin is also an anthracycline glycoside antibiotic. It differs from daunorubicin at C-8, in which a hydroxyacetyl group replaces an acetyl group. Because of this, doxorubicin is also called *hydroxyl daunorubicin*. Its mechanisms of action also involve stabilizing DNA–topoisomerase II complexes, DNA intercalation, and free radical formation.

Absorption, Fate, and Excretion: Doxorubicin has a triphasic plasma clearance with a half-life of approximately 30 hours. The drug is extensively metabolized in the liver to yield an active metabolite (doxorubicinol) and a number of inactive metabolites (aglycones). Within 7 days, more than 50% of an injected dose is excreted in the bile, but only 5%–10% of the drug is excreted in the urine. Penetration into the cerebrospinal fluid is poor.

Preparation and Administration: Doxorubicin is commercially available in vials of 10, 20, 50, 150, and 200 mg. The lyophilized

powder is reconstituted with either normal saline or sterile water for injection to yield a 2-mg/mL solution. The reconstituted solution must be protected from sunlight. The drug should be injected slowly into the tubing of a freely running IV infusion of normal saline or 5% dextrose in water. Erythematous streaking along the vein is often an indication that the administration rate is too rapid. The drug is a powerful vesicant, and in case of extravasation, the measures described for daunorubicin should be followed.

Toxic Effects: The toxic effects are similar to those of daunorubicin. It is important to emphasize that weekly low-dose regimens or administration by continuous infusion can decrease the risk of cardiotoxicity with doxorubicin.

Potential Drug Interactions: When used in combination with other drugs as treatment for leukemia or lymphoma, doxorubicin may decrease the oral bioavailability of digoxin. It is not physically compatible with heparin or 5-fluorouracil. Barbiturates may increase the plasma clearance of doxorubicin and decrease its cytotoxic effect. Doxorubicin is compatible with vincristine, and the two drugs can be administered together in the same IV solution.

Therapeutic Indications in Hematology: Doxorubicin is one of the most important drugs in the treatment of hematologic malignancies. It is used in the treatment of Hodgkin lymphoma (ABVD regimen), NHL (CHOP, MACOP-B), and MM (VBAP, VAD).

Idarubicin (Idamycin)

Chemistry and Mechanism of Action: Idarubicin, also called 4'-demethoxydaunorubicin (4-DMDR), is an analog of daunorubicin in which the methoxy group from the aglycone has been replaced with hydrogen. Idarubicin is also a topoisomerase II inhibitor and generates free radicals.

Absorption, Fate, and Excretion: The elimination half-life of the parent compound is 11.3 hours and that of the primary metabolite, 13-epirubicinol, is 40–60 hours. The major metabolite is as active as idarubicin. The oral bioavailability of this drug is approximately 30%; 80% of the drug is excreted in the urine as 13-epirubicinol.

Preparation and Administration: Idarubicin is supplied in 5- and 10-mg vials from which it is reconstituted with sterile water or normal saline to obtain a 1-mg/mL solution. The drug should be infused for 10–15 minutes through the tubing of a freely running IV infusion. Extravasation precautions should be instituted during administration. The oral formulation remains investigational.

Toxic Effects: The side effects of idarubicin are similar to those of daunorubicin and doxorubicin but are of lesser intensity at equal myelosuppressive doses.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: Idarubicin in combination with ara-C is equivalent, if not superior, to combination chemotherapy with daunorubicin in the treatment of adult AML and MDS. Idarubicin has been approved for use in combination therapy for adult AML.

Mitoxantrone (Novantrone)

Chemistry and Mechanism of Action: Mitoxantrone is a synthetic anthracenedione. Its mechanism of action appears to primarily involve the inhibition of DNA topoisomerase II. Its reduced potential for free radical formation may explain the decreased cardiotoxicity of this drug.

Absorption, Fate, and Excretion: Mitoxantrone is excreted via the renal and hepatobiliary systems, but the hepatobiliary elimination

accounts for approximately 30% of active drug elimination and appears to be of greater importance. The half-life is quite variable, with a range of 23–42 hours. Patients with severe hepatic dysfunction have been shown to eliminate the drug more slowly.

Preparation and Administration: Mitoxantrone is commercially available as a 2-mg/mL solution in 10-mL, 12.5-mL, and 15-mL vials (20, 25, and 30 mg per vial, respectively). The drug is further diluted in normal saline or 5% dextrose in water for injection and is administered for approximately 15–30 minutes into the tubing of a freely running IV infusion. As with the anthracyclines, erythema or streaking along the vein of infusion indicates that the drug is being infused too rapidly. Although mitoxantrone is not a vesicant, there have been rare reports of tissue necrosis after extravasation.

Toxic Effects: Myelosuppression, principally leukopenia, is the dose-limiting toxic effect. Thrombocytopenia is relatively mild. Nausea, vomiting, and alopecia are usually mild and occur in fewer than 30% of patients treated. Rarely, mucositis and elevation of liver enzymes occur. The drug imparts a blue color to the urine of patients treated. One of the primary advantages of mitoxantrone, compared with doxorubicin, is its reduced incidence of cardiac toxicity. Occasionally, patients develop congestive heart failure after treatment with mitoxantrone in the absence of prior anthracycline exposure, although the incidence appears to be less than 5%.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: Mitoxantrone is approved for induction therapy of AML in adults.

TOPOISOMERASE I INHIBITORS

Topotecan (Hycamtin)

Chemistry and Mechanism of Action: Topotecan is a semisynthetic derivative of camptothecin that stabilizes a complex between DNA topoisomerase I and DNA. The cytotoxic effect of this drug is believed to result from the collision of DNA replication forks with a ternary complex of topoisomerase I, DNA, and topotecan. The resulting double-strand DNA breaks are lethal. The lactone form of topotecan, which predominates at an acidic pH, is a much more potent inhibitor of DNA topoisomerase I.

Absorption, Fate, and Excretion: At neutral or physiologic pH the carboxylate form of topotecan is favored, and at a pH of less than 7 the lactone form is favored. Topotecan has been given as a bolus or by continuous infusion. In less than 1 hour after infusion, most of the circulating drug in the plasma is in the carboxylate form as a result of the physiologic pH. Whereas the terminal half-life of the lactone form of this S-phase-specific agent is 2.6 hours, the terminal half-life of the total drug is 3.3 hours. In an IV dose, 36% is excreted unchanged in the urine, and there is a 1.5-fold concentration of the drug in bile. Cerebrospinal fluid levels of topotecan lactone reach approximately 32% of plasma levels. Dose adjustment is required for creatinine clearance less than 60 mL/min, but no adjustment is necessary for bilirubin up to 10 mg/dL.

Preparation and Administration: Topotecan is commercially available as 4-mg vials that are reconstituted with 4 mL of sterile water. This solution can be further diluted in normal saline or 5% dextrose in water and should be used immediately.

Toxic Effects: The dose-limiting toxicity for topotecan for all schedules is neutropenia. Thrombocytopenia and anemia are less common, although there is an increase in thrombocytopenia with

continuous infusion schedules. Other less common and mild toxicities include nausea, vomiting, diarrhea, fever, fatigue, alopecia, skin rash, and increased liver function tests. Mucositis has been seen with prolonged infusion schedules over 5 days or when topotecan is given in higher doses.

Potential Drug Interactions: In vitro data suggest that there may be some synergism if a topoisomerase I inhibitor is given before a topoisomerase II inhibitor. In vitro data also suggest that synergism may be seen if a topoisomerase I inhibitor (topotecan) is given after an alkylating agent, suggesting that topoisomerase I may be involved in the repair of alkylator-induced DNA damage.

Therapeutic Indications in Hematology: Phase II studies suggest that topotecan has activity in MDS, AML, and MM.

Irinotecan (Camptosar or CPT-11)

Chemistry and Mechanism of Action: Irinotecan (Camptosar or CPT-11) is a prodrug that has a bulky piperidino side chain at C-10 that is cleaved in vivo by a carboxylesterase-converting enzyme to generate SN-38. SN-38 is approximately 1000-fold more potent a topoisomerase I inhibitor than CPT-11. The lactone forms of both SN-38 and CPT-11 are more potent inhibitors of topoisomerase I than the carboxylate forms, which is felt to be the mechanism of action of these drugs as described for topotecan.

Absorption, Fate, and Excretion: The terminal half-life of the lactone form of CPT-11 is 7 hours, and that of the total drug is 10.5 hours. The terminal half-life of SN-38 lactone is 8.7 hours, and that of the total drug is 14.7 hours. Of a dose of irinotecan, 22% is excreted unchanged in the urine. SN-38 is excreted into the bile and can undergo glucuronidation. Whereas the plasma protein binding of CPT-11 is reported to be between 30% and 68%, that of SN-38 is 95%.

Preparation and Administration: Irinotecan is available as a 100-mg single-dose vial with 20 mg/mL of irinotecan. This preparation also contains 45 mg of sorbitol/mL and 0.9 mg of lactic acid/mL with the pH adjusted to 3.5. This solution can be diluted with 5% dextrose in water (preferred) or in normal saline to a final concentration of 0.1–1.2 mg/mL. The solution is stable for up to 24 hours at room temperature or 48 hours when refrigerated. The dose should be modified for severe diarrhea.

Toxic Effects: The major toxic effect of irinotecan is diarrhea. This can be early-onset diarrhea, occurring within hours of administration, or during the infusion, which can be associated with cramping, vomiting, flushing, and diaphoresis. These side effects are attributable to the cholinergic effects of CPT-11 and can be managed with atropine. Severe later onset diarrhea can be treated with high-dose loperamide, which has been found to decrease the incidence of grade 4 diarrhea from 20% to 2%. Diarrhea has been found to be the dose-limiting toxicity when irinotecan is given on a weekly schedule, and neutropenia is the dose-limiting toxicity when the drug is given every 3 weeks. Also seen are alopecia, nausea, vomiting, mucositis, fatigue, increased liver function test results, and rare cases of pulmonary toxicity.

Potential Drug Interactions: As described for topotecan, in vitro data suggest some synergism when topoisomerase I inhibitors precede topoisomerase II inhibitors or follow alkylating agent administration.

Therapeutic Indications in Hematology: Phase I and phase II studies have shown responses in refractory leukemia and lymphoma.

APPENDIX

57.5

CLINICAL PHARMACOLOGY OF PLATINUM ANALOGS

Cisplatin (Platinol)

Chemistry and Mechanism of Action: Cisplatin [cisdiaminedichloroplatinum(II)] is an inorganic heavy-metal complex. This complex can have *cis*- and *trans*-isomers; the *cis*-isomer is the active antitumor drug. In the relatively higher chloride concentrations of plasma, cisplatin is uncharged in the dichloroform and passes through plasma membranes. Intracellularly, the low chloride concentrations allow the displacement of the chloride ligands by water to form the positively charged aquated complex. This forms covalent cross-links between two nucleophilic atoms of macromolecules such as the N⁷ positions of guanine and adenine in DNA. The cytotoxicity of cisplatin correlates closely with total platinum binding to DNA, to inter-strand cross-links and to the formation of intrastrand bidentate N⁷ adducts at d(GpG) and d(ApG), resulting in intrastrand cross-links that bend the DNA helix and inhibit DNA synthesis. Cisplatin damage to DNA induces apoptosis of sensitive cells.

Absorption, Fate, and Excretion: After IV injection, the drug concentrates in the liver, kidneys, and bowel. Plasma levels of cisplatin decay in a biphasic manner, with an initial half-life of 25–49 minutes and a terminal half-life of 58–73 hours. Although 15% of the administered cisplatin is excreted unchanged in the urine, up to 90% of the administered dose of the drug can be recovered from the urine.

Preparation and Administration: Cisplatin is commercially available as a lyophilized powder, supplied in 10- and 50-mg vials also containing mannitol, sodium chloride, and hydrochloric acid, and as an aqueous solution in 50- and 100-mg vials. Reconstitution of the powder for injection is achieved by adding sterile water to make a 1-mg/mL solution. The reconstituted solution should be further diluted in normal saline (usually 500 mL to 1 L) and administered over 1–3 hours. To prevent nephrotoxic effects, 25–50 g of mannitol is often added to the saline solution, and patients are aggressively hydrated before and after cisplatin infusion. Magnesium sulfate (12–24 mEq) is commonly added to the saline solution to preclude the development of hypomagnesemia.

Toxic Effects: Nephrotoxicity is the dose-limiting toxic effect. Cisplatin produces a dose-dependent impairment of renal tubular function manifested by an increase in serum creatinine as well as potassium and magnesium wasting. The renal dysfunction is usually reversible, but repeated treatments may produce a cumulative and permanent mild-to-moderate impairment of renal function. Administration of other nephrotoxic agents such as aminoglycosides, even between courses, can potentiate its toxicity. Nausea and vomiting are usually severe and require the use of aggressive antiemetic support. When doses greater than 70 mg/m² are used, it is also important to protect against delayed nausea and vomiting by administering antiemetic agents (e.g., prochlorperazine plus dexamethasone) for 3 days after therapy. Myelosuppression is usually mild. High-frequency hearing loss, tinnitus, and frank deafness may occur. Peripheral neurotoxicity, characterized by paresthesias or sensory loss in a glove-and-stocking distribution or as muscular weakness, is relatively common in patients who receive total cumulative doses of greater than 500 mg/m². The peripheral neuropathy may take many months to resolve, if it does at all. Vestibular toxicity and anaphylactic reactions may occur rarely.

Potential Drug Interactions: Aminoglycosides and amphotericin may enhance cisplatin nephrotoxicity. Caution should be exercised

when cisplatin is administered with bleomycin and methotrexate because cisplatin-induced renal damage may delay the excretion and thus increase the toxicity of these agents.

Therapeutic Indications in Hematology: Cisplatin is used in the treatment of refractory lymphomas, usually in combination with ara-C and high-dose dexamethasone.

Carboplatin (Paraplatin)

Chemistry and Mechanism of Action: Carboplatin is a second-generation platinum (II) complex. Its mechanism of action is very similar to that of cisplatin. However, the carboxyl ester groups in this platinum complex are less easily displaced and less chemically reactive. The peak levels of DNA cross-linking also occur 6–12 hours later for carboplatin than for cisplatin.

Absorption, Fate, and Excretion: Carboplatin is primarily eliminated through the kidneys. Its elimination is slower than cisplatin with a terminal half-life between 2 and 6 hours. After IV injection, approximately 60% of the total drug is excreted within 24 hours.

Preparation and Administration: Carboplatin is commercially available as a lyophilized powder in 50- and 150-mg vials containing carboplatin and mannitol. It is reconstituted with sterile water to a final concentration of 10 mg/mL. For injection, further dilution with 5% dextrose and water or normal saline to a concentration of 0.5 or 2 mg/mL, in which it is stable for 8 hours at room temperature. Carboplatin is often administered by IV injection over 15–30 minutes. Patients with reduced renal function (creatinine clearance of <60 mL/min) should have the dose of carboplatin decreased according to the formula described by Egorin et al.⁴²

For previously untreated patients:

$$\begin{aligned} \text{Dosage (mg/m}^2\text{)} &= (0.091)(\text{Creatinine clearance/Body surface area}) \\ &\quad \times [\text{Pretreatment platelet count} - \text{Platelet nadir desired} / \\ &\quad \text{Pretreatment platelet count} \times 100] + 86 \end{aligned}$$

For heavily pretreated patients:

$$\begin{aligned} \text{Dosage (mg/m}^2\text{)} &= (0.091)(\text{Creatinine clearance/Body surface area}) \\ &\quad \times [(\text{Pretreatment platelet count} - \text{Platelet nadir desired} / \\ &\quad \text{Pretreatment platelet count} \times 100) - 17] + 86 \end{aligned}$$

A formula developed by Calvert and colleagues²³ also takes into account the patient's pretreatment renal function, as follows:

$$\text{Dose (mg)} = \text{Target AUC (mg/mL} \times \text{min)} \text{ H} [\text{GFR (mL/min)} + 25]$$

where the dose in mg (not mg/m² body surface area) equals target AUC (area under the plasma clearance curve) × GFR (glomerular filtration rate) + 25.

In previously untreated adults, the AUC can be estimated at 7 when carboplatin is used alone and 4.5 when used in combination. If AUC is set lower, less toxicity is expected.

Toxic Effects: The dose-limiting toxic effect is myelosuppression, thrombocytopenia being more significant than leukopenia.

Carboplatin leads to less emesis than cisplatin. Although nausea and vomiting are common, they can be easily controlled with antiemetics. At high doses such as those used for bone marrow transplantation, hepatotoxicity, renal dysfunction, and moderate-to-severe cytotoxicity can occur.

Potential Drug Interactions: None reported.

Clinical Indications in Hematology: Carboplatin has been recently approved for the treatment of ovarian cancer. It is also used to treat small-cell lung, testicular, head and neck, and genitourinary cancers. High-dose carboplatin is presently under evaluation in acute leukemias and lymphomas.

HISTONE DEACETYLASE INHIBITORS

Panobinostat

Chemistry and Mechanism of Action: Panobinostat is a histone deacetylase (HDAC) inhibitor that inhibits the enzymatic activity of HDACs at nanomolar concentrations. HDACs catalyze the removal of acetyl groups from the lysine residues of histones and some non-histone proteins. Inhibition of HDAC activity results in increased acetylation of histone proteins, an epigenetic alteration that results in a relaxing of chromatin, leading to transcriptional activation. In vitro panobinostat caused the accumulation of acetylated histones and other proteins, inducing cell cycle arrest and/or apoptosis of some transformed cells. Panobinostat shows more cytotoxicity towards tumor cells compared with normal cells.

Absorption, Fate, and Excretion: The oral bioavailability of panobinostat is approximately 21%, and is 90% bound to human plasma proteins and is independent of concentration. Panobinostat is metabolized in the liver via reduction, hydrolysis, oxidation, and glucuronidation. About 40% of hepatic elimination occurs via CYP3A, while CYP2D6 and CYP2C19 are minor pathways.

Preparation and Administration: Panobinostat is available as a 10-mg size #3 light-green opaque capsule, a 15-mg size #1 orange opaque capsule, and a 20-mg size #1 red opaque capsule.

Toxic Effects: Panobinostat has been associated with severe diarrhea, severe and fatal cardiac ischemic events, severe arrhythmias, serious hemorrhage, myelosuppression, and elevations in aminotransferases and total bilirubin.

Potential Drug Interactions: All drugs undergoing metabolism by the CYP3A and CYP2D6 pathways should be used with caution.

Therapeutic Indications in Hematology: Multiple myeloma.

Romidepsin

Chemistry and Mechanism of Action: Romidepsin is a HDAC inhibitor. HDAC catalyzes the removal of acetyl groups from acetylated lysine residues in histones, resulting in the modulation of gene expression, which induces cell cycle arrest and apoptosis.

Absorption, Fate, and Excretion: Romidepsin undergoes extensive metabolism primarily by CYP3A4, with minor contribution from CYP3A5, CYP1A1, CYP2B6, and CYP2C19. It has a 3-hour half life and is >90% protein bound.

Preparation and Administration: Romidepsin is supplied as a kit including a sterile, lyophilized powder in a single-use vial containing 10 mg of romidepsin and 20 mg of the bulking agent, povidone, USP. In addition, each kit includes one sterile diluent vial containing 2 mL (deliverable volume) of 80% propylene glycol, USP, and 20%

dehydrated alcohol, USP. Romidepsin is administered IV over a 4-hour infusion.

Toxic Effects: Romidepsin is associated with cardiac toxicities including ST-segment changes and T-wave changes, along with QT prolongation, hypotension and ventricular arrhythmia, severe myelosuppression along with gastrointestinal symptoms, and TLS.

Potential Drug Interactions: All drugs undergoing metabolism by the CYP3A and CYP2D6 pathways should be used with caution.

Therapeutic Indications in Hematology: Cutaneous and peripheral T-cell lymphomas.

TYROSINE KINASE INHIBITORS

Bosutinib

Chemistry and Mechanism of Action: Bosutinib is a TK inhibitor, specifically BCR-ABL kinase.

Absorption, Fate, and Excretion: Bosutinib is primarily metabolized by CYP3A4. The major circulating metabolites identified in plasma are oxydechlorinated (M2) bosutinib (19% of parent exposure) and *N*-demethylated (M5) bosutinib (25% of parent exposure), with bosutinib *N*-oxide (M6) as a minor circulating metabolite. All the metabolites were deemed inactive. The half life of bosutinib is 22.5 hours and 95% is protein bound. Food increases the absorption of bosutinib. The bosutinib dose should be reduced in patients with severe (creatinine clearance [CLcr] <30 mL/min) or moderate (CLcr 30–50 mL/min) renal impairment.

Preparation and Administration: Bosutinib is available as a 100-mg yellow oval and a 500-mg red oval tablet.

Toxic Effects: Bosutinib is associated with gastrointestinal toxicity including diarrhea, nausea, vomiting, abdominal pain, myelosuppression, and hepatic transaminase elevations. Fluid retention occurs with bosutinib and may manifest as pericardial effusion, pleural effusion, pulmonary edema, and/or peripheral edema.

Potential Drug Interactions: All drugs undergoing metabolism by the CYP3A4 pathway should be used with caution.

Therapeutic Indications in Hematology: Philadelphia chromosome-positive (Ph+) chronic myelogenous leukemia (CML).

Crizotinib

Chemistry and Mechanism of Action: Crizotinib is an inhibitor of RTKs including ALK, hepatocyte growth factor receptor (c-Met), reactive oxygen species 1 (c-ros), and Recepteur d'Origine Nantaïs (RON). Crizotinib prevents the expression of oncogenic fusion proteins from activating gene expression. This inhibition impairs cell proliferation and survival of these proteins.

Absorption, Fate, and Excretion: Bioavailability ranges from 32% to 66%. Crizotinib is metabolized in the liver by CYP3A4/5. The primary pathways include oxidation of the piperidine ring to crizotinib lactam and *O*-dealkylation, with subsequent phase 2 conjugation of *O*-dealkylated metabolite. No starting dose adjustment is needed for patients with mild (CLcr 60–89 mL/min) or moderate (CLcr 30–59 mL/min) renal impairment based on a population pharmacokinetic analysis. Increased exposure to crizotinib occurred in patients with severe renal impairment (CLcr <30 mL/min) not requiring dialysis. Administer XALKORI at a dose of 250 mg PO once daily in patients with severe renal impairment not requiring dialysis.

Preparation and Administration: Crizotinib is provided as a hard, 250-mg gelatin capsule, size 0, and a hard, 200-mg gelatin capsule, size 1.

Toxic Effects: Rare but serious toxicities include hepatotoxicity, interstitial lung disease/pneumonitis, QT prolongation, and bradycardia. Other toxicities seen are vision disorders presenting as visual impairment, photopia, blurred vision, sensory neuropathy, renal cysts, nausea, vomiting and diarrhea, dizziness, and fluid retention.

Potential Drug Interactions: Co-administration of crizotinib with strong CYP3A inhibitors increases crizotinib plasma concentrations. Co-administration of crizotinib with strong CYP3A inducers decreases crizotinib plasma concentrations.

Therapeutic Indications in Hematology: ALK-positive anaplastic large-cell lymphoma.

Sorafenib

Chemistry and Mechanism of Action: Sorafenib blocks Raf kinases, which are serine/threonine protein kinases that are downstream effector molecules of Ras proteins. These kinases activate the Raf/MEK/ERK signaling pathway mediating cell proliferation, differentiation, and transformation. Sorafenib also inhibits tumor angiogenesis by VEGF receptor (VEGFR)-2, VEGFR-3, PDGFR β , Flt3, c-KIT, and p38- α .

Absorption, Fate, and Excretion: Bioavailability ranges from 38% to 49%. Sorafenib is metabolized through oxidative metabolism by CYP3A4 and glucuronidation with a mean elimination half-life of 25–48 hours. No correlation between sorafenib exposure and renal function was observed following administration of a single PO dose of 400 mg to subjects with normal renal function and subjects with mild (CLcr 50–80 mL/min), moderate (CLcr 30 to <50 mL/min), or severe (CLcr <30 mL/min) renal impairment who were not on dialysis. No dose adjustment is necessary for patients with mild, moderate, or severe renal impairment who are not on dialysis.

Preparation and Administration: Tablets containing sorafenib tosylate (274 mg) equivalent to 200 mg of sorafenib.

Toxic Effects: Sorafenib has been associated with cardiac ischemia, infarction hemorrhage, congestive heart failure and hypertension, and QT interval prolongation. Adverse dermatologic effects including hand-foot skin reaction, rash, Stevens-Johnson syndrome and toxic epidermal necrolysis, gastrointestinal perforation, drug-induced hepatitis, and impairment of TSH suppression in DTC have also been reported. Sorafenib also causes leukopenia, lymphopenia, anemia, neutropenia, and thrombocytopenia.

Potential Drug Interactions: Any drug that has an effect on or is metabolized by CYP3A4 has potential interactions.

Therapeutic Indications in Hematology: FLT3-ITD positive AML.

Nilotinib

Chemistry and Mechanism of Action: Nilotinib is a selective TK inhibitor active against BCR-ABL kinase. Nilotinib binds to and stabilizes the inactive conformation of the kinase domain of ABL protein. Nilotinib is 30-fold more potent than imatinib.

Absorption, Fate, and Excretion: Nilotinib is rapidly absorbed and reaches its peak concentration in 3 hours. The AUC of nilotinib increases by 82% when given 30 minutes after a high-fat meal compared with a fasting state. Its elimination half-life is approximately 17 hours. It is metabolized by oxidation and hydroxylation,

as well as undergoing metabolism by CYP3A4. None of the nilotinib metabolites have significant pharmacologic activity.

Preparation and Administration: Nilotinib is available in capsules for oral use, containing a 150- or 200-mg nilotinib base, anhydrous (as hydrochloride, monohydrate) with the following inactive ingredients: colloidal silicon dioxide, crospovidone, lactose monohydrate, magnesium stearate, and polyoxamer 188.

Toxic Effects: Nilotinib may cause anemia, neutropenia, and thrombocytopenia. Prolonged QT interval and sudden death has occurred. Pruritus, rash, and nausea are common. Also seen with nilotinib are arthralgias and myalgias. Cough has also been associated with nilotinib.

Drug Interactions: Nilotinib is a competitive inhibitor of cytochrome P450 (CYP) isoenzymes 3A4, 2C8, 2C9, and 2D6, and has the potential to increase concentrations of drugs metabolized by these enzymes. Nilotinib plasma concentration is increased during concomitant use with potent CYP3A4 inhibitors (e.g., atazanavir, clarithromycin, indinavir, itraconazole, ketoconazole, nefazodone, nelfinavir, ritonavir, saquinavir, telithromycin, voriconazole). Decreased nilotinib plasma concentration occurs during concomitant use with potent CYP3A4 inducers (e.g., dexamethasone, carbamazepine, phenobarbital, phenytoin, rifabutin, rifampin, and St. John's wort). Drugs that increase the pH of the upper gastrointestinal tract may decrease the solubility of nilotinib and reduce its bioavailability. The oral administration of esomeprazole results in a 34% reduction in the AUC of nilotinib.

Therapeutic Indications in Hematology: Nilotinib has demonstrated activity in the case of CML resistance resulting from BCR-ABL kinase mutations from treatment with imatinib. This includes accelerated-phase CML resistant or intolerant to prior therapy. ALL, Ph+, relapsed/refractory. Blastic phase chronic myeloid leukemia, Resistant or intolerant to imatinib. Chronic phase, Ph+, newly diagnosed. Chronic-phase CML, resistant or intolerant to prior therapy.

Ponatinib

Chemistry and Mechanism of Action: Ponatinib is a kinase inhibitor that inhibits the in vitro TK activity of ABL and T315I mutant ABL with IC₅₀ concentrations of 0.4 and 2.0 nM, respectively. Ponatinib inhibits the in vitro activity of additional kinases with IC₅₀ concentrations between 0.1 and 20 nM, including members of the VEGFR, PDGFR, FGFR, EPH receptors and SRC families of kinases, and KIT, RET, TIE2, and FLT3. The drug also inhibits the in vitro viability of cells expressing native or mutant BCR-ABL, including T315I.

Absorption, Fate, and Excretion: Phase I (oxidative) and phase II (hydrolysis) metabolism are involved in at least 64% of a ponatinib dose. In phase I metabolism, CYP3A4 is primarily involved, with CYP2C8, CYP2D6, and CYP3A5 involved to a lesser extent. Ponatinib is also metabolized by esterases or amidases. Ponatinib has a half-life of 24 hours.

Preparation and Administration: Ponatinib is provided as 15- and 45-mg round white tablets.

Toxic Effects: The use of ponatinib has led to arterial and venous thrombosis and occlusions, including fatal myocardial infarction, stroke, and stenosis of large arterial vessels of the brain, and severe peripheral vascular disease. Fatal and serious heart failure or left ventricular dysfunction has occurred. Hypertension. Other toxicities include peripheral neuropathy pancreatitis, ocular toxicity, serious bleeding events, fluid retention, and myelosuppression.

Potential Drug Interactions: All drugs undergoing metabolism by the CYP3A4 pathway should be used with caution.

Therapeutic Indications in Hematology: Philadelphia chromosome–positive chronic myelogenous leukemia and Philadelphia chromosome–positive acute lymphoblastic leukemia.

JANUS KINASE INHIBITORS

Ruxolitinib

Chemistry and Mechanism of Action: Ruxolitinib is a JAK inhibitor (JAK1 and JAK2) that inhibits dysregulated JAK signaling associated with myelofibrosis. JAK signaling involves recruitment of signal transducers and activators of transcription (STATs) to cytokine receptors, activation, and subsequent localization of STATs to the nucleus, leading to modulation of gene expression.

Absorption, Fate, and Excretion: Ruxolitinib is 95% absorbed and 97 % protein bound. Ruxolitinib is metabolized primarily by CYP3A4, with a half-life of approximately 3 hours. Ruxolitinib is not

removed by dialysis, although some active metabolites may be removed; therefore, the drug should be administered after dialysis.

Preparation and Administration: Ruxolitinib is supplied as a 5- and 10-mg round tablet, a 15- and 25-mg oval tablet, as well as a 20-mg capsule. For patients unable to ingest tablets, Jakafi can be administered PO by suspending one tablet in approximately 40 mL of water with stirring for approximately 10 minutes.

Toxic Effects: Ruxolitinib has been shown to cause myelosuppression, progressive multifocal leukoencephalopathy, and infections such as Herpes zoster.

Potential Drug Interactions: All drugs undergoing metabolism by the CYP3A4 pathway should be used with caution,

Therapeutic Indications in Hematology: Myelofibrosis and polycythemia vera,

APPENDIX

57.6

CLINICAL PHARMACOLOGY OF MISCELLANEOUS AGENTS

Idelalisib

Chemistry and Mechanism of Action: Idelalisib is an inhibitor of PI3K δ kinase, which is expressed in normal and malignant B cells. Idelalisib induces apoptosis and inhibits proliferation in cell lines derived from malignant B cells and in primary tumor cells. Idelalisib inhibits several cell signaling pathways, including B-cell receptor (BCR) signaling and CXC-chemokine receptor (CXCR)4 and CXCR5 signaling, which are involved in trafficking and homing of B cells to the lymph nodes and bone marrow.

Absorption, Fate, and Excretion: Idelalisib is metabolized via aldehyde oxidase and CYP3A to an inactive metabolite. It is 84% protein bound, with a half-life of 8.2 hours. AUC is increased up to 1.7-fold in subjects with ALT or AST, or bilirubin values greater than the upper limit of normal (ULN) compared with subjects with normal AST or ALT or bilirubin values. CLcr has no effect on idelalisib exposure. No dose adjustment is needed for patients with CLcr ≥ 15 mL/min.

Preparation and Administration: Idelalisib is available as a 100-mg orange oval tablet as well as a 150-mg pink oval tablet.

Toxic Effects: Fatal and/or serious hepatotoxicity occurred in 14% of patients treated with idelalisib. Severe diarrhea or colitis with possible perforation occurred in 14% of patients. Fatal and serious pneumonitis as well as grade ≥ 3 cutaneous reactions were also seen. 31% of patients treated also had significant neutropenia.

Potential Drug Interactions: All drugs undergoing metabolism by the CYP3A pathway should be used with caution.

Therapeutic Indications in Hematology: Follicular lymphoma, small lymphocytic lymphoma, and CLL.

Oblimersen

Chemistry and Mechanism of Action: Oblimersen is an 18-mer phosphorothioate antisense oligonucleotide that targets human Bcl-2 mRNA and prevents Bcl-2 expression. Oblimersen downregulates Bcl-2 expression, with enhancement of tumor cell apoptosis.

Absorption, Fate, and Excretion: The half-life of oblimersen averages 0.5–2 hours, and it is excreted primarily unchanged in the urine.

Preparation and Administration: Oblimersen is given by continuous IV infusion or subcutaneously.

Toxic Effects: Oblimersen is associated with hyperglycemia, diarrhea, thrombocytopenia, and hepatic toxicity.

Potential Drug Interactions: Unknown.

Therapeutic Indications in Hematology: AML, NHL, and MM.

Thalidomide

Chemistry and Mechanism of Action: The mechanism of action of thalidomide is not fully understood. Thalidomide has immunomodulatory, antiinflammatory, and antiangiogenic properties. The immunologic effects vary substantially under differing conditions but seem to suppress TNF- α production and downmodulate cell surface adhesion molecules. Other antiinflammatory and immunomodulatory properties include suppression of macrophage involvement in prostaglandin synthesis and modulation of IL-10 and IL-12 production by peripheral blood mononuclear cells. Angiogenesis inhibition is described, but the exact mechanism is not yet definitively defined.

Absorption, Fate, and Excretion: Thalidomide absorption is slow after oral administration, and the bioavailability of capsules has not yet been determined, but based on radiolabeled thalidomide, greater than 90% is recovered in urine, suggesting good oral absorption. The mean elimination half-life of thalidomide ranges from 3 to 6.7 hours, but the exact metabolic fate of thalidomide is unknown. Protein binding is 55%–66%.

Preparation and Administration: Thalidomide is available as 50-, 100-, 150-, and 200-mg PO capsules. A 20-mg/mL PO suspension may be prepared with capsules and a 1:1 mixture of Ora-Sweet and Ora-Plus by emptying the contents of twelve 100-mg capsules into a glass mortar. Add small portions of the vehicle and mix to a uniform paste; mix while adding the vehicle in incremental proportions to almost 60 mL; transfer to an amber calibrated bottle and add quantity of vehicle sufficient to make 60 mL. Stable for 35 days refrigerated.

Toxic Effects: Thalidomide frequently may cause deep venous thrombosis and pulmonary embolism. Thalidomide causes birth defects in humans. It must not be given during pregnancy. Leucopenia along with thrombocytopenia is observed. Pruritus and rash as well as constipation are seen.

Drug Interactions: Thalidomide increases cyclosporine A metabolism and clearance. An increase in the thrombogenic state in patients with MDS has been observed in patients receiving darbepoetin alfa and thalidomide. The addition of docetaxel to thalidomide increases the risk of venous thromboembolism.

Therapeutic Indications in Hematology: Thalidomide has been used to treat MM and MDS.

Lenalidomide

Chemistry and Mechanism of Action: Lenalidomide, a thalidomide analog, is an immunomodulatory agent with antineoplastic and antiangiogenic activity. Lenalidomide affects ligand-induced responses (angiogenesis, inflammation, cell adhesion, immune response), inhibits production of TNF, increases production of IL-2 and IFN- γ , and increases cytolytic T-cell and NK cell responses. It inhibits trophic signals to angiogenic factors in cells, and inhibits growth of myeloma cells by inducing cell cycle arrest and apoptosis.

Absorption, Fate, and Excretion: Lenalidomide is rapidly absorbed after oral administration. Lenalidomide has a half-life of 3 hours with 67% of the drug excreted unchanged in the urine. Adjustment to the initial dosage is recommended in patients with moderate or severe renal impairment. Compared with patients with normal renal function, those with moderate and severe renal impairment have a 66%–75% decrease in drug clearance, and patients on hemodialysis have an 80% decrease in clearance. Although the drug is 30% protein bound, lenalidomide is partially removed by hemodialysis and should be given after dialysis. Food does not alter the extent of absorption nor the AUC of lenalidomide.

Preparation and Administration: Lenalidomide is available in 2.5-, 5-, 10-, 15-, and 25-mg capsules for PO administration. Each capsule contains lenalidomide as the active ingredient along with lactose anhydrous, microcrystalline cellulose, croscarmellose sodium, and magnesium stearate.

Toxic Effects: Lenalidomide frequently may cause deep venous thrombosis and pulmonary embolism. Severe myelosuppression across all cell lines is common. Pruritus and rash as well as constipation and hypokalemia are seen. Lenalidomide is an analogue of thalidomide and may cause birth defects in humans. It must not be given during pregnancy.

Drug Interactions: Lenalidomide increases digoxin plasma concentrations. Dexamethasone increases the thrombogenic effect of lenalidomide.

Therapeutic Indications in Hematology: Lenalidomide has activity in MM when used in combination with dexamethasone. It also is has activity in chronic lymphoid leukemia as well as MDS with deletion 5q abnormalities.

Pomalidomide

Chemistry and Mechanism of Action: Pomalidomide is structurally and functionally related to thalidomide. Its mechanism is not fully understood but it has effects on angiogenesis, alters inflammatory and regulatory cytokines, and may affect T cells.

Absorption, Fate, and Excretion: Pomalidomide is administered orally. Pharmacokinetic data are still being elucidated.

Preparation and Administration: Pomalidomide is an investigational agent administered orally.

Toxic Effects: Pomalidomide has extensive bone marrow toxicity affecting all three cell lines, peripheral neuropathy, orthostasis, rashes, pulmonary toxicity, and clotting abnormalities.

Drug Interactions: Data not available.

Therapeutic Indications in Hematology: Pomalidomide has been studied in MM.

Temsirolimus

Chemistry and Mechanism of Action: Temsirolimus is an inhibitor of mammalian target of rapamycin (mTOR) and binds to an intracellular protein (FKBP-12). This protein–drug complex inhibits the activity of mTOR and results in G1 growth arrest. When mTOR is inhibited, its ability to phosphorylate p70S6k and S6 ribosomal protein, which are downstream of mTOR in the PI3K/AKT pathway, was blocked.

Absorption, Fate, and Excretion: Temsirolimus is predominantly metabolized in human liver microsomes by cytochrome P450 3A4 (CYP3A4). Temsirolimus is extensively metabolized to sirolimus. Four other metabolites account for less than 10% in the plasma. The

mean half-life of temsirolimus is 17.3 hours, and the mean half-life of sirolimus, the active metabolite, is 54.6 hours. Neither the parent drug nor its metabolite is dialyzable. Dosage reduction or discontinuance may be warranted in patients with hepatic impairment to reduce the potential for toxicity.

Preparation and Administration: Temsirolimus is supplied as a kit consisting of two vials: temsirolimus injection (25 mg/mL) and a diluent of 1.8 mL. Temsirolimus is mixed with 1.8 mL of the diluent. The resultant solution contains 10 mg/mL. The concentrate–diluent mixture is stable below 25°C for up to 24 hours. To administer, withdraw the required amount of concentrate–diluent mixture and further dilute into an infusion bag containing 250 mL of 0.9% sodium chloride injection, USP. Patients should receive prophylactic IV diphenhydramine 25 mg before the start of each dose.

Toxic Effects: Temsirolimus causes a decreased lymphocyte count, leucopenia, decreased hemoglobin, and thrombocytopenia. Hyperglycemia, edema, and rash (which may progress to Stevens-Johnson syndrome) have also been seen.

Drug Interactions: The concomitant use of strong CYP3A4 inhibitors (e.g., ketoconazole, itraconazole, clarithromycin, atazanavir, indinavir, nefazodone, nelfinavir, ritonavir, saquinavir, telithromycin, and voriconazole) may increase plasma concentrations of sirolimus (a major metabolite of temsirolimus). The use of concomitant strong CYP3A4 inducers (e.g., dexamethasone, phenytoin, carbamazepine, rifampin, rifabutin, rifampicin, phenobarbital) may decrease plasma concentrations of sirolimus (a major metabolite of temsirolimus).

Therapeutic Indications in Hematology: Temsirolimus has been shown to have activity in MCL.

Everolimus

Chemistry and Mechanism of Action: Everolimus is an analogue of rapamycin (sirolimus) with immunosuppressive and antiproliferative activity. Everolimus is an inhibitor of rapamycin (mTOR), a serine–threonine kinase, downstream of the PI3K/AKT pathway. After binding and forming a complex with the cytoplasmic FK506-binding protein 12 (FKBP-12), the complex binds to and inhibits mTOR and phosphorylates P70 S6 ribosomal protein kinase (a substrate of mTOR). Everolimus reduces the activity of S6 ribosomal protein kinase (S6K1) and eukaryotic elongation factor 4E-binding protein. In addition, everolimus inhibits the expression of hypoxia-inducible factor 1 and reduces the expression of VEGF.

Absorption, Fate, and Excretion: Peak everolimus concentrations are reached 1–2 hours after oral administration with protein binding of 74%. Everolimus is extensively metabolized by the liver, with everolimus being a substrate of CYP3A4 and PGP. Metabolism involves demethylation, hydroxylation, and ring degradation. There are six main metabolites of everolimus, which have approximately 100-times less activity than the parent everolimus compound, including three monohydroxylated metabolites, two hydrolytic ring-opened metabolites, and a phosphatidylcholine conjugate of everolimus. The elimination half-life is 30 hours and is prolonged to a mean of 79 hours in patients with moderate hepatic impairment.

Preparation and Administration: Everolimus is available in 2.5-, 5-, 7.5- and 10-mg nonscored tablets.

Toxic Effects: Everolimus causes bone marrow suppression across all cell lines, hyperglycemia, rash, and mucositis along with pulmonary toxicity.

Drug Interactions: Everolimus concentrations are increased when administered with CYP3A4 or PGP inhibitors such as ketoconazole,

itraconazole, clarithromycin, atazanavir, nefazodone, saquinavir, telithromycin, ritonavir, indinavir, nelfinavir, voriconazole, amprenavir, fosamprenavir, aprepitant, erythromycin, fluconazole, verapamil, diltiazem, grapefruit, grapefruit juice, or St. John's wort. Everolimus concentrations are decreased when administered with strong CYP3A4 inducers such as phenytoin, carbamazepine, rifampin, rifabutin, rifapentine, or phenobarbital.

Therapeutic Indications in Hematology: Everolimus has been used in MCL, diffuse large B-cell lymphoma, and Hodgkin lymphoma.

Arsenic Trioxide

Chemistry and Mechanism of Action: The mechanism of action of arsenic trioxide is not completely understood. Arsenic trioxide causes morphologic changes and DNA fragmentation characteristic of apoptosis in NB4 human promyelocytic leukemia cells in vitro, possibly mediated by activation of cysteine proteases (caspases). Arsenic trioxide also causes damage or degradation of the fusion protein PML-RAR β .

Absorption, Fate, and Excretion: The metabolism of arsenic trioxide involves reduction of pentavalent arsenic to trivalent arsenic by arsenate reductase and methylation of trivalent arsenic to monomethylarsinic acid and dimethylarsinic acid by methyltransferases. The main site of methylation reactions appears to be the liver. The pharmacokinetics of trivalent arsenic, the active species, have not been characterized.

Preparation and Administration: Arsenic trioxide is available in 10-mL, single-use ampules containing 10 mg of arsenic trioxide. It is formulated as a sterile, nonpyrogenic, clear solution of arsenic trioxide in water for injection using sodium hydroxide and dilute hydrochloric acid to adjust to pH 8. Trisenox should be diluted with 100–250 mL of 5% dextrose injection, USP, or 0.9% sodium chloride injection, USP. Arsenic trioxide should be administered IV over 1–2 hours. The infusion duration may be extended up to 4 hours if acute vasomotor reactions are observed. A central venous catheter is not required.

Toxic Effects: Arsenic trioxide has electrocardiographic abnormalities, including QT interval prolongation, T-wave flattening, and atrioventricular block. Nonspecific edema and weight gain have been reported. Dry skin, pruritus, and rashes have occurred relatively frequently. Anemia, thrombocytopenia, and neutropenia are also observed.

Drug Interactions: Arsenic trioxide can cause QT interval prolongation and complete atrioventricular block. QT prolongation can lead to a torsade de pointes-type ventricular arrhythmia. The risk of torsade de pointes is related to the extent of QT prolongation, and concomitant administration of QT-prolonging drugs may exacerbate this phenomenon.

Therapeutic Indications in Hematology: Arsenic trioxide is effective in newly diagnosed acute promyelocytic leukemia, FAB M3. Moreover, in patients who are refractory to or have relapsed from retinoid and anthracycline chemotherapy, arsenic trioxide has some activity as a single agent for relapsed or refractory MM. Arsenic trioxide produced hematologic improvement in a subset of patients with MDS.

Bortezomib (Velcade)

Molecular Formula: The molecular formula is C₁₉H₂₅BN₄O, molecular weight 384.24 g/mol, *N*-pyrazinecarbonyl-L-phenylalanine-L-leucine boronic acid.

Absorption, Fate, and Excretion: After IV administration of a 1.3-mg/m² dose, the median estimated maximum plasma

concentration of bortezomib was 509 ng/mL (range: 109–1300 ng/mL). The mean elimination half-life of bortezomib after the first dose ranged from 9 to 15 hours at doses ranging from 1.45 to 2.00 mg/m² in patients with advanced malignancies. In vitro studies with human liver microsomes and human cDNA-expressed cytochrome P450 isozymes indicate that bortezomib is primarily oxidatively metabolized via cytochrome P450 enzymes 3A4, 2D6, 2C19, 2C9, and 1A2. The major metabolic pathway is deboronation to form two deboronated metabolites that subsequently undergo hydroxylation to several inactive metabolites.

Preparation and Administration: Bortezomib for injection is supplied as a lyophilized powder for reconstitution. Each sterile single-use vial contains 3.5 mg of bortezomib and 35 mg of mannitol, USP. Each vial is reconstituted with 3.5 mL normal (0.9%) saline such that the reconstituted solution contains bortezomib at a concentration of 1 mg/mL. The pH of the reconstituted solution is between 5 and 6. The drug is given without any further dilution as an IV bolus over 3–5 seconds. Intact vials of lyophilized bortezomib for injection are stored in a refrigerator at 2–8°C (35–47°F) and protected from light. Stability studies are ongoing to monitor each clinical lot. Product should be administered immediately after reconstitution. The solution as reconstituted is stable for 43 hours at room temperature. Bortezomib is administered as an IV bolus (over 3–5 seconds) twice weekly for 2 weeks followed by a 1-week rest period.

Toxic Effects: The most commonly reported adverse events are asthenic conditions (including fatigue, malaise, and weakness; 65%), nausea (64%), diarrhea (51%), decreased appetite (including anorexia; 43%), constipation (43%), thrombocytopenia (43%), peripheral neuropathy (including peripheral sensory neuropathy and peripheral neuropathy aggravated; 37%), pyrexia (36%), vomiting (36%), and anemia (32%). Fourteen percent of patients experienced at least one episode of grade 4 toxicity, with the most common being thrombocytopenia (3%) and neutropenia (3%).

Potential Drug Interactions: No formal drug interaction studies have been conducted with bortezomib. In vitro studies with human liver microsomes indicate that bortezomib is a substrate of cytochrome P450 3A4, 2D6, 2C19, 2C9, and 1A2. Bortezomib may inhibit 2C19 activity (IC₅₀ = 18 μ M, 6.9 μ g/mL) and increase exposure to drugs that are substrates for this enzyme. Patients who are concomitantly receiving bortezomib and drugs that are inhibitors or inducers of cytochrome P450 3A4 should be closely monitored for either toxicities or reduced efficacy. Patients on oral antidiabetic agents receiving bortezomib treatment may experience hypo- or hyperglycemia and require close monitoring of their blood glucose levels and adjustment of the dose of their antidiabetic medication. Finally, patients should be cautioned about the use of concomitant medications that may be associated with peripheral neuropathy (e.g., amiodarone, antivirals, isoniazid, nitrofurantoin, or statins), or with a decrease in blood pressure.

Therapeutic Indications in Hematology: Bortezomib is approved by the US Food and Drug Administration (FDA) for the initial treatment of MM patients.

Carfilzomib

Chemistry and Mechanism of Action: Carfilzomib is an epoxomicin derivative that irreversibly binds to and inhibits the chymotrypsin-like activity of the 20S proteasome. Inhibition of proteasome-mediated proteolysis results in an accumulation of polyubiquitinated proteins, which may lead to cell cycle arrest, induction of apoptosis, and inhibition of tumor growth.

Absorption, Fate, and Excretion: Carfilzomib is an investigational product. It has rapid clearance with an elimination half-life of less than 30 minutes and a clearance higher than liver blood flow, which suggests there are multiple clearance pathways.

Preparation and Administration: Carfilzomib currently is available investigationally as an IV product.

Toxic Effects: Carfilzomib has been shown to produce mild-to-moderate nausea and diarrhea. Respiratory symptoms occur and include cough, dyspnea, and exertional dyspnea. Neurologic symptoms include hypoesthesia, headache, and paresthesia. Additional adverse events seen are fatigue, pyrexia, and peripheral edema.

Drug Interactions: Data not available.

Therapeutic Indications in Hematology: Carfilzomib has been approved by the FDA for the treatment of MM of patients who have received at least two prior therapies, Hodgkin lymphoma, and NHL.

Ibrutinib

Chemistry and Mechanism of Action: Ibrutinib is a first-in-class oral therapy that is a selective, irreversible inhibitor of Bruton tyrosine kinase (BTK) and inhibits BTK activity, preventing B-cell activation and B-cell-mediated signaling, and inhibiting the growth of malignant B cells that overexpress BTK.

Absorption, Fate, and Excretion: No data available.

Preparation and Administration: Ibrutinib is an approved agent available as an oral dose.

Toxic Effects: Ibrutinib may cause diarrhea, fatigue, nausea, and skin bruising. Also, transient high lymphocyte counts are frequently seen.

Drug Interactions: No data available.

Therapeutic Indications in Hematology: Ibrutinib is used in CLL/small lymphocytic lymphoma, MCL, diffuse large B-cell lymphoma, and MM. It is approved for the treatment of MCL patients who have received two prior therapies and CLL patients with the 17p deletion.

Dasatinib

Chemistry and Mechanism of Action: Dasatinib is an orally active TK inhibitor against BCR-ABL, SRC family, c-KIT, EPH receptor A2, and PDGFR β . The primary mechanism of resistance to dasatinib is the *T315I* mutant clone.

Absorption, Fate, and Excretion: Dasatinib is orally absorbed and extensively metabolized in human liver microsomes, primarily by cytochrome P450 CYP3A4, to an active metabolite. CYP3A4 is the primary enzyme responsible for the formation of the active metabolite. Flavin-containing monooxygenase 3 and uridine diphosphate-glucuronosyltransferase enzymes are also involved in the formation of dasatinib metabolites. In human liver microsomes, dasatinib was a weak time-dependent inhibitor of CYP3A4. The exposure of the active metabolite, which is equipotent to dasatinib, represents approximately 5% of the dasatinib AUC.

Preparation and Administration: Dasatinib is an oral agent usually taken twice daily without regard to meals.

Toxic Effects: Treatment with dasatinib is associated with severe thrombocytopenia, neutropenia, anemia, and platelet dysfunction. Also seen is fluid retention, including pleural and pericardial effusion, pulmonary edema, severe ascites, and generalized edema. A prolonged QT interval has been observed as well as extensive skin rashes.

Drug Interactions: Dasatinib is a CYP3A4 substrate. Administration with drugs that are CYP3A4 inhibitors may cause increased dasatinib plasma concentrations and subsequent increase in toxicities.

Drugs that induce CYP3A4 activity may decrease dasatinib plasma concentrations and decrease its effectiveness. The solubility of dasatinib is pH dependent. Simultaneous administration of SPRYCEL with antacids should be avoided, and there should be 2 hours' separation in the administration of dasatinib and antacids. Long-term suppression of gastric acid secretion by H₂ blockers or proton pump inhibitors may reduce dasatinib exposure, and antacids are preferred. Dasatinib is a time-dependent inhibitor of CYP3A4; therefore, CYP3A4 substrates may have their plasma concentration altered by dasatinib.

Therapeutic Indications in Hematology: Treatment with dasatinib results in hematologic and cytogenetic responses in patients with lymphoid blast crisis, Ph+ chronic myeloid leukemia, and Ph+ ALL as initial treatment and in disease-resistant or intolerant to imatinib.

Bleomycin

Chemistry and Mechanism of Action: Bleomycin is a glycopeptide. Its antitumor effect correlates with its ability to cause scission of both double- and single-stranded DNA via activated oxygen formed by the iron-bleomycin complex. Bleomycin also affects DNA repair by inhibiting DNA ligase.

Absorption, Fate, and Excretion: Bleomycin is rapidly distributed throughout the body and concentrates in the skin, lungs, kidneys, peritoneum, and lymph nodes. Its plasma half-life is 2–4 hours. Within 24 hours of injection, approximately 50% of an administered dose is excreted unchanged in the urine. Bleomycin elimination correlates well with creatinine clearance; accordingly, patients with renal failure should receive reduced doses. In the tissues, bleomycin is inactivated by bleomycin hydrolase. Tissues lacking this enzyme, such as the lungs and skin, are more susceptible to the drug's toxic effects.

Preparation and Administration: Bleomycin is commercially available in vials containing 15 U (approximately equivalent to 15 mg), from which it is reconstituted for injection with 3–5 mL of sterile water, normal saline, 5% dextrose in water, or bacteriostatic water. For IV infusion, the reconstituted solution can be further diluted with either normal saline or 5% dextrose in water and administered over 5 minutes. Bleomycin can also be administered by the SC, IV, IM, intracavitary, and intraarterial routes. Because patients with lymphomas are at an increased risk of anaphylactoid reactions, which may not occur until 12 hours after administration, the first two doses should be IM "test doses" of 1–2 mg. If no reactions occur, full doses may be given.

Toxic Effects: The most serious toxic effect is interstitial pneumonitis, which is dose related and occurs in approximately 10% of patients treated with cumulative doses of greater than 350–400 U. The interstitial pneumonitis may evolve into life-threatening pulmonary fibrosis. Pulmonary toxicity is more common in patients older than 70 years, in those receiving a total dose of greater than 400 U, and in those who received prior radiotherapy to the lung. It is important to emphasize, however, that the pulmonary toxicity is unpredictable; it has been reported in patients who had none of these risk factors and has occurred in a patient after administration of only 20 U. Some reports suggest that an increased concentration of inspired oxygen acts synergistically with bleomycin to produce pulmonary fibrosis. During critical illness and perioperatively, therefore, an attempt should be made to maintain the inspired oxygen concentration at 21%. The early phases of the pulmonary toxicity are clinically manifested by dyspnea and fine rales. Although corticosteroids are often used in this setting, it is not clear that they are of benefit.

Mucocutaneous toxicity occurs in 50% of patients treated and is manifested by hyperpigmentation, pruritic erythema, mucositis, desquamation of the plantar surface skin of the hands or feet, ridging of the nails, and alopecia. The mucositis can be severe and is the acute

dose-limiting toxic effect. Febrile reactions, which occur a few hours after bleomycin administration and may last 4–12 hours, are also common. Fever becomes less frequent with continued use of the drug and can usually be prevented by concurrent administration of glucocorticosteroids (e.g., 100 mg of hydrocortisone). Bleomycin has virtually no myelosuppressive effect. Anaphylactoid reactions are observed in approximately 1% (up to 8% in some series) of patients with lymphomas treated with bleomycin.

Potential Drug Interaction: Bleomycin, administered with other drugs for the treatment of lymphorrhea, can decrease the oral bioavailability of digoxin and the pharmacologic effect of phenytoin and certain anesthetic drugs.

Therapeutic Indications in Hematology: Bleomycin is often incorporated in the chemotherapy regimens of Hodgkin lymphoma (ABVD and MOPP-ABV hybrid regimens) and NHL (MACOP-B, PROMACE-CYTABOM, M-BACOD, and CHOP-Bleo).

Asparaginase

Chemistry and Mechanism of Action: Asparaginase contains the high-molecular-weight enzyme L-asparaginase amidohydrolase, type EC-2, derived from *Escherichia coli*. Asparaginase hydrolyzes serum asparagine to nonfunctional aspartic acid and ammonia, depriving tumor cells of a required amino acid; thus, tumor cell proliferation is blocked by the interruption of asparagine-dependent protein synthesis. The drug appears to be most active in the G₁ phase.

Absorption, Fate, and Excretion: Asparaginase is not absorbed orally. Its plasma half-life varies from 8 to 30 hours and is not influenced by dosage, age, sex, surface area, or renal or hepatic function.

Preparation and Administration: Asparaginase is commercially available in vials containing 10,000 IU of asparaginase in 80 mg of mannitol. For IV use, the drug should be reconstituted with 5 mL of either sterile water or sodium chloride for injection and injected in the tubing of a freely running infusion of either normal saline or 5% dextrose in water over 30 minutes. For IM or SC use, each vial should be reconstituted with 2 mL of sodium chloride for injection to obtain a 5000-U/mL solution. For dosages that exceed 2 mL, use of two injection sites is recommended. For both IV and IM administration, the drug must be used within 8 hours of reconstitution, and only if it is clear. Because of the possibility of HSRs (particularly in patients with lymphomas), an intradermal skin test is recommended before initial administration of asparaginase or when 1 week has elapsed between doses. For this test, 2 IU should be injected intradermally and observed for a wheal or erythema for 1 hour. A negative skin test result, however, does not preclude possible development of a HSR. It is recommended that oxygen, epinephrine, and corticosteroids be available at the bedside during administration of the drug. For allergic patients, the *E. coli* form of asparaginase should be replaced by the asparaginase derived from *Erwinia carotovora*, provided by the NCI as an investigational group C agent.

Toxic Effects: The toxicity of asparaginase is reported to be greater in adults than in children. Anorexia, nausea, or vomiting occurs in approximately one-third of patients. Most of the other side effects can be divided into two main groups, those related to HSRs to the foreign protein and those resulting from decreased protein synthesis. The HSR is characterized by urticaria, laryngeal edema, bronchospasm, or hypotension and may occur with the initial dose of the drug even if the skin test result is negative. More commonly, however, allergic phenomena are observed after multiple courses of treatment. Adverse effects related to the inhibition of protein synthesis include hypoalbuminemia and decreases in serum fibrinogen, prothrombin, antithrombin III, and other coagulation factors, which may lead to both clotting and hemorrhagic complications; decreased serum

insulin with hyperglycemia; and decreased serum lipoproteins. In 25% or fewer of patients, cerebral dysfunction, characterized by confusion, stupor, and frank coma, can occur. Although the neurotoxic effects resemble those of ammonia toxicity, they are apparently caused by low concentrations of either L-asparagine or L-glutamine in the brain. Acute pancreatitis, which may progress to severe hemorrhagic pancreatitis, may occur in 15% of patients. Elevation of liver enzymes and serum bilirubin is almost universal and is histologically represented by fatty metamorphosis. Liver toxicity, although usually not clinically significant, has resulted in occasional fatalities. Asparaginase can occasionally produce renal functional impairment with oliguric renal failure.

Potential Drug Interactions: When asparaginase is administered immediately before or concurrent with methotrexate, it decreases the cytotoxic effect of the latter. When administered to patients with acute leukemia 9–10 days before or shortly after methotrexate, however, asparaginase appears to enhance the cytotoxic effect of methotrexate. Concurrent administration of asparaginase with vincristine may increase vincristine's neurotoxic effects, but this effect appears to be less pronounced when asparaginase is given after vincristine. The effects of asparaginase on liver function may potentially interfere with the activation or metabolism of other cytotoxic agents.

Therapeutic Indications in Hematology: Asparaginase is used in combination therapy for remission induction of ALL.

Glucocorticoids

Chemistry and Mechanism of Action: Glucocorticoids are synthetic compounds derived from the natural adrenal hormone cortisol. Glucocorticoids mediate their biologic actions predominantly by binding to their cytosolic receptor, which then translocates to the nucleus. There, as a homodimer, it binds to specific DNA sequences located in the regulatory regions of a number of genes. Gene transcription can be upregulated or downregulated by glucocorticoids. They can also inhibit binding of the AP-1 transcription factor to its DNA consensus sequence site. Lymphocytes treated with glucocorticoids undergo apoptosis mediated by glucocorticoid receptors. An early cytostatic phase is marked by growth inhibition and cessation of proliferation caused by inhibition of cellular uptake of glucose, amino acids, and nucleosides, as well as inhibition of macromolecular synthesis. This is followed by a cytolytic phase characterized by chromatin condensation and internucleosomal DNA cleavage.

Absorption, Fate, and Excretion: Many synthetic glucocorticoids are available, the three most commonly used in hematology being prednisone, dexamethasone, and methylprednisolone. Glucocorticoids are well absorbed orally and are primarily metabolized in the liver. Unlike the other two glucocorticoids, the activity of prednisone depends on hepatic conversion to the 11-hydroxy form (prednisolone). Whereas the biologic half-lives of prednisone and methylprednisolone are approximately 12–36 hours, dexamethasone has a biologic half-life of 36–72 hours. Plasma half-lives for all three drugs are within the range of 3–4 hours. Compared with cortisol, the relative antiinflammatory potencies of dexamethasone, methylprednisolone, and prednisone are 25, 5, and 4, respectively, for equivalent doses.

Preparation and Administration: Prednisone is available only for oral administration, but methylprednisolone and dexamethasone are available in oral and parenteral dosage forms.

Toxic Effects: When glucocorticoids are used for less than 14 days, as is often done when they are used in combination with other cytotoxic agents, the most common side effects include euphoria, insomnia, psychosis, hyperglycemia, hypokalemia, increased appetite, metabolic alkalosis, proximal muscular weakness, and fluid retention with edema formation and hypertension. When used on a chronic

basis, glucocorticoids also may induce a “Cushingoid” appearance, easy bruisability, peptic ulcers, osteoporosis, subcapsular cataracts, and an increased susceptibility to infections related to impaired cellular immunity. Because of this, H_2 blockers, antifungal agents (e.g., ketoconazole), and sulfamethoxazole–trimethoprim have been used in certain glucocorticoid chemotherapy combinations.

Potential Drug Interactions: Glucocorticoids interact with a variety of drugs, including barbiturates, oral contraceptives, erythromycin, hydantoins, rifampin, isoniazid, and salicylates. Given the wide range of doses of glucocorticoids used, however, these interactions are of no major clinical relevance.

Clinical Indications in Hematology: Glucocorticoids have direct anticancer activity in many hematologic malignancies, including ALL, CLL, Hodgkin lymphoma, NHL, and plasma cell neoplasms. Because of their efficacy and toxic profiles, which do not overlap with the toxic effects of the other cytotoxic agents, glucocorticoids are used in many chemotherapy regimens. In addition, they are useful in the management of hypercalcemia secondary to myeloma and lymphomas, and are of paramount importance in the treatment of autoimmune hematologic disorders.

Flavopiridol

Chemistry and Mechanism of Action: Flavopiridol is a semi-synthetic flavone and selective inhibitor of CDKs 1, 2, 4–7, PKC, PKA, and PDGF causing cell cycle arrest. It also may inhibit CDK9/TEFb, which causes downregulation of Mcl-1, BIRC4, cyclin D1, and p21CIP1.

Absorption, Fate, and Excretion: Flavopiridol is 94% protein bound and is metabolized by the UDP glucuronyltransferase isoenzymes. Its half-life varies with infusion duration and ranges from 3.5 hours (1-hour infusion) to 27 hours (72-hour infusion).

Preparation and Administration: Flavopiridol is supplied as a 10-mg/mL yellow-greenish solution in a 5-mL vial. Contents may be diluted in either 5% dextrose injection or 0.9% sodium chloride injection to achieve a final concentration of 0.09–1 mg/mL. If the drug is administered through peripheral IV access, a concentration of less than 0.5 mg/mL is thought to decrease thrombotic complications. Flavopiridol has been administered as a 1-, 24-, and 72-hour infusion.

Toxic Effects: Grade 4 neutropenia and grade 3 lymphocytopenia occur and are more common with shorter durations of infusion. Thrombocytopenia is seen infrequently. Secretory diarrhea is a dose-limiting toxicity and may last for up to 3 days. Orthostatic hypotension is a frequently seen occurrence. Thrombosis with the 72-hour infusion duration was far more common than in the shorter infusion durations. A fatigue rate approaching 75% has been reported. Other toxicities include pleuritic chest pain, hyperbilirubinemia, and nausea.

Potential Drug Interactions: Paclitaxel in combination with flavopiridol has been associated with severe dose-limiting neutropenia.

Therapeutic Indications in Hematology: Flavopiridol's place in therapy is still being assessed. It has activity and use in hematologic malignancies, including MCL, leukemias, and MM. It may cause potential solid tumors in combination with other agents. The FDA has granted orphan drug status for flavopiridol to treat patients with AML.

Tanespimycin (17-AAG, Geldanamycin, NSC 330507)

Chemistry: Tanespimycin is a water-soluble benzoquinone ansamycin antibiotic that binds to HSP90.

Fate, Absorption, and Excretion: Tanespimycin has a mean terminal half-life of 2.3 hours and is primarily metabolized by liver microsomal enzymes, specifically CYP3A4. One metabolite, 17-AG, is known to be active and has a mean terminal half-life of 4.6 hours. Peak plasma concentrations of 17-AAG and 17-AG occur at 30 and 60 minutes, respectively. 10.6% of 17-AAG and 7.8% of 17-AG is recovered in the urine over a 72-hour period.

Preparation and Administration: Tanespimycin is available as a single-use amber vial containing 50 mg of tanespimycin in 2 mL of dimethylsulfoxide. Before administration, the tanespimycin concentrate must be completely thawed at room temperature (over a period of ≤ 1 hour). Incomplete thawing affects the concentration of the drug because of changes in volume. Tanespimycin concentrate must be diluted to 1 mg/mL by withdrawing 2 mL and adding it to 48 mL of EPL diluent 2% egg phospholipids with 5% dextrose in water. A clear solution should be obtained with gentle mixing. Shaking should be avoided to prevent foaming. No further dilution is required and the final solution should be dispensed in a glass bottle. A 0.45- μ m filter may be used, but is not required. The infusion should be completed within 8 hours of mixing. Intact vials of Tanespimycin should be stored in the freezer (-10° to -20°C). EPL diluent should be stored in the refrigerator (2° – 8°C) and not frozen. Administration is by IV infusion.

Toxicity: Anemia, diarrhea, nausea, vomiting, fatigue, transaminitis, and muscle pain.

Drug Interactions: Tanespimycin is metabolized by CYP3A4. Agents that alter CYP3A4 activity may affect drug levels and metabolism, although this has not been shown to affect clinical use.

Therapeutic Uses: Lymphoma and leukemia in clinical trials.

Imatinib (Gleevec)

Chemistry and Mechanism of Action: Imatinib, a phenylaminopyridine derivative, is a selective protein TK inhibitor effecting BCR-ABL TK. This enzyme is found commonly in chronic myeloid leukemia and in some clones of ALL. Imatinib also inhibits the kinases for PDGF, SCF, and KIT.

Absorption, Fate, and Excretion: Imatinib is well absorbed and achieves peak levels within 2–4 hours and follows linear pharmacokinetics at the standard doses. Cytochrome P450 is the major route of metabolism, with CYP3A4 being the primary pathway. An *N*-desmethyl piperazine is the main metabolite and is active. Pediatric patients follow the same pharmacokinetics as in adults.

Preparation and Administration: Imatinib is available in a film-coated tablet. In its pure form, it is a white to brownish to yellowish powder and is soluble in aqueous buffers of less than 5.5.

Toxic Effects: Gastrointestinal effects are common and include nausea and diarrhea. Muscle cramps are seen in one-third of patients receiving imatinib. Myelosuppression reflected as thrombocytopenia, anemia, and neutropenia occurs, with thrombocytopenia and neutropenia seen more frequently in patients in accelerated phase or blast crisis. Fluid retention is dose related and is exhibited as edema and weight gain, but pleural and pericardiac effusions are also seen. Fatigue and headache, although low grade, occur in 25% of patients.

Potential Drug Interactions: Drugs that inhibit CYP3A4 may increase imatinib plasma concentrations; these include ketoconazole, itraconazole, erythromycin, and clarithromycin. CYP3A4 inducers that may decrease plasma concentration of CY3A4 are dexamethasone, rifampin, phenytoin, and carbamazepine. Imatinib increases concentrations of simvastatin, cyclosporine, and warfarin, along with other medications that are metabolized by CYP3A4.

Therapeutic Indications in Hematology: Imatinib is considered first-line therapy in Ph+ CML and has activity in accelerated or blast-phase CML. Some effect has been shown in ALL as well as hypereosinophilic syndrome and polycythemia vera.

Topotecan (Hycamtin)

Chemistry and Mechanism of Action: Topotecan is a semisynthetic derivative of camptothecin that stabilizes a complex between DNA topoisomerase I and DNA. The cytotoxic effect of this drug is believed to result from the collision of DNA replication forks with a ternary complex of topoisomerase I, DNA, and topotecan. The resulting double-strand DNA breaks are lethal. The lactone form of topotecan, which predominates at an acidic pH, is a much more potent inhibitor of DNA topoisomerase I.

Absorption, Fate, and Excretion: At neutral or physiologic pH, the carboxylate form of topotecan is favored, and at a pH less than 7, the lactone form is favored. Topotecan has been given as a bolus or by continuous infusion. In less than 1 hour after infusion, most of the circulating drug in the plasma is in the carboxylate form because of the physiologic pH. The terminal half-life of the lactone form of this S-phase-specific agent is 2.6 hours, and the terminal half-life of the total drug is 3.3 hours. Thirty six percent of an IV dose is excreted unchanged in the urine, and there is a 1.5-fold concentration of the drug in bile. Cerebrospinal fluid levels of topotecan lactone reach approximately 32% of plasma levels. Dose adjustment is required for a creatinine clearance less than 60 mL/min, but no adjustment is necessary for a bilirubin up to 10 mg/dL.

Preparation and Administration: Topotecan is commercially available as 4-mg vials that are reconstituted with 4 mL of sterile water. This solution can be further diluted in normal saline or 5% dextrose in water and should be used immediately.

Toxic Effects: The dose-limiting toxicity for topotecan for all schedules is neutropenia. Thrombocytopenia and anemia are less common, although there is an increase in thrombocytopenia with continuous infusion schedules. Other less common and mild toxicities include nausea, vomiting, diarrhea, fever, fatigue, alopecia, skin rash, and increased liver function test results. Mucositis has been seen with prolonged infusion schedules over 5 days or when topotecan is given in higher doses.

Potential Drug Interactions: In vitro data suggest that there may be some synergism if a topoisomerase I inhibitor is given before a topoisomerase II inhibitor. In vitro data also suggest that synergism

may be seen if a topoisomerase I inhibitor (topotecan) is given after an alkylating agent, suggesting that topoisomerase I may be involved in the repair of alkylator-induced DNA damage.

Therapeutic Indications in Hematology: Topotecan has activity in MDS, AML, chronic myeloid leukemia, and MM.

Vorinostat (Zolinza)

Chemistry and Mechanism of Action: Vorinostat is a HDAC inhibitor. It inhibits HDAC 1, HDAC2, HDAC3, and HDAC6 at nanomolar concentrations. Inhibition prevents removal of the acetyl groups from lysine residues in target histones and transcription factors. Loss of deacetylase function results in persistence of acetyl groups on histones, resulting in larger segments of open chromatin and a general increase in gene expression. Often this promotes differentiation and cell cycle arrest with apoptosis. The number of genes affected continues to grow so that the impact of vorinostat is complex.

Absorption, Fate, and Excretion: Reported pharmacokinetics after a 400-mg oral administration are an AUC of 5.5 micromolar-hours, a C_{max} of 1.2 micromolar, and T_{max} of 2–10 hours. Fatty meals decrease the rate of absorption but increase overall drug levels. There is no recommended dosing relative to meals. Vorinostat is heavily plasma protein absorbed. It undergoes glucuronidation hydrolysis, and later β -oxidation to inactive metabolites. Little is excreted unchanged.

Preparation and Administration: Oral dosing of 400 mg with food is standard. If side effects are noted, reduce the dose to 300 mg. There is no approved pediatric dosing.

Toxic Effects: Many side effects are noted. Common are fatigue, thrombocytopenia, muscle spasms, and anorexia. Serious reported adverse effects in clinical trials included pulmonary embolism in 4.7% and anemia in 2.3%.

Potential Drug Interactions: Vorinostat can prolong the effect of coumadin, raising the international normalized ratio. It can also induce glucose intolerance.

Therapeutic Indications in Hematology: Vorinostat is approved for cutaneous manifestations of CTCL in patients who have become refractory to standard treatments. It is being tested in other disorders such as myeloma and leukemias to determine whether it works through the HDACs or through altered expression of numerous proteins.

PATHOBIOLOGY OF ACUTE MYELOID LEUKEMIA

Andrew M. Brunner and Timothy A. Graubert

Acute myeloid leukemia (AML) is a cancer of hematopoietic stem/progenitor cells, characterized by recurrent genetic and epigenetic alterations. Historically, human leukemias were distinguished according to clinical and histological features, and subsequently by morphology. More recently, analysis of the AML genome at increasing resolution, from the level of whole chromosomal changes to individual base pairs, together with an appreciation of epigenetic changes and interactions within the bone marrow microenvironment, have furthered the understanding of the biology and clinical behavior of this disease.

PHENOTYPE OF ACUTE MYELOID LEUKEMIA

Normal hematopoiesis is characterized by self-renewal and differentiation of long-term hematopoietic stem cells (HSCs) to short-term HSCs, multipotent progenitors, and common lymphoid and myeloid progenitors. These lineage-committed progenitors further differentiate to mature lymphoid or myeloid cells, including erythrocytes, granulocytes, macrophages, and platelets. This process is regulated by lineage-specific transcription factors at key points during normal hematopoiesis. Functional analysis of recurrent chromosomal, molecular, and epigenetic alterations in AML has revealed that many of these lesions cause aberrant activation or derepression of hematopoietic differentiation programs, impacting proliferation, survival, and maturation of myeloid progenitor cells. Consequently, a hallmark of the AML phenotype is an accumulation of immature myeloid precursors. A myeloblast count of 20% or greater distinguishes AML from other myeloid malignancies.

Historically, leukemias were classified according to morphologic criteria using the French–American–British (FAB) classification, first proposed in 1976. This system classifies AML by the extent of maturation and lineage specificity, ranging from M0 (undifferentiated) to M3 (promyelocytic), M4eo (myelomonocytic with eosinophilia), M6 (erythroid), or M7 (megakaryocytic). Certain FAB subtypes were subsequently found to correlate with underlying cytogenetic abnormalities, notably M3 with t(15;17), M4eo with inv(16), and M2 with t(8;21). As greater understanding of recurrent cytogenetic and now molecular and epigenetic aberrations have been identified, it has become clear that morphology alone is inadequate to fully describe the disease spectrum of AML.

ETIOLOGY OF ACUTE MYELOID LEUKEMIA

The majority of patients who develop AML lack any recognized antecedent disease or predisposition, and for these patients their disease is classified as sporadic or de novo. In these cases, AML appears to result from the accumulation of spontaneously acquired somatic mutations in self-renewing hematopoietic cells. In contrast, a diagnosis of secondary AML (sAML) is preceded by a known predisposing condition, including environmental exposure, antecedent hematologic malignancy, or inherited factors.

Toxins and Exposures

A number of environmental, occupational, and iatrogenic exposures have been identified that contribute to sAML via genotoxic damage to hematopoietic cells. Exposure to benzene, an organic component

of many commonly used chemicals including plastics, dyes, pesticides, solvents, and petroleum products, has been linked to the subsequent development of AML. This relationship was identified in the 19th century, when bone marrow aplasia and myeloid leukemia were noted among workers exposed to benzene-containing chemicals. Individuals with occupational benzene exposure have an approximately threefold increased relative risk of developing AML. Workplace benzene exposures have decreased significantly since this discovery, but other sources of benzene exposure remain a concern; for example, through cigarette smoking. Although cytopenias can occur within months of benzene exposure, there is a latency of several years between benzene exposure and the development of leukemia.

Two classes of chemotherapy drugs are associated with an increased risk of sAML; cases of AML arising after chemotherapy or radiation have been historically designated as therapy-related AML (tAML). One class of drugs with clear links to tAML are the topoisomerase II inhibitors. The most commonly used topoisomerase II inhibitors are anthracyclines, such as doxorubicin, idarubicin, and daunorubicin, and the epipodophyllotoxin etoposide, which are critical components of many treatment regimens for both solid tumors and hematologic malignancies. Topoisomerase II is an adenosine triphosphate-dependent enzyme that re-ligates DNA at sites of double-strand breaks to manage supercoils; inhibition of this enzyme increases the number of double-strand breaks. Resolution of these double-strand breaks may occur via error-prone nonhomologous end joining, resulting in accumulation of DNA damage or apoptotic cell death. tAML arising after exposure to topoisomerase II inhibitors typically occurs with a latency of 1–3 years, and is often characterized by balanced chromosomal translocations, with the majority involving the Mixed Lineage Leukemia (*MLL*) locus on chromosome 11q23. Typical lesions are reciprocal translocations such as t(9;11)(p21;q23) and t(11;19)(q23;p13); other translocations that do not involve the *MLL* locus have also been described, including the t(15;17), t(8;21), and inv(16) rearrangements. The risk of tAML varies based on the chemotherapy dosing schedule, cumulative dose received, additional cytotoxic agents, and underlying disease characteristics, but generally does not exceed 5% of patients treated with topoisomerase II inhibitors.

Alkylating agents are the second class of chemotherapy drugs with a clear role in the pathogenesis of tAML. The first leukemogenic agents identified in this category were nitrogen mustards. Frequently implicated drugs in contemporary clinical practice include cyclophosphamide, ifosfamide, and melphalan; weaker associations have been described with other alkylating agents such as busulfan, thiotepea, and cisplatin. Alkylating agents create adducts in DNA bases, which are variably mutagenic or cytotoxic. Cytogenetic lesions in alkylator-associated tAML are typically unbalanced, including loss of the long arms of chromosomes 5 or 7 [del(5q), del(7q)], or complete loss of these chromosomes (–5, –7). The risk of tAML following alkylator exposure is up to 1% per year, but typically has a longer latency (5–7 years), compared with topoisomerase II-associated tAML. The risk increases with age and cumulative exposure to these agents. Given the long latency period, it is likely that alkylating agents cause genomic instability, which accumulates over time prior to progression to AML. Consistent with this, heterozygous loss of *TP53* appears to be a common event leading to gain of additional somatic mutations and development of tAML. In some cases of tAML, small clonal populations harboring *TP53* mutations antedate chemotherapy exposure. *TP53* deficiency may confer enhanced fitness on these clones, allowing them to expand under the selective pressure of therapy.

Exposure to ionizing radiation also has been identified as a causative mechanism for tAML. This relationship was identified in the context of occupational exposures during the development of radiography, and subsequently in the setting of mass exposures such as the atomic bomb detonations or nuclear power plant disasters, where a time-limited spike in leukemia incidence occurred following the event. Outside of these events, therapeutic radiation therapy represents the most common setting for significant radiation exposure, which is associated with a small but significant increase in tAML risk. Radiation-associated tAML is characterized by an increased frequency of mutations otherwise implicated in de novo AML pathogenesis—for instance, mutations in *RUNX1*, as well as balanced translocations such as *RUNX1-RUNX1T1* and *DEK-NUP214*—suggesting some selectivity in the patterns of DNA damage.

Prior Hematologic Malignancy

Other myeloid malignancies, including myelodysplastic syndromes (MDS) and myeloproliferative neoplasms (MPNs), carry a risk of disease evolution to sAML. The risk varies depending upon the underlying disease, and may be facilitated by certain exposures, including genotoxic chemotherapy.

Patients with MPNs have an approximately 10% risk of evolution to AML over 10 years, which varies according to the underlying disease. The risk is lowest in essential thrombocythemia and as high as 20% for myelofibrosis. There is a clear association between therapies used in treating MPNs, specifically alkylating agents and radioactive phosphorus, and AML evolution; treatment with these agents results in a three to fourfold increase in incident AML. Another mechanism that may contribute to clonal evolution and disease progression may be a chronic inflammatory state related to the underlying MPN. Sequencing of sAML cases developing in the background of an MPN has identified recurrent mutations in *TET2*, *JAK2*, *IDH*, *IKZF1*, and *ASXL1*. Moreover, a number of patients with a *JAK2* mutated MPN may develop *JAK2* wild-type AML, thought to arise either from a common pre-*JAK2* founding clone, or due to parallel expansion of a distinct hematopoietic clone. Post-MPN AML with mutated *JAK2* typically proceeds through an accelerated myelofibrosis phase, while post-MPN AML that no longer harbors a *JAK2* mutation tends to arise from chronic phase disease and may be associated with the use of cytotoxic therapies.

Prior to the introduction of tyrosine kinase inhibitors (TKIs) for CML, patients with CML typically progressed from chronic phase to blast phase within 5 years, at a rate of over 20% per year. Most cases of blast phase CML have a myeloid phenotype, while approximately 30% of patients have a lymphoid phenotype. Additional mutations may occur during transformation of CML, and approximately 80% of patients have additional cytogenetic abnormalities, such as duplication of the Philadelphia chromosome, and other trisomies that are recurrent in de novo AML. Up to one-third of patients with CML in myeloid blast phase harbor mutations in the tumor suppressor genes *P16* or *TP53*. Additionally, *BCR-ABL* signaling upregulates transcription factors implicated in AML pathogenesis, including *HOXA9* and *EVII*, which may contribute to leukemic transformation. Underscoring the continued requirement for *BCR-ABL1* signaling in CML evolution, the rate of transformation to blast phase CML in the TKI era has decreased markedly to approximately 1% per year.

Approximately one third of patients with MDS progress to sAML, although this varies significantly according to the underlying MDS subtype and disease characteristics, including the percentage of bone marrow blasts, presence of characteristic cytogenetic abnormalities, and cytopenias. Progression to leukemia is associated with acquisition of additional somatic mutations as well as epigenetic alterations within the MDS clone. Mutations in transcription factors and cytokine signaling genes, including *RUNX1*, *NRAS*, and *ETV6*, are more common at progression to sAML, compared with the frequency of these mutations at MDS diagnosis. Mutations in *RUNX1* are enriched in populations with tAML and other forms of sAML.

Epigenetic modifications of the MDS genome appear to also play a significant role in AML progression, particularly through DNA methylation-mediated silencing of tumor suppressor genes.

Congenital Bone Marrow Failure Syndromes

A number of inherited bone marrow failure syndromes are associated with an increased risk of developing advanced myeloid malignancies. This may be due to the proliferative stress imposed by chronic cytopenias or defects in DNA repair that are hallmarks of several of these syndromes.

Fanconi anemia (FA) is the most common inherited bone marrow failure disorder, and is caused by germline mutations in factors involved in DNA repair. These disorders have an autosomal recessive inheritance pattern except for *FANCB*, which is X-linked. To date, 17 genes have been identified as a part of the *FANC* gene family, and together their protein products are responsible for identifying DNA damage and targeting these sites for repair. The FA core complex is recruited to the site of DNA damage after exposure to crosslinking agents. *FANCD2* is ubiquitinated by the core complex, and forms the link between the FA and BRCA DNA repair pathways. Phenotypically, patients with FA have short stature, abnormalities of the thumb and radius, skin findings including hyperpigmentation and café au lait spots, microphthalmia, endocrinopathies, and often present with aplastic anemia later in childhood. The cumulative risk of AML or MDS among FA patients is approximately 10% to 15%, with peak incidence during the teenage years.

Dyskeratosis congenita (DKC) is a bone marrow failure syndrome characterized by inherited mutations in the telomere maintenance pathway. DKC can be inherited in an autosomal dominant (Online Mendelian Inheritance in Man [OMIM] 127550), autosomal recessive (OMIM 224230), or X-linked recessive pattern (OMIM 305000). Mutations in *TERT*, *DKC1*, *TERC*, or *TINF2* account for most cases. Typical findings among patients with DKC include the “triad” of skin hyperpigmentation, nail dystrophy, and oral leukoplakia, and these patients will typically develop bone marrow failure by 20–30 years of age. As a result of the underlying mutation, patients have markedly shortened telomeres, which contribute to bone marrow failure, as well as damage to other organs including pulmonary fibrosis and hepatic cirrhosis. Transformation to AML occurs in approximately 10% of patients, and is thought to occur via genomic instability related to shortened telomeres and associated DNA damage, resulting in dysplasia and an increased risk of hematopoietic malignancy.

Shwachman–Diamond syndrome (OMIM 260400) is an autosomal recessive disorder caused by mutations in *SBDS*. Hematopoietic manifestations of Shwachman–Diamond syndrome most often include isolated neutropenia, although many patients will eventually develop pancytopenia, which may progress to aplastic anemia. AML or MDS occurs in up to a third of patients by 30 years of age, and is thought to relate to chromosomal instability and accelerated rates of apoptosis, which may be due to the role of *SBDS* in stabilizing the mitotic spindle during mitosis.

Severe congenital neutropenia or Kostmann syndrome is associated with neutropenia at birth and has been associated with a variety of genetic mutations. The pattern of inheritance can be autosomal dominant (*ELANE* or *GFI1*), autosomal recessive (*HAX1*, *G6PC3*, *VPS45*, or *JAGN1*), or X-linked (*WAS*). The clinical course is marked by bacterial infections from a young age; some patients may be responsive to granulocyte colony-stimulating factor (G-CSF), but the rate of leukemic transformation is high among this group, with nearly a third of patients developing AML or MDS within 10 years. Transformation into AML is frequently characterized by the acquisition of somatic mutations in *CSF3R*, which encodes the G-CSF receptor. The causal relationship to chronic G-CSF therapy remains controversial.

Diamond–Blackfan anemia (DBA) (OMIM 105650) is characterized by red cell aplasia and typically spares the leukocyte and platelet lineages. DBA is typically inherited in an autosomal dominant

fashion and is associated with mutations in a number of ribosomal proteins. Defects in ribosome function result in anemia early in life and patients with DBA may have characteristic skeletal anomalies, including craniofacial defects, and at times the classic triphalangeal thumb; this anemia is often steroid responsive but many eventually require chronic transfusional support and hematopoietic cell transplantation. AML can occur in up to 20% of patients and typically occurs after 40 years of age.

Congenital amegakaryocytic thrombocytopenia (CAMT) (OMIM 604498) and thrombocytopenia with absent radii (TAR) (OMIM 274000) syndrome are both characterized by hypoplastic thrombocytopenia. CAMT is inherited in an autosomal recessive manner via mutations in the *MPL* gene, which encodes the receptor for thrombopoietin (TPO). Patients have concomitant elevations in serum TPO levels, and thrombocytopenia from birth, which typically progresses to aplasia. CAMT is associated with an increased incidence of AML, typically in the second decade of life. While CAMT does not have phenotypic manifestations outside of thrombocytopenia, TAR syndrome is also associated with thrombocytopenia at birth, as well as characteristic absence of the radii. TAR syndrome has been associated with mutations in *RBM8A*, which is involved in messenger RNA (mRNA) splicing. The thrombocytopenia in TAR syndrome often improves over time; both acute lymphoblastic leukemia and AML have been reported among patients with this rare disorder.

Down syndrome, caused by trisomy 21, is associated with an approximately 10–20-fold elevated relative risk of AML and MDS compared with the general population, and in particular an increased risk for acute megakaryocytic leukemia, FAB M7. Infants with Down syndrome may experience transient abnormal myelopoiesis (TAM), where circulating peripheral blood blasts are seen and may be accompanied by hepatic dysfunction, effusions, and rash; this occurs in approximately 10% of these patients. The majority of TAM cases harbor somatic mutations in *GATA1*, resulting in altered function of this transcription factor that plays an important role in hematopoietic cell maturation, particularly in the megakaryocyte lineage. Decreased *GATA1* expression results in megakaryocyte proliferation. Indeed, up to 30% of persons with TAM will progress to AML, commonly acute megakaryocytic leukemia. The development of AML in patients with Down syndrome likely relates both to acquired somatic mutations, such as *GATA1*, and also the presence of additional copies of genes on chromosome 21 that facilitate leukemogenesis, such as the oncogenes *RUNX1*, *ERG*, and *ETS2*.

Mendelian Acute Myeloid Leukemia Predisposition Syndromes

A number of genes that are targets of recurrent somatic mutation in AML are also mutated in the germline in families with predisposition to myeloid malignancy without a prodrome of bone marrow failure. These include mutations in *RUNX1*, *CEBPA*, and *GATA2*. Predisposition to AML is also associated with germline variants in *ANKRD26*, *SRP72*, *ETV6*, and *DDX41*. Although these familial syndromes are rare, they are important to recognize, since affected individuals and asymptomatic carriers require specific clinical management.

Familial platelet disorder with predisposition to acute myelogenous leukemia (OMIM 601399) is associated with autosomal dominant inheritance of germline mutations in *RUNX1*. Mutation carriers frequently present with easy bruising/bleeding due to quantitative or qualitative platelet dysfunction and have an approximately 40% lifetime risk of developing AML, typically in the third or fourth decade.

Germline mutations in the *CEBPA* gene are a rare cause of autosomal dominant familial predisposition to AML (OMIM 116897). The germline mutations are typically truncating at the N-terminus of the protein, with acquisition of a C-terminal somatic mutation as a common event in the development of AML among these patients. These cases have a relatively favorable prognosis, similar to de novo AML with somatically-acquired biallelic *CEBPA* mutations.

Inherited mutations in *GATA2* cause a spectrum of disorders with overlapping features, including Emberger syndrome (OMIM 614038) and immunodeficiency 21 (IMD21) (OMIM 614172), also described as monocytopenia with susceptibility to mycobacterial, fungal, and papillomavirus infection and myelodysplasia (MonoMAC syndrome) or dendritic cell, monocyte, B-lymphocyte and natural killer lymphocyte deficiency (DCML). Patients with IMD21 have decreased monocyte counts, natural killer and B-cell deficiency, and are at increased risk of viral and nontuberculous mycobacterial infections. Emberger syndrome patients have a similar presentation, but also have deafness and lymphedema, and often develop pancytopenia. AML or MDS arises in approximately 70% of carriers and is associated with cooperating genetic events, such as mutations in *ASXL1* or hemizygous deletions involving chromosome 7.

GENETIC AND EPIGENETIC ALTERATIONS IN ACUTE MYELOID LEUKEMIA

AML is characterized by a large number of recurrent cytogenetic, molecular, and epigenetic modifications that illustrate the pathophysiologic role of acquired somatic alterations affecting specific gene products. These mutations have been incorporated into strategies for prognostic stratification and risk-adapted treatment, in addition to providing a framework for targeted therapy. The World Health Organization (WHO) classification now recognizes a number of recurrent genetic abnormalities, including balanced translocations and inversions, as defining features of AML.

Early understanding of the pathogenesis of AML suggested a model where AML occurred in the setting of acquired mutations in two pathways: class I mutations, which activate cell proliferation and survival pathways, and class II mutations, which block normal mechanisms of differentiation. This arose out of the identification of mutations that commonly arose together or were both required in mouse models to produce leukemia, such as class I mutations in cytokine signaling pathways, and class II mutations in hematopoietic transcription factors. However, this model does not account for the wide spectrum of more recently described somatic alterations, nor do all patients carry class I and class II mutations.

Chromosomal Abnormalities

The central role of acquired mutations in AML was first recognized through the identification of recurrent nonrandom cytogenetic alterations in the mid-20th century. Recurrent karyotypic lesions are frequent events in AML, present in roughly 50% to 60% of patients at diagnosis, and have distinct prognostic significance that are central to treatment decisions, including the identification of patients for whom hematopoietic cell transplantation should be considered in first remission, as well as patients likely to achieve a favorable outcome with chemotherapy alone (Fig. 58.1). Common chromosomal abnormalities include chromosome translocations or inversions, chromosome deletions, and monosomies or trisomies. Patients can be stratified according to karyotype into favorable, intermediate, and poor-risk categories. Typically, favorable risk includes patients with t(15;17), t(8;21) or inv(16)/t(16;16), and adverse risk includes inv(3q)/t(3;3), t(6;9), monosomy 7, monosomy 5, loss of 5q, 7q, or 17p, and complex (greater than 3) chromosomal abnormalities, as well as most translocations involving the *MLL* locus on chromosome 11q23. In lieu of additional molecular studies, all other karyotypic lesions are generally classified as intermediate risk. This includes patients with a normal karyotype, which comprise approximately 45% of all AML cases.

Retinoic Acid Receptor Rearrangements

A distinct subset of AML, acute promyelocytic leukemia (APL) or FAB M3, comprises approximately 10% of adult AML cases, and is defined by the presence of a translocation involving the retinoic acid

Fig. 58.1 FREQUENCY OF CHARACTERISTIC CYTOGENETIC ABNORMALITIES IN ADULT PATIENTS WITH ACUTE MYELOID LEUKEMIA. The proportion of recurrent cytogenetic abnormalities in patients 15–60 years old and patients greater than 60 years old at diagnosis is shown. *Abn*, Abnormal; *Inu*, inversion; (Data derived from previously reported cytogenetic studies by CALGB, MRC, SWOG, ECOG, EBMT, and AMLSG.)

receptor- α (*RARA*) on chromosome 17q21. This results in a distinct phenotype characterized by a maturation arrest at the promyelocyte stage. APL is often accompanied by a coagulopathy that can be immediately life-threatening. RARs heterodimerize with retinoid X receptors (RXRs) to bind DNA at retinoic acid response elements, where they control gene expression during development and differentiation. In the majority of cases, *RARA* is fused with the *PML* gene on chromosome 15q22 as a consequence of t(15;17)(q22;q21). Other rare fusion partners include PML-like zinc finger (*PLZF*), nucleophosmin (*NPM1*), nuclear mitotic apparatus protein (*NUMA1*), and signal transducer and activator of transcription 5B (*STAT5B*). Each of these fusion partners has a self-association domain, similar to RXRs, and the fusion product interferes with expression of retinoic acid transcriptional targets. In mouse models, transgenic expression of *PML-RARA* results in APL after a long myeloproliferative phase; the long latency period prior to leukemia development implies a requirement for acquisition of cooperating mutations for full transformation. Introduction of the *FLT3-ITD* hastens APL onset in mice. Consistent with this finding, over 35% of human patients with APL have *FLT3-ITD* mutations and nearly 20% have *FLT3-TKD* mutations. *PML-RARA* appears to have a dominant negative effect on RAR α transcriptional function, as well as a role in DNA and chromatin modification, resulting in impaired myeloid differentiation. Additionally, the fusion protein disrupts the organization of PML nuclear bodies, which are subcellular structures that are involved in a number of cell cycle, metabolic, and apoptotic regulatory pathways.

Core Binding Factor Rearrangements

Rearrangements involving genes encoding components of the core binding factor (CBF) are present in roughly 15% of AML cases. CBF is a heterodimeric transcription factor that is comprised of an alpha subunit (encoded by *RUNX1*) that binds to a consensus DNA sequence, and a beta subunit (encoded by *CBFB*) that increases the affinity for DNA binding. The t(8;21) translocation is found in up to 10% of AML cases and creates an in-frame fusion of *RUNX1* with *RUNX1T1*. This rearrangement is enriched in the FAB M2 subgroup,

and comprises up to 40% of this patient subgroup. This fusion protein alters the CBF transcription factor complex, allowing it to oligomerize and interact with the nuclear corepressors *SMRT* and *N-CoR*, resulting in impaired hematopoietic differentiation. The *RUNX1-RUNX1T1* fusion protein functions as a dominant negative inhibitor of wild-type CBF, and consequently impairs hematopoietic differentiation. The fusion protein also leads to activation of TP53 response genes, which may in part explain the relative chemosensitivity of t(8;21) AML. *RUNX1* is involved in other rare translocations, including t(16;21)(q24;q22) with myeloid translocation gene on chromosome 16 (*MGT16*), and also t(3;21)(q26;q22), with *EVII*.

Chromosomal alterations involving *CBFB* include inv(16) and t(16;16)(p13;q22), which create an in-frame fusion between *CBFB* and *MYH11*, the gene encoding smooth muscle myosin heavy chain 11. AML with inv(16) or t(16;16) often has the FAB M4eo phenotype. The *CBFB-MYH11* gene product exerts a dominant negative effect on *RUNX1*, and can recruit nuclear corepressors to inhibit transcription of CBF gene targets. Mouse models with a *CBF-MYH11* knock-in mutation require additional mutations to progress to AML, and in humans up to two-thirds of all patients with inv(16) also harbor mutations in *KIT*, *FLT3*, or *RAS*. Given the clear link between CBF rearrangements, as well as the *PML-RARA* translocation, and the development of AML, the presence of any of these is sufficient for a diagnosis of AML, regardless of the percentage of myeloblasts in the bone marrow or peripheral blood.

Mixed-Lineage Leukemia Gene Rearrangements

Translocations in the mixed-lineage gene (*MLL*) are seen in up to 10% of patients with AML. *MLL* rearrangements are common in tAML leukemia following exposure to topoisomerase II inhibitors, and are enriched in cases with the FAB M5a phenotype. Wild-type *MLL* binds DNA and methylates histone H3K4 via its C-terminal SET domain, and regulates expression of target genes, including homeobox (*Hox*) genes. Members of the homeobox A cluster, including *HOXA7* and *HOXA9*, play critical roles in the regulation of hematopoiesis, and are normally expressed in early hematopoietic cells. Rearranged *MLL* retains its N-terminal DNA binding domain,

while the C-terminal portion is replaced by a fusion partner. More than 70 unique fusion partners have been identified, including AF4, AF9, AF10, and ENL; these can interact with and recruit the histone methyltransferase disruption of telomeric silencing 1-like (DOT1L), which methylates H3K79, and results in the expression of *HOXA* genes implicated in leukemic transformation. Expression of the *MLL-AF9* fusion in mice generates AML with high penetrance and short latency. Another mechanism by which *MLL* plays a role in leukemia is through an in-frame partial tandem duplication of exons 5–12 (*MLL-PTD*). Mouse knock-in models with *MLL-PTD* develop acute leukemias characterized by overexpression of *Hox* genes and an increase in H3/H4 acetylation with associated H4K4 methylation.

Rare Translocations

Less common cytogenetic abnormalities implicated in the pathogenesis of AML include the t(6;9), which fuses the *DEK* oncogene, which encodes a DNA binding protein involved in transcription regulation and introduction of supercoils, with *Nucleoporin 214* (*NUP214* or *CAN*), which encodes a nuclear envelope pore protein that regulates nuclear/cytoplasmic transport. This rearrangement is found in approximately 1% of patients with AML and is associated with a poor prognosis. It typically occurs as a sole chromosomal rearrangement; however, there is a high frequency of concurrent mutations in *FLT3-ITD*. The fusion retains most of the open reading frame from both proteins, but the molecular consequences of the fusion protein are not well understood. Retroviral transduction of long-term HSCs generates leukemias after transplantation into mice.

t(3;3)(q21;q26.2) and inv(3)(q21q26.2) are included in the “acute myeloid leukemia with recurrent cytogenetic abnormalities” category in the WHO classification. Collectively, the inv(3)/t(3;3) rearrangements are present in less than 5% of AML cases and are associated with poor survival. These rearrangements juxtapose *EVII* (*MECOM*) with regulatory elements of the *RPN1* locus. *EVII* interacts directly with DNA methyltransferase 3A (DNMT3A) and DNMT3B, which may account for the distinct DNA hypermethylation signature associated with dysregulated *EVII* expression. Patients with this translocation may have preceding MDS, and often the bone marrow morphology shows multilineage dysplasia with atypical megakaryocytes.

t(8;16)(p11;p13) is a rare translocation that occurs in de novo AML and topoisomerase II-associated tAML. The disease typically has a FAB M4 or M5 phenotype, and patients often present with extramedullary disease, coagulopathy, and hemophagocytosis. This translocation fuses two histone acetyltransferases: KAT6A (also known as MOZ or MYST3) and CREB binding protein. The fusion protein binds to DNA and the colocalized proteins result in upregulation of the *HOX* genes *HOXA9* and *HOXA10*, as well as their cofactor, *MEIS1*.

The t(1;22) involving one twenty two (*OTT*; or RNA-binding motif protein 15 [*RBM15*]) and megakaryocytic acute leukemia (*MAL* or *MKL1*) is a rare translocation found in infant acute megakaryocytic leukemia. *MAL* functions as a transcriptional coactivator of DNA-bound serum responsive factors (SRFs) and triggers histone modifications, including acetylation of H3K9. The translocation generates the *OTT-MAL* fusion protein, which alters *MAL* function, resulting in SRF-directed expression of *MYL9* and *MMP-9*, which play a role in megakaryocyte development and migration, and may contribute to the phenotype of t(1;22) megakaryocytic leukemia. Mice engineered to express *OTT-MAL* have altered megakaryocyte development and dysregulated NOTCH signaling. With concurrent activating mutations in *MPL*, these mice develop acute megakaryocytic leukemia.

Amplifications and Deletions

Recurrent cytogenetic abnormalities in AML also include somatically acquired chromosome copy or segment gains, chromosomal monosomies, as well as the accumulation of karyotypic abnormalities, classified

as complex karyotype, which typically has at least three or more distinct chromosomal abnormalities. Common abnormalities include those involving chromosomes 5 and 7, particularly in AML arising out of the background of MDS, and each of which are seen in approximately 5% to 10% of patients with AML. Enhancer of zeste 2 polycomb repressive complex 2 subunit (*EZH2*) is a histone methyltransferase that may play a role in leukemogenesis via haploinsufficiency in the setting of loss of material from the long arm of chromosome 7. Interstitial deletions on the long arm of chromosome 5 at 5q33.1 are associated with the 5q minus syndrome, which has a low risk of progression to sAML. *RPS14* and miR145/146a have been implicated in the pathogenesis of this syndrome. In contrast, deletions involving a more proximal region at 5q31.2 are associated with higher risk of sAML transformation. Most chromosome 5 deletions in high-risk MDS and AML are large, including most of the long arm or the entire chromosome. Many genes have been implicated in diseases associated with these larger deletions, including *APC*, *CTNNA1*, *HSPA9*, *EGR1*, and *NPM1*.

Loss of chromosome 17p, including the *TP53* locus at 17p13, is associated with complex cytogenetics as well as abnormalities in chromosome 5 and 7. Indeed, there appears to be cooperativity between 17p alterations and deletions at chromosome 5q13 at the site of *SSBP4*, another tumor suppressor gene, which may influence the progression to leukemia. Alterations in 17p are enriched in patients with alkylator-associated tAML and sAML rising from an underlying MPN or MDS. In contrast to AML with balanced translocations, leukemias that develop in the context of 17p alterations are characterized by greater genomic instability.

Common trisomies in AML include somatic acquisition of trisomy 8 and trisomy 21, seen in approximately 10% and 3% of patients, respectively. Trisomy 8, the most common chromosomal gain seen in AML, may contribute to leukemogenesis via amplification of *MYC*, which is located at chromosome 8p24 and is implicated in a number of malignancies including AML. Acquired trisomy 21, similar to AML in Down syndrome, appears to progress to AML via the subsequent acquisition of mutations in *RUNX1* or *GATA1*. Unlike Down syndrome, acquired trisomy 21 often occurs in conjunction with other cytogenetic aberrations, in particular with complex cytogenetic rearrangements.

Recurrently Mutated Genes

For many patients, a recurrent chromosomal abnormality cannot be detected by either cytogenetic analysis or fluorescence in situ hybridization, using probes for common rearrangements and copy number alterations. This group of patients with normal cytogenetics accounts for approximately 45% of AML cases and has historically been categorized as having intermediate prognosis with standard treatment. Molecular testing of this group, as well as patients in other cytogenetic risk groups, has identified a number of recurrent genetic alterations that play critical roles in AML pathogenesis, prognosis, and response to therapy. On average, AML genomes contain fewer somatic mutations compared with other adult cancers (fewer than 20 mutations in protein-coding genes per case). Genes that are mutated across multiple AML cases at a frequency higher than expected by chance are more likely to be biologically relevant. AML mutations can be categorized according to the type of gene that is affected and the functional impact of the mutation. Many gene mutations cooperate with other alterations, including the large-scale copy number changes and rearrangements described earlier (Fig. 58.2).

Cytokine Signaling

A number of mutations have been identified that result in altered signal transduction, enhancing leukemic cell proliferation and survival. These include mutations in the *fms*-related tyrosine kinase 3 (*FLT3*) gene, *RAS* genes, and *KIT*. Mutations in *FLT3* can occur either as an in-frame internal tandem duplication within the juxtamembrane

Fig. 58.2 COOCCURENCE AND MUTUAL EXCLUSIVITY OF SOMATIC MUTATIONS AMONG PATIENTS WITH ACUTE MYELOID LEUKEMIA. A combination of exome, genome, and transcriptome sequencing in 200 patients with de novo acute myeloid leukemia identified a number of mutations which cooccur or are mutually exclusive according to nine categories of biological function: transcription factor fusions, cytokine signaling, transcription factor mutations, tumor suppressor genes, regulators of DNA methylation, polycomb complex, spliceosome, cohesin complex, and nucleophosmin. *TF*, Transcription factor. (From Ley TJ, Miller C, Ding L, et al: *The Cancer Genome Atlas Research Network. Genomic and epigenomic landscapes of adult de novo acute myeloid leukemia*. *N Engl J Med* 368:2059, 2013. Copyright © 2013 Massachusetts Medical Society. Reprinted with permission.)

domain of the receptor (*FLT3-ITD*), found in up to 30% of AML patients, or as a mutation in the tyrosine kinase domain (*FLT3-TKD*), the most common being a point mutation resulting in an aspartate to tyrosine substitution at codon 835, detectable in 5% to 10% of AML cases. Both mutations result in constitutive activation of the receptor. *FLT3* signaling activates the RAS/mitogen-activated protein kinase (MAPK) signaling pathway, and mutated *FLT3-ITD* can also activate the STAT5 pathway, which induces the serine-threonine Pim kinases, and results in enhanced cell growth and survival. Murine models that combine *FLT3-ITD* with other mutations, such as *PML-RARA*, *MLL-ENL*, or *NUP98-HOXD13*, have demonstrated cooperativity between these mutations with respect to latency and penetrance of leukemia, while either mutation on its own has low efficiency for disease initiation. The *FLT3-ITD* alteration in particular appears to be associated with increased rates of relapse and worsened patient outcomes; it is not clear whether *FLT3-TKD* mutations have the same impact on outcomes. The *FLT3-ITD* alteration may be present at the time of diagnosis, and can be acquired or lost at relapse. Moreover, the length of the duplication, position of the mutation, and number of distinct ITDs can vary within a given patient. Together, this suggests that the *FLT3-ITD* alteration may be a later event in the development of AML and illustrates the subclonal heterogeneity of AML.

CD117, encoded by *KIT*, is another example of a protooncogenic receptor tyrosine kinase implicated in a number of malignancies. *KIT* is the receptor for stem cell factor, and is upregulated in most patients with AML. *KIT* mutations are most frequently seen at codons D816 or N822 in the tyrosine kinase domain, or in the extracellular domain; rare internal tandem duplications have also been identified in AML. Mutations at D816 or N822 occur in the activating loop of the kinase domain, interrupt autoinhibitory feedback, and result in constitutive activation. Mutations in *KIT* occur in less than 10% of patients and are enriched in patients with AML harboring CBF alterations. In mouse models, *KIT* mutations cooperate with *RUNX1-RUNX1T1* and *CBFB-MYH11* to induce AML. *KIT* mutations in patients with CBF AML, particularly with *RUNX1-RUNX1T1*, are associated with increased rates of relapse.

Mutations in the *RAS* proto-oncogenes, most commonly *NRAS* and *KRAS*, are also recurrent events in AML, identified in approximately 10% and 5% of patients, respectively. *RAS* family members are small membrane-associated guanosine triphosphatase signaling proteins that activate the MAPK/extracellular signal-related kinase (ERK) pathway, leading to cell growth and survival. The most common mutations in *NRAS* occur at codons 12, 13, and in *KRAS* at codon 12. These mutations result in a guanosine triphosphate-bound state of the *RAS* protein, leading to constitutive activation. In

murine models, expression of mutant *NRAS* or *KRAS* results in a spectrum of myeloid disease, with variable features of acute leukemia, myeloproliferation, or MDS/MPN overlap. Consistent with this finding, *RAS* is frequently mutated in patients with MPNs and CMML.

Transcription Factors

In addition to their frequent identification in novel fusion proteins, transcription factors are also recurrently mutated in AML. *RUNX1* mutations occur in approximately 5% to 15% of all patients with AML, but are slightly more common in patients with intermediate-risk AML, particularly in association with trisomy 8 or trisomy 13. Approximately 80% of *RUNX1* mutations are located in a DNA-binding domain that is homologous to the *Drosophila runt* protein. C-terminal domains of *RUNX1* are involved in nuclear matrix localization and recruitment of transcriptional trans-activating and repressing factors. Overexpression of mutant *RUNX1* in mice causes AML with dysplastic changes, and, in combination with *EVII* mutations, results in a more rapid AML phenotype.

CEBPA is mutated in almost 10% of AML cases; these mutations are enriched in younger patients and patients with otherwise normal cytogenetics. *CEBPA* encodes the CCAAT/enhancer binding protein- α , a basic leucine zipper transcription factor. Patients with *CEBPA* mutations most often have normal cytogenetics; mutations result in loss of function and typically arise in the transactivation domain or in the basic leucine zipper domain. Favorable prognosis is restricted to cases with biallelic *CEBPA* mutations, which is associated with a distinct gene expression signature. When biallelic mutations were engineered in a mouse model, hematopoietic differentiation was impaired, but cooperating mutations were required for AML transformation, such as the addition of *FLT3-ITD*.

Tumor Suppressor Genes

Mutations in tumor suppressor genes facilitate the development of AML. Common examples include the canonical tumor suppressors *TP53* and Wilms tumor 1 (*WT1*). Mutations in *TP53* are found in fewer than 10% of AML cases overall, but are enriched in patients with AML with a complex karyotype, two-thirds of which will also harbor a mutation in *TP53*. *TP53* is a transcription factor that regulates multiple signaling pathways in response to cellular stress, with an output that may culminate in cell cycle arrest, senescence, or apoptosis. Mutations occur throughout the *TP53* gene, usually resulting in loss of function; over half of cases have loss of heterozygosity at 17p.

Mutations in *WT1* occur in fewer than 10% of patients with AML, but wild-type *WT1* is frequently overexpressed. *WT1* is a zinc finger transcription factor that is required for normal development. Mutations may occur throughout the gene and generally predict loss of function. One mechanism by which loss of *WT1* may influence tumorigenesis appears to relate to DNA methylation; mutations in *WT1* result in a DNA methylation pattern similar to that in *TET2* mutated AML, apparently due to a lost interaction between *WT1* and wild-type *TET2*. In addition to loss of function, *WT1* may also have oncogenic effects. In a *RUNX1-RUNX1T1* mouse model of AML, forced overexpression of *WT1* resulted in more rapid progression to AML.

Regulators of DNA Methylation

Methylation of cytosine residues is an important epigenetic mark that contributes to regulation of gene expression. Genes encoding factors directly or indirectly involved in DNA methylation or demethylation, including *TET2*, *DNMT3A*, and isocitrate dehydrogenase-1 (*IDH1*) or *IDH2*, are recurrently mutated in AML.

DNMT3A encodes a de novo methyltransferase that catalyzes cytosine methylation at CpG dinucleotides. These mutations are seen

in approximately 20% of patients with de novo AML, but nearly 30% of patients with a normal karyotype. Nearly 50% of the *DNMT3A* mutations are heterozygous missense substitutions at codon R882 (most frequently R882H); the remainder are deletions, frameshifts, and missense substitutions throughout the open reading frame.

Mutations in ten-eleven-translocation 2 (*TET2*), have been identified in 10% to 30% of patients with AML, and are enriched in patients with prior MDS or MPN. Members of the *TET* gene family include *TET1* and *TET2*; *TET1* is also rearranged in t(10;11)(p12;q23). *TET2* converts 5-methylcytosine to 5-hydroxymethylcytosine, an initial step in the reversion to unmethylated cytosine. Hydroxylation of methylated CpG-rich regions by *TET2* activates gene programs important for cellular differentiation, including the homeobox A cluster. By contrast, *TET2* loss-of-function mutations are associated with impaired differentiation. Mice harboring a *TET2* null allele display enhanced stem cell self-renewal and develop myeloid malignancies with underlying features consistent with CMML or MDS. *TET2* mutations do not have a consistent impact on AML prognosis in multivariate analysis.

Mutations in *IDH1* or *IDH2* are also involved in *TET* deregulation via the oncometabolite 2-hydroxyglutarate (2-HG). *IDH1* is primarily cytosolic, while *IDH2* localizes to mitochondria. These proteins normally decarboxylate isocitrate to form α -ketoglutarate via the reduced form of NADPH, a key reaction in the Krebs cycle. Mutational hotspots include codon R132 in *IDH1* and codons R140 or R172 in *IDH2*. *IDH1/2* mutations are found in approximately 5% to 10% and 15% to 20% of patients with AML, respectively. The mutations are enriched in cases with a normal karyotype and frequently co-occur with *NPM1* mutations. Mutant *IDH1/2* catalyzes the conversion of α -ketoglutarate to 2-HG, which suppresses *TET2* due to competitive inhibition at the α -ketoglutarate binding site. Through this mechanism, excess 2-HG results in a DNA hypermethylation pattern similar to that observed in *TET2*-mutated AML; however, this oncometabolite also interferes with other α -ketoglutarate-dependent enzymes, including members of the Jumonji-C domain-containing histone demethylases. Mouse models with *IDH1* mutations in hematopoietic cells develop a disease phenotypically similar to human MDS.

Polycomb Complex

The polycomb complex plays a major role in silencing transcription during development; it functions in conjunction with trithorax group proteins, which activate transcription, to epigenetically modulate genes during embryogenesis. Recurrent mutations in polycomb complex genes or regulators have been identified in several cancers, including AML. Additional Sex Combs-Like 1 (*ASXL1*) is an enhancer of the trithorax and polycomb genes; it plays a critical role in *HOX* gene expression during embryogenesis. Mutations in *ASXL1* in AML typically occur in exon 12 and result in loss of function. Expression of mutated *ASXL1* in mice results in aberrant *HOX* gene activation, and, when conditionally deleted in hematopoietic cells, results in anemia and leukopenia with multilineage myeloid dysplasia. Acquired somatic mutations in *ASXL1* occur in approximately 10% to 20% of patients with AML and are enriched in those with underlying MDS.

ASXL2 is also involved in regulation of the polycomb repressor complex, and mutations in *ASXL2* are present in over 20% of patients with AML harboring the *RUNX1/RUNX1T1* translocation; they are mutually exclusive with *ASXL1* mutations in this group.

The nuclear receptor binding SET domain protein 1 (*NSD1*) gene encodes a histone methyltransferase, which similarly has a role in normal development; germline mutations result in Sotos syndrome, which is associated with a number of childhood cancers. *NSD1* methylates H3K36 and is associated with transcriptional activation. *NSD1* is involved as a fusion partner in the recurrent translocation t(5;11)(q35;p15.5) with *NUP98*, seen in approximately 15% of pediatric AML, but less than 5% of adult AML, and is associated

with a poor response to therapy. This fusion protein binds regulatory elements of the polycomb complex and results in *HOX* gene activation.

Spliceosome Complex

The spliceosome complex consists of a number of proteins around a small nuclear ribonucleic acid (snRNA) core, which identifies splicing motifs in pre-mRNA, removing introns and religating exons, to generate a diversity of mRNA isoforms from each coding gene. The splicing machinery is highly conserved, and in addition to five snRNAs, there are numerous associated proteins. Recurrent mutations have been identified in hematologic malignancies in a number of the core splicing components, most often affecting *SF3B1*, *U2AF1*, *SRSF2*, or *ZRSR2*. These mutations are typically heterozygous and tend not to cooccur within patients, suggesting that a second mutation in the pathway confers no additional selective advantage or is not tolerated by hematopoietic cells. Alternative splicing was noted in AML samples prior to the discovery of spliceosome mutations, but the cause and biological consequences were not understood. Collectively, splicing factor mutations are detectable in approximately 15% of patients with AML. These mutations are highly associated with specific subtypes of MDS and MPNs; consequently, AML with splicing factor mutations frequently have a history of these antecedent disorders. *SF3B1* is the most common mutation in the splicing complex; mutations in this gene are tightly associated with the refractory anemia with ringed sideroblasts MDS subtype. *SRSF2* mutations are common in CMML and are retained when these patients progress to sAML.

Cohesin Complex

The cohesin complex is involved in the alignment of sister chromatids throughout replication, from the initial DNA synthesis during S-phase and on through mitosis and segregation during M-phase. The cohesin core complex is comprised of the structural maintenance of chromosomes (SMC) proteins SMC1, SMC3, RAD21 (SCC1), and stromalins antigens STAG1 or STAG2. These core proteins form a ring structure, with a hinge formed by SMC1 and SMC3, and a closed loop formed through the binding of RAD21 with STAG1 and STAG2, which regulates chromosome segregation. Recurrent mutations in the genes for this core complex have been identified in approximately 15% of AML cases. The cohesin complex preferentially localizes at “super enhancers,” which regulate gene expression related to cell lineage and self-renewal. Perturbation of this mechanism may be more relevant to the pathogenesis of AML, since cohesin mutations have not been associated with increased risk of aneuploidy in this disease.

Nucleophosmin

Nucleophosmin (*NPM1*) is a molecular chaperone with multiple functions, including ribosomal protein assembly, the prevention of nucleolar protein aggregation, and regulation of the tumor suppressors TP53 and alternative reading frame (ARF). *NPM1* mutations are seen in approximately one third of patients with AML, and are enriched in patients with normal karyotypes. They occur as insertions in exon 12, most frequently of the four base pairs TCTG (type A), causing a frameshift mutation with an added nuclear export signal motif at the carboxy-terminus, and resulting in cytoplasmic localization and loss of function. Less common mutations with similar effect include alternate insertions of CATG (type B) or CCTG (type D), among others; there does not appear to be a clinical impact according to the type of mutation. Murine models incorporating the *NPM1* type A mutation result in increased megakaryocytes, but do not develop AML. Consistent with this, mutations in *NPM1* are thought to represent early events in the development of AML. Rarely, *NPM1* is involved in chromosomal translocations, including t(2;5)(p23;q35) with *ALK*, and t(5;17)(q35;q21) with *RARA*, the latter resulting in an uncommon variant of APL.

Epigenetic Alterations in Acute Myeloid Leukemia

AML is frequently characterized by epigenetic alterations, including covalent modifications to DNA and chromatin factors, dysregulated expression of small and large noncoding RNAs, and changes in long-range DNA interactions resulting in altered gene expression. In many cases (discussed earlier), these epigenetic regulators are targets of somatic mutation or are aberrantly recruited by fusion proteins in AML.

Methylation of cytosine on DNA at CpG sites, which are enriched at gene promoter regions, is a key regulator of gene expression. The AML genome has increased methylation when compared with normal tissues, and certain genetic subtypes of AML, such as AML with *RUNX1-RUNX1T1* or *PML-RARA* rearrangements, have distinct gene methylation patterns. Recurrent missense mutations in the *de novo* DNA methyltransferase, DNMT3A, likely function in a dominant negative fashion and lead to focal regions of reduced DNA methylation. Oxidation of 5-methylcytosine to 5-hydroxymethylcytosine by the TET enzymes is an intermediate step toward subsequent demethylation. TET2 inhibition, either through an acquired loss-of-function mutation, or via 2-HG produced preferentially in the setting of *IDH1/2* mutations, results in aberrant hydroxymethylation, particularly at key *HOX* sites, which leads to myeloid expansion and a dysplastic phenotype in mouse models. Causal links between mutations in these regulatory enzymes, cytosine modifications, altered gene expression, and leukemogenesis remain elusive, but it is unlikely that global changes in methylation are responsible for the leukemic phenotype.

DNA methylation and histone modification are often coordinately regulated. For example, *EVII* has DNA methylation activity, but also associates with histone deacetylases and methyltransferases. The polycomb repressive complex 2 (*PRC2*) catalyzes the methylation of histone H3K27, resulting in gene silencing. *PRC2* is comprised of a noncatalytic subunit, as well as a SET domain with methyltransferase activity via *EZH1* or *EZH2*. Mutations in *EZH2* found in myeloid malignancies are predicted to be loss of function. In mouse models, *EZH2* appears to have either tumor suppressor or oncogene characteristics, depending on the timing of the mutation in relation to the stage of disease, and has a role in inhibiting hematopoietic cell differentiation. Similarly, *ASXL1* interacts with *PRC2*, resulting in trimethylation at H3K27; loss-of-function mutations may promote leukemia due to relative activation of *PRC2*-specific genes. Finally, *MLL* rearrangements bring a diversity of fusion partners to targets normally regulated by *MLL*. Many of these fusion partners interact with DOT1L, a histone H3K79 methyltransferase, which then methylates critical *MLL*-dependent regulatory genes, such as *HOXA9*.

BIOLOGY OF ACUTE MYELOID LEUKEMIA

Role of the Bone Marrow Microenvironment

AML arises in hematopoietic cells residing in a bone marrow microenvironment known as the *niche*, where the stromal infrastructure helps to promote leukemic cell survival. AML cells in culture have improved survival when in the presence of bone marrow fibroblasts, which increase expression of the antiapoptotic proteins Bcl-2 and Bcl-XL. Moreover, the bone marrow stroma contributes to chemoresistance via the binding of fibronectin on stromal cells to VLA-4 expressed on AML blasts. Bone marrow stromal cells also produce the chemokine SDF-1, or chemokine CXC motif ligand 12 (CXCL12), which binds to CXC-chemokine receptor 4 (CXCR4), a chemokine receptor expressed on hematopoietic progenitors as well as leukemic cells. This signal maintains the normal hematopoietic progenitor niche; it also facilitates proliferation and survival.

A variety of strategies that interfere with the interactions between leukemic and stromal cells have been tested as a means to enhance the efficacy of cytotoxic agents. In addition, there is evidence that AML blasts sustain an immunosuppressive microenvironment via an arginase-dependent mechanism that may be amenable to pharmacologic inhibition.

Clonal Hierarchy of Acute Myeloid Leukemia

The recognition that some mutations may be lost or acquired at relapse (e.g., *FLT3-ITD*), while others are present at diagnosis and remain stable (e.g., *NPM1*, *PML-RARA*, and *CBF* rearrangements) suggests that distinct clonal populations can coexist in an AML sample. Sequencing of serially obtained samples has revealed a clonal hierarchy in AML, beginning with a founding clone that represents the initial population that becomes dominant in the bone marrow. The founding clone spawns subclones that retain founding clone mutations, but gain additional mutations that confer a growth advantage. The clonal architecture evolves over time as a feature of the natural history of the disease, or in response to selective pressure imposed by therapy. Analysis of AML cases that entered morphologic remission after cytotoxic chemotherapy, and later relapse, revealed that the dominant clone at relapse retains founding clone mutations. These observations raise the hypothesis that therapies directed at eradicating drivers of the founding clone may be more effective than therapies targeting subclones.

Somatic mutations accumulate in an age-dependent manner in normal individuals without perturbing hematopoiesis in most cases. However, several large cohort sequencing studies have demonstrated that up to 10% of apparently healthy individuals over 65 years of age have detectable clonal populations that are marked by somatic mutations, often in genes that are recurrently mutated in MDS/AML (particularly in epigenetic regulators, including DNMT3A, TET2, and ASXL1). Although clonally skewed hematopoiesis has been associated with an elevated risk of later developing a hematologic malignancy, the vast majority of these individuals do not progress to MDS or AML. Additional epidemiologic study will be required to determine how often clonal hematopoiesis is a precursor to MDS/AML and whether surveillance and/or early intervention are warranted.

Leukemia Stem Cells

Normal HSCs are characterized by their capacity for self-renewal and multilineage differentiation, properties that can only be assessed in vivo using functional assays such as xenotransplantation into immune deficient mouse models. The pioneering studies of John Dick and colleagues demonstrated that a similar cellular hierarchy exists in AML, in which rare cells with an immunophenotype similar to normal stem/progenitor cells are enriched for the capacity to initiate leukemia in xenotransplantation models. Further work has led to the identification of several cell surface antigens that are preferentially expressed on leukemia-initiating cells compared with normal HSCs, including CD123, CD99, and TIM3.

Interestingly, cells with an HSC immunophenotype that are capable of engraftment in mice and multilineage differentiation in vivo can be recovered from the bone marrow of patients with AML. These “preleukemic stem cells” may harbor the same class of mutations detected in individuals with clonally skewed hematopoiesis (e.g., DNMT3A), but lack the full complement of mutations found in the bulk AML sample, suggesting that they are ancestral. The contribution of these preleukemic stem cells to chemotherapy resistance and relapse remains to be determined.

FUTURE DIRECTIONS

AML comprises a heterogeneous spectrum of disease, which shares a common myeloid phenotype and is characterized by accumulation of abnormal leukemic myeloblasts. The development of AML occurs through serial acquisition of somatic mutations, resulting in clonal expansion and genetic evolution of this disease. As our understanding of the genetic underpinnings has grown, it is clear that there are various pathways to the development of AML (Fig. 58.3). Moreover, some mutations appear to be earlier, founding events, while other mutations are typically acquired during disease progression. The further identification of the sequence of mutation acquisition, as well as cooccurring and mutually exclusive genetic pathways, will help to better distinguish different subsets of this disease.

A broader understanding of the mutational landscape of AML has provided a basis for development and testing of novel targeted therapies and monitoring of disease. The role of residual disease monitoring may occur through cytogenetic, flow cytometric, and now also molecular assessment. The incorporation of these residual disease markers into clinical practice remains under intense investigation; similar to patients with chronic myeloid leukemia, it may eventually inform treatment duration and maintenance therapies.

Molecular Diagnostics in Acute Myeloid Leukemia

The various mutations and dysregulated pathways integral to the pathobiology of acute myeloid leukemia (AML) also yield specific therapeutic targets and offer clear prognostic implications for patients. As such, molecular testing at the time of AML diagnosis has become the standard of care, to assist with subclassification of disease, risk stratification, selection of an induction regimen, and consolidation preferences. Diagnosis of AML requires analysis of a specimen demonstrating excess myeloblasts. For patients with high levels of circulating disease, some studies may be performed with the use of peripheral blood samples; however, assessment of a bone marrow biopsy and aspirate is essential.

Standard Evaluation

The cornerstone of the diagnosis of AML remains morphologic assessment. In the current WHO guidelines, at least 20% of the bone marrow cellularity must be comprised of myeloblasts, except in the presence of the t(8;21), t(16;16)/inv(16), or t(15;17) rearrangements, which are sufficient for an AML diagnosis regardless of blast count. In addition, promonocytes in acute monocytic leukemia, megakaryoblasts in acute megakaryocytic leukemia, and abnormal promyelocytes in acute promyelocytic leukemia are added to the blast percentage. Only in pure erythroleukemia are erythroblasts included in the blast count.

Flow cytometry utilizes multiparametric analysis of single cells to assess cellular granularity and size, cell surface, intracellular antigen expression, and other features. The coexpression of certain cell surface markers may help to confirm myeloid cell origin, identify immature blasts, typically CD34⁺ and CD117⁺, and also to distinguish an aberrant phenotype of a leukemic blast population. Flow cytometry can enumerate small populations of leukemic cells, below the limit of detection by morphology. For this reason, flow cytometric analysis has been developed as a platform to monitor minimal residual disease (MRD). The role of MRD assessment by flow cytometry in routine AML care remains under investigation.

A critical element in the initial laboratory assessment of AML is cytogenetic analysis of a bone marrow aspirate specimen. This provides important prognostic data for risk stratification and informs therapeutic strategies. Cells from the aspirate are cultured, mitosis is interrupted, and the paired chromosomes are arranged to identify missing, translocated, or duplicated segments. Fluorescence in situ hybridization utilizes fluorescently labeled DNA probes and can identify gains and losses of chromosomal material, as well as rearrangements that may be cryptic using conventional banding techniques.

Detection of somatic mutations that are known drivers of AML biology can aid in the initial risk classification of patients with AML, particularly those with intermediate-risk cytogenetics. Current National Comprehensive Cancer Network guidelines recommend testing of four genes (*KIT*, *FLT3*, *NPM1*, and *CEBPA*) at diagnosis, because their prognostic significance has been validated in large cohorts (level 2A evidence). Testing for mutations in *RUNX1* is recommended for WHO classification. In addition, use of targeted therapies is increasingly dependent on detection of a specific tumor genotype.

Investigational Testing

Given the rapidly expanding number of genes that are recognized targets of recurrent somatic mutation in AML, more comprehensive mutational profiling is beginning to enter routine clinical practice. With increasing numbers of genes to query, next-generation sequencing approaches offer advantages in sensitivity, cost, and efficiency over traditional testing methods (e.g., polymerase chain reaction, Sanger sequencing). Large panels of genes can be tested simultaneously by pre-enriching for the targets of interest (by automated amplicon generation, or hybridization capture). With further improvements in analytical workflow and cost reduction, whole-genome and transcriptome sequencing could displace some existing diagnostic tools, as these platforms can provide simultaneous detection of mutations, gene expression, copy number alteration, and structural variation.

CLINICAL MANIFESTATIONS AND TREATMENT OF ACUTE MYELOID LEUKEMIA

Stefan Faderl and Hagop M. Kantarjian

INTRODUCTION

Acute myeloid leukemia (AML) is a clonal disorder of hematopoietic stem or progenitor cells causing a differentiation block and unregulated proliferation of hematopoietic cells in the marrow, blood, and in some cases extramedullary sites. The consequences of this malignant transformation include marrow failure, profound immune deficiencies, and not infrequently manifestations of a systemic inflammatory response of varying severity. The high malignant potential of AML with rapid progression, universally fatal outcome if left untreated to, and challenging clinical course and management continue to attract a high level of interest.

Knowledge of the pathobiologic aspects of AML as it relates to origin of blast cells, their biologic behavior, sensitivity to therapeutic interventions, and their interactions with and interdependence on the microenvironment is growing. Extensive application of whole-genome sequencing has identified numerous gene mutations and molecular footprints in AML, highlighting the heterogeneity of AML, devising better tools for prognosis, and identifying abnormal cellular and signaling pathways as central to the development of the leukemic phenotype against which novel targeted therapies are increasingly being developed.

Progress in basic, translational, and clinical research is cutting inroads into decade-old management paradigms. Although standard induction therapy for most patients with AML has not changed much in four decades and remains rooted in cytarabine/anthracycline combinations, newer studies are addressing a variety of questions: higher doses of cytarabine and/or anthracyclines during induction therapy, incorporation of novel drugs into existing chemotherapy backbones, separate approaches to core-binding factor (CBF) leukemias, chemotherapy-free treatment of most patients with acute promyelocytic leukemias (APL), alternative ways of treating AML in older patients, the expanding role of epigenetic therapies, and a steadily increasing armamentarium of small-molecule targeted therapies in AML salvage. New drugs allow old concepts such as maintenance therapy to be revisited. More extended application of measurements of minimal residual disease (MRD) may have the same helpful impact in AML as it proved to have in other forms of acute leukemias. A major challenge for the future lies in the ability to effectively incorporate and utilize the vast amount of generated data in the most effective way to extend to patients with AML the benefit of the exploits of research.

EPIDEMIOLOGY

In 2014, 18,860 new cases of patients with AML were diagnosed in the United States and an estimated 10,460 patients with AML died from it.¹ The age-adjusted incidence rate of AML is 3.6/100,000 population. However, with a median age at diagnosis of 66 years, incidence rates are as high as >15/100,000 in the older age group, and about 70% of all diagnoses of AML are in patients over 55 years of age. This is important as older patients have more comorbidities, respond less well to chemotherapy than younger patients, and carry the worst prognosis of any age group. AML is slightly more frequent in men than women (lifetime risk of acquiring AML: 1 in 227 [male]

to 1 in 278 [female]). Based on Surveillance, Epidemiology, and End Results (SEER) data from 2005 to 2009, small differences in frequency also exist by race; AML is more common in whites than other ethnic groups (<http://seer.cancer.gov>). According to one study of 27,525 patients with AML, based on the SEER database from 1999 to 2008, African-Americans and Hispanics had a 12% and 6% increased hazard of death, respectively. This unfavorable hazard rate pertained despite the higher rate in these two ethnic groups of AML with translocations t(8;21) and t(15;17), both associated with a better outcome.

Several studies have suggested associations between leukemia diagnosis and season of the year. One study looking at this association found December and January as the two months with the highest number of new diagnoses, particularly for patients older than 65 years and men. Observations such as these raise interesting questions about the role of infectious agents in the etiology of AML.

PATHOBIOLOGY

Molecular genetic analysis has greatly contributed to a better understanding of the pathobiology that underlies the initiation and evolution of AML. AML is characterized by a relatively well-defined set of a small number of recurrent mutations. A series of transforming events (e.g., mutational processes intrinsic to the particular cell, exposure to external mutagens, genotoxic treatment of unrelated malignancies) leads to the development of preleukemic stem cells. Through the aggregate action of a network of mutated genes, these cells are characterized by impaired self-renewal properties, blocks in differentiation, limited capacity to undergo apoptosis, and altered signaling and metabolic pathways. Frequently, a given type of mutation is not sufficient to elicit the full leukemogenic phenotype and a second set of mutations is necessary for the fully transformed leukemic stem cells to develop. The transformation of immature hematopoietic cells that arises out of genetic changes in hematopoietic stem and more committed progenitor cells is thus considered a stepwise process in which genes of complementary mutation classes act together. This view gave rise to the two-hit model of leukemogenesis. In this model, two separate classes of mutations are operative: mutations that activate signal induction pathways and lead to uninhibited proliferation and survival; and mutations that affect transcription factors or other transcription elements that cause impaired hematopoietic differentiation and aberrant acquisition of self-renewal properties. Whereas mutations between these two groups easily coexist, mutations within one class are typically mutually exclusive. Since the initial publication of this model in 2002, whole-genome sequencing has identified many more gene mutations involved in AML pathobiology. Although most of these more recently described genes do not neatly fit into one or the other mutation classes, the principle of synergistic activity in the process of malignant transformation remains nevertheless valid.

Once compromised by a set of genetic mutations and in the context of propitious interactions with the microenvironment, leukemic cells may quickly accrue additional abnormalities (on a genetic or epigenetic level), and a new level of genomic instability

may result in evolution and progression. An interesting aspect of such a dynamic model of acquisition of genetic abnormalities is the possibility that AML therapy itself may induce further genetic changes and become a driving force in selection of some AML clones over others.^{2,3}

CLINICAL AND LABORATORY MANIFESTATIONS

Signs and symptoms of AML mostly reflect the effect of cytopenias. Patients typically present with a short history (1–8 weeks) of constitutional complaints (fatigue, lack of energy, malaise, profuse sweats), manifestations of bleeding (such as from gums, bruising in the skin, epistaxis, menorrhagia), or fevers. Fevers should always be presumed to be secondary to infections even in the absence of an identifiable focus and lead to rapid institution of antibiotic therapy. “Tumor fever” remains a diagnosis of exclusion. Extramedullary infiltrations of leukemia cells in the gingiva, skin, lymph nodes, or other organs occur occasionally. Bone pains are infrequent even with excessive leukocytosis and should raise the suspicion of an acute lymphoblastic leukemia (ALL), especially in children. Likewise, signs and symptoms referable to central nervous system (CNS) involvement (cranial nerve defects and other focal neurologic abnormalities, mental status changes, seizure activity) are rare, with the exception of AML with monocytic/monoblastic differentiation or in any AML with considerable leukocytosis ($>100,000/\mu\text{L}$).

Signs at physical examination are often nonspecific but in their aggregate can lead to a correct diagnosis. It is impossible to distinguish AML from ALL based solely on clinical presentation or examination findings. Patients may demonstrate pallor, ecchymoses or petechiae, enlargement of lymph nodes, or rarely, hepatosplenomegaly. Examination of the lungs may reveal signs of symptoms of an infectious process. Some patients with AML have no abnormal findings on physical examination.

The laboratory evaluation should include blood counts with evaluation of the blood smear, a standard chemistry panel (electrolytes, urea nitrogen, creatinine, total bilirubin, transaminases, uric acid, lactate dehydrogenase [LDH]), and coagulation studies, including prothrombin time (PT), partial thromboplastin time (PTT), and fibrinogen levels. Anemia and thrombocytopenia are universal. The white blood cell (WBC) count can vary from low to high and will range from $5000/\mu\text{L}$ to $100,000/\mu\text{L}$ in most patients. The highest degrees of leukocytosis can be seen in AML with myelomonocytic differentiation. Leukocytosis of $100,000/\mu\text{L}$ or higher is considered an emergency and requires immediate efforts to reduce the disease burden (e.g., leukapheresis, chemotherapy) because (1) leukostasis in some vascular beds may have catastrophic consequences (e.g., lung, brain), and (2) it may elicit a systemic inflammatory response with serious secondary organ damage (e.g., diffuse alveolar injury, hepatic failure). However, there is not always a good correlation between the severity of leukocytosis and immediate adverse clinical effects, and far lower WBC levels may elicit life-threatening symptoms. The WBC must therefore be assessed in the context of the patient's overall physical condition and other clinical and laboratory abnormalities (e.g., LDH, uric acid, coagulation parameters). Disseminated intravascular coagulation (DIC) is often seen in patients with myelomonocytic AML, APL, and any high-WBC AML. PT, PTT, and fibrinogen levels should be carefully followed and coagulation factors be replaced as clinically indicated. Subclinical DIC is common in many forms of AML and can worsen with the institution of therapy. Abnormalities of renal and hepatic values may represent infiltration of these organs, even in the absence of clinical symptoms.

Imaging studies are of little help in diagnosis but allow assessment of complications (pneumonia, cerebral bleed). If patients present with any neurologic deficit, the threshold for computed tomography (CT) scan (noncontrast if bleeding is of concern) or any other imaging modality of the brain should be low. Further evaluations should be based on the clinical assessment of the patients.

DIAGNOSIS AND CLASSIFICATION

The diagnosis of AML relies on morphologic evaluation (cytochemical stains), immunophenotyping by flow cytometry, and assessment of karyotype and molecular studies (Fig. 59.1).

Blast percentage is best determined on a 500-cell differential of the marrow aspirate. Three broad types of myeloblasts are described based on the granular content and nuclear features of the blasts (type 1: agranular basophilic cytoplasm, nucleus with fine chromatin, and two to four distinct nucleoli; type 2: basophilic cytoplasm with 20 or fewer azurophilic granules and similar nuclear features as type 1 blasts; type 3: basophilic cytoplasm with more than 20 azurophilic granules), although the morphologic variety of blasts exceeds the defined categories (Fig. 59.2). Promyelocytes have moderately basophilic cytoplasm with numerous azurophilic granules, and monoblasts and promonocytes usually exhibit folded/convoluted nuclei and may contain prominent acidophilic nucleoli. Promyelocytes, promonocytes, and atypical pronormoblasts are considered blast equivalents in some subgroups (e.g., APL, acute monoblastic leukemia, and acute erythroleukemia, pure erythroid type). Micromegakaryocytes and pronormoblasts are not considered blasts (see Fig. 59.2K and L). Auer rods are rod-like filaments of aggregated primary granules that are found in 30% to 50% of newly diagnosed patients with AML and, if present, are one of the hallmark morphologic features to establish a diagnosis of AML (see Fig. 59.2C). AML marrows are typically hypercellular with decreased or absent megakaryocytes. Exceptions are marrows of older patients or those with therapy-related AML, which may be hypocellular with dysplastic changes of one or several hematopoietic lineages. Prominent dysplasia may suggest a previous diagnosis of myelodysplastic syndrome (MDS) but can also be found in patients with de novo AML, where the prognostic significance of dysplastic changes is less clear. Cases with extensive fibrosis may represent a preceding myeloproliferative neoplasm or acute megakaryocytic leukemia.

Several cytochemical reactions further highlight morphologic characteristics (myeloperoxidase [MPO], periodic acid–Schiff, Sudan black B, naphthol AS-D chloroacetate esterase [specific esterase], α -naphthyl acetate/butyrate esterases [nonspecific esterases], acid phosphatase; Fig. 59.3). MPO is the most specific granulocytic marker, and MPO positivity in at least 3% of the blasts is consistent with a diagnosis of AML. On the other hand, lack of MPO staining does not rule out AML because it is often not present in AML with minimal differentiation, acute monoblastic leukemia, and acute megakaryocytic leukemia. Monoblastic leukemias are stained by nonspecific esterases. Whereas the MPO reaction is relatively uncomplicated and results are available quickly, this is not the case with most of the other cytochemical reactions, and their diagnostic utility is nowadays mostly outdone by immunophenotyping by flow cytometry.

The first systematic attempt of an AML classification goes back to the French–American–British (FAB) group, and was based solely on morphology (blast percentage, degree of differentiation, lineage involvement). Because of its limited scope, the FAB system is now considered inadequate. Rapidly growing insights from genetic mutation analyses, their association with prognosis, and, in some cases, prediction of response to therapy triggered a revision of the old system and led to the changes in the 2008 edition of the World Health Organization (WHO) classification of AML. The focus has shifted to identification of recurrent cytogenetic–molecular abnormalities, information regarding exposure to prior chemotherapy and/or radiation therapy, and morphologic features related to dysplasia-related changes and remnants of the FAB system (Table 59.1). Several categories have been defined:

- 1) AML with recurrent genetic abnormalities. This includes AML with relatively common cytogenetic changes: AML with $t(8;21)(q22;q22)$, *RUNX1-RUNX1T1* (Fig. 59.4); AML with $inv(16)(p13.1q22)$ or $t(16;16)(p13.1;q22)$, *CBFB-MYH11* (Fig. 59.5); AML with $t(15;17)(q22;q12)$, *PML-RARA* (Fig. 59.6); and AML with $t(9;11)(p22;q23)$, *MLLT3-MLL* (Fig. 59.7). Less common

Fig. 59.1 WORKUP OF ACUTE MYELOID LEUKEMIA. The diagnostic workup consists of a morphologic assessment, immunophenotyping by flow cytometry, assessment of the karyotype, and a panel of gene mutations. Whereas morphologic assessment by itself is often not sufficient to render a diagnosis, flow cytometry will confirm the lineage assignment (myeloid vs. lymphoid) and stage of differentiation in more than 95% of cases. In the remainder, either no lineage-specific antigens are expressed (acute undifferentiated leukemia) or antigens of more than one lineage are present (mixed-phenotype acute leukemia). In the latter scenario, antigens of several lineages can be found on one (biphenotypic) or separate populations of blasts (bilineal). Karyotyping and gene mutation analysis may add diagnostic information in morphologically ambiguous situations but is otherwise of more interest in determining prognosis. Additional information (exposure to previous chemotherapy and/or radiation therapy, history of an antecedent hematologic disorder, dysplasia) forms the basis for the 2008 revision of the WHO classification of AML (see Table 59.1). *AHD*, Antecedent hematologic disorder; *AML*, acute myeloid leukemia; *CBF*, core-binding factor; *MPO*, myeloperoxidase; *WHO*, World Health Organization.

Fig. 59.2 SPECTRUM OF BLASTS, BLAST EQUIVALENTS, AND OTHER CELLS. Blast cells in acute myeloid leukemia (AML) exhibit a wide spectrum of morphologic features. The French–American–British classification described three types of blasts depending on the granule content (A–C). However, blasts with nuclear invagination (frequently associated with *NPM1* and/or *FLT3* mutations) (D); blasts with pseudopods (frequently shown to be megakaryoblasts) (E); and monoblasts (F) are also quite distinctive. Blast equivalents include granular or hypogranular promyelocytes (G and H) for acute promyelocytic leukemia, promonocytes (I) for AML with a monocytic component, and atypical pronormoblasts (frequently with cytoplasmic vacuoles) (J) for acute erythroleukemia of the pure erythroid type. Micromegakaryocytes (K) and pronormoblasts (L) are not considered blasts.

Fig. 59.3 CYTOCHEMISTRY: MYELOPEROXIDASE, α -NAPHTHYL ACETATE ESTERASE, AND COMBINED ESTERASE REACTIONS. The MPO reaction is easily performed, can be done in less than a few minutes, and provides important initial information about the lineage of the blasts, particularly in cases in which morphologic assessment is difficult. In many laboratories it is routinely performed for all new acute leukemias. The MPO reaction should be interpreted in the blast population and expressed as a percentage of blasts that are positive. (A) The positive MPO reaction is strong. (B) The reaction is weak and seen in only some blasts. A counterstain would have obscured the weak reaction product. A weak MPO reaction is not uncommon in cases of acute myeloid leukemia (AML) associated with myelodysplasia (as in [B]). The neutrophils in such cases are also only weakly positive (*bottom cell* [B]). The ANAE reaction is a nonspecific esterase reaction positive in most monocytic cells ([C] *orange-brown cell on left* compared to negative neutrophil, and erythroid cell, *middle and right*). The ANAE reaction is interpreted as positive in cells as a percentage of nonerythroid elements. A significant monocytic component is usually defined as 20% or greater of the non-erythroid elements and is usually required for making a diagnosis of acute myelomonocytic leukemia. It is notable that in some cases of AML with *inv*(16) (i.e., AML with abnormal eosinophils), the monocytes are ANAE negative. A COES reaction uses another nonspecific esterase reaction for monocytes, α -naphthyl butyrate esterase, together with the specific esterase, chloroacetate esterase, for granulocytes. The combination allows simultaneous evaluation of granulocytes (blue reaction product) and monocytes (orange-brown reaction product). (D) Acute myelomonocytic leukemia. A monocyte (*top*), a granulocyte (*right*), and a myelomonocytic hybrid cell that exhibits both the orange-brown and blue reaction products (*bottom*). ANAE, α -Naphthyl acetate esterase; COES, combined esterase; MPO, myeloperoxidase.

TABLE 59.1

WHO Classification of Acute Myeloid Leukemia (2008)

Category	Subtype/Definition	Category	Subtype/Definition
AML with recurrent cytogenetic abnormalities	t(8;21)(q22;q22); <i>RUNX1-RUNX1T1</i> ^a	Myeloid sarcoma	
	<i>inv</i> (16)(p13.1q22); <i>CBFB-MYH11</i> ^a		
AML with MDS-related changes	t(16;16)(p13.1q22); <i>CBFB-MYH11</i> ^a	Myeloid proliferations related to Down syndrome	Transient abnormal myelopoiesis Myeloid leukemia associated with Down syndrome
	t(15;17)(q22;q12); <i>PML-RARA</i> ^a		
Therapy-related myeloid neoplasms	t(9;11)(p22;q23); <i>MLLT3-MLL</i>	Blastic plasmacytoid dendritic cell neoplasm	
	t(6;9)(p23;q34); <i>DEK-NUP214</i>		
AML, not otherwise specified	<i>inv</i> (3)(q21q26.2); <i>RPN1-EVI1</i>	Acute leukemia of ambiguous lineage	Acute undifferentiated leukemia Mixed phenotype acute leukemia with t(9;22)(q34;q11.2); <i>BCR-ABL1</i>
	t(3;3)(q21;q26.2); <i>RPN1-EVI1</i>		t(v;11q23); <i>MLL</i> rearranged
	t(1;22)(p13q13); <i>RBM15-MKL1</i>	Provisional entities	Mixed phenotype acute leukemia, B/myeloid, NOS Mixed phenotype acute leukemia, T/myeloid, NOS
			AML with mutated <i>NPM1</i> AML with mutated <i>CEBPA</i> NK-cell lymphoblastic leukemia/lymphoma

^aDiagnosis of AML regardless of percent blasts

^bExcluded are patients with AML who have transformed from MPN

AML, Acute myeloid leukemia; MDS, myelodysplastic syndrome; MPN, myeloproliferative neoplasm; NK, natural killer cell; NOS, not otherwise specified.

Fig. 59.4 ACUTE MYELOID LEUKEMIA WITH $t(8;21)(q22;q22)$, (*RUNX1-RUNX1T1*). (A) Low-power, Wright-stained bone marrow aspirate smear showing increased blasts associated with differentiating myeloid cells. (B) Details illustrating some of the features associated with this leukemia. They include blasts with long thin Auer rods (*top left*), immature cells with abnormal eosinophilic globules (*top and bottom, second from left*), abnormal salmon-colored granulation in the maturing cells, sometimes associated with a basophilic periphery (*top and bottom, fourth from left*), and slightly abnormal features in the mature neutrophils (*far right*). Pseudo-Chediak-Higashi granules were not seen in this case. (C) Biopsy specimen illustrates the significant degree of maturation that can sometimes be seen. In fact, in some cases the blast count can be less than 20%, but the diagnosis of acute myeloid leukemia is still made with the cytogenetic finding of $t(8;21)$.

Fig. 59.5 ACUTE MYELOID LEUKEMIA WITH ABNORMAL BONE MARROW EOSINOPHILS AND $INV(16)(p13.1;q22)$ OR $t(16;16)(p13.1;q22)$, (*CBFB-MYH11*). (A) Low-power, Wright-stained bone marrow aspirate showing blasts, monocytic cells, granulocytic cells, and abnormal eosinophils. (B) Features of the abnormal eosinophils in three abnormal eosinophils (*left three cells*). Note the abnormal basophilic granules in the eosinophilic myelocytes. These granules are large, tend to cluster or coalesce, and are interspersed among the large eosinophilic granules, which are more difficult to see. As the eosinophils mature, the abnormal basophilic granules are less prominent and sometimes disappear (*far right*). A common misconception is that the basophilic granules are the granules of basophils and that the abnormal eosinophils are “hybrid cells.” (C) A basophil in the same case (*top cell*) for comparison. (D) Cells from a case of reactive eosinophilia, also for comparison. Immature eosinophils (*cell to the right*) do have primary blue granules. However, they are usually less prominent and less atypical than the basophilic granules of the abnormal eosinophils. It is notable that the monocytes in cases of AML with $inv(16)$ or $t(16;16)$ are sometimes α -naphthyl acetate esterase (ANAE) reaction negative. (E) Negative ANAE reaction. (F) Abnormal eosinophils cannot be recognized in hematoxylin and eosin-stained sections of the biopsy.

Fig. 59.6 ACUTE PROMYELOCYTIC LEUKEMIA, ACUTE MYELOID LEUKEMIA WITH $t(15;17)$ ($q22;q12$), (*PML-RARA*). (A–C) Acute promyelocytic leukemia (APL). (D and E) Hypogranular or microgranular subtype. (F) Bone marrow biopsy. (G) APL cells maturing after all-trans retinoic acid (ATRA) therapy. In the typical granular type of APL (A), the abnormal promyelocytes can exhibit variable morphologic features. Even within the same case, the granules can range from coarse, dark, and dense to fine and dust-like (B). The nuclei in the abnormal promyelocytes frequently exhibit a bilobed, dumbbell, or reniform shape. This is a diagnostically important feature, which can sometimes be difficult to recognize beneath the granules (B). Auer rods can be single, multiple, coalesced into Auer bodies, and even present in maturing cells (C). The microgranular type usually presents with an elevated white blood cell count (D). Although granules cannot be readily appreciated at the light microscope (E), granules can be demonstrated by electron microscopy. The abnormal nuclear shapes (bilobed, dumbbell, and reniform) can be easily appreciated (E). Bone core biopsy sample typically shows sheets of cells with abundant granular cytoplasm (F). After ATRA therapy the abnormal promyelocytes mature to abnormal neutrophils ([G] *top and bottom right*, compared with normal neutrophil, *left*). These can be seen for weeks after therapy and do not signify a failed response to the differentiating agent.

Fig. 59.7 ACUTE MONOBLASTIC LEUKEMIA WITH $t(9;11)(p22;q23)$, (*MLLT3-MLL*). Acute monoblastic leukemia with $t(9;11)$. (A) Such cases typically present with high counts because of circulating monoblasts. (B and C) Bone marrow aspirate is packed with monoblasts and shows few granulocytic elements. (D) Absence of a granulocytic component can be illustrated with the combined esterase reaction, in which most of the cells show the α -naphthyl butyrate reaction product (*orange-brown*), with only rare granulocytes with the blue reaction product from the chloroacetate esterase reaction. (E) The biopsy sample is usually packed with sheets of monoblasts with fine nuclear chromatin and abundant pink cytoplasm.

Fig. 59.8 ACUTE MYELOID LEUKEMIA WITH LESS COMMON CYTOGENETIC AND GENETIC CHANGES. (A and B) Acute myeloid leukemia (AML) with $t(6;9)(p23;q34)$. These cases are characterized by marrow dysplasia and basophilia. However, the morphologic characteristics can be quite varied among cases. AML with $inv(3)(q21q26.2)$ or $t(3;3)(q21;q26.2)$ is characterized by normal or high platelet counts, (C) and by a bone marrow with numerous micromegakaryocytes (D). AML with $t(1;22)(p13;q13)$ is uncommon and occurs in infants. The blasts are megakaryoblasts (E) but in the bone marrow can have a sarcomatous appearance (F). AML with *NPM1* or *NPM1* and *FLT3* mutations frequently presents with high peripheral blast counts, and the blasts sometimes have nuclear invaginations (G). *NPM1* mutation is associated with the abnormal cytoplasmic localization of *NPM1* rather than the normal nuclear staining (H).

Fig. 59.9 ACUTE MYELOID LEUKEMIA WITH MULTILINEAGE DYSPLASIA. (A) Bone marrow aspirate shows increased blasts and maturing cells with dysplastic features. (B–D) Details of the dysplasia. (B) Maturing erythroid elements exhibit megaloblastoid change and bizarre nuclear abnormalities. (C) Dysplastic granulocytes (*bottom three*) are compared with a rare normal granulocyte (*top*). The dysplastic forms have pale cytoplasm and abnormal nuclear shapes with hypolobation, hypersegmentation, and prominent nuclear excrescences. (D) Dysplastic micromegakaryocytes have single or double small nuclei but mature cytoplasm with platelet material within. (E) Increased blasts. (F) Dysplasia is difficult to appreciate on a biopsied section. This is true except for the megakaryocytes. Dysplastic megakaryocytes can be recognized on the biopsy specimen by their abnormally small nuclei, which are sometimes multiple and widely spaced.

subtypes are AML with $t(6;9)(p23;q34)$, *DEK-NUP214*; AML with $inv(3)(q21q26.2)$ or $t(3;3)(q21;q26.2)$, *RPN1-EVII*; and AML with $t(1;22)(p13;q13)$, *RBM15-MKL1* (Fig. 59.8). Diploid AML with mutations of the nucleophosmin gene (*NPM1*; see Fig. 59.8G and H), and *CEBPA* (and in the absence of additional mutations) have been assigned a provisional status. This group of AML is expected to expand with subsequent editions.

- 2) AML with myelodysplasia-related changes is defined in one of three ways: a) AML in patients with a preceding history of MDS; b) AML with multilineage dysplasia recognized morphologically

(Fig. 59.9); and c) AML associated with a myelodysplasia-related cytogenetic abnormality.

- 3) The category of therapy-related AML was retained from the 2001 WHO classification, although the distinctions between AML associated with alkylating agents or radiation and those with topoisomerase II inhibitors were abandoned. Many patients receive complex therapeutic regimens, making this distinction difficult and impractical.
- 4) Not otherwise specified subtypes of AML are a “wastebasket” of sorts for AML cases that do not fit the categories already described

Fig. 59.10 ACUTE PANMYELOSIS WITH MYELOFIBROSIS. (A) Bone marrow biopsy specimen shows a loosely packed marrow with a swirling appearance to the cellular elements due to underlying fibrosis. (B) The latter is illustrated on the reticulin stain. (C) Proliferations of erythroid cells (*top left*), megakaryocytes (*bottom left*), and immature cells within the fibrotic areas (*right*). (D) Immunohistochemical staining shows increased megakaryocytes (*top*, CD61) and increased blasts (*bottom*, CD34).

Fig. 59.11 MYELOID SARCOMA. Myeloid sarcomas can sometimes present a diagnostic challenge. In this case the touch imprints (A) and frozen section preparation (B) from a mass lesion in the cecal area from a 44-year-old patient were thought to represent a high-grade lymphoma. However, initial immunohistochemical stains did not support the diagnosis, and on closer inspection of the tumor and with subsequent immunomarkers, a diagnosis could be reached. The tumor (C) is composed of sheets of noncohesive cells. A diagnostic clue to the origin was the presence of eosinophilic myelocytes (D), which indicate that some tumor cells have the capacity to differentiate into eosinophils. The granules of neutrophilic myelocytes cannot be recognized on tissue section. The immunohistochemical stains showed the cell to be CD45⁺ (not shown), (B) and T marker negative (E and F), but myeloid marker (myeloperoxidase and CD33) positive (G and H). Cytogenetic analysis showed the case was inv(16)(p13.1;q22).

and for the most part are classified using the FAB scheme (AML with minimal differentiation, AML without maturation, acute myelomonocytic leukemia, acute monocytic or monoblastic leukemia, acute erythroleukemia, acute megakaryoblastic leukemia, AML with maturation, acute basophilic leukemia). The AML-like disease of acute panmyelosis with myelofibrosis is included here (Fig. 59.10).

- 5) Lastly, the classification now includes myeloid sarcoma (Fig. 59.11), myeloid proliferations associated with Down syndrome (see chapter), and the rather rare entity of blastic plasmacytoid dendritic cell neoplasm (Fig. 59.12).

PROGNOSIS

Prognosis in AML is dependent on patient- and disease-related factors. The former determine the likelihood of surviving induction chemotherapy and are strongly influenced by age, performance status, and a basic assessment of organ function (hepatic, renal, cardiac).⁴ There is no standardized assessment tool and physicians may variably apply weighted integer prognostic scores or comorbidity scores such as the Charlson comorbidity index and the hematopoietic cell transplantation comorbidity index. Comorbidity indices (ideally as part of a more global geriatric assessment strategy) are particularly useful in older patients where the question of intensive chemotherapy versus

lower intensity interventions assumes more significance. Disease-related factors determine resistance to therapy. They include antecedent hematologic disorders (e.g., MDS), prior exposure to chemotherapy or radiation therapy (therapy-related AML), and biologic features of the blasts. Among the latter, karyotype has historically been considered as the most important prognostic factor dividing patients into those with favorable (CBF leukemias associated with t(8;21) and inv(16) or t(16;16); APL with t(15;17)), unfavorable (complex abnormalities and monosomies, among others), and intermediate prognosis (mainly diploid; Fig. 59.13).⁵

Karyotype is increasingly supplemented by analyses of commonly mutated genes. Whereas prognosis is hardly or not at all augmented by gene mutation testing in cytogenetically favorable and unfavorable groups, the situation is different in the intermediate-risk group, which is characterized by its size and heterogeneity in outcome. It is here where fine tuning of prognostic markers matters most. Early identified commonly mutated genes (FMS-like tyrosine kinase-3 [*FLT3*], *NPM1*, *CEBPA*) have formed the basis of many revised cytogenetic-molecular risk stratifications which led to identification of patients with more favorable outcome (e.g., diploid and *NPM1*^{mutated}/*FLT3-ITD*^{wild-type} or *CEBPA*^{double allele mutated}/*FLT3-ITD*^{wild-type}) and others with unfavorable prognosis (*FLT3-ITD*^{mutated}; *KIT*^{mutated} in CBF AML). Ongoing efforts at whole-genome sequencing have identified additional repetitively mutated genes that are being considered in risk assessment with partly incongruous results (e.g., *KIT*,

Fig. 59.12 BLASTIC PLASMACYTOID DENDRITIC CELL NEOPLASM. The blastic plasmacytoid dendritic cell tumor is an unusually aggressive malignancy that was previously called *hematodermic malignancy*. It is now classified in the acute myeloid leukemia category of myeloid neoplasms. It frequently presents in the skin with a blastic proliferation of cells in the dermis (A and B), which inevitably spreads to the blood (C) and bone marrow (D and E).

Fig. 59.13 DISEASE-FREE SURVIVAL BY CYTOGENETIC RISK GROUP. (Data from Byrd JC, Mrózek K, Dodge RK, et al: Pretreatment cytogenetic abnormalities are predictive of induction success, cumulative incidence of relapse, and overall survival in adult patients with de novo acute myeloid leukemia: Results from Cancer and Leukemia Group B [CALGB 8461], *Blood* 100:4325, 2002.)

IDH1 and *IDH2*, *MLL-PTD*, *TET2*, *DNMT3A*, *ASXL1*, *RUNX1*, *PHF6*, *TP53*).⁶ In general practice, testing is recommended for mutations of *NPM1*, *CEBPA*, and *FLT3* in all patients with a new presentation of AML, and *KIT* in patients with CBF AML. The European Leukemia Net has published a revised risk model based on integration of cytogenetic and gene mutation information (Table 59.2).⁷

Assessment of posttherapy response provides additional valuable information. Traditional criteria such as achievement of complete morphologic remission (CR) after one course of induction therapy retain significance, whereas others (assessment of early blast response based on a midcycle marrow evaluation during standard induction therapy) are of more limited predictability. The most powerful post-treatment prognostic factor is MRD. MRD is defined as disease that remains below the threshold of detection by morphology and immunohistochemical assays. It is estimated that patients in morphologic CR still harbor up to 10⁹ leukemic cells, which constitute an important reservoir for later recurrences. Assessing MRD has several advantages: (1) better determination of the quality of response, (2) more timely diagnosis of an impending relapse and improvement of

TABLE 59.2 Risk Groups Based on Cytogenetic-Molecular Features (According to European Leukemia Net)			
Risk Group	Karyotype	Molecular Abnormality	Estimated 4-Year Survival (%)
Favorable	t(15;17)	<i>PML-RARα</i>	60-80+
	t(8;21)	<i>AML-ETO (KIT^{wt})</i>	
	inv(16)	<i>CBFB-MYH11 (KIT^{wt})</i>	
	t(16;16)	<i>CBFB-MYH11 (KIT^{wt})</i> <i>CEBPA^{dm} (CN)</i> <i>(FLT3-ITD^{wt})</i> <i>NPM1^{mut} (FLT3-ITD^{wt})</i>	
Intermediate-1	t(8;21)	<i>NPM1^{mut}/FLT3-ITD^{mut}</i>	30-50
	inv(16)	<i>NPM1^{wt}/FLT3-ITD^{mut}</i>	
	t(16;16)	<i>NPM1^{wt}/FLT3-ITD^{wt}</i>	
		<i>AML-ETO1 plus KIT^{mut}</i> <i>CBFB-MYH11 plus KIT^{mut}</i> <i>CBFB-MYH11 plus KIT^{mut}</i>	
Intermediate-2	t(9;11) Karyotype neither favorable nor adverse	<i>KMT2A-MLL2</i>	20-40
Adverse	inv(3)	<i>RPN1-EVI1</i>	< 10-15

abnl, Abnormal; *CN*, cytogenetic normal (diploid); *dm*, double allelic mutation; *mut*, mutated; *Wt*, wild type (unmutated).
Data from Döhner H, Estey EH, Amadori S, et al: Diagnosis and management of acute myeloid leukemia in adults: recommendations from an international expert panel, on behalf of the European LeukemiaNet. *Blood* 115:453, 2010.

Fig. 59.14 GENERAL APPROACH TO ACUTE MYELOID LEUKEMIA THERAPY. *AML*, Acute myeloid leukemia; *APL*, acute promyelocytic leukemia; *ATRA*, all-trans retinoic acid; *CBF*, core binding factor; *FLAG*, fludarabine, cytarabine (ara-C), and granulocyte colony-stimulating factor.

outcome by early intervention, and (3) support in decision to intensify postremission therapy (transplant) or not. Efficacy of preemptive therapy based on MRD has been established for APL but data in support for other subtypes of AML are still accumulating.

MRD can be detected by reverse-transcriptase polymerase chain reaction (RT-PCR) or multiparameter flow cytometry (MPFC). Both assays have comparable sensitivity. RT-PCR requires a suitable molecular target such as fusion transcripts (e.g., *PML-RARA*, *RUNX1-RUNX1T1*, *CBFB-MYH11*, *DEK-CAN*) or overexpressed (WT1) or mutated genes, and thus applies to a more limited number of patients than MPFC. MPFC is based on the identification of a leukemia-associated immunophenotype, which can be detected in the majority of patients with AML in various ways: a) “different-from-normal” antigen expression in leukemic blasts; b) detection of lineage-foreign markers; c) asynchronous expression of markers; d) altered density of surface antigens; e) detection of surrogate marker profiles (associated with cytogenetic–molecular markers); f) detection of leukemia stem cells.⁸ Commonly, a level of 0.1% has been determined to distinguish patients with MRD from those without. This level is a log higher than what defines the threshold for MRD in ALL (<0.01%). MRD levels following induction or early in consolidation have been associated with relapse and survival in all age groups regardless of cytogenetic and mutational status. Even though MRD levels tend to be higher in patients with unfavorable pretreatment characteristics, the prognostic impact of MRD extends to all risk groups and has shown to improve standard risk classification independently of cytogenetic–molecular markers. Evaluation of MRD has led to renewed interest in strategies for its elimination. Besides intensification of therapy by means of hematopoietic stem cell transplantation (HSCT) as a response to persistence of MRD, other approaches have been or are being pursued: maintenance therapy (interleukin-2 [IL-2] based), cellular therapy (dendritic cell vaccination, T-cell manipulations), monoclonal antibodies (e.g., anti-CD123), epigenetic priming, or maintenance.

THERAPY: FRONTLINE

AML therapy is one of the most challenging of oncologic interventions. Treatment often needs to be fast, physicians need to deal with a multitude of complications (disease or treatment related), and from the start a patient’s condition can deteriorate rapidly. Given its complexity, treatment of patients with AML requires a multidisciplinary effort including oncologists, pharmacists, a well-educated and committed nursing staff, and various consulting services (e.g., infectious disease, pulmonology, nephrology, cardiology). Supportive care

measures including transfusion services and symptom control have played an important part in improving the outcome of patients with AML over the last decade.

The general approach to AML therapy is summarized in Fig. 59.14. Besides AML subtype (APL, CBF leukemias, other) attention needs to be paid to age and a more global assessment of fitness (performance status, comorbidities, geriatric assessment scores). Treatment of patients “unfit” for standard intensive induction therapy (often equaled to patients older than 60 to 65 years) is frequently approached differently from that of younger patients, and hence this chapter addresses therapy separately for each age group. It should be understood, though, that age alone is increasingly considered inadequate to assess a patient’s fitness status.

Treatment of AML consists of induction and postremission therapy. The goal of induction is to produce a CR and that of postremission therapy to maintain it by eliminating residual disease. CR is defined as achievement after chemotherapy of less than 5% marrow blasts, a neutrophil count of greater than 1000/μL, a platelet count of greater than 100,000/μL, independence of red blood cell transfusions, and resolution of all signs and symptoms referable to AML. CR defines a landmark point in time because patients who achieve CR on any given day after beginning therapy have longer survival subsequent to that day than patients who are resistant to therapy on the day in question. Lesser response criteria (CR without platelet recovery, CR with incomplete blood recovery including neutropenia, partial remission, morphologic leukemia-free state) may serve as useful end points in the context of investigational studies (phase I, II, or III), but they do not carry the same significance for survival as does CR. Postremission therapy consists of repeated cycles of chemotherapy or HSCT in its various forms (autologous, allogeneic, haploidentical, cord blood, reduced intensity). The role of HSCT for AML therapy will be the topic of a separate chapter of this book. The debate as to which patients should receive chemotherapy consolidation versus HSCT is most divisive for patients with intermediate-risk disease. In this population, characterization of the genotype has become helpful in guiding that decision.

Leukemia has been at the forefront of the development of “targeted” therapy, mostly small-molecule drugs directed against defined intracellular proteins (e.g., kinases). Given the increasing number of genetic abnormalities and the identification of diverse intracellular pathways of blast cells, the specter of “personalized therapy” looms high in AML therapy. Yet, despite intense research activity, to date no “targeted” drug has been approved for any type of AML (exceptions: gemtuzumab ozogamicin [GO], an anti-CD33 monoclonal antibody–calicheamicin conjugate with activity in some subtypes of AML was approved in 2000, but then withdrawn in the United States

in 2010; decitabine, a DNA methyltransferase inhibitor, was approved in 2013 for older patients with AML in Europe, but not in the United States).

Induction Therapy

Patients Less Than 60 Years of Age

Induction therapy is still built on the same two drugs as 40 years ago: cytarabine and anthracycline. Cytarabine, an analogue of a physiologic pyrimidine nucleoside, is an antimetabolite that requires intracellular conversion to its triphosphate compound, ara-CTP, and incorporation into DNA to become active. When given by itself at standard doses of 100–200 mg/m² intravenously (IV) daily for 5–7 days, it produces CR rates of around 40%. Anthracyclines (daunorubicin, idarubicin, mitoxantrone, aclarubicin) act by stabilizing the normally occurring complex between DNA and the enzyme topoisomerase II, thereby leading to apoptotic cell death. Daunorubicin, the anthracycline that was first available, achieves similar CR rates as does cytarabine alone. The combination of cytarabine 100–200 mg/m² as a continuous IV infusion (its serum half-life is only 15 minutes) daily for 7 days and daunorubicin 45–60 mg/m² IV daily for 3 days on days 1–3 has become known as the “3 + 7” regimen and, for more than 40 years, has been the standard induction combination for most patients with AML. Remission rates range from 60% to 80%, and long-term disease-free survival is about 35%.⁹

In clinical practice, patients undergo a repeat marrow study between 14 and 21 days from the start of treatment (Fig. 59.15). If

the marrow continues to show blasts and is cellular, a reinduction is usually given. The reinduction may be an attenuated repetition of the induction (“2 + 5”) or an intensification with intermediate-dose cytarabine (IDAC) or high-dose cytarabine (HiDAC). If the day 14 or 21 marrow is hypoplastic and hence appropriately chemoablated, hematopoietic growth factors (granulocyte colony-stimulating factor [G-CSF]) are initiated and supportive care continues. Marrow studies are repeated 2 weeks later and then weekly if necessary until it becomes clear whether the patient is going into CR or not. If in CR, postremission therapy starts shortly thereafter, whereas in case of no response (“primary refractory”), treatment is often changed. Remissions following reinductions are usually shorter lasting than remission after one induction cycle. The degree of neutrophil and platelet recovery at the time of remission has prognostic significance. Higher neutrophil and platelet counts at the time of remission are predictive of better relapse-free survival. In some cases a regenerating marrow may have an increased number of blasts, which may look like persistent leukemia. Immunophenotyping by flow cytometry often helps to make that distinction. Further follow-up marrow studies will show reduction in blasts concomitant with a rise of neutrophils and platelets.

Many modifications to the 3 + 7 regimen have been tried over the years. Giving 10 instead of 7 days of cytarabine (3 + 10), increasing the dose of cytarabine from 100 mg/m²/day to 200 mg/m²/day, adding a third drug (e.g., etoposide, thioguanine, topotecan, fludarabine) or modulators of drug resistance, and priming leukemic blasts with hematopoietic growth factors (G-CSF and granulocyte-macrophage colony stimulating factor) have not proven superior.

However, in 2012, the Polish Adult Leukemia Group published the outcome of an open-label, randomized study where addition of

Fig. 59.15 ACUTE MYELOID LEUKEMIA AT DIAGNOSIS AND AT DAY 14 AND DAY 28 FOLLOWING THE START OF STANDARD INDUCTION CHEMOTHERAPY. A 43-year-old man presented with fatigue and was found to have a white blood cell count of 70,300/μL composed of mostly blasts. A bone marrow study (A–C) showed a 90% cellular marrow packed with blasts (80%). The blasts were myeloperoxidase positive and had the following phenotype: CD34⁺, HLA-DR⁺, CD117⁺, CD13⁺, CD33⁺ with partial CD15 and CD11b. Cytogenetic analysis demonstrated a normal male karyotype, and molecular studies showed wild-type *FLT3* and *NPM1*. The patient was treated with standard induction chemotherapy, and a day-14 bone marrow study (D–F) showed chemoablation effects with an empty marrow, stromal injury, dilated sinuses, and only scattered stromal cells and plasma cells with no obvious blasts. A bone marrow study performed at day 28 (G–I) showed regenerative changes of trilineage hematopoiesis.

cladribine, but not fludarabine, to a standard daunorubicin/cytarabine backbone resulted in significantly increased rates for remission (68% versus 56%; $p = .01$) and 3-year overall survival (OS; 45% versus 33%; $p = .02$). In a publication in 2013 by the MD Anderson Cancer Center, addition of clofarabine, a second-generation nucleoside analog, to idarubicin and cytarabine (IA) led to significantly better event-free and OS in the three drug combination when compared with a historical IA-treated group, especially in patients younger than 40 years of age. The use of fludarabine, idarubicin, HD-AC versus 3 + 7 in the Medical Research Council (MRC) trials is discussed later.

The choice and dose of anthracyclines has been the subject of debate. Substitution of daunorubicin by doxorubicin produced more toxicity without added benefit. Idarubicin is a 4-demethoxy anthracycline analogue of daunorubicin, which results in increased lipophilicity and better cellular uptake compared with daunorubicin.

A study by the Eastern Cooperative Oncology Group (ECOG 1900) randomized patients between the ages of 17 and 60 years with untreated AML to a 3 + 7 combination with either standard-dose daunorubicin (45 mg/m² daily $\times$ 3) or high-dose daunorubicin (90 mg/m² daily $\times$ 3).¹⁰ High-dose daunorubicin achieved higher rates of CR (70.6% versus 57.3%, $p < .001$) and improved median OS (23.7 months versus 15.7 months, $p = .003$). This improvement was limited to patients younger than 50 years and with intermediate cytogenetics in the absence of *FLT3* mutations. A more recent follow-up of the study suggested that the benefit extends to all cytogenetic risk groups regardless of age. The study also found a significant association with improved survival between the high-dose daunorubicin arm and presence of *DNMT3A* mutations.⁶ The daunorubicin dose of 90 mg/m²/day did not lead to a higher incidence of adverse events (particularly cardiomyopathy and infectious complications). The study can be criticized on the basis that the dose of the comparator arm, daunorubicin 45 mg/m² daily for 3 days, is no longer considered the standard of care in AML, and instead 60 mg/m²/dose should be considered standard. A recent MRC trial compared daunorubicin 60 mg/m² versus 90 mg/m² during induction and showed equivalent results (Burnett ASH 2014). Daunorubicin 90 mg/m² daily $\times$ 3 equals 270 mg/m², which may prohibit further anthracyclines therapy (cumulative cardiotoxic dose of daunorubicin 360–450 mg/m²).

A metaanalysis of 29 randomized controlled trials compared the efficacy of different anthracyclines and dosing schedules during AML induction therapy.¹¹ Idarubicin compared with daunorubicin improved remission rates, although this effect was limited to studies with a daunorubicin/idarubicin ratio of <5 . Likewise, higher dose compared with lower dose daunorubicin improved remission rates. Survival estimates suggest that both high-dose daunorubicin (90 mg/m²/dose $\times$ 3 days or 50 mg/m²/dose $\times$ 5 days) and idarubicin (12 mg/m²/dose $\times$ 3) can achieve 5-year survival rates of between 40% and 50%. Rather than the type of anthracycline, what matters most is to use equitoxic doses.

A metaanalysis of trials using HiDAC during induction encompassed 1691 patients and arrived at the following conclusions: there were no differences between HiDAC and standard-dose cytarabine (SDAC) with respect to percent CR and rates of persisting leukemia and early death; 4-year OS and recurrence-free survival, on the other hand, were significantly better with HiDAC but at the cost of more toxicities (infections, nausea/vomiting, CNS).¹² HiDAC benefited mostly patients who already were more likely to achieve CR (i.e., patients with intermediate and favorable karyotype). The major drawback of HiDAC during induction is that it may make further consolidation therapy difficult.

The MRC AML 15 trial randomized 1268 patients to receive fludarabine, high-dose cytarabine (ara-C), G-CSF, and idarubicin (FLAG-Ida; fludarabine 30 mg/m² on days 2–6, cytarabine 2 g/m² on days 2–6, idarubicin 10 mg/m² on days 4–6, and G-CSF on days 1–7) and 1983 to receive cytarabine (ara-C), daunorubicin, and etoposide (ADE; daunorubicin 50 mg/m² on days 1, 3, 5; cytarabine 100 mg/m² on days 1–8; and etoposide 100 mg/m² on days 1–5), the latter representing the SDAC arm.¹³ FLAG-Ida resulted in higher

response rates following the first induction and fewer patients on FLAG-Ida relapsed. However, more myelosuppression and deaths in CR offset the survival benefit unless FLAG-Ida treated patients were able to receive four courses (FLAG-Ida $\times$ 2, HiDAC $\times$ 2) where 8-year survival was 63% for patients (versus 47% with 3 + 7) with intermediate risk and 95% for those with favorable risk.

The European Organization for Research and Treatment of Cancer (EORTC)-Italian Group for Haematological Diseases in Adults (GIMEMA) AML-12 trial randomized 1942 newly diagnosed AML patients between 15 and 60 years of age to an induction with SDAC or HiDAC (3 g/m² every 12 hours on days 1, 3, 5, and 7).¹⁴ With 6-year of follow up the study demonstrated significantly higher CR rates in all patients and significantly improved event-free (43.6% versus 35.1%; $p = .003$) and OS (51.9% versus 43.3%; $p = .009$) for patients between 15 and 45 years of age. The impact on survival was particularly evident in younger patients with secondary AML, high-risk cytogenetics, and mutations of *FLT3*, emphasizing that HiDAC may overcome poor-risk features during induction that SDAC cannot.

Patients Aged 60 Years or Older

In an analysis of SEER data spanning the years from 1977 to 2006, the 1- and 2-year OS of patients aged 65–74, 75–84, and >85 years was only 30.3%, 14.8%, 7.8%, and 15.8%, 5% and 1.7%, respectively.¹⁵ Although AML is mostly diagnosed in patients over age 60 years, available AML therapy has had its least impact in this age group and prognosis has not appreciably changed to the better in decades. Older patients do worse for various reasons. Comorbidities are frequent, and they are more likely to have a poor performance status. Hence, tolerance to the myelosuppressive and immunosuppressive consequences of intensive chemotherapy is diminished. There are also differences intrinsic to the blast biology between older and younger patients. Patients over 60 years of age are more likely to have secondary AML (following MDS or another antecedent hematologic disorder), demonstrate unfavorable cytogenetics, have reduced sensitivity to anthracyclines, and more often express multidrug-resistant phenotypes. Assuming that therapy is mostly futile and palliation more appropriate, only about one-third of older patients receive treatment for AML. Yet, patients over age 60 years of age should not be precluded from therapy. In a landmark randomized analysis by the EORTC from 1989 comparing intensive chemotherapy to supportive care, intensive therapy produced a measurable survival advantage. Other studies have also demonstrated the benefits of therapy over supportive care only, with respect to survival and quality of life.

To pursue a middle ground between supportive care and intensive treatment, lower intensity therapies are increasingly used. Although they hold promise for many older patients with AML, a select group of patients may still benefit from more intense interventions. Older patients are not a homogeneous group and several models have been devised to identify variables that predict which patients may do well with conventional therapy versus those who will not (Table 59.3). These models are comprised of patient characteristics, easily accessible clinical variables, and tumor characteristics. Although performance status can be a powerful predictor of the probability to survive intensive therapy, age remains an arbitrary variable and is increasingly understood to be a poor discriminator of outcome. Efforts are therefore underway to capture multiple patient characteristics (physical and cognitive function, nutritional status, comorbidity, psychological state and social support) as part of a comprehensive geriatric assessment and to better distinguish patients into fit, vulnerable, and frail (indicating a significantly increased risk of treatment complications).¹⁶

Three broad avenues of therapy in older patients with AML are standard intensive chemotherapy, lower intensity therapy (low-dose cytarabine, hypomethylating agent [HMA]), and clinical studies. Intensive chemotherapy follows the outline already discussed in the section on younger patients. Given current data, the benefit of intensive therapy may be restricted to diploid AML with mutated

TABLE 59.3 Prognostic Models in Older Patients With Acute Myeloid Leukemia

Study	Outcome	Unfavorable Characteristics
Study Alliance Leukemia	Survival Disease-free survival	CD34 expression >10% WBC >20 × 10 ⁹ /L Age >65 years LDH >700 U/L NPM1 status wild-type ^a

^dOnly significant for prediction of survival.

AHD, Antecedent hematologic disorder; BMI, body mass index; CHF, congestive heart failure; EF, ejection fraction; LAFR, laminar air flow room (isolation floor); LDH, lactate dehydrogenase; MI, myocardial infarction; WBC, white blood cell count;

Cancer Research Institute AML 14 Trial, 217 unfit patients were randomized to low-dose cytarabine 20 mg subcutaneously twice daily for 10 days or hydroxyurea.¹⁷ Both survival and remission rate (18% versus 1%; $p < .001$) were superior with low-dose cytarabine with the exception of patients with adverse cytogenetics, who did poorly on either treatment arm. Achievement of CR was related strongly to survival, with those patients in CR surviving for a median of 19 months compared to only 2 months in nonresponders. Multiple clinical trials are exploring combinations of low-dose cytarabine with other (mainly investigational) agents to improve response rates and survival over low-dose cytarabine alone. Although many agents have been tried (e.g., clofarabine, sapacitabine, lenalidomide, vosaroxin, volasertib, plerixafor, all-trans retinoic acid [ATRA]), as of the end of 2014 no combination has unequivocally demonstrated superior outcomes over standard therapy alone.

HMA have found widespread use in the treatment of myeloid disorders including MDS and AML. Their different mechanism of action associated with a manageable toxicity profile, low incidence of mortality, and administration in the outpatient setting make them ideal agents for use in older patients. Azacitidine 75 mg/m² subcutaneously daily for 7 days was compared with conventional care (best supportive care, low-dose cytarabine, or intensive chemotherapy) in a subset of 113 patients (median age: 70 years) entered on a randomized MDS study but with 20% to 29% blasts (“oligoblastic AML”).¹⁸ Median OS was 24.5 months in the azacitidine group and 16 months in the conventional care group ($p = .005$). A more recent study of azacitidine versus conventional care in older patients with AML and more than 30% marrow blasts comes to similar conclusions in favor of azacitidine, with a median survival of 12.7 months versus 6.3 months. The survival difference was maintained when comparing azacitidine with specifically low-dose cytarabine-treated patients among the conventional care group (American Society of Hematology meeting 2014). Decitabine 20 mg/m² IV daily for 5 days every 4 weeks was compared to supportive care or low-dose cytarabine in a large randomized multicenter study across the United States and Europe.¹⁹ The decitabine arm achieved a higher CR rate (17.8% versus 7.8%; $p = .001$), and in a post hoc sensitivity analysis of the mature data a survival advantage was observed at fixed time points over 2 years. The results of this study led to approval of decitabine for the treatment of AML in older patients in Europe but not in the United States.

Higher response rates have been reported with a 10-day schedule of decitabine, although these results have not yet been validated pending results from a randomized trial comparing it to the more common 5-day schedule. Data from single studies suggesting higher response rates of decitabine in patients expressing higher baseline levels of miR-29b or mutations of *DNMT3A* or *TET2* are awaiting confirmation. In almost all comparisons between intensive induction therapy and HMA-based treatments, patients receiving intensive therapy achieve higher CR rates, yet OS is similar. Besides the lower treatment-related mortality associated with HMAs, the beneficial effect of HMAs on survival appears to extend to patients with lower levels of responses (defined by traditional criteria). In this context it is also noteworthy that HMAs elicit responses in patients with unfavorable karyotypes, an important difference from low-dose cytarabine.

Postremission Therapy

Patients Under 60 Years of Age

In CR, as many as 10⁹ leukemia cells survive as MRD below the threshold of detection by morphologic assessment. Further therapy is therefore necessary to reduce this number and minimize the chances of relapse. In a series of clinical studies in which patients did not receive postremission therapy, relapse was universal, and the median remission duration was about 4 months. Postremission therapy is mainly predicated by pretreatment prognostic factors and can take the form of intensified therapy (HSCT) or continued chemotherapy.

NPM1 and wild-type *FLT3-ITD*, and possibly also to patients with CBF AML. Once a choice for standard therapy is made doses should not be attenuated. The optimal dose of cytarabine lies between 100 mg/m² daily × 7 days to up to 1.5 g/m² daily for 3 or 4 days and all anthracyclines are equal (if given attention to dose). Intensive induction chemotherapy is not appropriate for frail or vulnerable patients (simplified as reflected in a poor performance status), for those presenting with an adverse cytogenetic-molecular profile, and rarely for those over age 80 years.

Lower intensity therapy is therefore indicated for patients who are accordingly “unfit” for standard chemotherapy. In the National

As for the latter, debate continues with regard to dose, number of cycles, and whether or not there is a role for maintenance.

In a landmark study by the CALGB, patients with newly diagnosed AML in CR following a 3 + 7 induction were randomized to SDAC (100 mg/m² continuous IV infusion daily × 7), IDAC (400 mg/m² continuous IV infusion daily × 5), or HiDAC (3 g/m² IV over 3 hours every 12 hours on days 1, 3, and 5) for a total of four cycles.²⁰ This was followed by an additional four cycles of 2 + 5, a consolidation-maintenance omitted from all subsequent CALGB studies. The probability of remaining in continuous CR after 4 years was 24% for SDAC, 29% for IDAC, and 44% for HiDAC ($p = .002$). Over the ensuing years, studies have shown that there is no benefit by extending consolidation therapy by a fifth cycle and that even three cycles may be equivalent. HiDAC in consolidation holds less benefit for patients older than 60 years and those with intermediate and especially unfavorable karyotypes.

CBF leukemias are characterized by translocation t(8;21), inv(16), or t(16;16) and, at the molecular level, by a disruption of *CBF* transcription genes, which play a crucial role in hematopoietic differentiation. CBF AMLs comprise about 15% to 20% of patients with AML. They stand out in that they are very sensitive to cytarabine-based therapy, which is reflected in high remission rates (80–90%) and more patients achieving long-term OS (about 60% at 5 years). Postremission therapy with HiDAC (e.g., 3 g/m² IV every 12 hours on days 1, 3, and 5) for three to four cycles is most commonly used. Questions remain with regard to the optimal number of cycles, intensification, and addition of further drugs. One cycle (with a cumulative dose of up to 18 g/m² of cytarabine) is worse than three or four cycles (cumulative dose: 54–72 mg/m²). On the other hand, giving two cycles in combination with idarubicin, daunorubicin, or mitoxantrone is comparable to three or four cycles with HiDAC. According to the MRC AML10 trial, one consolidation cycle of IDAC (cumulative dose: 5 g/m²) was equivalent to three or four consolidation cycles as given in the CALGB studies. Addition of GO to cytarabine-based conventional chemotherapy resulted in lower risk or relapse and higher OS, especially in patients with favorable karyotype.²¹ Given the excellent responsiveness to chemotherapy vis-à-vis the higher risk for treatment-related mortality and morbidity with stem cell transplant, there is no role for transplant as consolidation in these patients. Less frequently in the United States compared with other regions, autologous transplant is sometimes performed following one or two cytarabine-based consolidations, albeit with comparable results to chemotherapy-only regimens. Subgroups of patients with CBF AML have been identified with worse than expected outcome. Long-established poor prognostic factors include older age, a high WBC at diagnosis, presentation with granulocytic sarcoma in t(8;21), and expression of CD56. Worse survival has also been described in the presence of *KIT* mutations (more frequently of exon 17 than exon 8). These mutations occur in up to one-third of patients with inv(16) and about 20% of those with t(8;21). Although remission rates are similar, CBF AML with mutated *KIT* are more likely to relapse. Screening for *KIT* mutations should therefore be routinely added to cytogenetic analysis. Clinical trials adding tyrosine kinase inhibitors active against *KIT* (e.g., dasatinib) to chemotherapy are being conducted. Given the worse prognosis, allogeneic stem cell transplant in this situation is also advocated by some.

Patients with diploid karyotype and mutations of *NPM1* or biallelic mutations of *CEBPA* without mutations for *FLT3-ITD* have a similarly favorable outcome to that of patients with *KIT* wild-type CBF AML. They also do not benefit from allogeneic stem cell transplant in first remission and are typically treated with standard consolidation chemotherapy.

Patients in the intermediate-risk group comprise the largest (about 60%) and most heterogeneous AML population (about 60% of AML). The majority demonstrate a diploid karyotype. It is in this group of patients where there is an ongoing debate about the role of chemotherapy versus stem cell transplant in consolidation. It is also in this group where the prognostic impact of gene mutation analysis is most helpful to facilitate this decision, at least in select patients (Table 59.4).

TABLE 59.4

Indications for Postremission Hematopoietic Stem Cell Transplantation Based on Cytogenetic–Molecular Profile

Prognostic Group	Subgroups	HSCT
CBF AML	<i>KIT</i> ^{wt} <i>KIT</i> ^{mut}	No Possible
Intermediate	<i>FLT3-ITD</i> ^{mut} <i>FLT3-D835</i> ^{mut} <i>NPM1</i> ^{mut a} <i>CEBPA</i> ^{mut a}	Yes Possible No No
Unfavorable	Not relevant	Yes

^aWithout concomitant mutations of *FLT3-ITD*. In the case of *CEBPA*, only if the mutation is biallelic.

AML, Acute myeloid leukemia; CBF, core-binding factor; HiDAC, high-dose cytarabine; HSCT, hematopoietic stem cell transplant; mut, mutated; wt, wild type.

No advantage for HSCT has been observed for patients with cytogenetically normal karyotype and mutations of *NPM1* or biallelic mutations of *CEBPA* without mutations of *FLT3-ITD*. On the other hand, transplant in first CR should be considered for all other patients with intermediate- or high-risk disease. A systematic review and metaanalysis of 24 prospective trials including 6007 patients demonstrated significant relapse-free and OS benefit in these patient groups when compared with nonallogeneic HSCT.²²

Outcome following standard chemotherapy remains poor for patients with adverse-risk cytogenetics and unfavorable gene mutations, most notably of *FLT3-ITD* (but not the kinase domain mutation of *FLT3* at D835) and *TP53*. There is an ongoing discussion about the significance of allele burden with respect to *FLT3-ITD* mutations in that patients with a low allelic ratio (usually <0.5) have similar outcomes to patients without the mutation. Contrary to earlier reports, however, increasing evidence suggests that the allele burden has little significance and that the detection of the mutation per se is what matters for treatment decisions. Although the same prognostic markers also worsen prognosis following HSCT, the latter still carries a better survival. Patients with high-risk disease are appropriate candidates for clinical trials in lieu of standard chemotherapy and even HSCT.

Patients Aged 60 Years or Older

The value of intensive postremission therapy is a matter of debate for older patients with AML. Unlike in younger patients, HiDAC is less effective and given its higher potential for toxicities, it is less feasible to administer four repetitive cycles. There are conflicting data as to the number of postremission cycles (one cycle has been shown to be as effective as several cycles) and to the required intensity of postremission therapy. It is generally accepted that intensive postremission therapy most benefits patients with mutations of *NPM1* (without *FLT3-ITD* mutations) and possibly leukemias expressing CBF rearrangements.

Reduced-intensity and nonmyeloablative conditioning regimens have opened HSCT to a wide range of especially older patients. Age only retains significance by virtue of its association with other covariates (performance status, comorbidities), but per se is not a predictor for nonrelapse mortality. This notion comes with the caveat that very little data exist for HSCT in patients over 75 years of age. The fact that less than 10% of older patients are receiving an allogeneic HSCT underlines the need for better tools in decision-making between HSCT and chemotherapy. The European LeukemiaNet AML Working Party has proposed an integrated dynamic risk-adapted assessment tool that takes into account disease-specific biological factors, clinical and laboratory characteristics, as well as estimates for relapse and nonrelapse mortality following either intervention.

Molecular markers and MRD serve to distinguish favorable from unfavorable subsets, although it needs to be recognized that ostensibly favorable molecular groups of older patients carry a higher risk of relapse than what would be expected for younger patients.

Maintenance Therapy

Maintenance therapy (i.e., additional therapy following consolidation) aims to improve the quality of remission, eliminate residual disease, and maximize the chances to remain disease free. The concept is effective in some acute leukemias (ALL, APL), but to date has not led to any appreciable improvement in the outcome of patients with AML.

The antileukemic effect of the immune system is displayed in the graft-versus-leukemia effect following allogeneic HSCT (not if T-cell depleted), resulting in decreased relapse rates. Initial studies focused on stimulation by IL-2 of immune effector cells such as tumor-specific cytotoxic lymphocytes and natural killer cells. Although IL-2 has demonstrated antileukemic activity in preclinical models, not one study applying low-dose IL-2 (high doses of IL-2 were not feasible because of drug-related toxicities) showed any improvement of disease-free or OS. Only with the combination of IL-2 plus histamine dihydrochloride could an improvement of leukemia-free survival at 3 years be demonstrated when compared with a randomized observation cohort (40% versus 26%; $p = .01$). The benefit was restricted to patients in CR1 and did not extend to OS. Recent success with chimeric antigen receptor-transfected T cells and the emergence of bispecific T-cell antibodies (although harder to apply in AML than lymphoid malignancies) has revived the specter of cellular therapy in maintenance strategies.

Other concepts have been developed based on lenalidomide and HMAs (azacitidine, decitabine), including following HSCT. Results as to their impact remain inconclusive and maintenance therapy remains investigational.

Therapy: Salvage

Most patients with AML relapse and do so within the first year following achievement of remission. In an analysis of 1069 consecutive AML patients in first CR who were treated and followed at the MD Anderson Cancer Center, the risk for treatment failure was 69%, 38%, 17%, 8%, and 7% in the first to fifth year, respectively. With a 6-year relapse-free survival of 84% for patients who were alive and disease free at 3 years, it is reasonable to consider patients cured once in CR for at least 3 years. For patients over 60 years of age, relapse-free survival was only 56% and therefore a substantial relapse risk persists without any discernible “safe haven”.

The prognosis for patients in relapse remains poor, but outcomes are more heterogeneous than first impressions suggest. An important predictor for prognosis is the duration of first remission. In a study of 243 patients with AML in first relapse, the likelihood of CR was 60% if the duration of first remission exceeded 2 years and 19% if it was shorter than 1 year. Treatment was not associated with prognosis. In a multivariate analysis of 667 patients in first relapse, a prognostic score was derived from four clinical parameters (duration of first remission, karyotype at diagnosis, age at relapse, and previous HSCT or not) that identified three risk groups: a) favorable group: CR 85% and 5-year OS 46%; b) intermediate group: CR 60% and 5-year survival 34%; c) poor risk group: CR 18% and 5-year survival 4%. In another prognostic model for relapsed/refractory AML, disease status (relapse <12 months), *FLT3-ITD* mutation, and high-risk cytogenetics were independent adverse prognostic factors for OS and event-free survival (EFS). Three subgroups with different outcomes at 2 years were identified: a) favorable (no adverse features): OS 58%, EFS 45%; b) intermediate (one adverse factor): OS 37%, EFS 31%; c) poor ($\geq$ two adverse factors): OS 12%, EFS 12%. Prognosis is worse for patients after more than one salvage attempt, but even then 1-year survival probabilities vary between 2% and

24%. Patients who are primary refractory to at least one cycle of HiDAC-based induction therapy do equally poorly, with a subsequent CR rate of 22%, median CR duration of around 9 months, and survival of 3.8 months.

The goal of salvage therapy is to recapture a remission or at least achieve sufficient reduction of disease burden (absence of circulating blasts, marrow blasts <10%) to transition patients to HSCT. Five-year survival expectations following HSCT vary from 30% to 40% (first relapse/second CR) to <10% (refractory relapse), but remain superior to nontransplant therapies across all scenarios.

There is no one standard salvage regimen. An intensive chemotherapy regimen may benefit the few patients with favorable prognostic features at relapse. Commonly used intensive regimens are fludarabine, cytarabine, G-CSF (FLAG), fludarabine, cytarabine, idarubicin (FAI), high-dose cytarabine, mitoxantrone (HAM), mitoxantrone, etoposide, cytarabine (MEC), and cytarabine, daunorubicin, etoposide (ADE). Outcome is similar with any of the combinations. The MEC regimen is not infrequently associated with severe mucositis. Large randomized studies are rare. One international multicenter trial randomized 326 patients ≥ 55 years of age with relapsed and refractory AML to cytarabine 1 g/m² daily for 5 days or cytarabine plus clofarabine. CR rate and EFS were superior in the combination arm but the primary OS endpoint was not met. Another more recent multicenter study randomized 711 patients with first relapse and refractory AML ≥ 18 years of age to cytarabine 1 g/m² daily for 5 days versus the combination of cytarabine with vosaroxin, a first-in-class anticancer quinolone derivative. Without an increase in early mortality, the combination arm achieved significantly higher CR rates (30.1% versus 16.3%, $p = .00001$) and OS benefit (median 7.5 versus 6.1 months; $p = .06$; stratified = 0.02), which was more obvious if patient groups were censored for subsequent allogeneic HSCT (median 6.7 months versus 5.3 months, $p = .02$).²³ Benefit was greatest in patients aged ≥ 60 years and those with early relapse.

Any of these strategies only rescue a minority of patients with AML relapse. It therefore remains imperative to pursue more effective treatments with investigational agents through clinical trials.

Therapy: Investigational

Anti-CD33–Directed Therapy

CD33 is a cell surface antigen that is present in more than 80% of patients with AML but is absent from pluripotent hematopoietic stem cells. GO is a humanized anti-CD33 monoclonal antibody linked to the DNA-binding cytotoxin calicheamicin. As a single agent in relapsed/refractory patients with AML, it achieved response rates close to 30% and resulted in GO's accelerated approval in the year 2000 by the US Food and Drug Administration (FDA). Subsequent combinations of GO with chemotherapy demonstrated hepatic toxicities (in particular sinusoidal obstruction syndrome), which were not observed before. This problem was largely resolved by reducing GO doses to as low as 3 mg/m² in combinations. The expanded spectrum of toxicities plus the observation that GO failed to improve outcome of patients in a large randomized trial by the Southwest Oncology Group (SWOG S0106) led the FDA to revoke the approval in 2010 and GO was voluntarily withdrawn from the market (except for Japan). However, subsequent randomized trials in which GO was combined with standard chemotherapy produced favorable results. A metaanalysis of five randomized trials (including SWOG S0106) with a total of 3325 patients can be summarized as follows: 1) GO does not increase remission rate; 2) although early mortality is higher in GO-treated patients, OS is improved as the reduction in the relapse rate of GO-treated patients far outweighs early mortality; 3) the survival benefit is mostly seen in patients with favorable and intermediate-risk cytogenetics, but not with adverse karyotype; 4) doses of 3 mg/m² are as effective as higher doses and were associated with fewer early deaths.²⁴ In other studies, GO has also been shown to be effective and safe for patients with APL.

Whether GO will return to the United States market is unknown. Yet, interest in anti-CD33–directed therapies persists. SGN-CD33A is an anti-CD33 engineered cysteine antibody conjugated to an average of two molecules of a pyrrolobenzodiazepine dimer, a highly potent DNA crosslinking agent. SGN-CD33A has shown single-agent antileukemia activity, and combinations with standard AML and MDS therapy are underway. AMG 330 is a novel CD33/CD3-directed bispecific T-cell engaging (BiTE) antibody. It is highly active against CD33⁺ AML cell lines and can potentially lyse leukemic blasts from AML patients. Clinical studies are in progress.

CPX-351

CPX-351 is a liposomal formulation of cytarabine and daunorubicin at a fixed 5:1 molar ratio within 100-nm bilamellar liposomes. This formulation allows delivery of a maximally synergistic drug ratio to tumor cells and may enhance treatment efficacy. In a phase II randomized study of CPX-351 versus 3 + 7 in older patients with untreated AML, the investigational combination achieved significantly higher remission rates than standard 3 + 7 and significantly better OS in the subgroup with secondary AML. Final results of a randomized phase III study of CPX-351 versus standard 3 + 7 in patients aged 60 to 75 years with high-risk (secondary) AML confirmed the significant improvement in remission rate and median OS with CPX-351. Pending filing and FDA assessment of this compound, CPX-351 may become a new standard of care for this patient group.

FLT3 Inhibitors

Inhibitors of FLT3 have been in clinical trials for many years. Yet no FLT3 inhibitor has received FDA approval. The clinical activity of single-agent first generation inhibitors (midostaurin, lestaurtinib, sunitinib, sorafenib, semaxanib, tandutinib) has been limited, only demonstrating transient reductions in blood and/or marrow blasts but, for most, without achievement of objective responses. In a randomized study of standard salvage therapy versus addition of lestaurtinib, no benefit with regard to response rate or survival was observed. A randomized study of standard induction therapy in patients 18 to 60 years of age with or without sorafenib (regardless of FLT3 status) demonstrated superior relapse and event free survival for the sorafenib treated group. The CALGB 10603 (RATIFY) study randomized 717 patients between ages 18 and 60 with newly diagnosed FLT3 positive (both ITD and TKD) AML to receive a standard 3 + 7 induction alone or in combination with midostaurin. Ten years after conception the final results were presented in 2016. Although the addition of midostaurin did not improve remission rates, the FLT3 inhibitor group enjoyed a statistically significant event free and overall survival benefit that extended to both ITD and TKD groups and persisted regardless of mutation load. The outcome of this study defines the combination of 3 + 7 and midostaurin (FDA approval pending) as a new standard of care for this patient population.

Higher single-agent activity (including objective remissions) has been observed with the next generation FLT3 inhibitors quizartinib, gilteritinib, and crenolanib. They are being actively evaluated in combination with standard chemotherapy in various clinical trials in frontline and relapsed FLT3 positive patients.

Various factors influence the activity of FLT3 inhibitors. Blasts with a low mutant allelic burden of *FLT3/ITD* may be less dependent on FLT3 signaling. Whether or not there is an association of the size of the ITD fragment with outcome is controversial. Secretion of FLT3 ligand is another resistance mechanism under discussion. The spectrum of activity of most of the FLT3 inhibitors extends to other kinases so that there are differences with regard to specificity between these agents. Next generation FLT3 inhibitors are more specific towards FLT3 compared to other kinases than is observed in the first generation compounds.

IDH Inhibitors

Somatic mutations in the metabolic enzymes IDH1 and IDH2 result in accumulation of the oncometabolite R-2-hydroxyglutarate (2-HG). High levels of 2-HG lead to epigenetic changes and impaired cellular differentiation. Several compounds have been developed that specifically target *IDH1 R132H* and *IDH2 R140Q*. Data from a phase I study of AG-221, an oral, reversible, and selective inhibitor of *IDH2*, showed high levels of clinical activity with objective response rates of 50%.

Inhibitors of Polo-Like Kinases

Polo-like kinases belong to a family of serine/threonine protein kinases that play a key role in mitotic checkpoint regulation and cell division. Volasertib is a low-molecular-weight, ATP-competitive kinase inhibitor that potently inhibits Polo-like kinases and has shown in vivo efficacy in AML xenograft models. A randomized phase II trial of low-dose cytarabine with or without volasertib in patients not suitable for intensive induction therapy (median age 75 years) showed higher rates of CR and significantly better EFS and OS with the addition of volasertib.³⁵ The volasertib arm was also associated with a higher frequency of adverse events (mainly myelosuppression, neutropenic fever, and gastrointestinal toxicities).

Other Novel Agents

Sapacitabine is an oral cytarabine analog whose cyano structure causes irreparable single-strand DNA breaks. It is active in AML and patients with MDS, including those who have lost response to standard HMAs.

Guadecitabine (SGI-110) is a second-generation dinucleotide of decitabine and deoxyguanosine with prolonged half-life and activity in AML and high-risk AML.

Signaling through the RAS/RAF/MEK pathway is activated in many cancers and has been one of the first targets for small-molecule kinase inhibitors. Inhibitors of MEK1/2 have demonstrated clinical activity in the salvage therapy for AML. Of 39 patients with relapsed or secondary AML, a third responded in the presence of KRAS or NRAS mutations compared with only 8% in the absence of mutations.

Inhibitors of DOT1L have shown activity in patients with *MLL*-rearranged AML.

Other targets are BCL2 and MDM2 and other antiapoptotic proteins; nuclear export proteins; multidrug resistance proteins; the ubiquitin–proteasome pathway; aurora kinases, which play an important role in the formation and organization of the mitotic spindle apparatus; the mammalian target of rapamycin/phosphatidylinositol 3-kinase/AKT pathway; components of the microenvironment (e.g., CXC-chemokine receptor 4 and CXC-chemokine ligand 12 inhibitors). Venetoclax is a recently approved BCL2 inhibitor for the treatment of chronic lymphocytic leukemia. Its activity in AML and MDS is being evaluated in clinical studies.

ACUTE PROMYELOCYTIC LEUKEMIA

APL is a rare subtype (approximately 10% of all AML diagnoses) with unique pathophysiologic, clinical, and therapeutic features. The median age at diagnosis of 40 years is younger than for other types of AML; APL occurs more frequently in Hispanics and the obese. If diagnosed promptly and managed appropriately, APL has the most favorable prognosis of all AMLs. On the other hand, catastrophic bleeding events (coagulopathies, thrombocytopenia), differentiation syndrome, or infectious complications can be associated with a high early mortality (in some reports 20–30%). In 80% of the cases, APL cells are hypergranular with many Auer rods. A microgranular variant

Fig. 59.16 EFFECT OF ALL-TRANS RETINOIC ACID THERAPY ON ACUTE PROMYELOCYTIC LEUKEMIA CELLS. All-trans retinoic acid (ATRA) therapy in acute promyelocytic leukemia (APL) causes the malignant promyelocytes (A) to differentiate, and the effects of differentiation can be seen within days of treatment (B). The differentiated APL cells are still somewhat atypical, frequently with bilobed nuclei (compare with normal neutrophil [B, inset center right]).

(M3v) is often associated with leukocytosis. APL cells are strongly positive for MPO staining and lack expression of CD34 and HLA-DR.

APL is almost always the result of translocation $t(15;17)$, which fuses the retinoic acid receptor alpha (*RARA*) gene with the promyelocytic leukemia (*PML*) gene. In very rare cases (<5%) translocation partners other than *PML* result in alternative fusion genes (e.g., *PLZF-RARA*, *NPM-RARA*, *NuMA-RARA*, *STAT5-RARA*), which often convey resistance to ATRA. *PML-RARA* is an abnormal retinoic acid (RA) receptor that represses transcription of RA-activated target genes by recruiting large protein complexes through the coiled-coil domain of *PML*, which in turn act as potent transcriptional corepressors. Pharmacologic doses of RA release the corepressors and allow recruitment of coactivators, resulting in the transcription of previously silenced genes. This leads to a sudden arrest in proliferation and a differentiation response that can be seen in vitro and in vivo within a few days following administration of ATRA (Fig. 59.16). APL is the most dramatic example of the success of differentiating therapy, which has proved disappointing in other forms of AML.

The clinical activity of ATRA was first demonstrated in a study from China, where oral ATRA alone when given over 30 to 90 days achieved CR rates of 85%, an observation that was later confirmed by groups in North America and Europe. ATRA has a dramatic effect on the coagulopathy, substantially reducing the risk of serious bleeding events, and should be instituted immediately upon suspicion of a diagnosis of APL even in the absence of confirmatory testing. ATRA therapy has also been associated in 10% to 25% of patients with “retinoic acid syndrome” (more appropriately called *differentiation syndrome* because it is also seen with other differentiating agents such as arsenic trioxide [ATO]). It occurs within a few days of the start of therapy and is reminiscent of manifestations of capillary leak and respiratory distress syndrome: fever, dyspnea, hypoxemia, pulmonary infiltrates, weight gain, peripheral edema, renal and hepatic dysfunction, and ascites. Differentiation syndrome carries a high mortality unless recognized and managed promptly. Therapy consists of

immediate administration of steroids (dexamethasone 10 mg twice daily until resolution of signs and symptoms) and interruption of therapy if no response or in the case of life-threatening complications. This intervention will rapidly reverse the manifestations of differentiation syndrome and has substantially reduced mortality to below 5%. Some investigators have proposed prophylactic use of dexamethasone 2.5 mg/m² every 12 hours for the first 15 days in patients with WBC exceeding 5000/ μ L.

Subsequent clinical studies confirmed significantly better disease-free survival for the combination of ATRA plus chemotherapy. In the French APL 93 trial, concurrent administration of ATRA with chemotherapy achieved identical CR rates of 92% but a lower relapse rate at 2 years (6%) compared with sequential administration (16%, $p = .04$). As standard induction therapy for patients with APL hence emerged the combination of ATRA with an anthracycline (daunorubicin or idarubicin). In two large trials from Italy (GIMEMA) and Spain (PETHEMA), CR rates were 95% and 89%, respectively, and 2-year disease-free survival was 79%.²⁶ A risk-stratification model was proposed based on WBC and platelet count. High risk was defined as a WBC of greater than 10,000/ μ L at diagnosis with significant differences in relapse-free survival between patients with high- and those with intermediate-/low-risk disease. The role of cytarabine in APL therapy is controversial. In two randomized studies of ATRA/anthracycline $\pm$ cytarabine from the AML MRC15 trial and the European APL Group, rates for CR and induction failure were comparable, but in the European trial (using daunorubicin as opposed to idarubicin in the MRC trial), the risk for relapse was increased when cytarabine was omitted. On the other hand, in the MRC15 trial not only was there no difference in relapse rate, the cytarabine-treated patients experienced a small increase of deaths and higher use of medical resources. In a joint analysis of the European results with those of the PETHEMA group, the benefit of cytarabine was restricted to patients with higher risk disease.

ATO has potent antiapoptotic activity in APL cells. Whereas its precise mechanism of action is not well defined and almost certainly depends on additional mechanisms, it is the most active drug available against APL. Based on previously published data by the MD Anderson Cancer Center, a phase III multicenter trial compared ATRA plus chemotherapy with ATRA plus ATO in low- to intermediate-risk patients.²⁷ CR rates between the ATRA/ATO and the ATRA/chemotherapy group were similar (100% vs. 95%, $p = .12$). Although designed as a noninferiority trial, EFS and OS at 2 years were superior in the ATRA/ATO-treated patients. The ATRA/ATO arm was also associated with less hematologic toxicity and fewer infections, but higher rates of hepatic toxicity. The combination of ATRA and ATO can therefore be considered a new standard of care for patients with non-high-risk APL.

Single-agent ATO induction may be particularly attractive where medical resources are scarce and access to cheaper therapies is an economic necessity. In two studies, one from India and one from Iran, single-agent ATO achieved CR rates close to 85%, with 3-year survival rates of 86% (India) and 5-year survival rates of 64% (Iran). Patients with higher risk disease responded equally favorably. ATO can cause prolongation of the QTc interval, which may rarely lead to serious cardiac arrhythmias. It is recommended to check an electrocardiogram before each course of therapy and maintain electrolytes such as potassium and magnesium at high-normal levels throughout therapy.

Monitoring response during induction consists of morphologic assessments of marrow smears and measurements of *PML/RARA* by RT-PCR. As the differentiation response of leukemic blasts may be delayed, repeat marrow studies are not recommended before blood counts recover at around 4 to 6 weeks of therapy. No change of therapy should be undertaken during this time. At the end of induction and by the time a morphologic and cytogenetic remission is achieved, *PML/RARA* is frequently still detectable, which at this early point in therapy is common and should not be interpreted as a sign of treatment resistance.

Postremission therapy consists of consolidation and maintenance, with the goal to convert a morphologic and cytogenetic remission

into a durable molecular (PCR-negative) response and maintain PCR negativity throughout. For patients who are treated with an ATRA/chemotherapy combination, common practice is to give another two or three anthracycline-based cycles. Addition of ATO to a standard consolidation has significantly improved EFS and disease-free survival in a large randomized United States Intergroup study.²⁸ For ATRA/ATO-treated patients, the combination is continued throughout consolidation. Following consolidation, maintenance therapy for 1 to 2 years with ATRA $\pm$ mercaptopurine and methotrexate has been recommended. There is debate as to the benefit of maintenance and it is very likely that the impact of maintenance on overall outcome will change now that ATRA and ATO are a standard treatment for lower risk patients during induction. High-dose ara-C and mercaptopurine-methotrexate maintenance may not add benefit in the context of optimal novel therapies using ATRA-ATO with or without anthracyclines or GO. PCR testing is essential in the follow-up of patients with APL. In no other leukemia, with the possible exception of chronic myeloid leukemia and emerging in CBF leukemias, does molecular testing play such a critical role and influences clinical decision-making processes. Patients who do not achieve a molecular response by the end of the consolidation (usually 3 months into CR) have a poorer prognosis with a higher likelihood of relapse. Furthermore, these patients have a better survival with early intervention at the time of molecular rather than morphologic relapse. Whereas no further monitoring may be necessary for molecular responders with low-risk disease because of the very low relapse likelihood, monitoring should take place every 3 months for 2 years for patients with high-risk disease, those older than 60 years, and patients for whom treatment delays occurred during consolidation. Positive PCR test results should be confirmed by a second PCR test within 1 to 4 weeks. If the repeat test results are negative, no further action is necessary; however, close prospective monitoring should be applied.

ATO is effective therapy for patients with relapsed APL, including those with persistent PCR-positive disease. Morphologic remissions are achieved in up to 90% and molecular remissions in 70% to 80% of patients, respectively. Three-year survival rates are between 50% and 70%. Addition of ATRA to ATO may provide little further benefit if ATRA was already part of the induction/consolidation, which is the case most of the time. HSCT should follow achievement of a second remission. Autologous HSCT is recommended for patients who have again achieved a molecular response. For those whose PCR results remain positive despite ATO-based therapy, allogeneic HSCT is favored. CNS involvement at the time of relapse is rare, so that there is no commonly agreed-upon strategy of CNS prophylaxis. Whereas some groups such as the National Comprehensive Cancer Network advocate prophylactic intrathecal therapy for patients in second morphologic remission, the Spanish PETHEMA group showed that two independent risk factors for CNS disease are a WBC $>10,000/\mu\text{L}$ and occurrence of CNS hemorrhage during induction. Under those circumstances the incidence of CNS involvement has been as high as 5.5%, but it was not higher than 1.2% at 5 years for the remainder of the patients.

ADDITIONAL ISSUES IN ACUTE MYELOID LEUKEMIA

Hyperleukocytosis

Hyperleukocytosis is often understood as a WBC $>100,000/\mu\text{L}$ (Fig. 59.17), although this definition is not always followed very closely in clinical practice. It should be noted that lesser degrees of hyperleukocytosis can have grave consequences dependent on the biologic properties of the blasts. Myeloid blasts are less deformable than normal myeloid cells or even lymphoid blasts, and adhere to vessel walls and extramedullary tissues due to a complex array of adhesion molecules. Hyperleukocytosis is a medical emergency with a high mortality rate, mainly due to pulmonary and CNS complications from bleeding (intravascular sludging, anatomic disruption of the endothelium, DIC, or a combination) and direct tissue infiltration

Fig. 59.17 HYPERLEUKOCYTOSIS IN ACUTE MYELOID LEUKEMIA. The patient was a 23-year-old man who presented with several weeks of abdominal pain, weight loss, and fatigue. He was found to have a marked leukocytosis of $165,300/\mu\text{L}$ composed of mostly blasts ([A] and higher power [B]), which were shown to be myeloblasts by flow immunophenotyping. The patient developed some shortness of breath and hypoxia, and underwent two cycles of leukapheresis and hydroxyurea before induction. Molecular analysis revealed the leukemia to have an *FLT3-ITD* mutation.

triggering inflammatory responses. It is therefore imperative that efforts be undertaken to reduce the blast burden as soon as possible. Because red blood cell transfusions increase the viscosity of blood flow, they should be used judiciously or if possible avoided as long as the WBC remains high. Leukapheresis is a fast and effective method for WBC reduction. Although it has an immediate effect in reducing early mortality, there has been no impact on survival. Leukapheresis does not affect cellular plugs that are already formed in a vascular territory, nor does it abate inflammatory reactions in tissues infiltrated by blasts. Rapid administration of cytotoxic chemotherapy with or without leukapheresis therefore plays an important role. The most effective drug is cytarabine. Hydroxyurea is an oral alternative that is well tolerated and easy to administer. However, hydroxyurea does not effectively infiltrate tissues and thus may not reach extravascular blast infiltrates. Care must be taken to avoid tumor lysis syndrome, using adequate hydration and uricosuric agents, and to meticulously follow electrolyte levels and renal function.

Myeloid Sarcoma

Myeloid sarcoma (granulocytic sarcoma, chloroma) is an extramedullary myeloid tumor composed of myeloid blasts. Myeloid sarcomas can occur in any tissue but most commonly present in the skin (leukemia cutis), lymph nodes, gastrointestinal tract, testes, CNS, soft tissue, and bones. They can easily be confused with lymphomas and soft-tissue sarcomas. Myeloid sarcomas can be isolated, occur together with marrow involvement, or precede it. In a few instances they may be the relapse manifestation of patients who have been treated for AML in the past, particularly following allogeneic stem cell transplantation. In the context of chronic myeloid malignancies (e.g., MDS, myeloproliferative neoplasms, chronic myeloid leukemia, chronic myelomonocytic leukemia), their appearance represents progression to a blast phase. Even when isolated, myeloid sarcoma should be treated systemically with chemotherapy, as for any other AML. Radiation therapy may be of help to optimize local control in challenging anatomic compartments. However, in the absence of systemic therapy, subsequent progression to systemic AML is very likely. There is controversy over whether patients with myeloid sarcoma do better or worse than those with AML. The majority of

retrospective comparisons between patients with myeloid sarcoma and those with AML suggest no significant differences in survival and a possible survival benefit with HSCT for all groups.²⁹

Central Nervous System Disease

CNS involvement occurs in less than 5% of patients with AML and is therefore much rarer than in ALL. Consequently, there is no role for CNS prophylaxis. Before HiDAC, inv(16) AML was associated with a 30% incidence of CNS leukemia, particularly intracerebral masses. This particular problem has been virtually eliminated with the use of HiDAC but may still be noted in patients with inv(16) AML in whom HiDAC is not delivered. In the presence of symptoms suggestive of CNS disease, further workup should be pursued. Symptoms are due to raised intracranial pressure, mass effect, or infiltration of cranial nerves. Whereas CT scan is a convenient modality to rule out significant anatomic disruptions, it is not very sensitive to detect more subtle signs of leptomeningeal disease, and, if concerns persist, a magnetic resonance image of any CNS structure where disease is suspected should be obtained. Lumbar puncture is a crucial component of the workup. Blasts in the cerebrospinal fluid may range from a few cells to several thousand. Treatment consists of intrathecal therapy with cytarabine and/or methotrexate via lumbar route or Ommaya reservoir. The dose of methotrexate should be reduced by 50% if administered into an Ommaya reservoir. A typical schedule includes twice-weekly intrathecal doses until the cerebrospinal fluid becomes clear. The frequency is then changed to weekly for 2 months, then every other week for 2 months, followed by monthly injections for up to 1 year (various similar schedules are used in practice). Radiation therapy can be a useful alternative, especially in the case of localized lesions such as isolated cranial nerve findings. Although high-dose cytarabine penetrates the blood–brain barrier and may have contributed to a lower rate of CNS involvement over the years, it alone is not sufficient therapy once there is CNS disease. The risk for CNS involvement is higher in AML with any type of monoblastic differentiation and those cases with a high WBC ($>100,000/\mu\text{L}$) at presentation (high LDH >100 IU/L), and perhaps in FLT3-positive AML. Although some authorities have recommended routine intrathecal therapy once in remission, this is not common practice.

Pregnancy

AML is rarely diagnosed during pregnancy. In a case-control study of 785 women with AML aged 15 to 50 years compared with 1576 age- and sex-matched controls, AML occurred at a rate of 1.3% in the pregnant group and 3.4% in the control group (odds ratio: 0.44 in favor of pregnant women). The response to treatment is not affected by pregnancy. AML therapy during the first trimester is problematic due to the toxic and teratogenic effects of chemotherapy on the fetus. Under those circumstances, termination of pregnancy before institution of induction therapy should be strongly considered. Pregnancy outcome during the second and third trimester is more favorable, and successful treatment of the AML and delivery of normal infants have been reported. Daunorubicin is preferable over idarubicin because the latter is more lipophilic and has higher DNA affinity, raising the question of higher maternal–fetal transfer and toxicity to the fetus. It is not advisable to delay therapy once the diagnosis of AML is made given the high risk for maternal death. In situations where the leukemia behaves indolently and women are close to delivery, a conservative approach can be chosen with supportive care and induction of labor as soon as possible. These decisions are based on clinical judgment and discussion with the patient.³⁰

FUTURE DIRECTIONS

Although standard induction therapy has not substantially changed over the previous four decades (unchanged 3 + 7 dose and schedule),

the context in which it is delivered has become more refined. More significance is given to particular subsets of patients: a) patients unfit for standard chemotherapy (often but not always rightfully understood as those over age 60 years) frequently receive lower intensity therapies or are enrolled in clinical studies with novel agents (e.g., volasertib, vosaroxin, guadecitabine, venetoclax, SGN-CD33A); b) more and more particular cytogenetic–molecular abnormalities are amenable to targeted, often single-agent, approaches (e.g., FLT3 inhibitors, IDH1/2 inhibitors, DOT1L inhibitors, multikinase inhibitors); c) addition of the FLT3 inhibitor midostaurin to standard induction therapy improves survival in FLT3 mutated AML; d) CPX-351 improves survival in older patients with secondary AML; e) the studies of immunotherapy may open up new options. Response assessment extends beyond morphologic and cytogenetic remissions and increasingly includes MRD measurements similar to what has been happening in adult ALL. Molecular signatures and cellular pathways that are abnormally activated or regulated in AML blasts are contributing to a more complex picture of the biology of AML and, besides providing prognostic information, offer targets for drug development.

MYELODYSPLASTIC SYNDROMES

Christopher J. Gibson, Benjamin L. Ebert, and David P. Steensma

Myelodysplastic syndromes (MDS) are clonal hematopoietic disorders characterized by ineffective hematopoiesis and peripheral blood cytopenias, abnormal cell morphology on blood and bone marrow examination (Fig. 60.1) and a risk of progression to acute myeloid leukemia (AML). It has a variable clinical course, manifesting in some patients as indolent cytopenias necessitating occasional transfusions and in others as aggressive diseases that rapidly evolve into treatment-refractory leukemias, with a broad spectrum of severity in between.

Despite this phenotypic variability, individual cases of MDS share many pathophysiologic mechanisms at the molecular and cellular levels, and our understanding of these mechanisms has evolved substantially in the last decade. At the same time, although MDS also shares features with AML and other myeloid malignancies, mounting evidence shows that it is appropriately conceived as a distinct class of diseases, and that the older conceptualization of MDS as “preleukemia” is overly simplistic.

While understanding of MDS pathophysiology is improving, the condition remains difficult to treat, and outcomes for patients with MDS have unfortunately not improved substantially since the last edition of this textbook. This chapter describes our current understanding of the classification, pathobiology, clinical features, and treatment approaches for this heterogeneous group of disorders.

HISTORY

Central to an understanding of how MDS is diagnosed and classified is the concept of *morphologic dysplasia*, a pathologic term that was originally introduced as a shortening of the phrase *dysmorphology of neoplasia*. Although specific criteria for diagnosis of MDS as a distinct clinical syndrome exist and are discussed subsequently, the term myelodysplasia refers more generally to an abnormal appearance of hematopoietic precursors during pathologic examination of bone marrow, which may result from many different causes (e.g., drug toxicity, nutritional deficiency, viral infection). The process by which our understanding of MDS has evolved from that of a morphologic oddity to that of a distinct disease process has been a century in the making, propelled forward at several points by paradigmatic shifts in pathologic and molecular characterization of hematologic diseases.¹

In describing the history of MDS as a distinctly categorized disease entity, it is perhaps most useful to separately describe the history of its major conceptual components. The earliest recognized of these, not surprisingly, was that of dysplasia itself. Although studies of peripheral blood in anemic patients were reported in the 19th century,² the first real characterization of actual dysplasia was probably made by Giovanni di Guglielmo in Pavia in 1923, when he described abnormal erythroid forms in the marrows of patients with various types of cytopenias.³ A second major concept, that of ineffective hematopoiesis, was developed in the 1930s with the description of *refractory anemia* in patients unresponsive to iron pills or liver extract (the precursor to vitamin B₁₂ supplementation);⁴ in the 1950s, others expanded this to include similarly refractory leukopenia and thrombocytopenia and termed the collective disorder “refractory cytopenias.”⁵ Importantly, however, ineffective hematopoiesis and marrow dysplasia were initially incompletely linked, and the ineffective hematopoiesis of many early refractory anemia patients was probably rooted in other disorders, such as anemia of inflammation caused by advanced rheumatologic disease or nonmyeloid neoplasia.

The third major component of MDS, and possibly the most prominent, is its temporal positioning as a potential preleukemic state. This was first conceptualized in 1942 as *odo-leukemia* (“odo” from the Greek for edge or threshold) by a group from France led by Paul Chevallier to describe a case of anemia evolving into leukemia,⁶ which they attributed to benzene exposure. A similar disorder was termed *preleukaemic anemia* by a British hematologist, J.L. Hamilton-Paterson, in 1949.⁷ This term was adopted and expanded by an American group based in Chicago in the early 1950s,⁸ providing one of the clearest descriptions of a disorder clinically defined by both cytopenias and a risk of leukemia. Other groups in the 1950s and 1960s published similar descriptions under different terminologies.⁹

The 1970s saw some of the greatest strides toward our modern conceptualization of MDS. In 1970, Dreyfus and colleagues coined the term *refractory anemia with excess blasts* (RAEB, described in French as *les anémies réfractaires avec excès de myeloblastes*)¹⁰ and later attempted to further characterize components of RAEB based on morphology and clinical characteristics.¹¹ The term *hematopoietic dysplasia* was used in the early 1970s to describe a heterogeneous group of disorders distinct from AML, and the term was later simplified to *myelodysplasia*.

One of the key events in the history of myeloid disease classification was the formation of the French-American-British (FAB) Cooperative Group in 1976, which in that year issued a comprehensive and influential categorization of AML¹² based on the 1975 classification of Galton and Dacie.¹³ The FAB classification persisted as the dominant descriptive system for AML until the early 2000s. The original FAB AML formulation from 1976 included two types of “dysmyelopoietic syndromes” that should not be confused with AML: RAEB and chronic myelomonocytic leukemia (CMML), which had first been described in the late 1960s.¹⁴ However, it was not long before MDS was recognized as a separate group of diseases and accorded a distinct classification system, described in more detail later.

CLASSIFICATION

The currently accepted classification scheme for MDS was initially published by the World Health Organization (WHO) in 2001 and most recently revised in 2008 (Table 60.1), with a third revision planned for 2016. Like the classifications of the FAB group, the WHO classification is principally a morphologic system and classifies disease chiefly based on the number of dysplastic lineages and the percentage of marrow blasts, though it also includes one specific cytogenetically defined subtype, MDS with isolated del(5q). The other WHO 2008 subtypes include refractory cytopenia with unilineage dysplasia (RCUD), which is most commonly refractory anemia (RA); refractory cytopenia with multilineage dysplasia (RCMD); refractory anemia with ringed sideroblasts (RARS); RAEB (subdivided into RAEB-1, 5%–9% blasts, and RAEB-2, 10%–19% blasts); and unclassifiable MDS (MDS-U) for those cases that do not clearly fall into any other category. In addition, the WHO system classifies cases with myeloproliferative features separately; this group includes CMML and RARS with thrombocytosis (RARS-T).

The WHO classification was intended to replace the prior FAB classification system, which was initially proposed in 1982 as an MDS correlate to the FAB system for classifying AML.¹⁵ The 1982

Fig. 60.1 ELEMENTS OF MYELODYSPLASTIC SYNDROME. Myelodysplastic syndromes are generally characterized by cytopenias (A) caused by ineffective hematopoiesis (B), which is related to multilineage dysplasia (C). (A) This patient presented with a white blood cell count of 1500/ μ L, hemoglobin 8.9 g/dL, and platelet count 47,000/ μ L. (B) The bone marrow was hypercellular, indicating ineffective hematopoiesis. (C) Evidence of trilineage dysplasia was apparent on the peripheral smear. Anisocytosis with macroovalocytes and poikilocytosis is seen in the red blood cells (C, *top*). The latter included the somewhat uncommon finding of Cabot ring forms (*right*). A large proportion of the granulocytes were severely hypogranular (C, *middle left*) compared to some normal forms still in the circulation (*right*). Platelets (C, *bottom*) were decreased in number, and many were severely hypogranular (*middle*, barely visible) compared with residual normal platelets (*left*).

FAB system distinguished five subtypes of MDS, namely (1) RA, (2) RARS, (3) RAEB (defined as 5%–19% blasts in the marrow), (4) RAEB in transformation (defined as 20%–29% blasts in the marrow), and CMML.

The WHO system thus bears some similarities to the FAB scheme, but there are several notable changes. First, the WHO system recognizes that MDS may present with isolated leukopenia or thrombocytopenia, albeit uncommonly, hence the change from RA to the broader RCUD and the addition of a second distinct class for patients with more than one affected cell line. Second, a mounting body of evidence suggested that MDS with proliferative features is clinically and biologically distinct from MDS without such features and thus warrants separate designation.^{16,17} Third, the unique clinical syndrome associated with isolated *del*(5q), in combination with its particular responsiveness to treatment with lenalidomide, warranted its designation as a specific entity.¹⁸ Finally, the cutoff for diagnosis of AML was changed from 30% to 20% bone marrow blasts or greater, rendering the designation of RAEB in transformation obsolete, although this change was not without its detractors.¹⁹

The WHO revision improved on certain aspects of the FAB system. In particular, the FAB system required that patients display at least 10% dysplasia in two different cell lineages to achieve even a diagnosis of RA; this excluded patients with mild or unilineage dysplasia, many of whom had natural histories indistinguishable from those who met the diagnostic criteria. While the WHO guidelines eliminated the dual-lineage requirement and allows a diagnosis of MDS in patients with unilineage dysplasia, it nevertheless draws arbitrary lines of distinction between subclasses of a heterogeneous disease, and patients with minimal dysplasia are still typically excluded from the diagnosis.²⁰ Artificial boundaries such as the 10% dysplasia, 15% ring sideroblasts and 5%/10%/20% blast cutoffs often prove themselves to be of variable relevance, both biologically and clinically, because they fail to capture a number of variables important in MDS, including age, sex, and most cytogenetic and genetic data.

Although some of the FAB and WHO subgroups imply very rough prognostic information—for instance, patients with FAB RAEB or WHO RAEB-2 are at higher risk of progression to AML than subgroups without excess blasts²¹—other systems specifically dedicated to estimating disease risk, such as the International Prognostic Scoring System (IPSS; see later), are better suited to this task.

Future iterations of a classification system may incorporate elements of genetic or clinical data that better group MDS patients based on disease biology, prognosis and natural history, or anticipated responsiveness to treatment modalities.²² For now, however, this classification scheme remains only one of several descriptive tools applied to patients with MDSs.

EPIDEMIOLOGY AND ETIOLOGY

Most available data suggest that MDS is one of the most common hematologic malignancies, although this claim has been difficult to validate until recently because of confusing terminology and incomplete reporting of cases to registries.^{23,24} Cases of MDS were not reported to the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) until 2001, and initial reports to the registry suggested an incidence of only about 10,000 new cases per year.²⁵ Subsequent comparison of these data with Medicare and insurance claims for MDS suggested that a substantial proportion of MDS cases went unreported to SEER, with an estimated age-adjusted incidence of >5.3 per 100,000, compared to the SEER estimate of 3.3.²⁶

The reporting difference was especially stark in patients age 65 and older, where it was estimated that the actual incidence of MDS might actually be close to fourfold higher than what was captured in the database (75 versus 20 per 100,000). Some of the underreporting was likely related to specific criteria for entry into the database (for instance, myeloid malignancies could only be counted once, such that patients presenting with a new diagnosis of secondary AML were usually coded as AML, without mention of MDS). Much of the underreporting, however, was likely because of the complexity of diagnosing and classifying MDS, as described earlier. The rate of reporting appears to have recently improved, with annual incidence in the 2007–2011 SEER database estimated at around 20,500 and an age-adjusted incidence of 4.9 per 100,000.²⁷

Even the most accurate database, however, would probably underestimate the total global burden of MDS, which is likely present in a substantial percentage of older patients with idiopathic cytopenias who never undergo bone marrow analysis.²⁸ Although some proportion of this uncaptured population likely has biologically indolent

TABLE 60.1 2008 World Health Organization Classification of the Adult Myelodysplastic Syndromes

Refractory Cytopenia With Unilineage Dysplasia	
Dysplasia	≥10% of cells from a single lineage
Blasts	<5% in marrow; <1% in peripheral blood; no Auer rods
Notes	Includes refractory anemia (RA), refractory neutropenia, refractory thrombocytopenia; RA is by far the most common subtype
Refractory Anemia With Ring Sideroblasts	
Dysplasia	Isolated erythroid dysplasia
Blasts	<5% in marrow; <1% in peripheral blood; no Auer rods
Notes	≥15% of erythroid precursors are ring sideroblasts Frequently associated with SF3B1 mutations
MDS With Isolated del(5q)	
Dysplasia	Normal or increased megakaryocytes with hypolobated nuclei
Blasts	<20% (though usually much less)
Notes	del(5q31) must be sole chromosomal abnormality
Refractory Cytopenia With Multilineage Dysplasia	
Dysplasia	≥10% of cells from two or more myeloid lineages
Blasts	<5% in marrow; <1% in peripheral blood; no Auer rods
Notes	Peripheral monocyte count must be <1 × 10 ⁹ /L; ring sideroblasts may be present
Refractory Anemia With Excess Blasts	
Dysplasia	No specific requirement
Blasts	RAEB-1: 5%–9% in marrow, <5% in peripheral blood, AND no Auer rods RAEB-2: 10%–19% in marrow, 5%–19% in peripheral blood, OR Auer rods
Notes	Old designation of RAEB-t (20%–30% blasts) now considered AML
Unclassifiable MDS	
Dysplasia	Minimal, or not meeting criteria for another subtype
Blasts	<5% in marrow; <1% in peripheral blood; no Auer rods
Notes	In presence of <i>clonal cytogenetic finding</i> considered diagnostic of MDS
Note: excludes refractory cytopenias of childhood. MDS/myeloproliferative neoplasms such as chronic myelomonocytic leukemia and RARS with thrombocytosis are classified separately. AML, Acute myeloid leukemia; MDS, myelodysplastic syndrome; RAEB, refractory anemia with excess blast.	

disease that would never require therapy, more thorough cross-sectional studies, particularly in older patients, would help clarify the distinction between this end of the MDS spectrum and more aggressive biology that brings patients to clinical attention.

As referenced earlier, MDS is by and large a disease of older adults and reflects the inexorable acquisition of genetic mutations by aging hematopoietic progenitor cells (Table 60.2). In the United States, the median age at diagnosis is approximately 71 years,²⁹ and in the absence of a congenital disorder or exposure to radiation or cytotoxic chemotherapy for another disease, diagnosis before the age of 50 is rare.³⁰ Recent data suggest that a substantial proportion of older adults, perhaps as many as 10% of those over age 70, harbor hematopoietic clones defined by the presence of mutations recurrently found in MDS and AML, and that this state of “clonal hematopoiesis of indeterminate potential” progresses to MDS at a rate of 0.5% to 1% per year.^{31,32} MDS occurs in children much more rarely, at an estimated annual rate of 1 per 1 million.³³ Most cases are classified as oligoblastic myelogenous leukemia (essentially RAEB), and other subtypes are even less common.³⁴ Several genetic syndromes confer an increased risk of MDS; these include Down syndrome,³⁵ Fanconi

TABLE 60.2 Genes Recurrently Mutated in Myelodysplastic Syndrome

Gene	Frequency (%)	Notes
Splicing Factors		
SF3B1	20–30	Strong association with RARS
SRSF2	10–15 (MDS) 40 (CMML)	Enriched in CMML
U2AF1	5–12	Association with del(20q)
Epigenetic Modifiers		
TET2	20–30 (MDS) 40–50 (CMML)	Enriched in CMML Mutually exclusive with IDH
DNMT3A	8–13	
ASXL1	10–20 (MDS) 30–40 (CMML)	Enriched in CMML
EZH2	5–10 (MDS) 20–30 (CMML)	Enriched in CMML May be functionally involved in 7q–
IDH1/2	<5	More frequent in AML
ATRX	Rare	Associated with acquired thalassemia
Transcription Factors		
RUNX1	10–15	Can be somatic or germline
GATA2	Rare	Mostly germline
ETV6	<5	Can be somatic or germline
TP53	10–12	Association with complex karyotype, therapy-related disease
Kinases and Receptors		
JAK2	<5	Enriched in RARS-T
NRAS	5–10	Seen in progression to AML
CBL	<5	Enriched in JMML
PTPN11	<5	More common in JMML
BRAF	Rare	Also seen in hairy cell leukemia
Cohesin Complex		
STAG2	5–10	Cohesin class mutations enriched in high-risk MDS and secondary AML.
RAD21	<5	
SMC3	<2	
SMC1A	<2	
GPCR Complex		
GNAS	Rare	Mutations recently described in wide range of hematologic malignancies, including MDS.
GNB1	Rare	

AML, Acute myeloid leukemia; CMML, chronic myelomonocytic leukemia; GPCR, G-coupled protein receptor; IDH, isocitrate dehydrogenase; JMML, juvenile myelomonocytic leukemia; MDS, myelodysplastic syndrome; RARS, refractory anemia with ring sideroblasts; RARS-T, RARS with thrombocytosis.

anemia,³⁶ dyskeratosis congenita and other telomeropathies, and germline mutations in *GATA2*,³⁷ *RUNX1*,³⁸ and *ETV6*.³⁹ In Fanconi anemia and the telomeropathies,⁴⁰ MDS during young adulthood may be the initial presenting sign of the disease.

Most subtypes of MDS appear to be more common in men than women, with the most recent SEER data suggesting respective age-adjusted incidences of 6.7 versus 3.9 per 100,000.⁴¹ The one exception to this is MDS with isolated del(5q), which most series show to be more common in women.⁴² The reason for these sex differences is unclear; some have postulated a protective factor encoded on the X chromosome, or a similar protective factor on the Y chromosome (which is clonally lost in some cases of MDS). Others have suggested

that the increased incidence in men overall is likely caused by differences in occupational exposures, but this has never been clearly demonstrated. Indeed, the only toxic chemical exposure definitively proven to cause MDS is benzene,⁴³ which is now significantly less prevalent in industrial workplaces than it had been in the past. Other environmental exposures, including cigarette smoking, have been postulated but never definitively proven to predispose to MDS.⁴⁴

MDS in the United States and Western Europe is epidemiologically similar, but there are differences between these geographic regions and other parts of the world. In Asia⁴⁵ and Eastern Europe,⁴⁶ for instance, the average age at MDS diagnosis is younger, and the frequency of both severe cytopenias and risk of progression to leukemia may differ.⁴⁷ Some of these differences are likely caused by variance in environmental exposures. In Japan, for example, broad population-wide exposure to ionizing radiation from the atomic bombings of Hiroshima and Nagasaki in the 1940s continued to influence MDS incidence well into the 1990s.⁴⁸ However, the cause of differences in MDS subtypes, such as the low incidence of RARS in Japan compared with the West, remain unclear.

Indeed, the two exposures most consistently associated with subsequent development of MDS are ionizing radiation and cytotoxic chemotherapy, and MDS arising in these settings, known as therapy-related MDS or t-MDS, is frequently characterized by TP53 mutations,⁴⁹ multiple large-scale chromosomal abnormalities including complex karyotypes (most commonly defined as ≥ 3 clonal chromosomal anomalies),⁵⁰ and frequent transformation to treatment-refractory AML.⁵¹ In the United States, radiation is most frequently encountered as treatment for other cancers, and radiation fields that include the hips or pelvis, the most active sites of hematopoiesis in adults, probably pose the greatest risk.⁵² Less commonly, exposure to radiation can occur as the result of occupational exposures (e.g., workers at nuclear reactors) or industrial accidents. Among chemotherapeutic agents, there is a substantial difference in the risk of subsequent MDS. In particular, alkylating agents (e.g., cyclophosphamide and melphalan)⁵³ appear to carry the greatest risk, while the risk with nucleoside analogues is lower. Of particular note, the rapidly progressive AML seen in association with topoisomerase inhibitors (e.g., doxorubicin, etoposide) is not typically preceded by MDS.⁵⁴

PATHOBIOLOGY

The past 10 years have witnessed significant advances in our understanding of the rich and complex pathobiology underlying MDSs. MDS is now recognized to arise from interactions between acquired genetic mutations in hematopoietic precursor cells, alterations in the microenvironment of the bone marrow, and dysregulated immune surveillance. Broadly speaking, the acquisition of sequential mutations in precursor cells drives the development of a malignant clone, and alterations in the microenvironment and the immune response allow that clone's expansion. This section details our current understanding of these concepts.

Myelodysplastic Syndrome Stem Cells

One of the central challenges in understanding the pathogenesis of MDS has been isolating the cell of origin and understanding that cell's mechanisms of self-renewal and propagation, both of which are necessary for the establishment of a malignant clone.⁵⁵ In theory, the exact state of hematopoietic differentiation from which a malignant clone arises could vary between cases of MDS, but the capacity for self-renewal implies that the origin cell was either a hematopoietic stem cell (HSC), and thus possessed intrinsic self-renewal capabilities, or it was a more differentiated myeloid progenitor that acquired the ability to self-renew. Clonal expansion then occurs through the acquisition of new mutations or epigenetic alterations that either enhance proliferation or confer resistance to apoptosis. MDS presumably becomes morphologically apparent when the dominant clone acquires a subsequent genetic lesion that leads to dysplasia within one

or more hematopoietic compartments; this may or may not coincide with genetic lesions that lead to ineffective hematopoiesis and cytopenias, at which point MDS also becomes clinically evident.⁵⁶

Proving that MDS is a clonal disease was not as straightforward a proposition as it was for AML, in which examination of the bone marrow typically identifies sheets of abnormal, morphologically identical blasts. In contrast, for MDS—particularly low-risk disease in which blasts are rare and the marrow architecture is disorganized and heterogeneous—a clonal origin was not immediately obvious based on morphology alone. Nonetheless, the clonal nature of MDS was established in the 1980s by studies that showed skewed inactivation of glucose-6-phosphate dehydrogenase (G6PD), an X-linked gene, in the hematopoietic cells of female MDS patients heterozygous for G6PD deficiency.⁵⁷ More recent studies have used deep sequencing techniques to track the clonal evolution from MDS into AML and have confirmed that in these cases, the preexisting MDS is as highly clonal as the resulting secondary AML.⁵⁸

That MDS is a disorder of stem or early progenitor cells has been more difficult to prove.⁵⁹ Some of this difficulty is a reflection of the elusiveness of human HSCs themselves: the ability of different human cell populations to self-propagate after xenotransplantation into immunodeficient mice, considered the functional hallmark of “stemness,” varies with the exact degree of immunodeficiency of the mice into which the cells are transplanted.⁶⁰ Moreover, xenotransplant experiments using immunophenotypically defined hematopoietic stem and progenitor cells (HSPCs; classically CD34⁺ CD38[−] Lin[−]) from MDS patients have not shown a striking proliferative or self-renewal advantage for the MDS cells compared to normal controls,⁶¹ and the degree to which these experiments accurately depict the clonal dynamics of MDS in humans is unclear. Some have further been troubled by the observation that lymphoid clonal expansion, which should occur with near-equal frequency to myeloid clonal expansion if MDS is indeed a disorder of very early hematopoietic progenitors, is only rarely observed.^{62,63} However, more recent studies combining immunophenotypic analysis with deep sequencing of clonal mutations in MDS cells have shown that the mutations appear to originate exclusively in the most primitive, stem-cell-like compartment,⁶⁴ and others have shown that differential expansion of specific progenitor compartments may vary between different phenotypes and risk profiles of MDS.⁶⁵ This evidence has contributed to the conclusion that MDS is, in fact, a disorder of transformed HSCs.⁶⁶

The conceptualization of MDS as a stem cell disorder explains, in large part, why it is so refractory to most attempts at conventional therapy. Both normal HSCs and leukemia stem cells remain quiescent for much of their lifetimes, and during these periods they are largely impervious to any agents, such as most chemotherapeutic drugs, that exert their effects during active DNA replication.⁶⁷ Overcoming the intrinsic resistance to therapy conferred by the existence of quiescent reservoirs of disease is one of the central challenges in developing effective treatments for MDS.⁶⁸

Genetic Alterations

Like other cancers, the core hypothesis underlying MDS pathogenesis is that the originating clone of MDS becomes increasingly abnormal, and ultimately malignant, through the sequential accumulation of acquired genetic or epigenetic abnormalities.⁶⁹ Improvement in our understanding of how these abnormalities are acquired, how they interact with each other, and their impact on pathways affecting proliferation, self-renewal, and differentiation, has been one of the major advancements in the study of MDS over the last decade.

Several different classes of genetic abnormalities may be found in MDS. The first to be recognized were cytogenetic abnormalities on standard karyotyping,⁷⁰ which are present in about 50% of patients.⁷¹ A second category of cryptic chromosomal aberrations, including microdeletions and copy number-neutral loss of heterozygosity, are too small to be detected by karyotype but may be found with fluorescence in-situ hybridization (FISH)⁷² or single nucleotide polymorphism (SNP) arrays.⁷³ The most common type of abnormality,

mutations in single genes, has been increasingly well characterized, and clinical tests for recurrent mutations are becoming increasingly available, though as discussed later, it appears that not all mutations have equal clinical relevance.⁷⁴ Finally, epigenomic alterations—global aberrations in histone and chromatin modification—are common in MDS, and are often, though not always, associated with mutations in genes involved in epigenetic regulation.⁷⁵

Somatic Mutations

Of the types of genetic abnormalities found in MDS, acquired mutations in individual genes are the most recently recognized; they are also the most frequent, currently estimated to be present in around 80% of MDS patients.⁶⁹ Although certain environmental exposures increase the risk of acquiring potentially deleterious mutations, most are acquired randomly, either spontaneously (e.g., deamination of cytosine to uracil), during DNA replication before cell division, or during DNA repair.

One of the central challenges of understanding the genetics of MDS has been determining which mutations contribute to the pathogenesis of the disease and which do not. Accumulating evidence has shown that HSCs acquire nonsynonymous exonic mutations with translational consequences at a rate of about one mutation per decade.⁷⁶ Since the incidence of MDS increases with age, HSPCs from an average MDS patient should typically contain between 5–10 such mutations (though the actual number varies widely between patients), against a background of hundreds of noncoding single nucleotide variations. The vast majority of these mutations, both coding and noncoding, are of no pathogenic consequence and are thus termed *passenger* mutations, while a minority, the so-called driver mutations, actually contribute to the development of the disease.⁷⁷

Distinguishing driver mutations from passenger mutations is not always trivial. Passenger mutations, without conferring clonal advantage, tend not to recur with any significant frequency in cohorts of MDS patients; however, whereas a few driver mutations are relatively common in MDS, many have been found in only a small fraction (<5%) of cases, suggesting novel mechanisms of disease pathogenesis.⁷⁸ Similarly, whereas noncoding mutations are unlikely to contribute to pathogenesis and can thus be ignored when analyzing MDS genomes, the majority of coding mutations, even those present within a majority of cells in the malignant clone, are also nonpathogenic and are simply artifacts captured by an aging HSPC. Classifying a mutation as a driver thus involves accumulating evidence that the mutation occurs recurrently in MDS, that its putative function could plausibly contribute to MDS pathogenesis, and, in the best-case scenario, that this function can be recapitulated using *in vitro* or *in vivo* models.

Large-scale genomic studies of MDS cohorts have shown that many of the recurrently mutated genes can be segregated into one of a few functional categories,^{78–81} and this functional characterization has in turn revealed insights about how an MDS clone develops over time. Genes affecting RNA splicing (*SRSF2*, *SF3B1*, *U2AF1*) are the most commonly mutated and tend to be early events in MDS pathogenesis. Genes affecting epigenetic regulation (*TET2*, *ASXL1*, *EZH2*, *DNMT3A*) are the next-most commonly mutated and also tend to occur early. On the other hand, mutations in genes for growth factors (*NRAS*, *JAK2*) tend to occur late and in subclonal populations.

These observations have contributed to an overarching model of how sequential somatic mutations cooperate to bring about MDS. In this model, early mutations in splicing factors and epigenetic genes do little to affect proliferation or differentiation on their own, but rather create a permissive environment for the acquisition of subsequent mutations in genes that confer proliferative advantages or blocks in differentiation. The latter group of mutations contributes more directly to the clinical features of MDS, but the former is responsible for its tendency towards genomic and epigenomic instability, which in turn may contribute to the disease's poor response to treatment. This section is a brief summary of our current understanding of some of the most important genes and pathways that are recurrently deranged in MDS.⁸²

Splicing Factor Mutations

Genes encoding splicing factors, which excise introns to create mature messenger RNA (mRNA) transcripts, are the most commonly mutated class of genes in MDS, with between half and two-thirds of patients harboring such a mutation.⁸³ As opposed to most of the other classes of mutations discussed here, which occur in other malignancies with significant frequency, splicing factor mutations are rarer in other cancers than MDS, and some have unique associations with specific morphologic phenotypes.⁸⁴ Splicing factor mutations tend to be mutually exclusive within MDS clones, and most of the affected genes encode proteins that comprise the E/A splice site recognition complex that acts at the 3' end of pre-mRNA, suggesting that the mutations converge on a shared biologic pathway.⁸⁵ Exactly how splicing factor mutations predispose to the development of MDS, and whether they can help predict aspects of natural history or treatment response, remain areas of active investigation.

SF3B1

SF3B1 encodes the U2 small nuclear riboprotein complex (snRNP) responsible for 3' branch site recognition and is the most frequently mutated splicing factor gene. *SF3B1* mutations can be found in about 20% to 30% of all MDS patients; there is a particularly strong association with ring sideroblast morphology, with mutations found in 60% to 85% of patients with RARS or RARS-T and substantial percentages of other MDS subtypes in which ring sideroblasts can be found.^{86,87} The most common mutations are missense substitutions that change lysine to glutamate at codon 700, with other smaller hotspots in the same vicinity. These mutations all occur within a cluster of 26 nonrepeating HEAT domains that are thought to be involved in binding of *SF3B1* to other members of the U2 snRNP.⁸⁸ As with other splicing factor mutations, they tend to be heterozygous and imply a gain of function. How exactly the mutations affect MDS pathogenesis is not completely clear, but they are often acquired early in disease development, tend not to be associated with complex karyotypes, and tend not to be associated with poor-prognosis mutations.⁸⁹ *SF3B1* mutations are clinically associated with a distinct phenotype of isolated, transfusion-dependent anemia with preserved white blood cell and platelet counts relative to *SF3B1*-wildtypes, as well as a lower risk of progression to AML.⁹⁰ Indeed, in larger studies of MDS cohorts, *SF3B1* mutations appear to confer an improvement in relative survival, making them somewhat unique among MDS-associated mutations.⁸⁰

SRSF2

SRSF2 encodes a member of the serine/arginine (SR)-rich family of pre-mRNA splicing factors that interacts with the U2 and U1 components of the spliceosome. After *SF3B1*, it is the second-most commonly mutated splicing factor, with mutations present in 10% to 15% of MDS⁹¹ and 40% of CMML.⁹² The overwhelming majority of mutations are heterozygous missense substitutions for proline at codon 95, implying a gain of function. A small minority of in-frame insertions or deletions affects the same region. *SRSF2* mutations co-occur with several other mutations, many of which are also frequently found in CMML, including *TET2*, *ASXL1*, *CUX1*, *IDH2*, and *STAG2*. In contradistinction to patients with *SF3B1* mutations, patients with *SRSF2* mutations tend to have more dysplasia in the granulocytic lineage and less in the erythroid lineage, and patients consequently tend to have a less prominent transfusion requirement, more enrichment in the RAEB subtypes, and, at least in some studies, a greater risk of progression to AML.⁹³ This phenotype is more heterogeneous than that associated with *SF3B1*, but most studies have nevertheless shown that *SRSF2* mutations appear to confer an inferior prognosis.⁹¹

U2AF1

U2AF1 encodes an auxiliary factor in the U2 spliceosome that is responsible for recognizing the AG splice acceptor dinucleotide at the 3' end of introns. *U2AF1* mutations occur in about 12% of patients with MDS.⁹⁴ Similar to other commonly mutated splicing factor genes, the two most common mutations are both heterozygous missense substitutions, again implying a gain of function, and both appear to alter sequence specificity of pre-mRNA binding and splicing.⁹⁵ The two mutations are in separate zinc finger DNA binding domains, one at codon 34 toward the N-terminal of the protein, and one at codon 157 toward the C terminal. Some studies have shown an increased tendency of MDS with *U2AF1* mutations to evolve into secondary AML,⁹⁶ but given the small numbers of patients in these studies, the strength of this effect is unclear.

Epigenetic Modifier Mutations

Epigenetic changes are biochemical modifications that affect chromatin structure, and thereby gene expression, without actually altering the DNA sequence itself. The two types of epigenetic changes most relevant to MDS are DNA methylation and histone modification.⁷⁵ DNA methylation involves the addition of a methyl group to the cytosine residues of cytosine-guanine pairs by members of the DNA methyltransferase (DNMT) family of enzymes. These cytosine-guanine pairs frequently cluster together in "CpG islands," which are typically located just upstream of promoter regions. CpG islands tend to be unmethylated at baseline, but their progressive methylation leads to transcriptional silencing of the downstream genes. Studies have shown that many MDS patients display aberrant methylation patterns compared to healthy controls, with isolated hypermethylation in the promoters of critical tumor suppressors despite global hypomethylation elsewhere. This phenomenon has been hypothesized to play a role in the pathogenesis of MDS, but attempts to glean prognostic or predictive information from specific methylation patterns in MDS patients have been largely unsuccessful, and the success of so-called hypomethylating agents such as 5-azacitidine and decitabine (which may in fact not truly act by reducing global methylation) has been variable.

A second type of epigenetic regulation involves the biochemical modification of histones, the structural protein complexes that form scaffolding for chromatin packaging. The interaction between histones and chromatin represents an additional level of transcriptional control, in which unwinding of chromatin is required for the transcription machinery to physically access DNA. The dynamics of chromatin-histone interactions are largely mediated by complex biochemical modifications of specific histone amino acids. In MDS and other myeloid disorders, these modifications can either be affected directly by mutations in genes coding for histone-modifying enzymes or indirectly by the permutation of biochemical pathways that regulate the balance between open and closed chromatin.

TET2

TET2, which encodes a member of the Ten-Eleven Translocation gene family, is the most commonly mutated epigenetic regulator in MDS.⁹⁷ *TET2* mutations occur in 20% to 30% of all MDS and are particularly enriched in CMML, where they can be found in 40% to 50% of cases.⁹⁸ The *TET2* protein is a methylcytosine oxygenase responsible for converting 5-methylcytosine (5mC) into 5-hydroxymethylcytosine (5hmC) using iron and α -ketoglutarate (α -KG, produced by *IDH1* and *IDH2*), and for further oxidizing 5hmC to 5-formyl- and 5-carboxycytosine.⁹⁹ These reactions are thought to contribute to active demethylation through base excision repair back to unmodified cytosine.¹⁰⁰ Mutations in *TET2* tend to be inactivating frameshift or nonsense mutations or specific missense substitutions predicted to lead to abrogation of protein function, and

many patients are either compound heterozygotes or have uniparental disomy (UPD) at chromosome 4q, leading to effective abrogation of *TET2* function.¹⁰¹ Indeed, patients with *TET2* mutations have been shown to have globally altered methylation profiles.¹⁰² *TET2* mutations often occur early in MDS pathogenesis and are thought to alter HSC homeostasis, a theory supported by the fact that HSCs in *TET2* knockout mice display enhanced self-renewal and repopulation capacity. In humans, however, *TET2* mutations do not appear to themselves confer a specific phenotype;⁷⁹ rather, they may create an epigenomic environment permissive to the acquisition of other mutations that are responsible for determining these factors. Recent evidence suggests that *TET2* mutations appear to predict a favorable response to hypomethylating agents, particularly in the setting of wildtype *ASXL1*.¹⁰³ *TET2* mutations were not previously felt to confer prognostic information, but newer data suggest that, at least in patients undergoing stem cell transplant, they predict an inferior outcome.¹⁰⁴

DNMT3A

DNMT3A is a member of the family of DNMTs, which catalyze the addition of methyl groups to cytosine residues of CpG dinucleotides. These dinucleotides tend to cluster in 5' promoter regions upstream of genes, and increased methylation of these CpG islands is associated with decreased expression of the associated downstream gene.¹⁰⁵ The observation that many cancers often display aberrant methylation relative to healthy tissue has led to the hypothesis that hypermethylation, particularly in the promoters of tumor suppressor genes, plays a role in cancer pathogenesis. This hypothesis has been somewhat supported by the efficacy, albeit imperfect, of so-called hypomethylating agents like decitabine and 5-azacitidine in MDS and AML (see section on Therapy, later).

The *DNMT3A* gene consists of 29 exons and encodes a 908-amino acid protein that, along with *DNMT3B*, is one of the two enzymes responsible for de novo CpG methylation independent of replication, whereas a third methyltransferase, *DNMT1*, is responsible for maintenance of baseline hemimethylation during active replication. Only *DNMT3A* mutations, however, have been found to occur recurrently in myeloid malignancies, perhaps suggesting differential expression in hematopoietic cells. Analysis of *DNMT3A* mutations in patients with MDS has shown a preponderance of missense single nucleotide variations predicted to alter protein function, although nonsense mutations, insertions, and deletions (indels) have been observed as well. The mutations occur throughout the gene, although a mutational hotspot at R882H, in the methyltransferase domain, has been described in a minority of MDS patients.¹⁰⁶ In AML, the R882H mutant protein has been shown to inhibit wildtype *DNMT3A*, suggesting a dominant negative mechanism.¹⁰⁷

In earlier studies, *DNMT3A*-null HSCs transplanted into mice displayed aberrant global methylation patterns, increased self-renewal, and impaired differentiation capacity compared to wildtype HSCs, but the mice themselves did not develop dysplasia or other hematologic malignancies.¹⁰⁸ In more recent studies, however, mice transplanted with *DNMT3A*-null HSCs had shortened overall survival and developed a spectrum of hematopoietic malignancies similar to that seen in humans, including leukemia and MDS.¹⁰⁹ The different outcomes in these two studies is thought to be caused in large part by the fact that mice in the older experiments were serially transplanted at 18 weeks, before they had a chance to develop overt hematologic disease, whereas mice in the later experiments were observed for 6 months. The long latency to development of malignancy in these experiments may speak to the subtlety of the epigenomic abnormalities initially conferred by acquisition of *DNMT3A* mutations.

In humans, the significance of *DNMT3A* mutations in the pathogenesis of MDS is not clear. They occur with somewhat less frequency than the most common recurrent mutations (between 8 and 13% in most studies^{80,110} although some studies have quoted much lower frequencies below 5%).¹¹¹ On the other hand, clonal

DNMT3A mutations have recently been shown to exist with modest frequency in healthy older adults and are in fact significantly more common than mutations in any other single gene,³¹ with an overall frequency that is significantly higher than their aggregate representation among hematologic malignancies. This discrepancy could either reflect the same long latency of *DNMT3A*-mutated hematologic malignancy that was observed in mouse models, or it could suggest that *DNMT3A* mutations have a relatively less potent pathogenic effect than some other genes (e.g., *TET2* mutations, which are less frequent in the general population but more frequent in MDS).

DNMT3A mutations appear to be negatively correlated with mutations in certain other genes, particularly *SRSF2* and *ASXL1*,⁸⁰ and in low-risk MDS they seem to have a positive correlation with *SF3B1* mutations.¹¹² There is evidence that *DNMT3A* mutations confer a poor prognosis in cytogenetically normal AML,¹⁰⁶ but that prognostic significance so far has not been convincingly shown to apply to *DNMT3A*-mutated MDS.

ASXL1

ASXL1 codes for a polycomb chromatin-binding protein and is involved in epigenetic regulation of gene expression. It acts as a co-activator of the retinoic acid receptor and directly interacts with chemical modifiers of histones (e.g., NCOA1, a histone acetyltransferase, and LSD1, a histone demethylase). *ASXL1* mutations occur in about 10% to 29% of total MDS and myeloproliferative neoplasm (MPN),¹¹³ 17% of AML, and 40% of CMML.¹¹⁴

The specific mechanisms by which *ASXL1* mutations affect the development of MDS are not clear. The first mice engineered to have constitutive *ASXL1* germline insufficiency survived to adulthood with relatively mild lymphopenia and modest splenomegaly, and did not develop myelodysplasia.¹¹⁵ Subsequently, *ASXL1* mutations were found to confer global reduction H3K27 trimethylation by disrupting normal recruitment of polycomb repressive complex 2 (PRC2), which places the H3K27 mark in vivo.¹¹⁶ This was followed by a more physiologic attempt at conditional *ASXL1* knockout in murine hematopoietic cells, which did induce abnormal myeloid differentiation that was compounded by additional loss of *TET2*. In this study, *ASXL1*-deficient cells displayed differential expression of a set of genes largely related to hematopoietic differentiation.¹¹⁷

In humans, most MDS-associated *ASXL1* mutations affect the C-terminal portion of the protein, specifically the plant homeo protein interaction domain.¹¹⁸ This observation has led to speculation that the mutant protein retains DNA-binding activity and thus exerts a dominant-negative effect on wildtype *ASXL1*, which may not have been captured in the mouse experiments. In studies of MDS cohorts, investigators have observed that *ASXL1* mutations co-occur less frequently with certain other recurrent genetic lesions, particularly *DNMT3A* and *JAK2*.¹¹⁹ On the other hand, *ASXL1* mutations have been found to cooccur with both *RUNX1* and *TET2* abnormalities.¹²⁰ The most recent rigorous studies suggest that *ASXL1* mutations have a modestly poor prognosis, but tend to occur in patients with low IPSS scores who would otherwise be felt to have indolent disease, perhaps suggesting a more profound pathogenic effect than might be suspected.⁷⁹

EZH2

EZH2 encodes the catalytic subunit of PRC2, which promotes the di- and trimethylation of lysine 27 on histone 3 (H3K27). Locally, methylated H3K27 results in closed chromatin and transcriptional repression, and global H3K27 trimethylation in particular is associated with reduced pluripotency and cellular senescence, suggesting a role for *EZH2* in regulation of cell fate.¹²¹ Recent studies have shown that α -KG also regulates relative levels of methylation at this locus, suggesting a possible convergence with the TET2/IDH pathway.¹²² *EZH2* resides on the long arm of chromosome 7, and its loss has been hypothesized to be at least part of the reason 7q- is such a

deleterious cytogenetic occurrence in MDS,¹²³ though not all 7q deletions affect the *EZH2* locus.¹²⁴ Mutations in *EZH2* itself are found in 5% to 10% of patients with MDS⁸⁰ and 20% to 30% of patients with CMML.¹²⁵ Consistent with the model of *EZH2* as a negative regulator of pluripotency and survival, mutations tend either to be inactivating frameshift or nonsense mutations, or missense mutations concentrated in the gene's SET domain, which is critical for DNA binding.^{126,127} *EZH2* mutations confer a negative prognosis in MDS that appears to be independent of other prognostic factors, including the IPSS score, in part because they tend not to be associated with specific clinical characteristics that are incorporated into these systems.⁷⁹

IDH Genes

The isoforms of isocitrate dehydrogenase, encoded by *IDH1* and *IDH2*, are responsible for the conversion of isocitrate to α -KG, which as above is used by TET2 in the conversion of 5mC to 5hmC. Mutations in *IDH1* and *IDH2* lead to enzymes with neomorphic activity that convert α -KG to d-2-hydroxyglutarate, which accumulating data suggests is an oncometabolite that can inhibit both TET2 and other epigenetic enzymes, including prolyl hydroxylases and a number of histone demethylases.¹²⁸ Mutations in *IDH1/2* and other members of the IDH pathway (including *WT1*) have repeatedly been shown to be important in AML,¹²⁹ but *IDH* mutations are relatively infrequent in MDS, occurring in 5% or fewer of patients.^{79,80} Both *IDH1* and *IDH2* mutations can cooccur with most other recurrent mutations besides *TET2*, with which they are essentially mutually exclusive.

Transcription Factor Genes

Transcription factors represent a third class of genes commonly mutated in MDS. Similar to epigenetic and splicing genes, mutated transcription factors can have pleiotropic effects on a number of gene targets, and these mutations are indeed also often early events in MDS pathogenesis.

RUNX1

RUNX1 (formerly known as *AML1*) is the transcription factor gene most commonly mutated in MDS, and its biology is complex. It encodes the alpha subunit of the core binding transcription factor and is involved in determining the lineage fate of HSCs.¹³⁰ *RUNX1* was initially identified as one of the genes involved in two different common pathogenic translocations: t(8;21), found in AML, and t(12;21), found in acute lymphoblastic leukemia.^{131,132} Subsequently, germline point mutations in *RUNX1* were identified in autosomal dominant familial platelet disorder with propensity for AML,³⁸ and later as somatic events in both sporadic AML and MDS.¹³³ Reflecting the complexity of *RUNX1* biology, mutations occurring throughout the gene, can be either monoallelic or biallelic, and can be frameshift insertions or deletions or nonsense or missense substitutions.¹³⁴ However, most mutations appear to have an inactivating effect on *RUNX1* function, either by affecting the DNA-binding RUNT domain or by disrupting the C-terminal protein interaction domain.¹³⁵ Many of the remaining mutations outside these regions appear to affect RUNX1 interactions with epigenetic regulators like MLL, thereby affecting histone methylation.¹³⁶ Both clonal and subclonal *RUNX1* mutations appear to confer a poor prognosis in MDS patients, irrespective of other prognostic factors.⁷⁸

ETV6

ETV6 encodes an ets-like transcription factor with mostly repressive activity.¹³⁷ It is situated on the short arm of chromosome 12, and its

role in hematologic malignancy has been best characterized by its involvement in recurrent translocations, including t(3;12)(q26;p13)¹³⁸ and deletions of 12p.¹³⁹ In MDS, however, both missense and inactivating frameshift point mutations have been described as well. There is some data that the missense mutations, which mostly cluster in the DNA-binding ETS domain, have a dominant negative effect on the wildtype allele.¹⁴⁰ However, whether malignant transformation requires *ETV6* activity below a critical threshold remains unclear, as not all frameshift mutations occur with loss of heterozygosity (and some frameshifts can confer dominant negative function as well). *ETV6* mutations are relatively rare events in MDS, occurring in at most 5% of cases;⁷⁹ recently, familial cases of MDS and AML because of inherited *ETV6* mutations have also been described.³⁹

GATA2

GATA2 encodes a transcription factor with pleiotropic effects in early hematopoietic progenitor cells.¹⁴¹ In contrast to most other genes described here, acquired mutations in *GATA2* are quite rare, but there are a number of clinical syndromes associated with germline *GATA2* mutations, several of which involve a risk of developing MDS and AML. These include Emberger syndrome (congenital lymphedema and risk of AML),¹⁴² autosomal dominant monocytopenia and mycobacterial infection syndrome,¹⁴³ and dendritic cell, monocyte, B and natural killer (NK) lymphoid deficiency syndrome.¹⁴⁴ In addition, *GATA2* mutations have also been described in kindreds with no accessory phenotype beyond a strong history of early-onset MDS/AML.³⁷ Several phenotypic components appear to be dependent on the type of mutation. For instance, nearly all patients who develop MDS or AML have mutations in or immediately 5' to the second zinc finger domain, which tend to be missense substitutions predicted to affect DNA binding.¹⁴⁵ On the other hand, a second group of patients with truncating frameshift mutations in the N-terminal region of the gene tend to present at younger ages with more pronounced immune deficits, but have a lower risk of MDS or AML. Although the mechanism by which these patients develop MDS is not completely clear, the subset of patients with *GATA2* germline mutations who develop MDS or AML has been observed to acquire *ASXL1* mutations with frequency much greater than would be expected to occur by chance.¹⁴⁶

TP53

TP53 mutations occur in about 10% of patients with MDS, and as in other settings imply a poor prognosis and response to therapy.⁷⁹ They are closely associated with a complex karyotype and tend not to cooccur with other recurrent driver mutations.^{147,148} They frequently cooccur with del(5q) and may represent a progression pathway for patients with 5q- syndrome.¹⁴⁹ They are also frequently found in t-MDS and AML.⁴⁹ Recently, a small series of patients with t-AML showed that *TP53* mutations present in the leukemia were detectable in samples collected 3–6 years earlier, which in at least two patients predated their original chemotherapy.¹⁵⁰ This suggests that the expansion of rare preexisting clones harboring *TP53* mutations may be the leukemogenic mechanism in at least some patients with therapy-related disease, rather than accumulation of DNA damage induced by the chemotherapy itself.

Tyrosine Kinases and Growth Factor Receptors

Mutations in tyrosine kinase and growth factor receptor genes are typically associated with proliferative signals and occur in a wide range of myeloid malignancies, including AML (*FLT3*¹⁵¹), MPNs (*JAK2*¹⁵² and *MPL*¹⁵³), and mast cell disorders (*KIT*).¹⁵⁴ While they do occur in MDS, they are usually late, subclonal events that often mark progression to secondary AML.¹⁵⁵ A few of these deserve specific mention. Activating mutations in *NRAS* are the most frequent

tyrosine kinase mutations found in MDS,¹⁵⁶ but still only occur in about 5% of cases and as mentioned earlier, tend to begin as subclonal, proliferative events that frequently drive the transition to AML.¹⁵⁷ Best known for its role in MPNs, *JAK2* is mutated in about 3% to 5% of MDS, particularly RARS-T and CMML.¹⁵⁸ *JAK2* mutations in MDS tend not to be associated with overproduction of mature hematopoietic cells as they are in MPNs, likely as a consequence of concomitant biologic defects contributing to ineffective hematopoiesis.¹⁵⁹

Cohesin Complex Genes

Genes encoding members of the cohesin complex family, including *RAD21*, *STAG2*, *SMC3*, and *SMC1A*, are each mutated in a small minority of MDS cases, but collectively, cohesin mutations can be found in about 10% of MDS.¹⁶⁰ Their physiologic role is in the maintenance of chromatid structural fidelity, particularly during mitosis. How cohesin complex mutations affect MDS pathogenesis is not completely understood, since they do not appear to directly promote chromosomal instability. Clinical studies, however, have shown that they appear to be disproportionately associated with multilineage dysplasia, and confer inferior survival and an increased risk of progression to AML.¹⁶¹

Other Genes

The genes described previously collectively account for the majority of mutations found recurrently in MDS, but this list is certainly not exhaustive. Even very recent, broad surveys of patients with MDS using the most updated panels of gene mutations and high-resolution FISH and karyotyping have shown that between 10% and 20% of patients lack a detectable genetic abnormality.^{78–81} There are multiple possible explanations for this observation. For example, some of these patients may have other types of aberrations not captured by sequencing or karyotyping, such as small copy number abnormalities that might be detected by SNP arrays, which are not routinely performed in clinical practice. More likely, however, many of these patients probably have mutations in genes that are less frequently altered in MDS pathogenesis. Some of these mutations are in pathways represented by other, better-known genes; for example, rare mutations have been described in *PTPN11*, a tyrosine phosphatase that acts as a downstream effector in the RAS pathway,¹⁶² and in *BRAF*, better known for its association with melanoma and hairy cell leukemia.¹⁶³ Similarly, rare mutations have been described in *EED* and *SUZ12*, other components of the PRC2 that affiliate with *EZH2* and collectively interact with *ASXL1*.¹⁶⁴ Other times, MDS can occur in the setting of mutations in genes better known for being associated with other diseases, such mutations in *CBL*, a gene better known for its association with juvenile myelomonocytic leukemia that encodes an E3 ubiquitin ligase responsible for degrading several tyrosine kinases.¹⁶⁵ Finally, mutations are occasionally described in relatively novel gene classes, including genes encoding the G-protein subunits *GNAS*¹⁶⁶ and *GNB1*¹⁶⁷ and the DNA repair enzymes *hOGG1*, *XRCC3*, and *XPB*.¹⁶⁸ Some patients may have mutations in other genes that have yet to be described. While it is unlikely that a major, frequently mutated pathway remains undiscovered in MDS, study of these low-frequency, “long-tail” mutations may yield valuable further insights into the molecular pathogenesis of the disease.

Karyotypic Abnormalities

Chromosomal abnormalities, larger-scale genetic aberrations that can be detected on either karyotype or FISH, are also common events in MDS.¹⁶⁹ The most common types of abnormalities in MDS are deletions or duplications of very large chromosomal regions; as opposed to some other hematologic cancers, translocations and

inversions are less common. Several of the most common karyotypic abnormalities have been shown to have prognostic value, and one, del(5q), has enough unique biologic features to be its own subclassification within the WHO criteria.

del(5q)

Interstitial deletion of the long arm of chromosome 5 [del(5q)] is the most common chromosomal abnormality in MDS,⁴² and del(5q) is the only karyotypically-defined subtype recognized by the WHO.¹⁷⁰ Although the specific region affected varies between patients, there are two commonly deleted regions (CDRs), one on 5q31.1 and the other at 5q32-33.3, with most patients having a deletion that includes both CDRs.¹⁷¹ MDS patients in whom del(5q) is the sole karyotypic abnormality often display the “5q-minus syndrome,” which is clinically characterized by anemia, normal or elevated platelet count, female predominance,¹⁷² lower risk of transformation to AML, and a striking response to lenalidomide.¹⁷³

Our understanding of the pathobiology underlying del(5q) MDS has improved substantially over the past several years; a key observation was the lack of recurrent point mutations in genes located on 5q in other patients with MDS, which, coupled with the fact that most patients with del(5q) retain one normal chromosome 5, suggested that the pathobiology could be best explained by haploinsufficiency of deleted genes.¹⁷⁴ Indeed, it now appears that different genes lost in the CDRs are responsible for different aspects of the 5q- phenotype. For instance, haploinsufficiency of *RPS14*, a ribosomal subunit gene located at 5q31.2, leads to p53 activation in erythroid progenitors and is responsible for the dyserythropoiesis seen in the syndrome,¹⁷⁵ and deletion of a key microRNA, miR-145, is responsible for the megakaryocytic component of the phenotype.¹⁷⁶ Separately, haploinsufficiency of *CSNK1A1*, which is located at 5q32 and encodes casein kinase 1-alpha, is responsible for the sensitivity to lenalidomide, which accelerates the ubiquitination and degradation of remaining casein kinase 1-alpha through a cereblon-dependent process.¹⁷⁷ Other studies have suggested that additional genes on 5q, including *EGRI*, *APC*,¹⁷⁸ *HSPA9*,¹⁷⁹ *NPM1*,¹⁸⁰ and others¹⁸¹ may contribute to features of the disease via a similar mechanism of haploinsufficiency in select cases.

These points apply only to del(5q) as a sole karyotypic abnormality in MDS. When del(5q) is found with other chromosomal abnormalities, especially in the context of a complex karyotype (three or more karyotypic abnormalities, a finding often associated with TP53 mutations or 17p loss), the prognosis is poor and the response to lenalidomide seen in 5q- syndrome usually does not exist.¹⁴⁹ Cooccurrence of del(5q) with TP53 mutation or 17p loss, in fact, occurs more frequently than would be expected by chance, suggesting cooperativity of the two abnormalities. Del(5q) seen in the context of AML, even if the sole karyotypic abnormality, is a universally poor prognostic sign.¹⁸²

Chromosome 7 Abnormalities

Deletion of one entire copy of chromosome 7 (i.e., monosomy 7) is also characteristic of MDS and portends a poor prognosis.¹⁸³ The pathogenesis of chromosome 7 abnormalities is incompletely understood. Several genes recurrently mutated in MDS, including *EZH2*,¹²³ *MLL3*,¹²⁴ and *CUX1*,¹⁸⁴ lie on 7q, and it has been hypothesized that loss of some or all of chromosome 7 contributes to MDS pathogenesis via a haploinsufficiency mechanism similar to that seen in del(5q). If such a mechanism exists, however, the evidence supporting it has not yet been produced. Part of the difficulty in proving its existence lies in the fact that unlike del(5q), there is no common deleted region on chromosome 7 in which to focus efforts at driver gene discovery.¹⁸⁵ It is important to note that in the revised IPSS (IPSS-R), del(7q) is considered to be an intermediate-prognosis abnormality distinct from monosomy 7, which is classified as poor prognosis.¹⁸⁶

Trisomy 8

Trisomy 8 is present in about 5% of MDS patients and can be found in a wide range of other myeloid disorders, including AML, MPNs, and aplastic anemia. In MDS, it can often be seen as a late, subclonal event.¹⁸⁷ Although its contribution to pathogenesis is incompletely understood, MDS patients with trisomy 8 appear to upregulate *WT1*, an oncogene that can be mutated in AML (but very rarely in MDS), which may behave as a neoantigen that stimulates the expansion of oligoclonal CD4⁺ and CD8⁺ T cells.¹⁸⁸ Some evidence suggests that these populations may contribute to impairment of hematopoiesis in MDS patients with trisomy 8,¹⁸⁹ which may explain why some patients with isolated trisomy 8 can have substantial responses to immune suppression with antithymocyte globulin (ATG).¹⁹⁰ Trisomy 8 has also been associated with the development of paraneoplastic autoimmune phenomena, such as Behçet disease,¹⁹¹ again reflective of the immune dysregulation characteristic of this cytogenetic abnormality.

del(20q)

del(20q) is an infrequent chromosomal aberration in MDS, occurring in about 2% of patients.¹⁹² Patients with del(20q) frequently have prominent thrombocytopenia, may have concomitant mutations of *U2AF1*, and appear to have an intermediate prognosis,¹⁹³ although 20q loss can also be a late event that indicates clonal progression of disease.¹⁹⁴ The best candidate driver gene lying within the common deleted region is a tumor suppressor gene known as *MYBL2*,¹⁹⁵ but recent studies suggest that in myeloid models, a reduction in *MYBL2* levels below what would be predicted for classic haploinsufficiency is required to drive clonal expansion.¹⁹⁶ Although *ASXL1* resides on 20q, it sits outside the CDR,¹⁹⁷ and most patients with 20q abnormalities do not have concomitant *ASXL1* mutations.

17p Deletions

Chromosome 17 abnormalities occur most often in MDS in association with complex karyotypes, which is most likely related to the fact that *TP53* resides within the common deleted region on 17p.¹⁴⁷ In MDS, many patients with loss of 17p will have an inactivating mutation of their remaining copy of *TP53*, implying that haploinsufficiency is not in and of itself enough to drive pathogenesis.¹⁹⁸ At the same time, patients almost never lose both copies of 17p as part of a larger chromosomal event, suggesting that some other gene or genes in this region may be essential for hematopoietic cell survival. As with *TP53* point mutations, loss of 17p is an exceedingly poor prognostic factor in MDS, is frequently seen in cases of therapy-related disease,⁵³ and often presages the development of treatment-refractory AML.¹⁹⁹

Complex and Monosomal Karyotypes

Complex karyotypes, meaning those with three or more cytogenetic abnormalities, are one of the more common abnormalities in MDS.¹⁶⁹ About half are associated with *TP53* mutations; conversely, many, but not all, patients with *TP53* mutations have complex karyotypes.¹⁴⁷ As opposed to 17p abnormalities, which are reflective of the *TP53* loss itself, complex karyotypes are instead downstream effects of p53 loss and represent the type of structural DNA damage that would have triggered p53-mediated apoptosis in normal cells. The exceedingly poor prognosis associated with complex karyotypes is in fact probably a proxy for p53 loss; the half of patients with complex karyotypes who have intact p53 function appear to have prognoses similar to patients with normal cytogenetics. Monosomal karyotypes, defined as complete loss of at least two entire chromosomes or one monosomy plus one other abnormality, are also common and also tend to confer a poor prognosis, particularly when associated with monosomy 7 or monosomy 5.²⁰⁰ When monosomal and complex karyotypes occur together,

however, the monosomy does not appear to confer an additional poor prognosis beyond that of the complex karyotype.²⁰¹

Other Karyotypic Abnormalities

A number of other cytogenetic abnormalities have been repeatedly described in MDS, including $-Y$,²⁰² $\text{del}(13q)$,²⁰³ $\text{del}(11q)$,¹³⁹ $\text{del}(12p)$ or $\text{t}(12p)$,²⁰⁴ $\text{del}(9q)$,¹⁹² $\text{idic}(X)(q13)$,¹⁹² $\text{t}(11;16)(q23;p13.3)$,²⁰⁵ $\text{t}(3;21)(q26.2;q22.1)$,²⁰⁶ $\text{t}(1;3)(p36.3;q21)$,²⁰⁷ $\text{t}(2;11)(p21;q23)$,²⁰⁵ $\text{inv}(3)(q21q26.2)$ ²⁰⁷ and $\text{t}(6;9)(p23;q34)$.²⁰⁸ Most of these do not have specific phenotypes or associated with them, but some do confer prognostic information and are included in the IPSS-R. In particular, $-Y$ and $\text{del}(11q)$ are designated “very good” prognosis; $\text{del}(12p)$, $\text{del}(20q)$, isolated $\text{del}(5q)$, and normal karyotypes are considered “good” trisomy 8, $\text{del}(7q)$, isochromosome 17(q), trisomy 19, and trisomy 21 are considered “intermediate;” monosomy 7, double deleted (7q), derivative (3q), and complex karyotype with exactly three abnormalities are considered “poor,” and complex karyotypes with more than three abnormalities are considered “very poor.” In addition, finding any of these in the appropriate clinical context, regardless of whether they are known to carry prognostic information, is typically enough to warrant a diagnosis of MDS, even in the absence of clear morphologic dysplasia.

The Microenvironment in Myelodysplastic Syndrome

The malignant transformation of hematopoietic progenitors in MDS occurs not in isolation, but within the rich microenvironment of the bone marrow stroma, which has come to be known as the “hematopoietic niche.”²⁰⁹ Evidence has shown that under normal circumstances, hematopoiesis is in part regulated by paracrine signals released from nonhematopoietic mesenchymal cells,²¹⁰ and evolving data suggest that some of these processes are dysregulated in MDS. Early circumstantial clues came from findings that patients with MDS and other hematologic malignancies have abnormal circulating levels of cytokines known to affect hematopoiesis, including monocyte-colony stimulating factor, interleukin (IL) 1a, and granulocyte-monocyte colony stimulating factor (GM-CSF),²¹¹ and other studies have shown that hematopoietic cells from MDS patients respond abnormally to these cytokines compared to cells from healthy controls.²¹² More recent studies have shown that hematopoietic progenitor cells transplanted into older mice display a narrower range of clonal expansion than identical cells transplanted into younger mice, suggesting that an aging niche might exert selective pressure on dominant hematopoietic progenitor cell clones.²¹³ Furthermore, it has been discovered that conditional deletion of the gene encoding *dicer1*, a microRNA processing enzyme, in osteoprogenitor cells can induce myelodysplasia and secondary AML in mice;²¹⁴ concurrently, other studies have shown altered expression of *DICER* and *DROSHA*, another microRNA-processing enzyme, in mesenchymal cells of MDS patients.²¹⁵ Even more intriguing, it has recently been shown that introduction of an activating B-catenin mutation in mouse osteoblasts can induce the development of AML through induction of the Notch ligand *jagged1*, which leads to Notch activation in HSCs.²¹⁶ As tantalizing as these findings are, the extent of their pervasiveness across all MDS patients, and how microenvironmental alterations interact with the well-validated recurrent mutations found in hematopoietic cells, has yet to be determined. It is worth noting that HSC transplantation, which involves only the transplantation of hematopoietic elements and not stroma, can be curative for some patients with MDS, implying that at least in these patients, the niche is not sufficient to sustain disease.

Immune Dysregulation

In normal human tissues, both the innate and adaptive immune systems play important roles in identifying, isolating, and destroying early clones with malignant potential before they are able to transform

into clinically evident cancers. Perturbation of this immune response presumably allows the persistence and propagation of abnormal clones in MDS, but the extent to which this is pathogenically important is not clear.²¹⁷

Several aspects of innate immunity have been shown to be abnormal in MDS patients.²¹⁸ Some toll-like receptors, including TLR4, are overexpressed on MDS progenitor cells,²¹⁹ and increased TLR signaling has been associated with higher degrees of apoptosis and the development of cytopenias. In patients with $\text{del}(5q)$, loss of miRs 145 and 146a from the common deleted region has been shown to upregulate tumor necrosis factor (TNF) receptor-associated factor 6, a TLR adaptor E3 ubiquitin ligase, as well as Toll IL-1 receptor domain-containing adaptor protein (TIRAP), two important downstream effectors of TLR4.²²⁰ $\text{del}(5q)$ may also lead to the upregulation of CD14 on granulocytes via heterozygous loss of *mDia1*, a scaffolding protein involved in actin polymerization, which appears to confer abnormalities of the innate immune response.²²¹ More recently, myeloid-derived suppressor cells have been shown to be significantly expanded in some patients with MDS, and increased signaling in these cells via interaction with S100A9, an important inflammatory mediator, has been shown to similarly stimulate inappropriate apoptosis in hematopoietic precursor cells.²²² Coincident with these findings, population-level data have suggested that patients with chronic inflammatory stimulation appear to be at increased risk of developing MDS and AML.²²³

Abnormalities in the adaptive immune system also exist in MDS. These have been particularly well described in hypoplastic variants, which have similarities to aplastic anemia at both the cellular and genetic level, and both can respond to immune suppression.²²⁴ More broadly, oligoclonal T-cell receptor gene rearrangements can be found in MDS patients of all subtypes,²²⁵ and clinically detectable abnormalities of NK-cell, B-cell, and T-cell number and function can be detected in a subset of patients as well.^{226–228}

Abnormal Apoptosis

Although MDS is typically characterized by normal or increased marrow cellularity, abnormalities of apoptosis are frequently described, particularly in low-risk variants, where increased apoptosis has been hypothesized to contribute to the development of ineffective hematopoiesis.²²⁹ There are two major mammalian apoptosis pathways. The death receptor pathway, also known as the external pathway, is triggered by ligation of TNF family members, which leads to the recruitment and activation of caspases at the cell surface.²³⁰ There is ample evidence of abnormalities in this pathway in MDS; for instance, TNF- α levels have been shown to be increased in all MDS subtypes,²³¹ and other proapoptotic cytokines, including IL-8, transforming growth factor β , interferon- γ , and Fas ligand, have been shown to be elevated as well.²³² The other major apoptotic pathway, known as the BCL-2 or intrinsic pathway, involves a complex balance between proapoptotic (BAX, BAK, BAD, PUMA, and others) and antiapoptotic molecules (BCL-2, BCL-XL, MCL-1, and others),²³³ and has also been shown to be abnormal in MDS. For example, ratios of proapoptotic (Bax/Bad) to antiapoptotic (Bcl-2/Bcl-XL) molecules are elevated in patients with lower-risk subtypes of MDS (RA and RARS), but the ratio reverses in RAEB and secondary AML, primarily driven by increased BCL-2 expression.²³⁴ Coordinate with this observation, but somewhat paradoxically, inhibition of apoptosis by BCL-2 appears to prevent leukemic transformation in murine models of MDS.²³⁵ Preclinical studies further suggest that inhibition of BCL-2 and other antiapoptotic molecules may delay progression of disease²³⁶ and may sensitize MDS cells to hypomethylating agents such as azacitidine, but clinical trials combining these approaches have not yet been performed.²³⁷

Transformation to Acute Leukemia

Although MDS and AML are often uttered in the same breath and conceptualized as two facets of a similar disease process, this is an

overly simplistic view that ignores the complexity and heterogeneity of each disease on its own.⁸² Although MDS can and often does transform into secondary AML, other types of de novo AML are biologically quite distinct from MDS, and conversely, some low-risk forms of MDS are biologically distinct from secondary AML. At the same time, however, there is a continuum between the two diseases that is only now starting to become fully understood. Recently, for instance, it has been shown that cases of AML harboring mutations in any of eight genes (*SF3B1*, *SRSF2*, *U2AF1*, *ZRSR2*, *ASXL1*, *EZH2*, *BCOR*, or *STAG2*) are highly likely to have evolved out of MDS, even when no antecedent stage of MDS was clinically evident.¹⁴⁸ The converse, that AML with driver mutations in other genes must have arisen de novo, is not necessarily true; *NPM1* mutations appear to be restricted to de novo AML, but mutations in *DNMT3A*, *TET2*, and *IDH1/2* can occur in both secondary and de novo AML and thus do not appear to be ontogeny-specific. In this study, *TP53*-mutated AML comprised its own category and was associated with prior chemotherapy and complex karyotypes, consistent with prior studies.

Understanding this shared genetic basis of MDS and secondary AML has also shed light on the transition from one to the other. Although the eight genes defining secondary ontogeny (i.e., disease arising from antecedent MDS) have different functions, they all tend to have broad, pleiotropic effects and for the most part have in mouse models been shown to be insufficient for leukemogenesis when they occur in isolation. The fact that they occur infrequently in de novo AML may imply that they have effects strong enough to commit cells to an MDS phenotype, with increased self-renewal and inhibitory effects on differentiation and hematopoiesis, whereas *TET2* and *DNMT3A* mutations may have more subtle effects that increase self-renewal but do not in and of themselves predispose to a specific phenotype in the absence of specific secondary mutations.

In most cases, progression of MDS to AML involves the acquisition of proliferative mutations, which tend to be late, subclonal events.²³⁸ These mutations frequently occur in tyrosine kinase genes like *FLT3*,¹⁵⁵ *NRAS*,²³⁹ or *KIT*,²⁴⁰ or in certain transcription factor genes such as *CEBPA*,²⁴¹ and lead to constitutively activated growth and proliferative pathways. As discussed elsewhere, patients who develop secondary AML from an antecedent MDS tend to have a poorer prognosis, with both a lower rate of complete remission and a poorer overall survival, independent of remission, than patients with de novo AML.²⁴² In unselected populations, some of this difference in outcome can be explained by proximate characteristics of the secondary AML cohorts, which tend to be older and have more comorbidities, mirroring the demographics of the MDS population. However, patients with secondary AML have inferior outcomes even compared to age-matched controls with de novo AML,²³⁵ which has remained the case when redefining ontogeny based on the genetic stratification outlined earlier.²⁴³ This inferior outcome has been presumed to reflect the intrinsic refractory nature of the antecedent MDS, and this presumption is now being proven true by sequencing bone marrow samples from secondary AML patients who morphologically appear to be in remission—in fact, the proliferative mutations are often eliminated but the preexisting driver mutations remain, suggesting that chemotherapy simply reverted the marrow to the preexisting clonal state.^{58,148} Overcoming the intrinsic resistance to therapy that appears to be common to most patients with MDS remains one of the central challenges of treating the disease.

Integrating the Pathobiology of Myelodysplastic Syndrome

With the continuous, deepening accumulation of data describing the pathogenesis underlying MDS, one of the central future challenges will be integrating these data into coherent models that correctly reflect fundamental aspects of the disease. The need for integration is twofold. First, there is a need to integrate disparate components of the biology itself, including somatic mutations, changes in gene expression, epigenetic disruption, and cell-cell interactions within the

marrow microenvironment and beyond. Second, it will also be necessary to integrate these biologic storylines with clinical information, in the hope that a fuller understanding of MDS biology may uncover new treatment approaches and better predictive and prognostic models than do single biologic features alone. Such work is already beginning; for instance, a recent report suggested that an algorithm integrating sequencing for common driver mutations with principal component analysis of gene expression better predicts some clinical features of MDS than sequencing or expression data considered in isolation, and the algorithm outperformed the IPSS in predicting overall survival (76% versus 64% accuracy).²⁴⁴ Thus far, however, these types of integrative studies remain in relative infancy. Making significant gains in this type of deep understanding will be a substantial undertaking, requiring large, well-coordinated clinical trials with rigorous banking of serial blood and marrow samples, careful annotation of clinical features and outcomes, and intensive collaboration between academics, industry, and clinicians in devising strategies for rationally targeting key elements of MDS biology.

CLINICAL FEATURES OF MYELODYSPLASTIC SYNDROME

Compared to other hematologic disorders, the clinical features of MDS are often underemphasized relative to laboratory aspects of the disease. This is in part because of the fact that the major common physiologic defect, ineffective hematopoiesis, usually leads to somewhat vague signs or symptoms. Nevertheless, it is important to understand these features within the context of the disease's pathogenesis and management. Some patients with MDS have distinct clinical phenotypes that are largely related to genetics or specific pathologic features. MDS can also coexist with other hematologic malignancies, including multiple myeloma (even in previously untreated patients)²⁴⁵, hairy cell leukemia,²⁴⁶ chronic lymphocytic leukemia (CLL),²⁴⁷ non-Hodgkin lymphoma,²⁴⁸ and large granular lymphocyte leukemia (LGL).²⁴⁹ Parsing the components of presentation that could be caused by a coexisting process (e.g., in a patient with both MDS and CLL, which is the primary contributor to the patient's cytopenias?) is an important task for clinicians and pathologists.

Differential Diagnosis

In the absence of clonal markers or excess blasts, MDS is a diagnosis of exclusion, requiring that other potential contributors to cytopenias and myelodysplastic morphology be ruled out to the greatest extent possible.²⁵⁰ Since cytopenias are the most common presenting clinical feature, the differential diagnosis is in theory broad and includes numerous other entities covered in more detail elsewhere in this book. In practice, however, all patients suspected of having MDS should undergo a bone marrow aspirate and biopsy, since the diagnostic criteria are almost entirely pathologic and marrow findings are critical for risk stratification and treatment planning.

Several nutritional deficiencies can cause cytopenias and morphology similar to MDS. Folate deficiency can cause macrocytosis and, in extreme cases, megaloblastic morphology in the marrow.²⁵¹ Vitamin B₁₂ (cobalamin) deficiency is a more classic cause of megaloblastic changes, and patients with severe B₁₂ deficiency can have bizarre morphology with an abundance of early forms that can occasionally be confused with evolving AML, especially erythroleukemia.²⁵² Since the hematologic changes of B₁₂ deficiency can occur in the absence of classic neurologic symptoms, B₁₂ and folate levels should be checked on all patients in whom a potential diagnosis of MDS is being entertained, and methylmalonic acid and homocysteine levels may help clarify whether deficiency is truly present in cases with borderline levels.²⁵³

Copper deficiency is less common than B₁₂/folate deficiency, but can also be mistaken for MDS. It classically arises in patients who have had gastrectomies or certain forms of gastric bypass surgery, particularly biliopancreatic diversion,²⁵⁴ and can also develop in patients taking high doses of zinc, which competes with copper for

absorption in the small bowel²⁵⁵ (it is important to note that newer forms of gastric bypass, including gastric sleeve procedures and newer iterations of the roux-en-y, maintain small bowel absorption such that patients do not typically develop copper deficiency). Clinically, patients with copper deficiency develop an anemia that can be normocytic or macrocytic and can occasionally be profound. Mild neutropenia can also be seen, while clinically significant thrombocytopenia is rare.²⁵⁶ Such patients can also develop neurologic symptoms similar to those seen in vitamin B₁₂ deficiency, including peripheral neuropathy, myelopathy, demyelination, and rarely optic neuritis.²⁵⁷ In the marrow, copper deficiency is classically associated with ring sideroblasts and erythroid and neutrophil vacuolization.²⁵⁸ In the right clinical setting, negative testing for somatic *SF3B1* mutations in the presence of definite ring sideroblasts should elevate the degree of suspicion.

Alcohol is a common cause of hematologic abnormalities, especially macrocytic anemia, even in the absence of folate or vitamin B₁₂ deficiency.²⁵⁹ Bone marrow examination often reveals sideroblastic changes, and sometimes megaloblastic morphology, but frank dysplasia is uncommon.²⁶⁰ Patients with borderline marrow findings who are suspected of significant alcohol intake should be advised to completely abstain from drinking (such advice is occasionally heeded), with a repeat marrow examination in 2–3 months.

Other drugs and toxins have also been associated with dysplastic changes in the marrow. Well-described offenders include valproic acid,²⁶¹ mycophenolate mofetil,²⁶² ganciclovir,²⁶³ alemtuzumab,²⁶⁴ nucleoside analogues such as fludarabine²⁶⁵ and cytarabine, and the antimetabolites mercaptopurine and methotrexate.²⁶⁶ These tend to cause macrocytic anemias and can also cause neutropenia and thrombocytopenia. On the other hand, isoniazid²⁶⁷ and chloramphenicol,²⁶⁸ and to a lesser extent cycloserine²⁶⁹ and pyrazinamide,²⁷⁰ have been associated with modest sideroblastic anemia. The anemia associated with isoniazid, in particular, can often be reversed with high doses of vitamin B₆ (pyridoxine).²⁷¹ Chloramphenicol can separately cause an idiosyncratic pancytopenia that is particularly distinguished by prominent vacuolization of erythroid precursors.²⁷²

Among infectious agents, HIV infection has specifically been associated with dysplastic changes in the marrow. Patients typically have hypercellular marrows with evidence of trilineage dysplasia most predominant in the erythroid line.²⁷³ The erythroid hematopoiesis almost always is megaloblastic, and reticulated fibrosis is often seen in bone marrow biopsies. The marrows also often have polyclonal plasma cell expansion, lymphoid aggregates, and granulomas are often seen. The differential diagnosis of erythrodysplasia in patients with HIV infection includes the influence of medications, opportunistic infections, or a direct effect of HIV on the hematopoietic progenitor cells.²⁷⁴ Since the US Preventive Services Task Force now recommends a one-time HIV test for all adults,²⁷⁵ essentially all patients in whom MDS is being considered should be tested to rule out HIV.

Other primary hematologic disorders are also on the differential diagnosis with MDS. Hypoplastic MDS, for example, can be difficult to distinguish from aplastic anemia and in the absence of characteristic cytogenetic or genetic abnormalities.²⁷⁶ Similarly, some patients with MDS may have a significant degree of co-existing fibrosis, which can complicate the distinction from a myeloproliferative disorder.²⁷⁷ Again, genetic analysis may help make this distinction clearer.²⁷⁸

Signs and Symptoms

Signs and symptoms of MDS are typically vague. Although some patients profess to being asymptomatic, fatigue is extremely common, as is a sense of general malaise.²⁷⁹ Rarely, patients may complain of diffuse arthralgias that can lead to suspicion for an underlying rheumatologic disorder like systemic lupus erythematosus.

Smaller proportions of patients may present with severe or recurrent infections as a result of immune defects,²⁸⁰ most commonly neutropenia. Bleeding or easy bruising as a result of thrombocytopenia or qualitative platelet defects also bring some patients with MDS

to medical attention.²⁸¹ When present, fever is most commonly a sign of infection, though a small number of patients may run low-grade fevers in the absence of a discernible infection. Splenomegaly or hepatomegaly are rare and should prompt consideration of either an alternate diagnosis or an MDS/MPN overlap syndrome.

Dermatologic Manifestations

Although dermatologic manifestations of MDS are uncommon,²⁸² a few deserve specific mention. Neutrophilic dermatosis (Sweet syndrome) is characterized by painful plaques on the face, neck, or extremities, often in association with fever and diffuse arthralgias.²⁸³ While neutrophilic dermatosis can be seen in any subclass of MDS, it is classically associated with an impending transformation to AML. It frequently responds to steroids or dapson therapy, but may recur as steroids are tapered.²⁸⁴ Recently, Sweet syndrome in MDS patients has been associated with heterozygous mutations in *MEFV*, a gene linked to Mediterranean fever.²⁸⁵

Pyoderma gangrenosum (PG) is an ulcerative, necrotic lesion that most frequently develops on the extremities.²⁸⁶ Histologically it is also characterized by neutrophilic infiltrates; clinically, it may be associated with pathergy and frequently develops at the site of recent minor trauma, such as intravenous (IV) catheter insertion sites. PG can be associated with a wide range of underlying conditions other than MDS. A high index of suspicion is necessary to distinguish it from necrotizing infections, since treatment of PG involves systemic steroids, and surgical debridement is contraindicated.

Other dermatologic manifestations of MDS include monocytic infiltrates, classically of the gingiva and other mucosal surfaces, a process most frequently seen in CMML;²⁸⁷ the development of a chloroma or granulocytic sarcoma, which by definition implies progression to AML; and petechial lesions, which most frequently develop on the lower extremities and imply severe thrombocytopenia.

Autoimmune Manifestations

A percentage of patients with MDS may have overlapping immunologic or rheumatologic features to their disease, which may in part arise from the immune dysregulation that occurs during disease pathogenesis.²⁸⁸ In a few patients, these may be the presenting complaint. Such manifestations can include episodes of seronegative oligoarthritis or polyarthritis,²⁸⁹ cutaneous vasculitis,²⁹⁰ polymyositis,²⁹¹ or autoimmune peripheral neuropathies. Rare patients can present with a lupus-like syndrome that can include fever, polyarthralgias, polychondritis, pleuritis, pericarditis, and cytopenias (including hemolytic anemias). Other autoimmune phenomena have also been reported, including mucocutaneous ulcerations, iritis, polymyositis, inflammatory bowel disease, and erythrocyte aplasia. Many of these, which are essentially paraneoplastic syndromes, respond to the initiation of immunosuppressive agents such as corticosteroids.²⁹²

Some reports have additionally documented cases of patients who were diagnosed with rheumatologic conditions only weeks or months before they were found to have MDS, including relapsing polychondritis,²⁹³ polymyalgia rheumatica or temporal arteritis,²⁹⁴ Raynaud phenomenon, Sjögren syndrome, and autoimmune glomerulonephritis.²⁹⁵ However, since some of these conditions are relatively common themselves, particularly in older populations, whether they represent a true association with MDS or are merely coincidental occurrences is not entirely clear.

Objective Findings: Erythroid Lineage

The majority of patients with MDS present with some degree of anemia, which contributes significantly to fatigue and lethargy, the most common presenting complaint.^{296,297} The anemia is often macrocytic, and the peripheral blood smears of MDS patients

Fig. 60.2 ERYTHROID DYSPLASIA. Examples of dysplastic erythroid precursors (*bottom*) compared to those with normal morphology in the sequence of erythroid maturation (*top*). The dysplastic forms include (*left to right*) abnormal immature forms with multinucleation; maturing forms with multinucleation and nuclear-to-cytoplasmic dyssynchrony; and more mature forms with megaloblastoid change, nuclear budding, cloverleaf forms, cytoplasmic vacuolization, and cytoplasmic stippling. Ringed sideroblasts (*far right*) also are evidence of erythroid dysplasia. Photomicrographs are from patients with refractory cytopenia with multilineage dysplasia and ringed sideroblasts.

frequently show a variety of abnormal forms, including oval macrocytes, and less commonly dacryocytes, elliptocytes, or acanthocytes.

Anemia in MDS is usually caused by ineffective hematopoiesis. Consequently, the erythropoietin (EPO) level is typically normal or modestly elevated, though in many elderly patients it is still lower than would be expected for the degree of anemia, in some cases because of subclinical renal insufficiency.²⁹⁸ The ineffective hematopoiesis causes abnormal iron utilization in a substantial number of patients, many of whom have evidence of iron overload based on ferritin or transferrin saturation.²⁹⁹ Studies have shown other abnormalities of erythrocytes as well, including increased levels of fetal hemoglobin,³⁰⁰ aberrant surface antigens,³⁰¹ increased osmotic fragility, and low levels of pyruvate kinase,³⁰² although none of these are routinely checked in clinical practice. Hemolysis is not routinely observed in MDS patients, but may occur in those with some of these latter abnormalities or with concomitant autoimmune disorders.

Morphologic changes in the erythroid lineage on bone marrow examination can vary widely from patient to patient. Many patients have megaloblastoid erythroid precursors that contain multiple nuclei or asynchronous maturation of the nucleus and cytoplasm (Fig. 60.2). It is this asynchrony, with continued membrane synthesis in the absence of normal nuclear maturation, which is thought to give rise to the macrocytosis displayed by most patients. Ring sideroblasts, erythroid precursors containing iron-laden mitochondria, are another relatively common finding.³⁰³ They are defined by the presence of at least five granules that are positive with the Prussian blue reaction and line at least one-third of the circumference of the cell nucleus. Ring sideroblasts are not in and of themselves diagnostic of MDS and can be seen in a number of other disorders (including congenital sideroblastic anemias and nutritional deficiencies), but their presence in association with other dysplastic changes is highly specific for MDS and, as described earlier, is tightly linked to acquired *SF3B1* mutations.⁸⁸ Ring sideroblasts may be seen in all subtypes of MDS; the specific designation of RARS is made when ring sideroblasts comprise at least 15% of the cellularity, blasts are not increased, and dysplasia in other lineages is minimal.

In a normal bone marrow, myeloid precursors typically outnumber erythroid precursors by a ratio of 2–4 to 1. A special case arises in cases of MDS in which this normal ratio is significantly skewed towards the erythroid lineage, that is, 50% or more of the total cellularity is erythroid. If in this case 30% or more of the remaining cellularity is comprised of myeloblasts, the case may be diagnosed as erythroleukemia (WHO AML, not otherwise specified, subtype acute erythroid leukemia, erythroid/myeloid type; formerly FAB-M6A).^{15,170}

Acquired hemoglobin H disease is a rare but well-described development in MDS that has been associated with acquired mutations of *ATR-X*,³⁰⁴ a gene encoding a chromatin-remodeling protein; when mutated in the germline, *ATR-X* has been associated with X-linked alpha thalassemia/mental retardation (ATR-X) syndrome. The pathogenesis of the syndrome is related to severe reduction in synthesis of alpha globin chains, and indeed, patients with acquired *ATR-X* mutations have clinical features resembling alpha thalassemia, including microcytosis, anisocytosis, poikilocytosis, target cells, schistocytes, dacryocytes, and beta-chain tetramers on crystal violet staining.³⁰⁵ As opposed to the macrocytosis seen in most MDS patients, those with acquired *ATR-X* mutations are typically profoundly microcytic, again similar to thalassemia.

Myeloid Lineage

About one-half of patients with MDS are neutropenic at the time of diagnosis.³⁰⁶ Many also have defective neutrophil function irrespective of the absolute neutrophil count (ANC), and patients with MDS have been shown to have inadequate inflammatory responses to infections. Many have diminished production of hematopoietic growth factors like granulocyte colony-stimulating factor (G-CSF) and GM-CSF, and their neutrophils often have reduced phagocytic, chemotactic, or bactericidal capabilities.^{307–309} In place of neutrophils, the proportion of monocytes is often elevated, which can sometimes be shown to have been the case for months or even years before diagnosis. Such a history can be observed patients with pure MDS, not just those with MDS/MPN overlaps like CMML.

The granulocytes of MDS patients also display frequent morphologic abnormalities (Fig. 60.3). In the marrow, either myeloid hyperplasia or hypoplasia can occur, and there is often a prominent left shift towards immature forms. Myeloid precursors often display asynchronous maturation of the nucleus and cytoplasm. In promyelocytes this can manifest as an early hypergranulation coupled with reticulated nuclei and a prominent Golgi apparatus, but more mature myeloid forms are usually hypogranulated and hypolobated. The myeloid series may also be abnormally localized: rather than differentiating in an organized fashion inwards from the endosteum, immature cells often cluster centrally in a morphologic process known as abnormal localization of immature precursors (ALIP).

Morphologic characterization of the myeloid series is particularly important with regard to the blast count, since $\geq 20\%$ myeloblasts is characterized as AML using the WHO classification, and $\geq 5\%$ qualifies as RAEB. Even patients with lower blast percentages, however,

Fig. 60.3 GRANULOCYTIC DYSPLASIA. Granulocytic dysplasia is most evident in mature neutrophils and can be contrasted to features of normal forms (*far left, top*), which are usually still present as a subpopulation of the total cells in most cases. Granulocytic dysplasia is characterized by (*left to right, starting at second column*) reduced cytoplasmic granulation, nuclear hypolobation (resulting in the binuclear or single-lobed pseudo-Pelger-Huët forms), hypersegmentation, ringed forms (“rodent cells”), cells with nuclear twinning, and cells with excessive nuclear excrescences. Photomicrographs are from a number of cases of refractory cytopenia with multilineage dysplasia and refractory anemia with excess blasts.

Fig. 60.4 MEGAKARYOCYTIC DYSPLASIA. Dysmegakaryopoiesis is most obvious with the presence of micromegakaryocytes and abnormal larger forms (*panels 2–5*). These are compared with a normal megakaryocyte at same magnification (*panel 1, far left*). Micromegakaryocytes have single, two, or four small nuclei, which indicate a low-ploidy level. Normal low-ploidy megakaryocytes can be seen in the bone marrow, but these are immature forms and do not have mature granular cytoplasm with platelet material, as do the micromegakaryocytes. Larger dysplastic megakaryocytes have multiple, small, widely spaced nuclei. Photomicrographs are from a number of cases of refractory anemia with excess blasts and refractory cytopenia with multilineage dysplasia.

still have an increased risk of developing AML, and some have proposed designating any MDS patient with more than 2% marrow blasts as having “oligoblastic leukemia.”³¹⁰ ALIP has been shown to occur in most cases of RAEB and in about a third of cases in which the blast percentage is less than 5%.³¹¹ In these latter cases ALIP has been shown to be an independent risk factor for subsequent development of AML.³¹²

In the peripheral blood, visible morphologic abnormalities include so-called pseudo Pelger-Huët cells, which have condensed chromatin and bilobed nuclei resembling an old-fashioned pince-nez (true Pelger-Huët cells are a benign congenital abnormality seen in children). Granulocytes may display other nuclear abnormalities as well, including hypersegmentation reminiscent of vitamin B₁₂ deficiency, and aberrant ring shapes. The hypogranulation visible in the marrow typically persists in the peripheral blood, and the left shift typical of MDS marrows is often, though not always, present to some degree in the blood as well.

Despite these quantitative and qualitative defects in leukocytes, only a minority of MDS patients have problems with recurrent infections.³¹³ When infections do occur, they tend to be bacterial and often arise from the lower respiratory tract, skin, and mucous membranes. Patients without absolute neutropenia may still develop recurrent infections as a consequence of abnormal neutrophil function. Even though only some patients have recurrent infections, an infection is the most common cause of MDS-associated death.

Megakaryocytic Lineage

Thrombocytopenia is present in 25% to 50% of MDS patients at the time of presentation,^{296,306} and some patients with normal platelet counts can have functional platelet defects.³¹⁴ Laboratory abnormalities include prolonged bleeding times, defective granulation, and abnormal platelet aggregation indices mediated by hypofunctional platelet glycoprotein IIb/IIIa, leading to what is known as a *Glanzmann-type defect*.^{315,316} These defects can occasionally manifest as spontaneous bleeding, or can be unmasked after trauma or surgery.

Thrombocytosis, by contrast, is relatively unusual in patients with MDS, except in those with MDS/MPN overlap syndromes, 5q-syndrome, or RARS-T.³¹⁷ *JAK2* mutations, in particular, are associated with thrombocytosis. Thrombocytosis can occasionally be subtle, especially in patients with advanced disease, in whom a normal platelet count may in fact represent a relative thrombocytosis counteracted by dwindling megakaryocytic reserves.

In the marrow, megakaryocytes are most commonly present in normal or increased numbers. A number of morphologic abnormalities can be observed, including abnormally small forms (micromegakaryocytes), hypersegmentation, and nuclear hypolobation (Fig. 60.4).^{318,319} Megakaryocytes may also be abnormally distributed in clusters scattered throughout the marrow in MDS, rather than their normal parasinusoidal positioning.

Lymphoid Lineage

A number of abnormalities in the lymphoid lineage have been described in subsets of patients with MDS. Some patients have been shown to have global decreases in NK cells,^{226,320} some have deficient receptor localization on B cells,²²⁸ and some have abnormal T-cell responses to mitogenic stimuli.²²⁷ Certain types of immune functions, however, appear to be preserved, such as antibody-dependent cellular cytotoxicity.³²¹

The mechanism by which these abnormalities develop in MDS is unclear. One hypothesis proposes that they could be indirectly reflective of shared somatic defects in a multipotent progenitor. Although this has not been directly proven, it is theoretically possible given data showing that most driver mutations in MDS patients are present in the long-term hematopoietic stem cells (LT-HSC) compartment and could therefore be passed both to myeloid and lymphoid cells.⁶⁴ Alternatively, a number of immune functions, including both B-cell and T-cell diversity, diminish as a function of normal aging,^{322,323} and in this context, deficiencies of immune function could develop as a consequence of lymphoid cells arising from and interacting with an abnormally aged hematopoietic niche.

Other Objective Findings

Patients with MDS may have a variety of other laboratory abnormalities as a consequence of their disease. Ineffective erythropoiesis may lead to inappropriate iron deposition, resulting in abnormally elevated ferritin and transferrin saturation.³²⁴ Nonspecific markers of cellular turnover, such as elevations in lactate dehydrogenase,³²⁵ uric acid, and phosphate, may also be seen. Reflective of underlying immune dysregulation, some patients may have abnormalities of immunoglobulins (Igs), including hypogammaglobulinemia, polyclonal hypergammaglobulinemia, and even monoclonal gammopathies.^{326,327} Whether this latter phenomenon is directly related to MDS or to an unrelated, early plasma cell dyscrasia has not been definitively established, and the answer may indeed be different in different patients.

DIAGNOSTIC SYSTEMS AND CLINICAL SYNDROMES

As discussed throughout this chapter, MDS is heterogeneous in both morphology and clinical course, a characteristic that requires diagnostic criteria sufficiently broad to capture the entire spectrum of disease, and diagnostic criteria are typically left purposefully vague to allow for inclusion of patients in whom a high suspicion of MDS exists but who do not specifically meet these formal criteria (Table 60.3). Patients with MDS typically have at least one persistent, otherwise unexplained cytopenia (hemoglobin less than 11 g/dL, ANC <1,500/mm³, or platelet count less than 100,000/mm³), plus one of the following: (1) ≥5% blasts in the bone marrow, (2) any of several chromosomal abnormalities that are found recurrently in MDS; (3) a meaningful degree of dysplasia, usually 10% or more, detectable in at least one cell lineage on bone marrow examination, or (4) other evidence of clonal hematopoiesis.¹⁷⁰ In the past this latter category has usually comprised either karyotype or FISH results demonstrating chromosomal abnormalities missed by conventional karyotype, but evidence of clonal hematopoiesis based on detection of recurrent somatic mutations may need to be considered as well. However, given that at least 10% of the population aged 70 or older harbor point mutations in genes associated with myeloid malignancies,^{31,32} detection of such a mutation in the absence of other diagnostic criteria cannot be considered equivalent to MDS.

As described elsewhere, the 2008 WHO criteria divide adult MDS into six general categories: RCUD (including RA, RARS, refractory neutropenia, and refractory thrombocytopenia), RCMD, RAEB-1, RAEB-2, MDS with isolated del(5q), and MDS-U. Despite the detail of the criteria, they still have a number of limitations, a fact that is probably inescapable when attempting to categorize a disease with so many disparate manifestations. The most obvious limitation is the

TABLE 60.3

Diagnostic Criteria for Myelodysplastic Syndrome

A. Presence of at Least One Unexplained Cytopenia for at Least 6 Months^a

Hemoglobin <11 g/dL, or

Absolute neutrophil count <1.5 × 10⁹/L, or

Platelet count <100 × 10⁹/L

plus B. Presence of One or More MDS-Qualifying Criteria:

>10% dysplasia in one or more hematopoietic lineage, or

5%–19% blasts in bone marrow, or

MDS-defining cytogenetic abnormality, such as:

t(1;3)(p36.3;q21.1) t(2;11)(p21;q23) inv(3)(q21;q26.2)

t(3;21)(q26.2;q22.1) –5 or del(5q) t(6;9)(p23;q34)

–7 or del(7q) del(9q)

del(11q) t(11;16)(q23;p13.3) del(12p) or t(12p)

–13 or del(13q) i(17q) or del(17p) idic(X)(q13)

plus C. Exclusion of Alternative Diagnoses

AML (i.e., <20% blasts, and no t(8;21), inv(16), t(16;16), t(15;17), or erythroleukemia) or ALL

Other hematologic diseases (aplastic anemia, PNH, LGL, lymphoma, myelofibrosis and other MPN)

Viral infections (HIV, EBV, parvovirus)

Nutritional deficiencies (iron, copper, B₁₂, folate)

Medications (methotrexate, azathioprine, isoniazid, cytotoxic chemotherapy)

Alcohol or other toxins

Autoimmune diseases (SLE, Felty syndrome, ITP, autoimmune hemolytic anemia)

Congenital disorders (Diamond-Blackfan anemia, Shwachman-Diamond syndrome, Fanconi anemia, and others)

^aDiagnosis can be made earlier than 6 months if no other cause is apparent for cytopenias, or there are excess blasts or an MDS-defining cytogenetic abnormality

ALL, Acute lymphoblastic leukemia; AML, acute myeloid leukemia; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; ITP, immune thrombocytopenic purpura; LGL, large granular lymphocyte leukemia; MDS, myelodysplastic syndrome; MPN, myeloproliferative neoplasm; PNH, paroxysmal nocturnal hemoglobinuria; SLE, systemic lupus erythematosus.

complexity of the criteria themselves, which can make them cumbersome for clinicians to use. Second, as described previously, there are a number of conditions that can mimic aspects of MDS, and the diagnostic criteria assume these diagnostic possibilities have been eliminated. Third, morphologic criteria are still based around strict, arbitrary percentages of dysplasia and blasts, which can be interpreted differently by different pathologists or may be vulnerable to sampling variations.^{328,329} Finally, although WHO criteria incorporate cytogenetics to a limited extent, the criteria have not yet been updated to include types of newer genetic results that have been shown to have diagnostic value, and it is likely that incorporating some of these features will improve diagnostic clarity. A 2016 revision of the WHO criteria eliminated the term “refractory anemia” so that, for example, RAEB-1 is now known as “MDS with excess blasts” (MDS-EB). This revision also noted that MDS with ring sideroblasts (MDS-RS) can be diagnosed with 5% to 14% ring sideroblasts if a somatic SF3B1 mutation is present; if SF3B1 is wild-type, at least 15% ring sideroblasts are needed.

IPSS and IPSS-R

Although the WHO classification system (and the FAB system before it) is the accepted standard for diagnosing MDS, it does not confer

TABLE 60.4 1997 International Prognostic Scoring System for Myelodysplastic Syndromes (IPSS)

Variable	Score			
	0	0.5	1	1.5
Marrow blasts (%)	<5	5–10	–	11–20
Karyotype	Good	Intermediate	Poor	–
Cytopenias	0–1	2–3	–	–

TABLE 60.5 Survival Based on International Prognostic Scoring System for Myelodysplastic Syndromes (Percent)

IPSS Risk Group	# Patients	2 Years	5 Years	10 Years	15 Years
Low	267 (33%)	85	55	28	20
Intermediate-1	314 (38%)	70	35	17	12
Intermediate-2	179 (22%)	30	8	0	–
High	56 (7%)	5	0	–	–

much specific prognostic information, and other systems have been developed expressly for this purpose. The most widely used has been the IPSS³³⁰ and its newer revised iteration, the IPSS-R.³³¹ The original IPSS was first published in 1997 and was derived by analyzing baseline characteristics in over 800 newly diagnosed MDS patients from all diagnostic categories. Patients were scored based on three characteristics: the percentage of blasts in the marrow, the presence of specific cytogenetic abnormalities, and the number of cytopenias in the blood. They were then stratified based on total score into four risk groups (low, intermediate-1, intermediate-2, and high) that were shown to have prognostic value, both in estimating the chance of progressing to AML and in estimating the duration of overall survival. This is shown in Table 60.4 and Table 60.5. The original IPSS excluded patients with t-MDS, patients with proliferative CMML, and patients who ultimately underwent allogeneic stem cell transplantation or other disease-modifying therapy.

The original IPSS had several limitations that ultimately necessitated its revision. First, it was formulated 4 years before the adoption of the first iteration of WHO classification criteria, and some of changes in those criteria (for instance, changing the cutoff for AML from 30% blasts to 20% blasts) effectively invalidated certain aspects of the IPSS. Furthermore, broad application of the criteria to larger populations of MDS patients began to reveal that the original IPSS gave insufficient weight to some important clinical features, particularly the presence of severe cytopenias. The IPSS was only validated in de novo disease, not t-MDS, and only in patients treated with supportive care alone. In response to some of these evident limitations, several alternative prognostic systems have been proposed over the last decade, but none of them have been widely adopted.^{332–334}

The IPSS-R (Table 60.6), which was introduced in 2012, revised the MDS blast cutoff to 20% and assigned a point for each individual cytopenia present at the time of diagnosis, stratifying on the basis of severity. Furthermore, it incorporated a broader range of cytogenetic abnormalities than the original IPSS, and stratified patients into five risk categories instead of four. The resulting system thus incorporates more informative biology and offers better refinement of prognosis than its predecessor.^{335,336}

The median survival times estimated by the IPSS and IPSS-R are largely reflective of natural history since they were originally derived in patients who did not receive any therapy for their MDS (Table 60.5). However, IPSS-R stratifications have been shown to retain relevance when applied to treated populations, including risk stratification of patients receiving hypomethylating agents³³⁷ and those who undergo allogeneic stem cell transplantation.³³⁸

Nevertheless, the IPSS-R still has prognostic limitations. It does not incorporate laboratory findings, such as lactate dehydrogenase

TABLE 60.6 2012 Revised International Prognostic Scoring System for Myelodysplastic Syndrome (IPSS-R)

Cytogenetic Risk	Included Karyotypic Abnormalities				
Very good	del(11q), –Y				
Good	Normal, del(20q), del(5q) alone or +1 other abnormality, del(12p)				
Intermediate	+8, del(7q), i(17q), +19, +21 Any other single or double abnormality Two or more independent clones				
Poor	der(3q), –7, double with del(7q), complex with exactly 3 abnormalities				
Very poor	Complex with >3 abnormalities

AML, Acute myeloid leukemia; NR, not reached.

and the serum ferritin, that have been shown to have independent prognostic value in dedicated studies. It does not capture the kinetics of disease or comorbid conditions. In addition, similar to the WHO classification criteria, IPSS-R does not include any molecular data other than cytogenetics.

Other Risk Stratification Systems

The limitations of the IPSS prompted attempts at more refined risk stratification using alternative models. Few of these have gained much traction in clinical practice but retain value for use in clinical trials and retrospective studies. For instance, a need for better stratification of lower-risk patients (i.e., IPSS-low or Int-1) led to the creation of the Lower-Risk Prognostic Scoring System (LR-PSS) by the MD Anderson group.³³² The LR-PSS uses criteria similar to the IPSS but sets lower thresholds for point assignment (e.g., 2 points for a platelet count <50 × 10⁹/L and 1 point for bone marrow blasts ≥4%). Subsequent studies have confirmed the ability of LR-PSS to risk-stratify patients, with those in the highest risk group having the greatest risk of developing AML, and the poorest overall survival,³³⁹ and addition of genetic sequencing has shown that in these low-risk patients, EZH2 mutations, though rare, portend a poor prognosis.¹¹² Other attempts to improve prognostic systems have included attempts to incorporate formal measures of comorbidity into the IPSS,³⁴⁰ and an attempt to combine the WHO classification system with the IPSS that has been dubbed the WPSS.³⁴¹ This latter system was formulated

before the introduction of the IPSS-R, but subsequent studies have suggested that the WPSS and the IPSS-R are about equal in their accuracy of predicting prognosis.³⁴²

Specific Clinical Syndromes

Although MDS is a heterogeneous disorder, it contains a number of specific entities, either defined by cytogenetics, pathologic findings, or clinical features, which possess distinctive clinical features or biologic behaviors. Some of these are discussed in more detail later.

The 5q- Syndrome

Patients with isolated loss of the long arm of chromosome 5 [so-called del(5q) or 5q minus syndrome] are a unique group whose biology is described in more detail earlier. Clinically, 5q- syndrome is characterized by a predominant anemia with preservation or even elevation of platelet counts, striking pathologic feature is the presence of mononuclear micromegakaryocytes identified in the bone marrow biopsy (Fig. 60.5A–C) and an indolent course with progression to AML in fewer than 25% of cases.^{343,344} For unclear reasons, it is more common in women, who comprise 60% to 70% of cases. The anemia in lower risk del5q MDS is usually very responsive to the initiation of lenalidomide,¹⁷³ which is discussed in more detail in the subsequent section on Treatment. Those patients who become refractory to lenalidomide

typically remain transfusion dependent, and management of iron overload then becomes increasingly important.

The designation of 5q- syndrome applies only to patients in whom loss of 5q is the only cytogenetic abnormality. Patients in whom 5q- is only one of several cytogenetic aberrations in fact tend to have a worse prognosis than average, with a more rapid progression to AML. As referenced previously, loss of 5q often occurs in tandem with *TP53* mutations (or loss of 17p), another poor-prognosis combination.¹⁴⁹

Hypocellular Syndromes

Most patients with MDS have hypercellular or normocellular marrows. Hypocellular marrows, in contrast, are found in fewer than 15% of patients, and delineate the entity of hypoplastic MDS (Fig. 60.5D–E).²²⁴ These patients have substantial overlap, both morphologically and clinically, with other hypoplastic syndromes, including aplastic anemia,³⁴⁵ paroxysmal nocturnal hemoglobinuria (PNH),³⁴⁶ and T-cell LGL.^{249,347} In fact, distinction between these entities can sometimes be difficult, as patients with MDS may occasionally have PNH or LGL clones detectable by flow cytometry, though these are usual small and transient. Some of the resemblance may in fact reflect a shared pathogenesis; for instance, studies have shown that a sizable minority of aplastic anemia cases harbor clonal somatic mutations in genes recurrently mutated in MDS, including *ASXL1* and *DNMT3A*,³⁴⁸ and that these patients have an inferior

Fig. 60.5 SPECIFIC MYELODYSPLASTIC SYNDROMES. The 5q- syndrome (A–C); hypocellular myelodysplastic syndrome (D and E), and myelodysplastic syndrome with fibrosis (F and G). The 5q- syndrome has specific morphologic correlates. There is a macrocytic anemia (A) and a cellular bone marrow characterized by increased small monolobated megakaryocytes (B and C). The megakaryocyte nuclei have little segmentation and are fairly round. Although some true micromegakaryocytes may be present (C, inset, same magnification), the typical monolobated forms are not as tiny as the micromegakaryocytes. Hypocellular myelodysplastic syndrome (D and E) can present a diagnostic problem and can be difficult to differentiate from aplastic anemia. Dysplasia may be difficult to evaluate if the smears are paucicellular. The finding of dysplastic megakaryocytes (note small widely separated nuclei, E) on the biopsy sample can be helpful. Myelodysplastic syndrome with fibrosis (F) can be difficult to differentiate from myeloproliferative neoplasms (MPNs). However, the lack of large megakaryocytes, which typically are seen in the MPNs along with presence of dysplasia in the circulating neutrophils (G) are useful clues to the correct diagnosis.

prognosis compared to patients with mutations in *PIGA* and *BCOR*.³⁴⁹ It is therefore possible that these studies are defining distinct disease processes within a homogeneous-appearing morphology, with *ASXL1* and *DNMT3A* mutations defining disease more similar to MDS, and *BCOR* and *PIGA* mutations defining disease more akin to true, immune-mediated aplasia. At the same time, finding somatic mutations characteristic of the alternative diagnoses (for instance, members of the telomerase family in aplastic anemia,⁴⁰ or *STAT3* mutations in LGL³⁵⁰) may clarify the picture as well.

Myelodysplastic Syndrome/Myeloproliferative Neoplasm Overlap Syndromes

Although previously included as a subtype of MDS, disorders with overlapping features of both MDS and MPN are no longer included in the WHO classification system and are now considered an entity unto themselves; they are discussed in more detail elsewhere.

Myelodysplastic Syndrome With Fibrosis

Marked fibrosis rarely occurs in cases of MDS (Fig. 60.5F–G) without myeloproliferative features, but when it does occur, it can be difficult to distinguish these cases from MPN.³⁵¹ Evaluation for somatic mutations may be helpful, since finding a *JAK2*, *CALR*, or *MPL* mutations is more common in pure MPNs than in MDS,³⁵² while certain other mutations, including *TET2* and *SRSF2*, are somewhat enriched in MDS-MPN overlap syndromes.^{101,353} On the other hand, extensive dysplasia is more suggestive of MDS. In addition, a few genetic lesions appear to be more specific for pure MDS syndromes, including *SF3B1* mutations and complex cytogenetics.

Patients with overlapping MDS and fibrosis often have severe, progressive cytopenias with evidence of myelophthisis on peripheral smear, but the splenomegaly associated with myelofibrosis in an MPN background is less common. Nevertheless, the prognosis for these patients appears to be relatively poor.

Therapy-Related Myelodysplastic Syndrome

t-MDS is a well-recognized and feared consequence of cytotoxic chemotherapy for other cancers, but the overall incidence is difficult to estimate.^{243,354} This is partly because of the fact that it is not usually reported as a distinct entity, and in part because it can be difficult to establish causality in all patients who develop MDS following treatment for a prior cancer. t-MDS has been best characterized in patients with a prior history of breast cancer,^{52,355,356} lymphoma,^{357,358} and myeloma,³⁵⁹ where the overall incidence is usually reported at around 1%. On the other hand, t-MDS is rare following treatment for other types of tumors, such as gastrointestinal and genitourinary cancers. This difference is largely attributed to differences in the types and intensities of chemotherapeutic agents used to treat different tumor types. In particular, high doses of alkylating agents, such as cyclophosphamide, ifosfamide, melphalan, and busulfan, have been associated with classic t-MDS,³⁶⁰ as has extensive radiation therapy.³⁶¹ A distinct, well-characterized class of therapy-related myeloid malignancies occur after treatment with topoisomerase inhibitors but largely consists of AML without an antecedent MDS phase.^{54,205,362}

t-MDS has a relatively distinct clinical behavior. It is typically characterized by a latency of years and recurrent large-scale chromosomal abnormalities, especially of chromosomes 5 and 7 or 11q23. Complex karyotypes are also common.³⁶³ These karyotypic abnormalities, which occur in only about 10% to 15% of patients with de novo MDS, have a frequency of around 50% to 70% in t-MDS. They tend to have a more aggressive clinical course than patients with de novo disease, with more frequent progression to acute leukemia. They also tend to respond poorly to all classes of treatment, and even for those patients who undergo allogeneic stem cell transplantation, relapse is not infrequent.³⁶⁴

As discussed elsewhere in this chapter, the mechanism of pathogenesis for t-MDS has long been thought to involve the acquisition of severe, large-scale chromosomal damage, a theory that is circumstantially supported by the mechanism of alkylators (which induce double-stranded DNA breaks) and the fact that many patients with t-MDS have complex karyotypes. On the other hand, it has previously been observed that some patients with t-MDS have point mutations in *TP53*, which would not be expected to directly arise from alkylator-induced damage,³⁶⁰ but which can lead to the acquisition of chromosomal rearrangements even in the absence of chemotherapy. Recent deep studies of a small group of patients with therapy-related AML harboring *TP53* mutations have shown that clones harboring the mutations preceded the development of leukemia by years, and in some cases could be detected before the original initiation of chemotherapy.¹⁵⁰ This recapitulates older data showing that cytogenetic abnormalities present in the bone marrow of patients who developed therapy-related leukemia after autologous transplant for lymphoma could be found in the stimulated autologous specimens, which had been banked years before the development of t-AML.³⁶⁵ These findings suggest an alternate method of t-MDS pathogenesis, in which rare clones harbor preexisting mutations that either confer a selective growth advantage during marrow reconstitution, tolerance of DNA damage that would otherwise trigger apoptosis, or both, thus promoting clonal selection and expansion upon exposure to chemotherapy.

Refractory Anemia With Ringed Sideroblasts and Thrombocytosis

Although thrombocytopenia is the most common platelet abnormality in MDS, rare patients present with marked thrombocytosis.³¹⁷ This most frequently occurs in the setting of RARS, and in the second iteration of the WHO criteria, these patients are classified as having RARS-T.³⁶⁶ On bone marrow examination, there are often features of both MDS, such as frequent ringed sideroblasts, and MPNs, such as megakaryocytic hyperplasia. Molecularly, patients often have concomitant *SF3B1* mutations, which drive the ring sideroblast morphology,³⁶⁶ and *JAK2* mutations, which drive the thrombocytosis and are otherwise uncommon in MDS.³⁶⁷ Patients meeting criteria for RARS-T are relatively uncommon and prognostic information is thus limited, but one small series of patients had better 5-year survival than matched patients with RARS, perhaps because the proliferative drive of the *JAK2* mutation helps preserve blood cell counts.³⁶⁸

TREATMENT OF PATIENTS WITH MYELOYDYSPLASTIC SYNDROMES

Treating patients with MDS presents a number of challenges. First, MDS patients are often elderly and thus frequently have serious comorbid conditions and poor performance status. Second, the protean nature of MDS, which is particularly heterogeneous even compared with other cancers, means that treatments appropriate for some patients may be unhelpful for others. Third, a number of biologic factors, most importantly the disease's origin in a quiescent stem cell, make MDS highly refractory to most conventional treatments like intensive cytotoxic chemotherapy (which many MDS patients are not healthy enough to receive anyway).

In addition, although the biology of MDS is increasingly well understood, most of the common derangements, like mutations in splicing factors and epigenetic regulators, have wide-ranging, pleiotropic effects that render narrowly targeted therapies infeasible. While some agents like hypomethylators and histone deacetylase inhibitors are matched to biologic processes that are frequently deranged in MDS, their usual clinical impact is modest at best. Allogeneic stem cell transplantation remains the only curative therapy for MDS, but is unavailable to many because of age and comorbidities, and even for those who undergo it, relapse is not uncommon.

Despite these challenges, all patients with MDS should be offered some form of therapy. For elderly patients or those with serious comorbid conditions who are too unwell to undergo active treatment, this may consist primarily of supportive care and possibly hospice or palliative care service referral. Other patients with lower-risk disease may benefit from a period of observation, or judicious use of transfusion and growth factor support, balanced in carefully selected cases with chelation therapy to prevent or relieve iron overload. Patients with higher-risk disease may derive benefit from treatment with hypomethylating agents or other conventional therapies, and those patients with high-risk disease who meet other selection criteria should be referred for consideration of hematopoietic stem cell transplantation (HSCT). Finally, patients should whenever possible be encouraged to participate in clinical trials to the extent that this remains consistent with their personal goals of care.

Once the decision to pursue active treatment has been made, there are at least three major points to consider. One is the choice of initial treatment modality, which is guided in large part by risk stratification. This should typically start by computation of the IPSS-R, but IPSS-R score should not be the sole consideration in choosing therapy; for instance, a very young patient with otherwise lower-risk MDS that has evolved quickly may still warrant consideration of a stem cell transplant, and an elderly patient with very high risk disease may nevertheless opt not to pursue treatment with a hypomethylating agent after a thorough discussion of the risks and potential benefits. Second, there are a number of special cases for which there is no clear consensus about the single best treatment strategy; these include patients with lower-risk disease who have a dominant cytopenia other than anemia, anemic patients with lower-risk disease who lack del(5q) but also have an elevated serum EPO, and patients with high-risk disease who have progressed on a hypomethylating agent but are not candidates for transplant.

Finally, since therapies other than allogeneic HSCT are rarely if ever curative, defining what constitutes a meaningful response can be a nontrivial endeavor. Objective criteria for response were proposed by an International Working Group (IWG) in 2000 and revised in 2006, and include hemoglobin, number of metaphases with abnormal karyotypes, and percentage of the marrow involved by blasts.³⁶⁹ However, improvements in these objective variables may not always coincide with the ways patients perceive changes in their quality of life^{370,371} or MDS-related symptoms,²⁷⁹ and these perceptions may be more likely to impact patients' decisions to continue or discontinue active therapy for their disease.

Lower-Risk Disease

Many patients with lower-risk MDS do not require active treatment directed at the underlying disease process, but this does not mean they require no treatment at all. In fact, providing appropriate supportive care is an important undertaking that can at times be complex and time-consuming, and requires a detailed understanding of the evidence behind the available supportive measures.³⁷²

Management of Anemia

Because most MDS patients become anemic at some point during their disease, appropriate management of their anemia is of critical importance.³⁷³ Management can be broken down into two main components: transfusion support and use of erythropoiesis-stimulating agents (ESAs).

Transfusion Support

Many, if not most, patients with MDS will require packed red blood cell (PRBC) transfusion during the course of their disease. To minimize the risks associated with repetitive transfusion, it is usually appropriate to reserve transfusion until the hemoglobin is below

8–9 mg/dL or the patient has symptoms referable to anemia. More restrictive transfusion strategies, such as those suggested by studies in inpatient or critical care settings,^{374,375} may be appropriate in younger, healthy patients, while some older patients, particularly those with significant comorbid cardiac disease, may benefit from more liberal strategies targeting a hemoglobin of 9–10 mg/dL.^{376,377} Unless the patient is an HSCT candidate (in which case irradiated blood is essential), there is no consensus about leukocyte depletion or irradiation of the product.³⁷⁸ Since many patients with MDS will receive hundreds of units of PRBCs over the course of their disease, prevention and appropriate management of iron overload is also of substantial importance.^{379,380}

Erythropoiesis-Stimulating Agents

Transfusion dependency is a negative predictor of outcome in MDS.³⁸¹ While transfusion requirement may to some extent may be a marker of more severe hematopoietic insufficiency and worse disease not captured by other prognostic markers, the poor outcomes may also be a reflection of the adverse effects of repetitive transfusion, including accumulation of toxic iron species, immune modulation, and a risk of infection.³⁸² Given these facts, the administration of ESAs has been heavily investigated in MDS in an attempt to spare patients from unnecessary transfusions.

More than 20 studies of ESAs have been conducted in MDS, and 20% to 50% of patients experience meaningful, sustained improvements in their hemoglobin level in response to ESA supplementation.^{383–388} Predictors of response include lower pretreatment serum EPO levels (<500 U/L, but especially <100 U/L),³⁸⁹ lower IPSS scores,³⁹⁰ normal blast counts, normal or low-risk cytogenetics,³⁹¹ and lower serum and marrow levels of inflammatory cytokines.³⁹² The serum EPO level should be evaluated in the context of the degree of anemia; a trial of an ESA is usually reasonable in patients with EPO levels up to 200–300 U/L, which, while technically elevated on most laboratory reference scales, is still lower than would be predicted for most MDS patients' degree of anemia. Patients with EPO levels over 500 U/L, on the other hand, are unlikely to respond to any dose or duration of ESA.

There are two major formulations of ESA available in the United States. Epoetin alfa, the shorter-acting of the two, can either be given at a dose of 150–300 U/kg three times weekly, or in a fixed dose of 40,000 to 60,000 units once weekly.³⁸⁸ Higher doses above 60,000 U/weekly have not proven to be more effective.³⁹³ Darbepoetin alfa is longer acting and is typically given in doses of 500 µg once every 3 weeks.³⁹⁴ Retrospective comparisons of the two agents have not shown a significant difference in efficacy.³⁹⁵ Other ESA formulations are available outside the United States, such as epoetin zeta and bioequivalent ESAs. Although there is some increase in response with longer duration of therapy,³⁹⁶ in practical terms, a trial of 12 weeks is reasonable. Before starting therapy, other causes of anemia should be ruled out. In particular, response can be suboptimal if patients are absolutely or even relatively iron deficient, and oral or parenteral iron supplementation may be reasonable in patients with ferritin levels at the lower end of the normal range.

One limitation of the numerous studies of ESAs in MDS patients is the lack of a consistent definition of response, since most studies predated uniform IWG criteria. Some studies define this based on a hemoglobin increase (usually improvement by 1–2 g/dL),^{397,398} while others have defined response by transfusion reduction or quality of life metrics.³⁹⁹ In practice, any of these improvements could be a reasonable criterion for continuation of therapy. Of particular interest, supplementation with ESA has not been shown to increase the rate of progression to acute leukemia, and one comparative trial showed a nonsignificant trend toward a decreased risk of leukemia, although the biologic basis for this is not clear.⁴⁰⁰ In addition, several studies have shown an improvement in response in patients supplemented with a combination of ESA and G-CSF, especially in RARS, likely caused by pleiotropic effects of both growth factors on hematopoietic progenitors.^{399,401}

ESAs are no longer routinely used for management of anemia in solid tumor patients, where studies have shown them to be associated with an increased risk of poor outcomes.⁴⁰² Similar findings have also been noted in patients without cancer receiving ESAs for anemia associated with renal failure.⁴⁰³ Such a risk has not consistently been shown in MDS, although most studies published to date have not had long follow-up periods. The risk of thromboembolism has largely been correlated with the degree of improvement in hemoglobin, with patients targeted to hemoglobins over 12 mg/dL at greatest risk. Given this, the consensus recommendation in MDS is to initiate an ESA at hemoglobin <10 g/dL and target a level between 11–12 g/dL.⁴⁰⁴

Management of Neutropenia and Infections

As referenced previously, patients with MDS often become neutropenic but also appear to have other qualitative immune defects that are not accurately represented by the ANC.^{392,393} and infection is the leading cause of death in MDS.²⁸⁰ Despite this, supplementation with either G-CSF (filgrastim, tbo-filgrastim and others) or GM-CSF (sargramostim) has not consistently been shown to improve outcomes in MDS patients.^{405–407} Nevertheless, it is reasonable to consider a trial of growth factor (usually G-CSF, because of less frequent adverse effects) in lower-risk IPSS patients with significant neutropenia, typically defined as an ANC <1000/mm³. Supplementation in higher-risk patients, particularly those with any degree of excess blasts, is not usually recommended in the absence of chemotherapy, because of lingering concerns about promoting expansion of leukemic clones.⁴⁰⁸ Other therapeutic strategies for immune supplementation, including granulocyte transfusion and cytokine administration, have not been shown to be helpful.⁴⁰⁹

A thorough understanding of appropriate antibiotic use is an important component in the care of MDS patients. Patients should be counseled to seek medical attention for any fever greater than 100.4°F/38.4°C, and those who are neutropenic should be hospitalized and started on antibiotics while an appropriate search for infection is undertaken. A thorough discussion of treating febrile neutropenia can be found elsewhere in the text, but should begin with an antibiotic that covers a broad spectrum of gram-negative organisms including *Pseudomonas* species.⁴¹⁰ Although prophylactic antibiotics should not be started routinely, they may be appropriate for selected patients who demonstrate a pattern of recurrent infections.^{411,412} There is less consensus about prophylactic antivirals or antifungal medications, and the efficacy of the latter depends on local microbiologic isolates and epidemiologic patterns.

Management of Thrombocytopenia and Bleeding

Modest thrombocytopenia is common across many subtypes of MDS, while severe depression of platelet counts is more frequently seen in patients with higher-risk IPSS scores or those undergoing active treatment with hypomethylating agents or chemotherapy. Overall, bleeding is the second most common cause of nonleukemic death in MDS patients.⁴¹³ Conventional wisdom and observational studies indicate that the risk of bleeding with trauma begins to increase at a platelet count near 50×10^9 cells/L and that of spontaneous hemorrhage does not increase significantly until the count is below $10\text{--}20 \times 10^9$ cells/L. However, these cutoffs may underestimate the bleeding risk in MDS patients, many of whom have qualitative defects in platelet function that are not captured by the platelet count. A number of retrospective studies have evaluated the significance of thrombocytopenia in MDS, all of which have found that thrombocytopenia confers a poor prognosis caused by both the risk of bleeding and, in some cases, an elevated risk of transformation to AML.^{330,413–415}

As with red blood cells, management of thrombocytopenia can either involve transfusions or use of growth factors. Many institutions use a standard transfusion threshold of 10×10^9 cells/L,⁴¹⁶ but as discussed earlier, a higher goal may be appropriate in selected patients

who show a predilection for bleeding. In general, patients should be transfused prophylactically rather than waiting for bleeding to occur. Although there are few large studies comparing transfusion strategies specifically for MDS patients, a recent study of patients with other hematologic malignancies showed that for most patients (including those with AML), a prophylactic strategy using a trigger of 10×10^9 cells/L led to fewer significant hemorrhages than a therapeutic strategy in which patients were transfused only when bleeding.⁴¹⁷

Thrombopoietin (TPO) analogs, which are standard therapeutic options for refractory chronic idiopathic thrombocytopenia purpura (ITP),⁴¹⁸ are not yet approved by any regulatory agencies for use in MDS. The two major formulations approved in ITP are romiplostim, a “peptibody” consisting of 14 amino acid peptides that bind the extracytoplasmic domain of the TPO receptor fused to an IgG1 heavy chain, and eltrombopag, a small molecule without TPO homology that nevertheless binds and activates the TPO receptor.⁴¹⁹ Romiplostim is administered as intermittent subcutaneous injections, whereas eltrombopag is an oral formulation that is taken daily.

Both agents have shown efficacy in terms of reducing platelet transfusions and clinically significant bleeding events and increasing platelet counts in early-phase trials in MDS.^{420–424} In patients with IPSS low or intermediate-1 risk MDS who had platelet counts less than 50×10^9 /L, romiplostim consistently led to significant improvements in platelet count, which were durable in about half of patients.⁴²¹ A similarly designed phase I/II trial of eltrombopag is ongoing.

However, concerns have been raised about the safety of TPO agonists in patients with MDS. First, a number of studies in ITP have shown an increase in marrow reticulin fibrosis in subsets of patients.⁴²⁵ While the absolute risk of fibrosis has not been determined, and fibrosis has been moderate in most patients, some have speculated that the process could be accelerated within the abnormal marrow microenvironment of MDS patients.⁴²⁶ Second, there is concern about increased blast proliferation in the presence of TPO agonists, since some blasts have functional TPO receptors. A randomized controlled trial of romiplostim versus placebo (the only phase III study of either agent in MDS to date) was stopped early by the study’s safety monitoring committee because of interim analysis suggesting a higher rate of progression to AML in the romiplostim arm.⁴²⁷ At the time the study was stopped, 10 of 167 patients in the romiplostim group had progressed to AML, compared to two of 83 in the placebo group. Since the study was far from completion of accrual at the time it was stopped, the risk of disease progression could not be definitively assessed and the AML progression rate eventually nearly equalized; nevertheless, the manufacturer has now added a warning of risk of MDS progression to romiplostim’s label. Until there is more conclusive evidence evaluating the link between TPO analogs and the risk of disease progression, neither romiplostim or eltrombopag can be recommended for routine treatment of MDS-associated thrombocytopenia outside a clinical trial, although patients with refractory bleeding who fail to respond to platelet transfusions could consider trying one of these agents palliatively.

Management of Iron Overload (Transfusional Hemosiderosis)

Although it is clear that MDS patients who undergo repeated blood transfusions carry an increased risk of developing iron overload,³⁸¹ the importance of this relative to other disease-related risks, and how to assess and respond to it, remains a matter of some debate.³⁸² MDS is distinct from pediatric illnesses associated with iron overload, in which the benefit of chelation has been well established,⁴²⁸ in that many MDS patients will not live long enough for the clinical impact of end-organ iron deposition to be realized. Registry data suggest that patients with higher transfusion requirements have a greater risk of complications,^{429,430} but registry data cannot prove the direction of the relationship—that is, whether the transfusions lead to complications or whether the need for transfusion is simply a marker of more severe disease or underlying comorbidities. Other

retrospective studies have provided circumstantial evidence for deleterious effects of iron overload. For instance, one study has shown a higher rate of death from heart failure among MDS patients,⁴³¹ and another has shown increased rates of heart and liver failure among MDS patients with high lifetime numbers of transfusions,⁴³² but these observations again cannot prove causality.

There are two major formulations of chelating agent available in the United States, deferoxamine and deferasirox (a third agent, deferiprone/L1, is available only for thalassemia patients via a restricted distribution program). Deferoxamine is administered as a continuous subcutaneous or IV infusion, a cumbersome mechanism that has limited its applicability in widespread practice. Deferasirox, an oral formulation, is more convenient so is much more widely used, but is quite costly.

Deferasirox is typically started at 20 mg/kg (14 mg/kg for the new tablet form of deferasirox FDA approved in 2015) once daily and escalated to 30–40 mg/kg/day (28 mg/kg for the new tablet form of deferasirox FDA approved in 2015), depending on iron kinetics and patient tolerance. Although deferasirox has been shown to rapidly mobilize stored iron and reduce labile plasma iron species, it is frequently discontinued either as a result of disease progression or caused by side effects, which include gastrointestinal distress, renal impairment, and rash.

To date, there have been no randomized controlled trials to definitively evaluate the impact of iron chelation on outcomes in MDS. The largest prospective trial to date, a single-arm cohort study of 1744 patients treated with deferasirox, included a prespecified MDS subgroup of 341 patients. Over the study's single year, median ferritin levels decreased significantly compared to baseline regardless of whether patients were chelation naive or not, as did the median alanine aminotransferase, which was tracked as a marker of hepatic toxicity from iron overload. On the other hand, 48.7% of the MDS patients discontinued treatment because of side effects. Since there was no control arm and the study period was short, no conclusions could be drawn about the impact of chelation on more meaningful clinical outcomes. Other studies have shown improvements in hematopoiesis in patients started on chelation therapy,^{433,434} but these observations were not tied to longer-term outcomes either.

There are data from retrospective studies showing better outcomes for patients who undergo iron chelation, but all of these are subject to patient selection bias. In one, a Canadian study of 178 patients, only 18 received chelation therapy, suggesting that these patients were carefully selected and destined to have a better outcome anyway.⁴³⁵ In another, a French study of 97 patients in whom 46% received chelation, the regimen and duration of chelation therapy varied considerably, and no baseline assessment of iron stores was performed.⁴³⁶ A recent metaanalysis of iron chelation studies in MDS found that use of chelation therapy was associated with an increase in length of survival (overall 61.2 months longer for patients receiving chelation),⁴³⁷ but since the analysis included only retrospective studies, it is very possible that these numbers are again largely reflective of selection bias, with healthier or younger patients more likely to receive chelation therapy than those who were older or sicker.

Despite the limitations of the available data, there are several published consensus opinion guidelines regarding the use of chelation therapy in MDS.^{324,438} Although they differ with respect to their specific recommendations, most operate on similar principles that the patients best suited to iron chelation therapy are either those with lower-risk disease and significant anemia who presumably face a long period of transfusion dependency, or those who could potentially be eligible for stem cell transplantation, since in the transplant setting numerous studies have shown that a high ferritin is associated with inferior outcomes.⁴³⁹ A third category of patients comprises those with suspected end-organ damage as a result of iron overload.

Some of the guidelines recommend waiting to start chelation therapy until the ferritin is greater than 1000 µg/L or the patient has had more than 20–30 lifetime transfusions, but they also note that neither of these criteria is supported by high-level evidence. Serum ferritin is problematic since it is subject to variability based on

inflammatory state, and is an imperfect marker of total body iron burden. For quantitative assessment of hepatic iron overload, T2*-weighted magnetic resonance imaging of the liver has supplanted biopsy as the preferred method of validation.⁴⁴⁰

Other Therapies for Lower-Risk Disease

The literature is replete with attempts to treat lower-risk MDS with a variety of different drugs, especially so-called differentiating agents such as retinoic acid or arsenic trioxide (ATO). With the exception of lenalidomide for 5q- syndrome, most of these have been inconsistently effective at best.

Lenalidomide

As described previously, lenalidomide is a derivative of thalidomide that is uniquely effective in reversing the severe anemia associated with isolated del(5q). This was previously thought to be related to poorly characterized immunomodulatory effects (as implied by "Imid," the name given to the class of thalidomide derivatives).⁴⁴¹ However, more recent work has shown that lenalidomide actually exerts its effect in 5q- syndrome by mediating the binding of the E3 ubiquitin ligase cereblon to casein kinase 1α, thus triggering casein kinase's proteasomal degradation.⁴⁴² Casein kinase 1α is an essential kinase whose gene, *CSNK1A1*, lies within the minimally deleted region on 5q.¹⁷⁷ In normal cells, treatment with lenalidomide is insufficient to deplete casein kinase 1α to lethal levels, but the haploinsufficiency of *CSNK1A1* induced by loss of 5q renders 5q- cells sensitive to the drug through a p53-dependent mechanism and allows for repopulation of the marrow by wildtype hematopoietic progenitors. This activity appears to be unique to lenalidomide and is not shared, for instance, by thalidomide. Unfortunately, the effect is not permanent and resistance eventually develops in most cases, often through inactivating mutations in *TP53*.⁴⁴³ Hopefully, however, these new insights will enable further studies of how these resistance mechanisms arise.

Lenalidomide's efficacy was first observed in MDS-001, a phase I study of 32 patients with symptomatic anemia who had not responded to ESAs.⁴⁴⁴ Twenty of the 32 patients became independent of transfusion for some period of time, including 10 of 12 patients with del(5q). Of the responders, those with del(5q) had a significantly longer duration of response. This prompted further study of lenalidomide specifically in del(5q) patients in MDS-003, a phase II study in which 76% of 148 enrolled patients had an improvement in anemia and 67% achieved transfusion independence, with a median improvement in hemoglobin near 5 mg/dL. A second phase II trial, MDS-002, showed that lenalidomide was also effective in a substantially smaller subset of patients without del(5q), with an overall response rate of 43% and a transfusion independence rate of 26%. The factors that determine lenalidomide responsiveness in non-del(5q) MDS have not been determined.

The most conclusive evidence of lenalidomide's efficacy in del(5q) comes from the phase III MDS-004 trial,¹⁷³ a randomized, double-blinded study in which patients were randomized 1:1:1 to receive lenalidomide 10 mg/day on days 1–21 of a 28-day-cycle, lenalidomide 5 mg/day on days 1–28, or placebo on days 1–28. Those without an erythroid response at 16 weeks were unblinded and became eligible for open-label treatment. At the conclusion of the study, significantly more patients in both lenalidomide groups had achieved transfusion independence for at least 26 weeks than those in the placebo group (56% in the 10-mg group versus 43% in the 5-mg group versus 5.9% in the placebo group), with those in the 10-mg group having a longer median duration of response (82.9 weeks) than those in the 5-mg group (41.3 weeks). Intriguingly, treatment with lenalidomide also appeared to lower the risk of transformation to AML; at a median follow up of around 3 years, 36.4% of patients who had received placebo only and 30.4% who had started with placebo and crossed over to lenalidomide had

developed AML, compared to 23.2% in the 5-mg group and 21.7% in the 10-mg group, though the crossover model prevented an assessment of statistical significance.

Given recent progress in understanding of lenalidomide's mechanism of action, it is perhaps unsurprising that it demonstrates considerably lower efficacy in MDS patients who do not have del(5q). In these patients, studies have consistently shown an overall response rate of about 25%, which on average lasts less than a year.^{445,446} It is not known whether the patients who respond have abnormalities of casein kinase 1 α , or whether their sensitivity to lenalidomide occurs via a different mechanism.

Lenalidomide is generally well tolerated, especially compared to thalidomide. The most common side effects are neutropenia and thrombocytopenia, which are most common in the first month of treatment and which have some correlation to treatment response.⁴⁴⁷ Pretreatment thrombocytopenia, a feature atypical of pure del(5q), appears to negatively correlate with response and perhaps serves as a phenotypic proxy for cooperating genetic events that blunt the molecular sensitivity to the drug.¹⁴⁹ Significant thromboembolism has been observed in studies of patients with myeloma who receive lenalidomide, an effect that largely seems to be confined to co-administration of lenalidomide and dexamethasone;⁴⁴⁸ the manufacturer thus recommends thromboprophylaxis in del(5q) patients as well, though it is not clear that the thrombotic risk is the same in these populations, and thrombocytopenia may limit the safety of this approach.

Low-Dose Cytarabine

Cytarabine, also known as cytosine arabinoside or Ara-c, is a pyrimidine analog that is widely used in the treatment of a number of hematologic malignancies. In MDS, its use dates to the 1980s.^{449,450} The typical dosing schedule is 5–20 mg/m² per day via subcutaneous injection (daily or twice daily) or continuous IV infusion. Although 10% to 20% of patients with MDS have some degree of pathologic response during Ara-c therapy, these tend to last only a few months, and treatment has not been shown to improve survival or reduce the rate of transformation to AML.

One of the drawbacks to treatment with cytarabine or any other conventional chemotherapeutic agent is that they cause cytopenias as a primary side effect, and since cytopenias are a central problem in most MDS patients, the agents rapidly become limited in utility.⁴⁵¹ The worsening of cytopenias is likely one of the primary reasons for the lack of survival benefit for cytarabine in MDS.

Antitumor Necrosis Factor Therapy

The observation that MDS patients often have elevated levels of inflammatory cytokines and increased rates of apoptosis led to the postulate that blockade of these pathways might ameliorate the ineffective hematopoiesis found in many patients with MDS. Etanercept, a soluble TNF- α inhibitor, has been analyzed in two small pilot studies of MDS patients, with mixed results: cytopenias improved in one trial,⁴⁵² whereas no effect was seen in the other.⁴⁵³ The drug has also been combined with both ATG⁴⁵⁴ and azacitidine,⁴⁵⁴ but in neither case was it clear that the addition made a difference. A separate case report described sustained erythroid responses in two patients treated with infliximab, a monoclonal anti-TNF antibody.⁴⁵⁵ TNF- α and other inflammatory mediators may play a greater role in some subsets of MDS than others,⁴⁵⁶ and better delineation of these groups may make future study of anti-TNF therapy reasonable in selected patients.

Immunosuppressive Therapy

Corticosteroid therapy was once a mainstay of treatment for MDS, but despite reported response rates in the range of 10% to 20%,⁴⁵⁷

the complications of long-term steroid use in this population came to outweigh the benefits. Nevertheless, immunosuppressive therapy may be reasonable for certain subsets of MDS patients in whom autoreactive T-lymphocytes contribute to the inhibition of effective hematopoiesis. Patients with hypoplastic MDS, in particular, have been shown to have similarities to aplastic anemia, and may respond to treatment with ATG.⁴⁵⁸ Other studies have shown that patients with underlying PNH clones, which can be assessed by flow cytometry for PIG-anchored glycoproteins CD55 and CD59, may also respond to ATG, as may patients with a human leukocyte antigen (HLA) DR15 phenotype.⁴⁵⁹

Retrospective analysis of data from the International Myelodysplasia Risk Assessment Workshop showed that treatment with immunosuppression was associated with an improvement in overall survival (8.1 vs. 5.2 years, $p < .001$) and a lower risk of leukemic transformation, but these results could have been subject to selection bias since fewer patients with higher-risk disease are treated upfront with immunosuppression.⁴⁶⁰ On the other hand, a randomized study comparing ATG plus cyclosporine to best supportive care suggested a slight improvement in hematologic response in the ATG + cyclosporine A group, but there was no difference in disease-free or overall survival.⁴⁶¹ Subgroup analysis suggested that patients with hypocellular marrows were more likely to respond to immunosuppression, again hinting at biologic similarities to aplastic anemia. In studies making careful distinction between MDS and aplastic anemia, however, mortality with ATG treatment was higher in MDS than in aplastic anemia.³⁴⁵

Alemtuzumab, a monoclonal antibody against anti-CD52, has activity in highly selected subsets of MDS patients. In particular, one small phase I/II study of patients yielded a 77% overall response rate among patients with IPSS intermediate-1 disease.⁴⁶² Some patients with cytogenetic abnormalities normalized their karyotype, and the rate of complete response appeared to increase with time in those patients who were not lost to follow up. However, alemtuzumab is severely immunosuppressive and the study was hampered by a high rate of attrition and careful selection of patients, and the results have not yet been repeated. The biologic basis for the high response rate in this single study remains unclear.

Manipulating the Microenvironment: Vascular Endothelial Growth Factor and Other Targets

Observations of increased microvessel density in the bone marrow of MDS⁴⁶³ patients have led to some enthusiasm for targeting vascular growth factors and other molecules associated with the marrow microenvironment, but results so far have been somewhat disappointing. For instance, a phase II trial of bevacizumab, a monoclonal antibody directed against vascular endothelial growth factor (VEGF), showed a decrease in VEGF levels and a significant reduction in microvascular density, but only one of 21 patients had any type of hematologic response.⁴⁶⁴ Similarly, a phase II study of vatalanib, an oral VEGF receptor inhibitor, showed hematologic responses in only 5% of patients, though many patients had to withdraw from the study because of side effects.⁴⁶⁵

Other therapies directed at the microenvironment have similarly shown responses in only a minority of patients. For instance, the combination of pentoxifylline, a phosphodiesterase inhibitor, with dexamethasone and ciprofloxacin (PCD) has been shown to induce hematologic responses in some patients, but most of these are transient and probably represent neutrophil demargination from the corticosteroid.²³¹ A more recent study combining PCD with amifostine, an antiangiogenic agent usually used as a chemoprotectant, showed a hematologic response rate of 66%, but long-term results have not been reported.⁴⁶⁶ Lenalidomide and thalidomide were both previously thought to act via effects on the microenvironment,⁴⁶⁷ but with the discovery of lenalidomide's role as a catalyst for cereblon-mediated ubiquitination, as described earlier, the extent to which it also affects the microenvironment is unclear.

Signal Transduction Inhibitors

Activating mutations in receptor tyrosine kinases like *NRAS* and *FLT3* are relatively uncommon in MDS, not because they never occur in this population, but because they usually act as catalysts for progression to secondary AML.²³⁸ The consideration for use of FLT3 inhibitors in MDS is similar to those in s-AML, and data are limited. A more thorough discussion of these agents may be found in [Chapter 59](#) (AML).

Other Agents

A number of other agents have been used in MDS and reported either in anecdotes or small, nonrandomized series of patients. Historically, many patients with RARS were started on vitamin B₆ because of its efficacy in familial sideroblastic anemia, but it has shown little efficacy in adults.⁴⁶⁸ Other dietary supplements, include retinoids (vitamin A analogues), vitamin D,⁴⁶⁹ and vitamin K₂,⁴⁷⁰ have all been tried because of favorable effects on differentiation in vitro, but have not been effective in humans. A number of other drugs have also been trialed in humans based on similar observations of prodifferentiation effects in preclinical experiments, all without comparable efficacy in human patients. These include amifostine as a single agent,⁴⁷¹ the solvent hexamethyl bisacetamide,⁴⁷² and alpha and gamma interferon. Interferon, in particular, has recently been shown to cause normal HSCs to exit quiescence in mouse models,^{473,474} but whether it can be used for similar purposes to “prime” MDS stem cells for subsequent treatment with cytotoxic therapy has not yet been explored.

Given their efficacy in promyelocytic leukemia, both all-*trans* retinoic acid (ATRA) and ATO have been trialed in small numbers of MDS patients in a similar attempt to induce differentiation. ATO has shown responses in up to 20% of MDS patients in several small series,^{475–478} but the molecular basis for this action and how to predict who will respond are unclear. ATRA by itself has largely been ineffective, likely caused by the absence of the PML-RARA fusion protein that is the basis for its efficacy in acute promyelocytic leukemia (APML).^{479,480} In vitro data suggest that in some AML models, downstream targets of the retinoic acid receptor may be epigenetically silenced by abnormal induction of histone demethylases such as LSD1, which can be inhibited by tranlycypromine, a monoamine oxidase inhibitor (MAOI) approved in Europe to treat depression.⁴⁸¹ In vitro, the combination of ATRA with tranlycypromine in non-APML leukemia derepresses targets of the retinoic acid receptor and significantly impairs the ability of leukemia stem cells to engraft in immunodeficient mice. Whether this pathway can be similarly reactivated in MDS, and whether this is a viable therapeutic combination in patients, also remain as yet unexplored.

A number of other novel agents remain in clinical trials for lower-risk MDS at the time of this writing.⁴⁸² These include inhibitors of the transforming growth factor-beta receptor,⁴⁸³ inhibitors of toll-like receptors, chimeric antibodies to activin, mitochondrial modulators, RAS pathway inhibitors, and anti-CD33 molecules. In addition, there are ongoing trials evaluating combinations of existing therapies, including hypomethylating agents, histone deacetylase (HDAC) inhibitors, lenalidomide, and hematopoietic growth factors. While some of these trials may identify novel therapies or combinations with efficacy for subsets of MDS patients, whether any of them will have substantial impact on the treatment landscape for low-risk MDS remains to be seen.

Higher-Risk Disease

Hypomethylating Agents

MDS genomes frequently display aberrant methylation patterns relative to normal hematopoietic cells. This observation was initially made in the 1990s, when investigators noted hypermethylation in

the promoters of numerous tumor suppressor genes, including *CDKN2A*, *CDKN2B*,⁴⁸⁴ *FHIT*,⁴⁸⁵ *SOC1*,⁴⁸⁶ *CTNNA1*,⁴⁸⁷ and others. Later, with the advent of genome-wide methylation profiling, it was further observed that this aberrant methylation is often a global phenomenon in MDS and that global hypermethylation, in particular, appears to confer a poor prognosis.⁴⁸⁸

This characterization of aberrant methylation in MDS soon led to the identification of hypomethylating agents (HMA) as a candidate class of MDS drugs. The prototypical hypomethylator, 5-azacytidine (azacitidine), was synthesized in the 1960s and its hypomethylating activity first clearly characterized in 1980.⁴⁸⁹ It is an azo-substituted pyrimidine analogue that incorporates into RNA and is from there converted to a deoxynucleotide and incorporated into DNA, where it binds and irreversibly inhibits DNMT1. The in vitro result is a global decrease in cytosine methylation, which leads to differentiation in some leukemia cell lines. Of note, azacitidine also appears to have nonepigenetic mechanisms of action, including some degree of direct cytotoxicity and immune stimulation.⁴⁹⁰ Both azacitidine and the related compound decitabine (5-aza-2'-deoxycytidine) are now frequently administered in both MDS and AML.

Standard dosing of azacitidine is 75 mg/m² administered subcutaneously once per day for 7 consecutive days each month.⁴⁹¹ This was the dosing schedule used in the first major study of hypomethylating agents in MDS, CALGB 9221, in which azacitidine was found to be superior to best supportive care both in terms of quality of life and risk of progression to AML.⁴⁹² In this study, about 60% of patients had some degree of response to azacitidine, although consensus response criteria were not used. Most of these responses were minor hematologic improvement, but about 15% of patients had a pathologic complete response. Most of those who responded did so within 6 months. There was a nonsignificant trend toward an improvement in overall survival with azacitidine, and side effects tended to be mild, including nausea and vomiting and transient myelosuppression.

Based on these data and a large increase in requests for compassionate use of the drug after CALGB 9221 was first presented in 2002, the Food and Drugs Administration (FDA) granted approval to azacitidine for MDS in 2004. A subsequent study, AZA-001 comparing azacitidine 1:1 to the patient and doctor choice of either standard induction, low-dose cytarabine, and best supportive care in 358 patients with higher-risk MDS or CMML showed a median 9-month improvement in overall survival for those treated with azacitidine (24 versus 15 months).⁴⁹³ This represents the only major study to date in which a survival benefit has been shown for a drug in MDS. Other studies have shown that a more convenient 5-day azacitidine dosing schedule appears to be effective, but this has not been directly compared to the 7-day schedule, which remains the standard. One recent study suggested an improvement in response from prolonged administration of azacitidine, though all patients in this study had higher rates of hematologic normalization compared to historical controls, for unclear reasons.⁴⁹⁴

The other major hypomethylating agent, decitabine (5-aza-2'-deoxycytidine), is also FDA-approved for treatment in all subclasses of MDS. Although structurally similar to azacitidine, decitabine has a deoxyribose backbone that permits it to be directly incorporated into DNA. At higher doses it introduces DNA cross-linking and cell-cycle arrest, a mechanism more akin to a cytotoxic agent, but at lower doses it appears to primarily act as a hypomethylating agent.⁴⁹⁵

Similar to azacitidine, decitabine has been shown to improve outcomes for patients with MDS, including a reduced transfusion requirement and slower transformation to AML. It may induce responses more quickly than azacitidine; for instance, in the multicenter ADOPT (alternative dosing of decitabine for outpatient therapy) study, 90% of patients responded after four cycles, rather than the six cycles seen in the largest azacitidine trials.⁴⁹⁶ In contrast to azacitidine, however, decitabine has never been shown to confer an overall survival benefit. Some of the difference in outcomes may be explained by difficulties establishing the optimal dose and schedule; in the earliest trials it was administered at a dose of 15 mg/m² given IV every 8 hours for 3 days,⁴⁹⁷ but subsequent

studies showed better hypomethylation and an improved overall response rate when it was given at a dose of 20 mg/m² once daily for 5 consecutive days,⁴⁹⁸ the dosing strategy used in ADOPT. Some recent small studies have suggested an even different dosing strategy, using frequent administration of low doses of decitabine (0.1–0.2 mg/kg/day) in an attempt to minimize the cytotoxic effects of the drug while catching more cells in S phase, when the demethylating activity of the drug would be most effective.⁴⁹⁹

Despite the widespread use of hypomethylating agents in MDS, a number of key questions persist. Although studies have shown that each can demethylate the promoters of specific tumor suppressors (e.g., *P15INK4B*⁵⁰⁰ for decitabine and *PLCB1*⁵⁰¹ for azacitidine), it is not clear that this is the dominant in vivo mechanism. Some studies have shown increased demethylation in patients who respond to hypomethylating agents,⁵⁰² but this has not been a universal observation, and neither pretreatment methylation levels (either global or at specific promoters) nor the net change in methylation with treatment have been consistently predictive of treatment responsiveness.^{488,503} Recent studies have also interrogated the impact of somatic mutations on hypomethylating agent sensitivity, and *TET2* mutations in particular have been shown to increase the likelihood of HMA response,¹⁰³ but the overall impact of these findings in the long term remains unclear.

“Histone” Deacetylase Inhibitors

The observation that MDS frequently involves epigenomic abnormalities has provoked interest in other modalities beyond the hypomethylating agents. To date, the next most-studied class of agent is the histone deacetylase inhibitors, which as their name implies block the deacetylation of histone residues as well as deacetylation of other cellular protein. In vitro, application of these drugs leads to large-scale epigenetic modifications, but in vivo, the drugs have so far not proven as effective as hypomethylating agents, at least when used alone.⁵⁰⁴ Several agents, however, remain in trials, including valproic acid,⁵⁰⁵ vorinostat,⁵⁰⁶ panobinostat,⁵⁰⁷ and belinostat.⁵⁰⁸ Many of these trials combine the HDAC inhibitor with some other therapy. One cooperative trial of azacitidine with or without entinostat, E1905, showed no improvement in hematologic response in the entinostat arm, which in fact displayed less demethylation than azacitidine alone, perhaps suggesting some degree of pharmacologic antagonism.⁴⁹⁴ However, in vitro data have also shown significant pharmacologic differences between the different HDAC inhibitors, suggesting that results for one drug may not be generalizable to the class as a whole. Similar negative results were recently reported in the U.S./Canadian Intergroup S1117, a large three-arm trial comparing azacitidine alone to azacitidine plus vorinostat to azacitidine plus lenalidomide, as well as a study of azacitidine with or without pracinostat.⁵⁰⁹

Induction Chemotherapy

AML-like induction regimens (e.g., cytarabine plus an anthracycline) are not effective for most patients with MDS, with available studies suggesting a remission rate of less than 20%. Hematologic recovery is often incomplete, and in many cases the chemotherapy mainly serves to select for the malignant clone. In fact, a randomized trial comparing azacitidine to daunorubicin plus cytarabine in elderly patients with higher-risk MDS showed that the patients treated with azacitidine had better outcomes, although only small numbers of patients were treated with induction.⁴⁹³

Induction chemotherapy, however, may be reasonable in selected younger patients; some studies have suggested remission rates of up to 50% in patients younger than 60, though these may have contained some patients with de novo AML,⁵¹⁰ and the studies were performed before the widespread availability of deep sequencing techniques that might have shown persistence of clonal mutations even in the ablated marrows.¹⁴⁸ Adding other agents, such as liposomal doxorubicin,⁵¹¹ topotecan,⁵¹² and thalidomide, do not seem to improve the rates of

remission. Conventional chemotherapy alone is rarely curative in MDS, and even those younger patients who achieve a complete remission will need further consolidation, usually with an allogeneic stem cell transplant.

Allogeneic Stem Cell Transplantation

Allogeneic HSCT is the only known curative therapy for MDS.⁵¹³ This is thought to arise from the fact that MDS progenitor cells, being transformed stem cells, are mostly quiescent and are thus relatively resistant to most chemotherapy. Allogeneic HSCT, on the other hand, leverages both the chemotherapy of the conditioning regimen and the antitumor effect of the newly transplanted stem cells to eliminate all vestiges of the prior hematopoietic system. This is, of course, a simplified description of the best-case outcome for HSCT. The reality for most MDS patients is significantly more complicated, although outcomes have steadily improved in recent years as centers have gained more experience in transplanting older patients using unrelated and even unmatched donors.⁵¹⁴

An exhaustive review of stem cell transplantation is beyond the scope of this chapter, but a few points specific to MDS bear mention. Identification of patients for whom transplant might be a reasonable option is an important first step. This group typically includes patients younger than 60 years, who are often in otherwise good health and would otherwise be predicted to have a long life expectancy. Older patients who are in otherwise excellent health may be considered for transplantation as well, usually with a reduced-intensity conditioning regimen. Although there is no official upper age limit to eligibility, most centers are hesitant to transplant patients older than 75.⁵¹⁵

The stage of disease is also important: in older patients, transplant is usually reserved for those with excess blasts or other forms of higher-risk disease, but it is important to proceed to transplant before the disease has evolved into acute leukemia. On the other hand, some centers occasionally offer transplantation to younger patients with lower-risk categories of disease given that they have a longer latency period in which their disease could progress or evolve into leukemia. This decision, however, is not completely uniform, and some data suggest that delayed stem cell transplantation is associated with better overall survival in patients with low and intermediate-1 IPSS scores regardless of age.⁵¹⁶

Once a decision has been made to proceed to transplant, other decisions must follow. The first involves the source of the stem cells. If a healthy, HLA-matched sibling is available, this is often preferable;⁵¹⁷ however, reflective of the average age of MDS patients, most siblings are older and often have comorbidities, such as cancer or other illnesses, that preclude them from consideration as donors. If a related donor is unavailable, the next best option is a search of the national donor registry for an HLA-matched unrelated donor.⁵¹⁸ Compared to related donors, transplant from unrelated donors carries a higher rate of graft-versus-host disease as a consequence of minor antigen mismatch. If a matched unrelated donor cannot be found, options then include an unrelated donor transplant mismatched at one (or occasionally more) HLA loci, or an “alternative donor source,” which includes umbilical cord blood⁵¹⁹ and haploidentical donors.⁵²⁰ In the case of MDS patients, this latter type of transplant is often obtained from one of the patient’s children.

The specific choice of conditioning regimen is likely less important in MDS than in other hematologic diseases given the disease’s intrinsic chemoresistance, as described earlier. Options include fludarabine plus busulfan, fludarabine plus melphalan, busulfan plus cyclophosphamide, or cyclophosphamide plus irradiation. Many older patients with MDS are unlikely to tolerate myeloablative doses of conditioning agents and are instead given reduced doses of conditioning agents. These “reduced intensity conditioning” transplants rely more heavily on the graft-versus-tumor effect of the transplant to eliminate the malignant clone.^{521,522} Given the intrinsic chemoresistance of MDS stem cells, however, this is usually a reasonable tradeoff. Following transplant, patients must remain on immunosuppressive medications

to prevent the emergence of graft-versus-host disease. A full discussion of posttransplant considerations is outside the scope of this chapter, but most aspects of this area are less specific to MDS than those discussed previously.

As mentioned, despite being potentially curative therapy, transplant in MDS is associated with significant morbidity and mortality. One study has suggested that 50% to 60% of lower-risk patients and 20% to 40% with higher-risk disease can expect long-term disease-free survival following transplant,⁵²³ but the alternative view of these data is that a substantial proportion of patients (40%–50% of low risk and 60%–80% of high risk) either relapse or die of nonrelapse complications of transplant.

Numerous studies have attempted to dissect patient and disease attributes that may predict outcomes following transplant. Poor-risk cytogenetics, including monosomy 7 and complex karyotypes,⁵²⁴ have been shown to predict a high rate of relapse, and recent data suggest that pathogenic *TP53*, *DNMT3A*, and *TET2* mutations are predictors of poor outcomes following transplantation as well.¹⁰⁴ So far, no cytogenetic or genetic profiles have been clearly associated with a favorable response to transplant. Preexisting neutropenia has been shown to predict an increased risk of serious infections in the post-transplant setting.⁵²⁵ On the other hand, a low blast count (fewer than 5%) is associated with better outcomes, and other data show that patients who achieved a remission or significant response to pretransplant chemotherapy have better outcomes as well.⁵²⁶

Other Therapies for Higher-Risk Disease

Autologous Stem Cell Infusion

Though rarely used in current practice, infusion of autologous stem cells has been attempted in the past, primarily for patients with oligoblastic disease.^{527,528} There are a number of reasons why this approach is suboptimal for MDS patients. The most obvious drawback is that MDS is by definition a disorder of stem cells, such that any autologous infusion will ultimately lead to repopulation of the marrow with the original malignant clone, but without the graft-versus-leukemia effect imparted by an allogeneic transplant. Moreover, autologous stem cell infusion is really meant to serve as a rescue after high-dose chemotherapy, and is thus most successful when given for a chemotherapy-sensitive disease, which MDS is not. Finally, given the ineffective hematopoiesis many patients experience before treatment, hematopoietic recovery following high-dose chemotherapy is often poor. Since most patients who would be candidates for autologous stem cell rescue would also be eligible for other, more effective modalities of therapy, there are usually few reasons to pursue this avenue.

Other Drugs

Most drugs known to have activity in AML have been tried for MDS as well, usually with suboptimal results. These include etoposide,⁵²⁹ irinotecan, gemcitabine,⁵³⁰ low-dose melphalan,⁵³¹ idarubicin,⁵¹⁰ and clofarabine.⁵³² Both hydroxyurea and low-dose oral etoposide can be used to control proliferation in patients with excess blasts, but they do not target the underlying disease. Clofarabine is sometimes effective as a bridge to transplant therapy in patients with excess blasts despite hypomethylating agent therapy, but renal and hepatic toxicity and severe skin rash are limiting.⁵³³

As with lower-risk disease, there are a number of ongoing trials for patients with high-risk MDS as of this writing. Reflective of the poorer prognosis of these patients compared to those with lower-risk disease, many of these trials either examine different combinations of high-dose chemotherapy or modification of protocols for allogeneic stem cell transplant, and are often open to both MDS and AML patients. However, there are a number of novel or repurposed agents in trials as well, including immunotherapies (ipilimumab,⁵³⁴ adoptive T-cell transfer,⁵³⁵ and NK cell therapy⁵³⁶), small molecules

(PIM kinase inhibitors, B-catenin degraders⁵³⁷), and radioisotope-conjugated monoclonal antibodies. As mentioned earlier, whether any of these drugs will significantly change the landscape of MDS therapy is unclear.

FUTURE DIRECTIONS

While the last ten years have witnessed substantial improvements in our understanding of the molecular pathophysiology underlying MDS, similar strides have not been made in its treatment: at the time of this writing, it has been almost 10 years since the FDA last approved a new drug for treatment of MDS (decitabine in 2006). There are few therapies in clinical trials that offer hope of broad or deep efficacy, and much of the ongoing clinical effort is directed at incremental changes to current practice, such as adjusting dosing schedules of currently approved therapies or using modestly effective drugs in combination. The lack of progress is to a great extent caused by unfortunate facts of MDS biology, including its origin in quiescent stem cells, a paucity of targetable activating mutations, and enrichment for poorly targetable mutations with much more subtle effects on growth and differentiation. Efforts are further complicated by the heterogeneity of biology both between and within individual patients, as well as the advanced age and poor overall health of many patients with MDS.

Despite these significant challenges, there is nevertheless great opportunity for improvements in care. Advances in stem cell transplant techniques, including the availability of alternative donor sources, refinements of posttransplant immunosuppression, and augmentation of the graft-versus-tumor effect, should continue to improve the outcomes for MDS patients able to undergo transplant. An equally difficult challenge lies in treatment of those patients ineligible for transplant, and it is in these patients that effective unification of our improving biologic understanding of MDS with clinical care is most essential.

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR ACUTE MYELOID LEUKEMIA AND MYELODYSPLASTIC SYNDROME IN ADULTS

John Koreth, Joseph H. Antin, and Corey Cutler

Recent advances in molecular diagnostics are shedding considerable light on genetic underpinnings of myelodysplastic syndrome (MDS) and acute myeloid leukemia (AML). However, with notable exceptions both diseases remain therapeutic challenges. Fortunately our ability to provide more precise prognostic information has corresponded with advances in transplantation technology. We are increasingly able to apply transplantation to older people and those with comorbidities and to use alternative donors in patients without matched family members. By applying molecular prognostic criteria we can provide transplantation to patients with poor outcomes on conventional therapy, and we can avoid transplant-related toxicity in those patients who are likely to do well with supportive care or nontransplant therapy.

Allogeneic hematopoietic stem cell transplantation (HSCT) is curative in MDS and AML because of a combination of the cytotoxicity of the preparative conditioning regimen and the donor-mediated immunologic graft-versus-leukemia (GVL) effect. Regimen intensity ranges from high-dose myeloablative conditioning (MAC) that induces profound and prolonged pancytopenia to reduced-intensity conditioning (RIC) that induces milder cytopenias and is more appropriate for older patients and those with comorbidities in whom MAC may be intolerable. The risk-benefit ratio of conditioning regimen intensity varies with factors like patient age, comorbidities, and relapse risk. In general, more intense regimens cause more treatment-related morbidity and mortality but are associated with a lower relapse rate. Conversely, there are more relapses in RIC HSCT, but the procedure is more tolerable.¹

ACUTE MYELOID LEUKEMIA

AML displays clinical heterogeneity with markedly variable survival, traditionally defined by prognostic factors of patient age, white blood cell count, prior MDS or cytotoxic therapy, remission status, and karyotype, but increasingly further refined by its molecular heterogeneity. In addition to new prognostic indicators, there are now novel AML therapeutic agents in clinical trials, which also constitute an alternative to conventional cytotoxic chemotherapy and are potentially intercalatable with HSCT.

However, AML also constitutes the leading indication for HSCT worldwide, and accounts for 20,905 of 61,825 allogeneic transplants (34%) in the United States and reported to the Center for International Blood and Marrow Transplant Research (CIBMTR) in the decade 2003–13 (M. Pasquini, personal communication). Moreover, the use of molecular tissue typing in conjunction with better control of treatment-related complications has increased the use of alternative donors. Data from the CIBMTR indicate that 1286 of 1778 allogeneic HSCT (72%) undertaken for AML in 1998 involved related donors, compared with 1223 of 2557 allogeneic HSCT (48%) in 2008. In contrast, the number of unrelated donor HSCT for adult AML increased from 297 in 1998 to 1017 in 2008, while the number of umbilical cord blood (UCB) transplantations increased from 11 to 130 over the same time period.² As shown in a recent

analysis from the European Society for Blood and Marrow Transplantation, the ability to use donors that are not histocompatible will further increase the pool of patients in whom HSCT is an effective therapy.^{3,4}

Matched Related Donor HSCT for Adult Acute Myeloid Leukemia in First Complete Remission

Currently cytogenetics remains the most powerful prognostic indicator in AML, both at the time of diagnosis and at relapse, and can also direct choice of curative postremission therapy, especially for adult patients less than 60 years of age.^{5,6} Adult AML patients can be stratified into good-risk, intermediate-risk, and poor-risk groups on the basis of numeric and/or structural chromosomal abnormalities and the presence of specific mutations (see [Chapter 58](#)). Increasingly molecular genotyping supplements, and may ultimately supplant, karyotype-based AML prognostication. For instance, current European LeukemiaNet consensus incorporates molecular mutations to derive AML prognostic risk groups ([Table 61.1](#)).⁷

Numerous groups have evaluated prospectively the relative benefits of allogeneic HSCT versus nonallogeneic therapies (consolidation chemotherapy or autologous HSCT) in adult AML patients 18 to 60 years of age in first complete remission (CR1). Treatment allocation was by biologic assignment as a surrogate for true randomization, with allogeneic HSCT for patients with available human leukocyte antigen (HLA)-matched sibling donors (donor group) and nonallogeneic consolidation for those lacking matched sibling donors (no-donor group). Some studies further stratified postremission outcomes by cytogenetic risk. Individual studies, when analyzed on an intent-to-treat (ITT) donor versus no-donor basis, typically demonstrated that allogeneic HSCT was effective at improving disease-free survival, but overall survival benefit was hard to document because of graft-versus-host disease (GVHD) and other treatment-related mortality. Moreover, transplantation in CR2 salvages some of the patients who relapsed, thus making overall survival (OS) similar with the two approaches.

A meta-analysis of over 6000 patients in 24 biologic treatment assignment trials, however, confirmed that OS was in fact better in allogeneic matched related donor transplantation in AML-CR1, with a hazard ratio (HR) of death at 0.90 (95% confidence interval [CI], 0.82 to 0.97).⁷ Importantly, when stratified by cytogenetic risk, there was an OS benefit of allogeneic transplantation ([Table 61.2](#)) for both intermediate-risk (HR, 0.83; 95% CI, 0.74 to 0.93) and poor-risk (HR, 0.73; 95% CI, 0.59 to 0.90) cytogenetic groups, but not for good-risk AML-CR1 (HR, 1.07; 95% CI, 0.83 to 1.38) ([Fig. 61.1](#)). These findings were particularly relevant for patients with normal cytogenetic AML, who constitute the largest subgroup and for whom no consensus regarding optimal postremission treatment was previously available. These studies did not, however, have the benefit of prognostic assignment based on FLT3, NPM1, or other molecular markers.

TABLE 61.1 European LeukemiaNet AML Risk Classification¹⁰

Genetic Group	Subsets
Favorable	t(8;21)(q22;q22); <i>RUNX1-RUNX1T1</i> inv(16)(p13.1;q22) or t(16;16)(p13.1;q22); <i>CBFB-MYH11</i> Mutated <i>NPM1</i> without <i>FLT3</i> -ITD (normal karyotype) Mutated <i>CEBPA</i> (normal karyotype)
Intermediate-I ^a	Mutated <i>NPM1</i> and <i>FLT3</i> -ITD (normal karyotype) Wild-type <i>NPM1</i> and <i>FLT3</i> -ITD (normal karyotype) Wild-type <i>NPM1</i> without <i>FLT3</i> -ITD (normal karyotype)
Intermediate-II	t(9;11)(p22;q23); <i>MLL3-MLL</i> Cytogenetic abnormalities not classified as favorable or adverse ^b
Adverse	inv(3)(q21;q26.2) or t(3;3)(q21;q26.2); <i>RPN1-EVI1</i> t(6;9)(p23;q34); <i>DEK-NUP214</i> t(v;11)(v;q23); <i>MLL</i> rearranged -5 or del(5q); -7; abn(17p); complex karyotype ^c

^aIncludes all AMLs with normal karyotype except for those included in the favorable subgroup; most of these cases are associated with poor prognosis.

^bFor most abnormalities, adequate numbers have not been studied to draw firm conclusions regarding their prognostic significance.

^cThree or more chromosome abnormalities in the absence of one of the WHO designated recurring translocations or inversions, that is, t(15;17), t(8;21), inv(16) or t(16;16), t(9;11), t(v;11)(v;q23), t(6;9), inv(3) or t(3;3)

Prognostic Factors for Acute Myeloid Leukemia in First Complete Remission

Good-Risk Acute Myeloid Leukemia

In general, the 15% to 20% of AML patients with core binding factor (CBF) leukemia—t(8;21) (q22;q22) and inv(16)(p13.1;q22)—are considered to have good-risk disease, with a long-term disease-free survival of approximately 50–60% after consolidation chemotherapy, and allogeneic HSCT is not routinely recommended for patients achieving CR1. However, retrospective studies have identified activating mutations in C-KIT (*mKIT*)—a member of the type III receptor tyrosine kinase family—at exon 17 (*mKIT* 17) or exon 8 (*mKIT* 8) in approximately 30% of CBF AMLs that are associated with increased relapse incidence and likely poorer survival, though results from individual studies vary.^{8,9} For instance, in an analysis of 61 patients with inv(16), *mKIT* was associated with 5-year relapse rate of 56% compared with 29% ($p = .05$) without *mKIT* mutations. This effect is especially prominent with *mKIT*17, where 80% relapsed compared with 29% without the mutation ($p = .002$). Similarly, in 49 patients with t(8;21), the 5-year relapse rate was 70% in the presence of *mKIT* mutations compared with 36% with wild-type *mKIT* ($p = .017$). These relapse rates are similar to that of poor-risk AML, suggesting a potential benefit of allogeneic HSCT in this subset. Importantly, relative mutant level (mutant/wild-type allelic ratio [AR]) may also be relevant, with a retrospective analysis of prospective AML trials suggesting the negative prognostic impact of *mKIT* in CBF AML is restricted to cases with AR ≥ 0.25 .¹⁰

Intermediate-Risk Acute Myeloid Leukemia

The intermediate-risk cytogenetic group is heterogeneous and includes cytogenetically normal disease as well as those with karyotypic abnormalities not meeting criteria for good- or poor-risk AML.

It constitutes the largest risk category, accounting for approximately 40–50% of adult AML patients less than 60 years of age. Long-term disease-free survival of approximately 40–45% is anticipated after consolidation chemotherapy. However, identification of mutations with prognostic importance such as mutant *FLT3* internal tandem duplication (*FLT3-ITD*), nucleophosmin 1 (*NPM1*), and *CEBPA* (CCAAT/enhancer binding protein- α) can help further individualize the decision regarding allogeneic transplantation.

Patients with *FLT3-ITD* have inferior survivals compared with those without *FLT3-ITD*.^{10,11} The negative impact of *FLT3-ITD* appeared abrogated by allogeneic transplantation in CR1 when assessed on an ITT donor versus no-donor basis, although in this analysis the patients were not preferentially assigned transplantation on this basis. In an updated analysis, the *FLT3-ITD* mutant level appeared relevant to AML prognosis and HSCT benefit, with high levels (AR ≥ 0.51) associated with lower CR rates and poor survival. Importantly, these patients benefit from allogeneic HSCT, while those with low *FLT3-ITD* mutant levels clinically behave similarly to those without *FLT3-ITD*.¹² The *NPM1* and *CEBPA* mutations are associated with good outcomes independent of HSCT, and most investigators do not offer HSCT in first remission.^{10,12–14} The favorable impact of *NPM1* mutations appears to persist even in older patients, although this belief is in evolution, and allogeneic HSCT may be a consideration in older AML.^{15–17} There is a growing list of additional prognostic markers undergoing evaluation in AML. These include mutation analysis of *RAS*, *WT1*, *RUNX1*, *MLL*, *TET2*, *IDH1/2*, *TP53*; expression levels of individual genes like *EVI1*, *ERG*, *MN1*, and *BAALC*; and gene expression and microribonucleic acid (miRNA) profiling.^{6,10,16} In a large analysis to develop a prognostic model for AML based solely on molecular markers, Grossmann et al documented five distinct AML prognostic subtypes: (1) very favorable: *PML-RARA* rearrangements or *CEBPA* double mutations (3-year OS: 82.9%); (2) favorable: *RUNX1-RUNX1T1*, *CBFB-MYH11*, or *NPM1* mutation without *FLT3-ITD* (3-year OS 62.6%); (3) intermediate: none of the mutations leading to assignment in the other groups (3-year OS: 44.2%); (4) unfavorable: *MLL-PTD* and/or *RUNX1* mutation and/or *ASXL1* mutation (3-year OS: 21.9%); and (5) very unfavorable: *TP53* mutation (3-year OS: 0%).¹⁸ If validated, such analyses highlight the ability of molecular markers to further delineate prognosis within AML, especially within intermediate-risk AML. This suggests that this category of risk will gradually disappear as prognostic precision improves. Although the better-prognosis subgroup within intermediate-risk AML may not benefit from early allogeneic transplantation, HSCT appears to be the preferred postremission therapy for intermediate-risk AML patients at higher risk for relapse, including those lacking favorable gene mutations like *NPM1* without *FLT3-ITD*, or double mutant *CEBPA*. With the advent of mutation analysis an interesting question will be whether patients in remission but with detectable clonal hematopoiesis are better served going to HSCT despite the good-risk cytogenetics.

Poor-Risk Acute Myeloid Leukemia

In poor-risk AML relapse rates are high and survival rates are anticipated to be 15% or lower with conventional therapy. Allogeneic HSCT with a matched sibling or unrelated donor results in long-term survival of 30–40% and is considered the treatment of choice for adults less than 60 years of age with poor-risk AML. There is, however, a subgroup of poor-risk AML that may have particularly adverse prognosis, for whom additional novel therapeutic strategies may be necessary.

The monosomal karyotype (MK) is defined by the presence of a single autosomal monosomy, in association with at least one additional monosomy or non-good-risk structural chromosomal abnormality (i.e., excluding CBF mutation AML).¹⁷ In the original report, MK-positive AML patients had a long-term survival of only 3–4%, and these generally dismal chemotherapeutic outcomes have been confirmed by other investigators.¹⁸ Allogeneic transplantation

TABLE 61.2 Allogeneic Transplantation Guidelines for Adult Acute Myeloid Leukemia Based on Commonly Assessed Cytogenetic and Molecular Markers

AML Category	Prognostic Impact	Allogeneic Transplantation	Notes
AML-CR1: Younger Adults			
Good-risk disease			
APL	Favorable	No	APL is treatable by chemotherapy
CBF-AML <i>without</i> <i>mKIT</i>	Favorable	No	t(8;21) AML with high WBC count at diagnosis may have worse prognosis
CBF-AML <i>with</i> <i>mKIT</i>	Intermediate	Possible: MRD, MUD Uncertain: MMUD, UCB, haplo	
Intermediate-Risk Disease			
CN-AML <i>with</i> <i>CEBPA</i>	Favorable	No	Benefit likely restricted to <i>DM-CEBPA</i>
CN-AML <i>with</i> <i>mutant NPM1</i> <i>but not FLT-3-ITD</i>	Favorable	Possible: MRD	Emerging data suggests allogeneic HSCT benefit for this category, with reduced relapse and improved DFS in patients >40 years.
CN-AML <i>with</i> <i>FLT-3-ITD</i>	Unfavorable ^a	Yes: MRD, MUD Possible ^b : MMUD, UCB, haplo	Unfavorable risk may be restricted to AML <i>with</i> <i>FLT-3-ITD</i> <i>allelic ratio</i> >0.51
Other intermediate-risk disease	Intermediate or Unfavorable	Yes: MRD Likely acceptable ^a : MUD Possible ^b : MMUD, UCB, haplo	Likely considerable underlying clinical heterogeneity. Molecular risk profiling may further delineate risk in this category.
Poor-Risk Disease			
Monosomal karyotype <i>absent</i>	Unfavorable	Yes: MRD, MUD Likely acceptable ^b : MMUD, UCB, haplo	
Monosomal karyotype <i>present</i>	Very unfavorable	Yes: MRD, MUD. Acceptable ^b : MMUD, UCB, haplo	
Abnormal 17(p)	Very unfavorable	Yes: MRD, MUD Acceptable ^b : MMUD, UCB, haplo	
AML-CR1: older adults	Unfavorable	Yes: MRD, MUD Likely acceptable ^b : MMUD, UCB, haplo	
AML-CR1: t-AML, AML/MDS	Unfavorable	Yes: MRD, MUD Acceptable ^b : MMUD, UCB, haplo	Molecular risk profiling may supersede clinical classification of secondary AML, especially in older patients
AML-CR2	Very unfavorable	Yes: MRD, MUD Acceptable ^b : MMUD, UCB, haplo	
AML not in remission	Very unfavorable	Yes: MRD, MUD Uncertain: MMUD, UCB, haplo	For selected patients: good performance status, little comorbidity, lower leukemic burden; CIBMTR risk score may be useful

^aIf no sibling donor available.^bIf no timely matched donor available.

AML, Acute myeloid leukemia; APL, acute promyelocytic leukemia; CBF, core binding factor; CIBMTR, Center for International Blood and Marrow Transplant Research; CN, cytogenetically normal; CR1, first complete remission; CR2, second complete remission; haplo, haploidentical; MDS, myelodysplastic syndrome; MMUD, mismatched unrelated donor; MRD, matched related donor; MUD, matched unrelated donor; t-AML, therapy-related AML; UCB, umbilical cord blood; WBC, white blood cell.

appears to only partly ameliorate the impact of MK-positive karyotype, which remained an adverse prognostic factor after HSCT, and was associated with a relapse risk of 62% and poor survival of 15% at 4 years.¹⁹

Importantly, some if not all of the negative impact of MK and complex karyotype (CK) AML is its association with deletions of chromosome 5 (–5/5q–) and especially with abnormal 17p (site of TP53 gene). In a retrospective analysis of 236 high-risk AML-CR1 patients of whom nearly half (49%) received reduced-intensity allogeneic HSCT, patients with abn(17p) had a 2-year event-free survival (EFS) of 11%, those with –5/5q– but no abn(17p) had a 2-year EFS of 29%, and those with high-risk AML (including MK or CK) without either abn(17p) or –5/5q– had a 2-year EFS of 49%.²⁰ Further, in updated analyses, the negative impact of abn(17p) appears minimally improved after allogeneic HSCT.^{21,22} Improving HSCT outcomes in TP53 mutant AML must be a high priority for the future.

Transplantation Regimen Intensity

Myeloablative HSCT remains the standard of care for younger adults with AML. However, treatment-related mortality after MAC remains appreciable. Lower-intensity regimens offering less treatment-related toxicity are increasing in popularity. One report retrospectively compared RIC transplantation with chemotherapy in high-risk AML on a donor versus no-donor basis. They identified a leukemia-free survival benefit in the donor group (54% versus 30%, $p = .01$).²³ Several groups have compared MAC versus RIC transplantation, documenting similar overall and leukemia-free survival, with some reporting lower treatment-related mortality offset by increased relapse risk, especially for patients not in complete remission at time of HSCT. A CIBMTR study compared 3731 MAC, 1041 RIC, and 407 nonmyeloablative (NMA) transplantations, reporting adjusted 5-year OSs of 34%, 33%, and 26%, respectively.²⁴ The authors concluded that, although NMA transplantation increased relapse and

Fig. 61.1 META-ANALYSIS OF OVERALL SURVIVAL BENEFIT IN FIRST COMPLETE REMISSION OF ACUTE MYELOID LEUKEMIA FOR YOUNGER ADULTS. AML, Acute myeloid leukemia; CI, confidence interval; HR, hazard ratio. (Redrawn from Koreth J, Schlenk R, Kopecky KJ, et al: Allogeneic stem cell transplantation for acute myeloid leukemia in first complete remission: Systematic review and meta-analysis of prospective clinical trials, JAMA 301:2349, 2009. Sources cited within Fig. 61.1 can be found following the reference list online at expertconsult.com.)

impaired survival, RIC and MAC regimens had similar overall and leukemia-free survival. Although a small randomized trial documented similar outcomes of MAC versus RIC transplantation in AML-CR1,²⁵ a larger prospective randomized trial of MAC versus RIC transplantation in AML or MDS patients (Blood and Marrow Transplantation Clinical Trials Network protocol 0901) closed after accrual of 272 of planned 356 patients because of an increased relapse risk in the RIC arm (http://www.nlm.nih.gov/databases/alerts/2014_nhlbi_bmt_crn.html). RIC transplantation does, however, offer the option of curative allogeneic HSCT in older or sicker patients with AML-CR for whom the toxicity of MAC transplantation might be prejudicial. Conversely, patients with good performance status but high AML relapse risk might be preferentially selected for MAC.

Alternative Donor Transplantation

HSCT from an HLA-matched sibling donor has been the standard of care for prospective biologic treatment assignment studies evaluating postremission therapies. Patients lacking sibling donors could be considered for alternative donors: unrelated adult donors, UCB, or haploidentical donor transplantation.

Unrelated Adult Donors

Given the very poor outcomes after nonallogeneic therapy in poor-risk AML, and the documented benefit of HLA-matched sibling donor HSCT, clinical practice has been to undertake HLA-matched unrelated donor transplantation for younger adults with poor-risk AML in CR1 who lack sibling donors. A retrospective analysis of HLA-matched sibling compared with unrelated donor HSCT in poor-risk AML-CR1 documented comparable outcomes with HLA-matched siblings and HLA well-matched unrelated donors with 3-year OS of 45% compared with 53% ($p = .63$).²⁶ Outcomes were not as good for partially HLA-mismatched unrelated donors (one-locus HLA mismatch), with 3-year OS of 31% ($p = .026$). Smaller prospective studies have also shown equivalent results, confirming the suitability of well-matched unrelated donor HSCT in poor-risk AML.^{27,28}

There is limited data comparing HLA-matched sibling with unrelated donors in intermediate-risk AML, although at least one study documented similar outcomes with either donor type.²⁹ Current practice is to offer HLA-matched unrelated donor HSCT to intermediate-risk AML patients in first remission, especially if there are adverse molecular lesions.

Umbilical Cord Blood

Another important issue is the use of UCB transplantation for AML in CR1. These data are harder to interpret because most studies have reported outcomes for “acute leukemia,” rather than restricted to AML-CR1. A European registry study documented similar outcomes of UCB versus unrelated donor bone marrow (BM) transplantation in adults with acute leukemia, whereas a CIBMTR study showed better outcomes with HLA-matched unrelated donor BM transplantation but similar outcomes of UCB and HLA-mismatched unrelated donor BM transplantation.^{30,31} A large analysis of adult acute leukemia (including 880 AML patients) compared the outcomes of single-unit 4–6/6 HLA-matched (HLA-A, -B, -DRB1) UCB with 8/8 or 7/8 HLA-matched (HLA-A, -B, -C, -DRB1) BM or peripheral blood stem cell (PBSC) transplantation and documented similar leukemia-free survival regardless of stem cell source or degree of HLA match. There was higher treatment-related mortality after UCB transplantation.³² Transplantation in CR1 resulted in similar 2-year leukemia-free survivals of 44%, 50%, 52%, 39%, and 41% with UCB, 8/8 PBSC, 8/8 BM, 7/8 PBSC, and 7/8 BM transplantation, respectively. In contrast, a Japanese study evaluated outcomes of 484 AML patients receiving 4–6/6 UCB compared with 8/8 unrelated donor BM transplantation and documented a similar relapse risk with UCB transplantation, but higher treatment-related mortality and worse overall and leukemia-free survival.³³

Double-unit UCB (DUCB) transplantation is commonly used for larger patients. Indeed, since 2005 the number of adults receiving DUCB has exceeded those receiving single-unit UCB products. Limited data suggest similar outcomes of myeloablative DUCB, HLA-matched unrelated, and sibling donor HSCT in hematologic malignancies.³⁴ However, only a subset of patients had AML. The role of DUCB in AML remains to be better delineated. Reducing treatment toxicity will be important to advance UCB transplantation. A recent phase trial of 79 adult AML cord recipients (60% DUCB), identified a low 2-year NRM incidence of 20%, suggestive of progress in this metric.³⁵ In general however, current clinical practice envisages use of UCB transplantation in younger adults with high-risk AML in CR1 who lack suitable HLA-matched donors.

Haploidentical Donors

There is insufficient data on haploidentical transplantation to allow a precise recommendation for patients with AML. Several strategies have been used in high-risk patients, and the outcomes are encouraging.^{33,36–38} Haploidentical transplantation is particularly interesting given the potential enhancement of GVL activity by natural killer cells and allogeneic T cells responding to the HLA disparity. Regimens incorporating posttransplantation cyclophosphamide for the prevention of GVHD after haploidentical transplantation have gained increasing prominence, with low rates of treatment-related mortality and GVHD.^{39–41} For AML/MDS, a retrospective analysis found no significant differences between outcomes of matched unrelated ($n = 108$) and haploidentical ($n = 32$) donor HSCT with posttransplantation cyclophosphamide.⁴²

Relapsed, Refractory, and Induction-Failure Acute Myeloid Leukemia

Outcomes are typically poor for AML patients not in remission at the time of allogeneic HSCT, although the literature in this regard is limited, heterogeneous, and likely subject to patient selection and publication bias. A large analysis of MAC HSCT for acute leukemia in relapse or in primary induction failure (including 1673 AML patients) documented a 3-year OS of 19% in AML.⁴³ On multivariable analysis, risk factors at time of HSCT of poor-risk cytogenetic AML, CR1 duration of less than 6 months, circulating AML blasts, performance score of less than 90%, and lack of an HLA-matched

sibling donor predicted for 3-year survival ranging between 42% (zero risk factors) and 6% (three or more risk factors). The major cause of death remains AML relapse, and innovative strategies to reduce leukemic burden before transplantation and enhance GVL effect after transplantation are required to improve survival of this extremely high-risk patient population.⁴⁴ In this patient population, the ability of novel agents for targeting specific AML molecular lesions or pathways (e.g., *FLT3-ITD*, *IDH 1/2*, *mTOR*) with limited off-target toxicity, as a bridge to allogeneic HSCT, would be an important albeit putative clinical benefit. The ability to rapidly proceed to allogeneic transplantation may also be important given the dismal outcome of chemotherapy alone, suggesting a role for expeditious UCB and haploidentical BM transplantation in this setting, especially for patients achieving a remission.

Therapy-Related and Secondary Acute Myeloid Leukemia

Therapy-related AML (t-AML) currently accounts for approximately 10% to 20% of newly diagnosed AML, and its incidence is likely to rise in the future given increasing cancer survivorship. Postremission therapy using conventional chemotherapy is usually not curative in secondary AML (s-AML: t-AML and AML arising from antecedent MDS or MPD) with the rare exception of CBF-AML, specifically inv(16) and t(15;17). Allogeneic HSCT is less effective in s-AML. The poorer survival appears multifactorial, because of poor-risk cytogenetics, lower likelihood of entering remission, older patient age, and impaired organ function from prior cancer therapy; although some reports documented similar posttransplantation survival compared with de-novo AML when adjusted for risk factors like disease status and cytogenetics.^{2,45} An observational analysis of 545 patients with t-AML identified four risk factors influencing HSCT outcomes: age greater than 35 years, poor-risk cytogenetics, AML not in remission, and lack of well-matched donors. A prognostic score could stratify outcomes from 5-year OSs of 50% (zero risk factors) to 4% (four risk factors).⁴⁶

Molecular genotyping offers insights into the clinical heterogeneity of s-AML. In a seminal analysis, Lindsley et al identified eight genes specifically mutated in s-AML (*SRSF2*, *SF3B1*, *U2AF1*, *ZRSR2*, *SXL1*, *EZH2*, *BCOR*, *STAG2*) that also identify worse prognosis in “de-novo” elderly patients with AML, likely indicating undiagnosed antecedent MDS. They also identified a molecular signature of “de-novo” type AML. Finally, they confirmed that patients with *TP53* mutations comprised a distinct set of AML with the worst outcomes. Molecular risk stratification offers the potential to redefine the clinical diagnosis of s-AML, refine AML risk prognostication, and potentially, better select remission-inducing and postremission therapy.⁴⁷

Acute Myeloid Leukemia in Older Adults

AML incidence rises with age, with a median age at diagnosis of 67 years (Surveillance, Epidemiology and End Results data: <http://seer.cancer.gov/>). For AML patients older than 60 years, consolidation chemotherapy is unlikely to be curative (Fig. 61.2). Even after adjusting for increased incidence of poor prognosis features like adverse cytogenetic and molecular markers, secondary AML, comorbidities, and poorer performance status, older age remains an independent predictor of poor survival with conventional chemotherapy. A priori, age-related clonal hematopoiesis may be a relevant variable for impaired survival, though this remains to be confirmed.^{48,49} Although allogeneic HSCT is a curative therapy in the older age-group, there is considerable reluctance to refer these patients for transplantation, in contrast to younger adults with AML, in part because of outdated assumptions regarding the tolerability of allogeneic transplantation, but also because of lack of comparative data regarding outcomes.

Several reports have documented the feasibility of RIC transplantation with acceptable toxicity and reasonable survival in patients

Fig. 61.2 CHANGE IN ACUTE MYELOID LEUKEMIA OVERALL SURVIVAL WITH TIME. (A) Age 15 to 59 years. (B) Age 60 years or greater. (Data from Burnett A, Wetzler M, Lowenberg B: *Therapeutic advances in acute myeloid leukemia*, J Clin Oncol 29:487, 2011.)

60 years of age and above, including those with AML. Indeed, chronologic age alone does not appear to be a prognostic factor in RIC allogeneic transplantation for AML.^{50,51} In a case-control study comparing RIC transplantation with chemotherapy for AML patients 60 to 70 years of age, allogeneic HSCT was associated with lower relapse risk (32% versus 81%, $p < .001$), greater treatment-related mortality (36% versus 4%; $p < .001$), and longer 3-year leukemia-free survival (32% versus 15%, $p = .001$), with a borderline 3-year OS benefit (37% versus 25%, $p = .08$).⁵²

Overall, for physically fit older patients with AML, especially those between 60 and 70 years of age, a donor search should be undertaken promptly at diagnosis, disease control with intensive induction chemotherapy is beneficial, and they should be considered for potentially curative allogeneic transplantation upon entering complete remission. Broadly speaking, molecular and karyotypic AML risk prognostication also applies to older patients being considered for RIC HSCT, with several caveats. First, favorable risk (e.g., CBF-AML) disease retains a relatively favorable impact in older patients, though it is unknown if data indicating equivalent outcomes of nontransplantation and allogeneic HSCT treatment can be extrapolated to the older patient. Emerging data suggests that allogeneic HSCT offers additional benefit in the older patient with favorable risk disease. For instance, in the UK National Cancer Research Institute (NCRI) AML trial of 16 patients with median age >65 years, *NPM1* mutant *FLT3-ITD* negative AML treated patients with intensive chemotherapy had a 3-year OS of only 26%, with a relapse incidence of 73%.⁵³ Additionally, in a combined SWOG/NCRI cohort, patients with *NPM1* mutant *FLT3-ITD* negative AML who were aged 55–65 years had a significantly improved 2-year OS of 70% versus 27% for those aged >65 years ($p < .001$). The survival benefit of *NPM1* mutant *FLT3-ITD* negative AML was absent in patients aged >65 years.⁵⁴ Importantly, in a separate donor versus no-donor analysis, *NPM1* mutant AML patients with an allogeneic donor had significantly lower 3-year relapse rates (14% versus 46%) and improved relapse-free survival (71% versus 47%), indicating a beneficial antileukemic effect of allogeneic HSCT in this AML subgroup.⁵⁵ Secondly, *MK* and *TP53* mutant AML have an extremely poor prognosis,^{21,22,56} and the adequacy of RIC HSCT is questionable in this AML subgroup. Such patients should be appropriately counseled prior to proceeding with allogeneic HSCT, with consideration to conditioning intensity escalation if possible. Novel clinical trials are a priority for this AML subgroup.

Relapse After Transplantation

AML relapse after allogeneic transplantation is common, has a very poor prognosis, and remains a leading cause of death in this disease. Early identification of HSCT recipients at risk of disease relapse is therefore of considerable importance. While falling donor chimerism after HSCT can identify cohorts at higher relapse risk,^{57,58} more

specific detection of minimal residual disease in the HSCT context has included multi-parameter flow cytometry and molecular markers (e.g., AML-specific translocations or mutations).^{59,60}

Importantly, the identification of patients at high risk of relapse after allogeneic HSCT offers the opportunity for targeted early intervention. For instance, early phase trials of hypomethylating agents for MDS/AML (e.g., azacitidine), and targeting of *FLT3-ITD* AML (e.g., sorafenib) have been reported, with early evidence indicating safety and possible efficacy.^{61,62} Future prospective trials focused on those at high relapse risk (e.g., MRD or chimerism-based selection) offers an informative population for evaluation of intervention efficacy, and is a high priority for improving AML outcomes.

The treatment options for patients with disease relapse after HSCT include withdrawal of immune suppression, donor lymphocyte infusion (DLI), chemotherapy (including novel agents), second allogeneic transplantation, or supportive care.⁶³ Tapering of immune suppression and DLI are used especially in patients without GVHD to enhance antileukemic graft versus leukemia (GVL) effect. DLI has limited efficacy, in the range of 15% to 30%, for patients with relapsed AML, and many responses are incomplete or temporary. Outcomes are better in patients who relapsed beyond 6 months after HSCT, those with lower leukemic burden (less than 35% BM blasts), patients with good-risk cytogenetics, and those who achieved remission before DLI.⁶⁴ Novel options to enhance curative GVL effect include infusion of donor lymphocyte subpopulations (e.g., CD25-depleted DLI, enriched for T effector cells), and immune checkpoint inhibitors (e.g., *CTLA-4* blockade).^{65,66} A second allogeneic HSCT has demonstrable but limited efficacy, and duration of remission of more than a year after initial HSCT is the major predictor of survival.⁶⁷

TRANSPLANTATION FOR MYELOYDYSPLASTIC SYNDROME

The MDSs comprise a heterogeneous group of clonal hematologic stem cell disorders characterized by varying degrees of cytopenias and risk for transformation into acute leukemia⁶⁸ (see Chapter 60). The incidence and prevalence of MDS has increased significantly over the last 20 years as a result of increasing longevity of the population and increasing physician awareness.^{69–71} New therapeutic options such as hypomethylating agents, immunomodulatory drugs, and differentiation induction agents may improve hematologic parameters and reduce transfusion requirements,⁷² and even prolong survival,⁷³ but allogeneic HSCT is the only known curative therapeutic option.

MDS is currently the third most common indication for allogeneic HSCT as reported to the CIBMTR. MDS is a disease predominantly of older individuals, and with the increased use and acceptance of RIC into the eighth decade of life, it is anticipated that transplantation volume for MDS will continue to increase in the coming years.

Contemporary Results of Transplantation for Myelodysplastic Syndrome

Recent analyses of the CIBMTR have suggested improving outcomes for MDS transplantation. An analysis of 701 adult subjects that received a transplant between 2002 and 2006 demonstrated nearly 50% OS when a matched sibling donor was used.⁷⁴ While these results were not statistically different when compared with 8/8 HLA-matched unrelated donors, the 3-year OS in this group was 38%. Using a less well matched unrelated donor, however, was associated with poorer long term survival.

It is becoming increasingly evident that allogeneic transplantation offers a survival advantage over conventional therapies in MDS. One prospective trial that assigned subjects in a donor vs. no donor analysis demonstrated a survival advantage in the donor arm over those without a donor. Importantly, in this analysis, there did not appear to be a decrement in early survival in the donor arm, suggesting that early transplant-related mortality after transplantation is comparable to mortality associated with nontransplant therapies in a high-risk subject cohort. To confirm these findings, two additional large prospective biologic assignment trials have been initiated in Europe and North America.

Clinical Results in Myeloablative Transplantation

There are few reports of transplantation uniquely for patients with the myelodysplastic disorders, because most reports include both patients with AML and those with MDS. Those few analyses that do exist unfortunately often present biased results, because there is inherent patient selection in the reported studies. The bias in these analyses, although recognized by physicians and patients alike, is often overlooked, because patients who choose early HSCT often identify with those included in the analysis to justify their decision.

One of the largest reports of MAC HSCT for MDS is from the Seattle group. Using a targeted busulfan strategy in patients undergoing related or unrelated donor HSCT, results were stratified by pre-transplant International Prognostic Scoring System (IPSS; see Chapter 60) risk score.^{75,76} Patients were prospectively enrolled in the targeted busulfan treatment program; however, the decision to undergo transplantation was based upon physician and patient preference. Results in this study were correlated with IPSS stage, suggesting that outcomes were improved with HSCT at an earlier disease stage. This would be expected because patients with earlier-stage disease have received less treatment (thus less comorbidity) and may also have more indolent disease biology. Among the patients in the lowest IPSS score group there were no relapses, whereas the relapse rate was 42% for patients in the highest IPSS category. As a consequence, 3-year survival was 80% in the lowest IPSS risk group but was under 30% for patients in the high IPSS category. Mutation analysis will need to be incorporated into prognostic systems as we go forward.

Similarly, de Witte et al⁷⁷ examined outcomes of HSCT for patients with earlier-stage MDS (refractory anemia or refractory anemia and ringed sideroblasts). This analysis studied 374 patients who underwent HSCT from either matched, sibling, or unrelated donors. Both standard MAC and RIC regimens were used. IPSS score could be calculated in fewer than half of the patients, and HSCTs were performed over a decade-long period, such that inherent differences in transplantation technology resulted in improved overall survival over time. Although factors such as conditioning intensity, stem cell source, and donor status did not affect outcome, recipient age and duration of identified MDS diagnosis were important predictors of overall survival. Earlier transplantation was associated with an absolute increase in overall survival of 10% at 4 years (57% versus 47%, $p = .02$) and was associated with improved relapse-free survival in multivariable analysis. Despite the finding of improved outcome with earlier HSCT, this should not be interpreted as a recommendation for early HSCT in individuals with low-risk MDS, because the

authors did not compare outcomes to a cohort of patients treated with supportive care alone.

Clinical Results in Reduced-Intensity Conditioning Transplantation

Previously HSCT was available to only a minority of patients with MDS, because 75% of patients are older than 60 years at diagnosis and are not candidates for MAC regimens. Because older patients have a poorer prognosis than their younger counterparts, there is a great impetus to develop strategies for older individuals. Within the RIC literature, there is great variability in the reported conditioning intensity; however, the commonality of these regimens is that they can be safely offered to patients previously deemed too old or to have too much comorbidity for high-dose therapy. It appears that late relapses after MAC HSCT are not common,⁷⁸ but high-intensity regimens are associated with higher treatment-related mortality.⁷⁹ This further justified the shift towards reduced intensity conditioning.

The City of Hope group reported on their outcomes using a RIC regimen of fludarabine and melphalan in 43 patients with MDS or AML. OS was 53% at 2 years, with a 16% relapse rate.⁸⁰ Treating over 90 patients with AML ($n = 74$) or AML ($n = 22$) using a targeted busulfan and fludarabine regimen, de Lima et al⁸¹ reported 1-year treatment-related mortality of only 3%, without a compromise in antitumor activity. Using the more commonly applied RIC regimen of fludarabine with busulfan, albeit with different intensities (and including some patients with AML), other groups have demonstrated similar outcomes, with treatment-related mortality of 13–27%, relapse rates of 23–32%, disease-free survival of 38–68%, and OS of 39–79%.^{82–85}

Comparative Results: Myeloablative and Reduced-Intensity Regimens in Myelodysplastic Syndrome

Several analyses have compared RIC with conventional MAC transplantation, and the majority of them suggest similar outcomes. The premise behind all of these comparisons is that RIC should be associated with a reduction in early treatment-related mortality, whereas MAC approaches should be associated with a reduction in disease relapse. The net effect of these two opposing risks is no difference in outcomes. For example, at the Dana-Farber Cancer Institute, the outcomes of 136 patients with advanced MDS or acute myelogenous leukemia who underwent transplantation were compared when stratified by conditioning regimen intensity.¹ OS at 2 years was the same following RIC as for MAC transplantation (28% versus 34%, $p = .89$); however, the causes of treatment failure were significantly different, with more relapse in the RIC group (61% versus 38%, $p = .02$), but higher treatment-related mortality in the MAC group (32% versus 15% at 100 days) as anticipated. Overall treatment-related mortality, however, was no different ($p = .28$). In this report, patients were treated according to patient and physician preference, whereas in a similar single-center analysis reported by Martino et al,⁸⁶ patients were prospectively assigned to RIC or CD34⁺ selected MAC transplantation based on patient age. In this analysis, nonrelapse mortality and OS were no different between groups.

Similar to single-center studies, large retrospective database studies comparing RIC and high-intensity HSCT have been performed. A CIBMTR review of the outcomes of 550 patients 50 years of age or older who underwent matched sibling donor HSCT showed no difference in MAC and RIC outcomes. In an even larger CIBMTR analysis that included both patients with MDS and those with AML, patients were stratified into MAC, RIC, and truly NMA subgroups. Although results for MDS alone are not available, overall outcomes indicated less-favorable long-term results for NMA regimens when compared with higher-intensity regimens.²⁴ In an analysis by the European Group for Blood and Marrow Transplantation (EBMT) of over 800 patients with MDS, the 3-year relapse rate was significantly

Fig. 61.3 COMPETING RISK CUMULATIVE INCIDENCES FOR RELAPSE AND NONRELAPSE MORTALITY AMONG INDIVIDUALS ABOVE AGE 50 YEARS. *RIC*, Reduced-intensity conditioning. (Data from Lim Z, Brand R, Martino R, et al: Allogeneic hematopoietic stem-cell transplantation for patients 50 years or older with myelodysplastic syndromes or secondary acute myeloid leukemia, *J Clin Oncol* 28:405, 2010.)

higher after RIC (HR, 1.64; $p = .001$), but with less treatment-related mortality (HR, 0.61; $p = .015$), leading to similar 3-year OS (45% versus 41%, $p = .8$). When limited to individuals above 50 years of age, no difference in outcome stratified by conditioning intensity (32% versus 30%, $p = .73$) was noted.⁸⁷ Competing risk cumulative incidences for relapse and nonrelapse mortality are shown in Fig. 61.3.

It is important to consider that none of these retrospective studies adjusted for comorbidity, and it is almost certain that if reanalyzed, the RIC cohorts would contain a higher proportion of patients with more comorbid conditions. Because only a minority of studies suggested that regimen intensity is important for long-term outcomes, some patients, including those without significant comorbidity, have now opted for earlier RIC transplantation, because treatment-related morbidity and mortality after this procedure is lower than after traditional MAC transplantation. In order to compare outcomes prospectively among patients eligible to undergo both MAC and RIC transplantation, the Bone Marrow Transplant Clinical Trials Network initiated a randomized, controlled trial in patients 18 to 65 years of age. This trial was closed prior to completion of accrual because of better outcomes in the myeloablative cohort; however, the results for patients with MDS have not been released at the time of this publication.

A second prospective randomized trial was recently reported by the EBMT. The RIC-MAC trial randomized 129 subjects up to age 65 (60 with an unrelated donor) to either an ablative or reduced-intensity busulfan regimen. There were no statistical differences in nonrelapse mortality, relapse or disease-free survival, but in multivariable regression modeling, there was a survival advantage for subjects who received reduced-intensity conditioning.⁸⁸

Using Prognostic Models to Define the Role and Timing of Transplantation

Clinical, Laboratory, and Cytogenetic Prognostic Factors

Comparative registry analyses have documented the benefit of HSCT over conventional supportive and disease-modifying agents in MDS⁸⁹; however, this should not be interpreted as an indication for HSCT in all patients. Despite the curative potential of HSCT, transplantation carries substantial risk for early morbidity and mortality, and careful consideration must be made regarding the appropriateness of each potential recipient and the timing at which transplantation is

offered. Despite this, all patients who are potential candidates for HSCT should be referred to a transplantation center early in their disease course so that a discussion regarding the appropriateness of transplantation can occur and a donor search can be initiated, where appropriate. The correct timing of HSCT is therefore of paramount importance, and decisions regarding the timing of HSCT should be made on more than patient preference alone.

The most widely used clinical prognostic system is the IPSS, which can predict both nontransplantation outcomes as well as MAC transplantation outcomes.^{90,91} The IPSS-R will eventually supplant the IPSS as the dominant prognostic scoring system. Several groups have attempted to validate this newer prognostic construct with transplant outcomes. A cohort of 519 MDS patients were reported by the Gruppo Italiano Trapianto di Midollo Osseo (GITMO) and their outcomes were stratified by IPSS-R. In addition to the IPSS-R, MK and the HCT comorbidity index independently predicted outcomes. The 5-year survival outcomes were 71%, 58%, 39%, and 23% in the low, intermediate, high, and very high risk patients when classified by the IPSS-R.⁹²

Several Markov decision models have suggested that the optimal timing of transplantation is with the diagnosis of Intermediate-2 or higher disease,^{90,93} although one more heterogeneous analyses suggested that even patients with Intermediate-1 risk disease should be offered transplantation.⁹⁴ Most recently, the first decision model utilizing the IPSS-R was presented. The results of this analysis suggested immediate transplantation for all patients with Intermediate risk disease by IPSS-R, and delayed transplantation for those with low risk disease.⁹⁵

A shortcoming of all of these analyses is the inability to provide treatment decision guidance at clinically relevant times for patients not undergoing immediate HSCT, because other important clinical events, such as a new transfusion requirement, recurrent infection, or recurrent bleeding episodes certainly could be considered triggers to move on to transplantation. Thus it is useful to subdivide patients with lower-risk MDS into more-refined prognostic groups that may benefit from HSCT.

Transfusion frequency and resultant iron overload have both been demonstrated to be important prognostic factors in HSCT outcomes. Platzbecker et al⁶⁶ compared the effects of transfusion dependency at the time of HSCT. Even though the transfusion-dependent group had more low-risk features, OS was inferior, with a 3-year OS of 49% compared with 60% in the transfusion-independent group ($p = 0.1$). The Pavia group examined a cohort of patients stratified by IPSS to determine the relevance of the newer World Health Organization (WHO) histologic classification scheme and to determine if transfusion requirement influenced outcomes among different IPSS groups. For patients with low- and intermediate-1 risk IPSS scores, the WHO histologic classification scheme significantly differentiated survival among the different histologic subtypes within each IPSS range.⁶⁷ More importantly, the authors demonstrated a significant effect on survival based on the requirement for transfusion support. As would be expected, outcomes in patients with higher-grade myelodysplasia were affected less by transfusion requirement than were patients with less-advanced WHO histologic classifications. As a result, the impact of transfusion requirement was then incorporated into the WHO Prognostic Scoring System (WPSS).⁹⁶ In this system, the effect of regular transfusion requirement (defined as requiring at least one transfusion every 8 weeks in a 4-month period) was given the same regression weight as progressing between cytogenetic risk groups. In contrast to the initial IPSS publication, which carries prognostic information only at the time of initial MDS diagnosis, this model was time dependent, such that patients could be continually reevaluated by the scoring model and updated prognostic information could be generated at any time in the patient's treatment course. As such, the development of new cytogenetic changes or the development of a transfusion need adds useful information that helps guide treatment decisions, including the decision to proceed to HSCT as well as estimating transplantation outcomes.⁹⁷ Determining at which WPSS stage transplantation outcomes are superior to nontransplantation therapy has yet to be

determined, although this prognostic scoring system is used less frequently.

Molecular Prognostic Factors

Perhaps even more than in AML, mutation analysis undoubtedly led to a shift from rudimentary clinical prognostic models to molecularly defined models for prognosis and to guide therapy in MDS. As many as 75% of patients can be found to have one or more mutations.⁹⁸ Numerous individual genes and whole genome expression profiling have demonstrated significant associations with MDS outcome, and now, some of these mutational profiles have been associated with transplantation outcome.

Examining a cohort of 87 patients who underwent allogeneic transplantation at Dana-Farber Cancer Institute, Bejar et al were able to demonstrate the adverse prognostic impact of three specific mutations on outcome after transplantation.⁹⁹ In this cohort, although 92% of subjects had at least one identifiable mutation, those with *TET2* and *DNMT3A* had worse prognoses than those without these mutations, whereas those with mutations in *TP53* had the worst outcomes, with no subjects surviving beyond 2 years after transplantation. Mutations in *TP53* were extremely powerful predictors of relapse, and were better prognosticators than cytogenetic status; subjects with complex karyotypes in the absence of *TP53* mutations had similar outcomes to subjects without complex karyotypes, possibly heralding the decline of the cytogenetic signature as the most important prognostic marker in transplantation. In addition, this finding calls into question the role of conventional HSCT off clinical trials for those with the poorest risk profiles, since in the absence of strategies to reduce relapse after transplantation, transplantation appears to offer little benefit.

Incorporating Comorbidity for Patient and Conditioning Intensity Selection Before Transplantation

With increased comorbidity comes an increase in the rate of adverse outcomes in hematologic malignancies, and, in particular, the treatment of MDS.¹⁰⁰ Previously, it was demonstrated that age alone cannot be used as a surrogate for comorbidity, as demonstrated by an analysis of over 500 individuals with MDS who underwent a first RIC transplantation.¹⁰¹ Several comorbidity scores have been developed to help provide prognostic information in myeloid malignancies. In MDS, the Hematopoietic Cell Transplantation Comorbidity Index, developed by Sorror and colleagues,^{102,103} has been shown to carry prognostic value, even in patients with MDS not undergoing transplantation.¹⁰⁴ The consideration of comorbidity before HSCT is even more relevant now that RIC has been shown to be effective in the treatment of MDS, and patients can elect to undergo RIC transplantation. Patients were divided into four separate groups, with each group being defined on the basis of comorbidity and malignant disease risk. Within each of the four risk groups, patients who underwent MAC and RIC were compared with each other. As expected in each of the four groups, the RIC arm experienced higher relapse rates but lower treatment-related mortality rates when compared with the MAC arm. As a result, disease-free and overall survival was similar between conditioning arms in all four groups.¹⁰³ More recently, an enhanced index that incorporates both age and clinical comorbidity was developed and demonstrated even more prognostic power than either of the components alone. In this scoring system those with the highest age-adjusted comorbidity scores have nonrelapse mortality that might exceed 50% at 5 years, with concomitant survival that is less than 20%.¹⁰⁵ Transplantation for this group of individuals should be seriously considered outside the spectrum of routine practice.

The effects of elevated ferritin levels on HSCT until recently have been largely limited to patients undergoing MAC transplantation.⁵ We previously reported that an elevated pre-HSCT serum ferritin level was strongly associated with lower overall and disease-free

survival in patients with AML and MDS after transplantation, and this was largely attributable to increased treatment-related mortality.⁵ Similarly, a prospective single-institution study of 190 adult patients undergoing MAC HSCT demonstrated that elevated pretransplantation serum ferritin level was associated with increased risk for 100-day mortality, acute GVHD, and bloodstream infections or death as a composite endpoint.¹⁰⁶ It has now been recognized that elevated ferritin level can predict inferior outcomes even after RIC transplantation.⁸⁷ As a laboratory prognostic factor, ferritin should be considered a marker of comorbidity, because ferritin is a marker of inflammation. As such, ferritin levels could influence the decision to pursue high-intensity or reduced-intensity HSCT. Optimally, if high-intensity HSCT is planned, proceeding before the accumulation of a critical amount of iron should be pursued, or, alternatively, chelation therapy before HSCT can be considered, although this latter approach has not yet been demonstrated to be effective in prospective clinical trials.

Pretransplantation Therapy

The role of cytoreductive chemotherapy before HSCT for MDS remains controversial. Many analyses have demonstrated that outcomes are improved with lower disease burden at the time of HSCT,¹⁰⁷ but previously only conventional chemotherapy was offered. The analyses that compare chemotherapy to no chemotherapy before HSCT are inherently biased, because patients who do poorly or expire with chemotherapy are not included in HSCT outcome data and might have had favorable outcomes if not exposed to cytotoxic agents. On the other hand, responsiveness to chemotherapy may indicate more favorable disease biology and this has been correlated with improved outcomes after HSCT.¹⁰⁸

With the advent of DNA hypomethylating therapy, the use of conventional chemotherapy has diminished for MDS patients. The effect of DNA hypomethylating therapy on HSCT outcomes has recently been studied by several groups.⁹⁴⁻⁹⁶ Compared retrospectively, it does not appear that pretransplantation hypomethylating therapy offers a survival advantage,¹⁰⁹ but these agents continue to be used widely to prevent disease progression and to reduce transfusion needs while donor selection is performed in patients destined to undergo transplantation. Two recent analyses have compared the use of traditional chemotherapy with hypomethylating therapy prior to transplantation. In the smaller of the two analyses, there was no advantage to hypomethylating therapy over conventional chemotherapy,¹¹⁰ while in the larger of the two, the use of both chemotherapy and hypomethylating therapy prior to transplantation was associated with adverse outcomes, presumably on the basis of identifying subjects with more aggressive disease biology.¹¹¹ Only a prospective randomized trial with survival measured from the time of randomization to pretransplant therapy can rationally answer the question as to the most appropriate pretransplant therapy.

There may be some advantage to the use of these agents before HSCT, because DNA hypomethylating therapy has been shown to upregulate the expression of cancer-testis antigens,^{112,113} killer immunoglobulin-like receptor (KIR) ligands,¹¹⁴ HLA molecules,¹¹⁵ and other minor antigens on tumor cells,¹¹⁶ all of which may enhance graft-versus-MDS effects. Hypomethylating agents have been used after transplantation to reduce the risk for relapse,⁶² but more studies will need to be undertaken before this type of therapy can be routinely recommended.

FUTURE DIRECTIONS

Despite the progress that has been made in conventional therapy for both AML and MDS, allogeneic HSCT has the best track record for curing the disease. Although HSCT has limitations, reductions in toxicity, improvements in donor availability, and new strategies to enhance GVL while limiting GVHD promise to further improve survival. Advances in mutation analysis provide insights into the

pathophysiology of MDS and AML and suggest routes for targeted therapy. However, in many circumstances targeted therapy may not be feasible, and thus the utility of molecular prognostic indicators is to identify patients who will benefit from early transplantation.

ACUTE MYELOID LEUKEMIA IN CHILDREN

Tanja A. Gruber and Jeffrey E. Rubnitz

Acute myeloid leukemia (AML) is a complex and heterogeneous group of malignancies in which genetic and epigenetic alterations lead to the transformation of myeloid cell precursors. The tremendous diversity of abnormalities across subtypes of AML suggests that we must strive to develop therapies that target specific subgroups. Nevertheless, intensification of broadly active chemotherapy, the selective use of hematopoietic stem cell transplantation (HSCT; [Box 62.1](#)), improvements in supportive care and risk stratification, and the use of minimal residual disease (MRD) to monitor response to therapy, have contributed significantly to improvements in the treatment outcome for children with this disease. Survival rates for children with AML who are treated on contemporary clinical trials are now greater than 60%. A subset of patients, including those with acute promyelocytic leukemia (APL), Down syndrome and acute megakaryoblastic leukemia (AMKL), and core-binding factor (CBF) leukemia, have excellent outcomes, with survival rates that approach 90%. However, the cure rates for other subtypes of AML are unacceptably low and cannot be improved simply by further intensification of standard chemotherapy. Genomic and biologic insights into the mechanisms of leukemogenesis have provided opportunities to develop targeted and less toxic therapies for the treatment of AML. Their ability to improve outcomes, however, will be dependent on the requirement of the biologic targets for the survival of the leukemic cell. Thus, a comprehensive understanding of compensatory processes and mechanisms of resistance are critical for the ultimate success of these agents.

EPIDEMIOLOGY

AML accounts for approximately 20% of cases of acute leukemia in children and adolescents younger than 20 years of age. The incidence rates have remained constant over the past 40 years, are similar between boys and girls and, in general, are highest during the first 2 years of life. However, the age distribution may vary between subtypes. For example, APL and CBF leukemia are rare in children younger than 3 years of age, whereas the incidence of AMKL is highest in this young age group and rare among teenagers. The distribution of AML subtypes may also vary among ethnic groups, with some studies suggesting a higher incidence of APL among Hispanic populations.

Although we have learned much about the biology and genetics of AML, the causes remain elusive. The majority of cases are believed to result from interactions among genetic factors that may be inherited or acquired and environmental factors. Constitutional syndromes that are associated with an increased predisposition to AML include Down syndrome, Fanconi anemia, Bloom syndrome, neurofibromatosis, Noonan syndrome, congenital neutropenia, and germline haploinsufficiency of the *RUNX1* gene. Exposure to ionizing radiation, alkylating agents, topoisomerase II inhibitors, and benzene are among the few environmental factors proven to increase the risk of AML. In the majority of cases of childhood AML, neither a genetic nor environmental cause can be identified.

PATHOBIOLOGY

The morphologic and histochemical features of the leukemic cells served as the initial way to subdivide AML into distinct clinical

entities, with the French-American-British (FAB) classification being the prototype of this approach. This classification scheme, however, was limited in biologic, prognostic, and therapeutic significance. The identification of specific cytogenetic alterations and submicroscopic molecular genetic lesions led to newer classification schemes, with the most recent widely used approach being the World Health Organization classification of AML ([Table 62.1](#)). With the development of genome-wide gene expression profiling, array-based comparative genomic hybridization methodologies, and next-generation sequencing, newer insights have been gained into the heterogeneity within AML. These studies have helped to validate the distinct nature of some of the previously described genetic subtypes, including AMKL, APL, the CBF leukemias, and AML with translocations involving the mixed lineage leukemia (*MLL*) gene. In addition, these approaches have identified new genetic subtypes as well as lesions that are enriched within leukemias that have normal karyotypes or miscellaneous chromosomal alterations ([Fig. 62.1](#)). Some of these lesions provide prognostic information and may serve as therapeutic targets for directed therapies.

AML-associated chromosomal translocations are genetic drivers that are believed to be initiating lesions, but are generally insufficient on their own to induce a full leukemic phenotype. Thus, like all cancers, multiple genetic and epigenetic alterations are necessary to convert a normal lineage-restricted stem or progenitor cell into a fully transformed leukemia cell. Although the exact number of mutations necessary to generate a leukemia is likely to differ between specific subtypes of AML, it has been useful to conceptualize the mutations as falling into two broad classes: class I mutations confer a proliferative or survival advantage; and class II mutations block differentiation and result in enhanced self-renewal ([Fig. 62.2](#)). It appears that it takes at least one mutation in each class to transform a normal cell into a leukemic one. Interestingly, many of the class II mutations arise from translocation events that lead to chimeric transcription factors with oncogenic properties. The recent efforts to more deeply explore the molecular lesions that underlie AML have significantly expanded the list of genes whose alterations contribute to leukemogenesis. One of the most surprising findings from these studies was the identification of a very limited number of somatic mutations in AML compared with the much larger numbers seen in other malignancies, such as breast cancer, pancreatic cancer, small-cell lung carcinoma, and melanoma. The number of mutations in pediatric AML is also significantly lower than the number of mutations seen in pediatric acute lymphoblastic leukemia (ALL), with one study finding an average of only 2.38 somatic copy-number alterations (CNAs; e.g., deletions and/or amplifications) in AML compared with an average of 6.46 CNAs in pediatric ALL. Even more striking was the lack of any CNAs in 34% of patients.

One of the early dogmas of cancer biology purports that tumors are clonal and arise from single cells. In support of this are cytogenetic studies demonstrating that leukemia cells within a patient are uniform in their abnormalities. As our ability to detect mutations has increased with the advent of next-generation sequencing, it has become apparent that while there is typically a founding clone that carries a subset of mutations present in all tumor cells, there is also significant tumor heterogeneity at diagnosis when taking into account the full complement of lesions. This is perhaps not surprising, given that cells can acquire new mutations with each cellular division. Furthermore, this heterogeneity provides an advantage to the tumor cells in that

BOX 62.1 Allogeneic Hematopoietic Stem Cell Transplantation in First Remission

Although the use of allogeneic hematopoietic stem cell transplantation (HSCT) in first remission is controversial, we recommend it for high-risk patients, including those with -7, t(6;11)(q27;q23), t(10;11)(p12;q23), t(10;11)(p11.2;q23), t(5;11)(q35;p15.5), t(6;9)(p23;q34), t(8;16)(p11;p13), inv(16)(p13.3q24.3), and t(16;21)(q24;q22). Until the impact of FLT3 inhibitors on the outcome of patients with *FLT3* internal tandem duplication (ITD) has been determined, we recommend HSCT for patients with *FLT3*-ITD and high allelic ratios or poor response to therapy. Patients who do not have high-risk genetic features but who have high (>1% after the first course of therapy) or persistent (>0.1% after two courses of therapy) levels of minimal residual disease (MRD) are also at high risk of relapse and are therefore candidates for HSCT in first remission. Because recent studies have demonstrated that outcomes after HSCT are similar regardless of donor type, we believe that the decision to perform HSCT in first remission should be based on the factors described above, rather than on the availability of a matched donor. Thus, patients who are classified as high-risk acute myeloid leukemia based on genetic features or MRD should undergo HSCT using a matched sibling donor, matched unrelated donor, haploidentical donor, or cord blood in first remission. Prior to transplant, reasonable efforts should be made to reduce the level of MRD as much as possible without causing organ toxicity or infectious complications that may increase transplant-related morbidity or mortality.

TABLE 62.1 2016 World Health Organization Classification of Acute Myeloid Leukemia and Related Neoplasms

Acute myeloid leukemia with recurrent genetic abnormalities
AML with t(8;21)(q22;q22); RUNX1-RUNX1T1
AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); CBFβ-MYH11
APL with t(15;17)(q22;q12); PML-RARA
AML with t(9;11)(p22;q23); MLL-MLLT3
AML with t(6;9)(p23;q34); DEK-NUP214
AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2); RPN1-EVI1
AML (megakaryoblastic) with t(1;22)(p13;q13); RBM15-MKL1
AML with mutated NPM1
AML with mutated CEBPA
<i>Provisional entity:</i> AML with BCR-ABL1
<i>Provisional entity:</i> AML with mutated RUNX1
Acute myeloid leukemia with myelodysplasia-related changes
Therapy-related myeloid neoplasms
Acute myeloid leukemia, not otherwise specified
AML with minimal differentiation
AML without maturation
AML with maturation
Acute myelomonocytic leukemia
Acute monoblastic/monocytic leukemia
Pure erythroid leukemia
Acute megakaryoblastic leukemia
Acute basophilic leukemia
Acute panmyelosis with myelofibrosis
Myeloid sarcoma
Myeloid proliferations related to Down syndrome
Transient abnormal myelopoiesis
Myeloid leukemia associated with Down syndrome

AML, Acute myeloid leukemia.

Modified from Arber DA, Orazi A, Hasserjian R, et al: The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia, *Blood* 127:2391, 2016

different subclones may have different growth characteristics and drug sensitivities depending on the complement of mutations present. However, the most robust AML clones in the laboratory, as determined by engraftment into immunodeficient mice, do not necessarily equate to the dominant clone at diagnosis nor the clone that leads to relapse. It is thus clear that we still have an incomplete understanding

of the molecular pathology of pediatric AML. Ongoing DNA sequencing efforts and studies on the epigenetic state of leukemia cells, coupled with biologic studies to understand the role of individual mutations as well as the spectrum of mutations within a given patient, will likely produce a much deeper understanding of the disease and mechanisms of drug resistance over the next several years. In this chapter we discuss the major subtypes of AML and our current understanding of the biologic processes that mediate disease.

The Core-Binding Factor Leukemias

The CBF transcription complex is a heterodimeric complex composed of an alpha DNA-binding subunit (RUNX1, RUNX2, or RUNX3), and a non-DNA-binding beta subunit (CBFβ). The complex functions as a master regulator that controls the birth of the definitive hematopoietic stem cell (HSC) during embryogenesis and plays important roles in normal hematopoietic cells, both in the control of their differentiation state as well as their effector functions. *RUNX1* was the first identified mammalian CBF gene and was isolated as part of the AML-associated translocation t(8;21)(q22;q22.3). Following the discovery of *RUNX1*, the inv(16) and the less common t(16;16)(p13;q22), which are found in the majority of acute monoblastic leukemias with eosinophilia (FAB-M4Eo), were cloned and shown to result in a fusion between *CBFβ* and *MYH11*, the gene that encodes smooth muscle myosin heavy chain (SMMHC). Subsequently, rare somatic mutations of *RUNX1* were detected in de novo AML, with the highest frequency (40%) seen in the FAB-M0 subtype. These mutations lead to impairment in DNA binding or decreased transcriptional activity. Collectively, these data reveal that mutations in the genes encoding the RUNX1/CBFβ transcription factor complex are one of the most common lesions seen in de novo AML, occurring in approximately 25% of cases.

The most frequently observed rearrangement in AML is the t(8;21), which fuses the 5' portion of *RUNX1* to almost the entire coding region of *RUNX1T1*. The *RUNX1-RUNX1T1* fusion product functions primarily as a transcriptional repressor, inhibiting the expression of lineage-specific genes that are normally activated by the RUNX1-CBFβ complex to promote myeloid differentiation. In human and murine systems, expression of *RUNX1-RUNX1T1* is insufficient to induce leukemia, but does establish a preleukemic population that has enhanced self-renewal properties and can acquire additional mutations over time to lead to overt leukemia. Consistent with this hypothesis, in bone marrow samples from patients that have achieved a clinical remission, rare progenitors expressing *RUNX1-RUNX1T1* are present and can persist for years without expanding. These cells also retain the ability to differentiate into multiple lineages, so arguably they are not fully leukemic in nature. Cooperating mutations that promote full transformation identified in patients with CBF alterations include *FLT3*, *c-KIT*, and *RAS* among others, many of which confer a proliferative advantage.

The inv(16)/t(16;16)-encoded CBFβ-MYH11 fusion protein retains the RUNX1 binding domain and therefore its ability to interact with wild-type RUNX1. This chimeric protein functions in a dominant manner to inhibit normal RUNX transcriptional activity. Interestingly, 90% of *CBFβ-MYH11* conditional knock-in mice spontaneously developed AML with a latency of 5 months, implying that fewer cooperating mutations are necessary for this chimeric oncogene than *RUNX1-RUNX1T1*. These results may be explained by increasing evidence that CBFβ-MYH11 has functions independent of RUNX1 repression. Knock-in mice expressing a mutant Cbfb-MYH11 allele that has low binding affinity for Runx1 demonstrate decreased repression of Runx1, but this did not correlate with reduced leukemogenesis. In fact, the mice developed leukemia faster, suggesting that there are Runx1-independent mechanisms of transformation by the chimeric protein. An analogous setting occurs in patients as well, whereby a small percentage of inv(16) AML patients produce a fusion protein that lacks the high-affinity binding domain responsible for enhanced binding to RUNX1. The clinical course and characteristics of these cases do not differ from cases in which the

Fig. 62.1 FREQUENCIES OF RECURRENT GENETIC LESIONS IN CHILDHOOD ACUTE MYELOID LEUKEMIA. *MLL*, Mixed lineage leukemia.

fusion protein retains the high-affinity binding domain, further suggesting that dominant repression of *RUNX1* is not the only mechanism through which the fusion gene contributes to leukemogenesis. The targets of the *RUNX1*-independent mechanism are unknown, as are the relative importance of the dependent and independent activities.

MLL Gene Rearrangements

The *MLL* gene, located on chromosome 11 band q23, is a mammalian homologue of the *Drosophila* trithorax (*Trx*) protein. The trithorax protein in *Drosophila* positively regulates homeodomain (*HOX*) genes, a set of transcription factors that specify cell identity along the anteroposterior axis of segmented animals during embryonic development. Their positive regulation is countered by Polycomb-group (PcG) proteins, such as BMI1, which act as transcriptional repressors of the *HOX* genes.

MLL encodes a protein of approximately 500 kDa with multiple domains that form part of a multiprotein complex involving transcription regulators including TFIID, SWI/SNF, NuRD, hSNF5H, and SIN3A. This complex is responsible for chromatin remodeling, including acetylation, deacetylation, and methylation of nucleosome-attached histones. *MLL* is thought to play a role in the recruitment of proteins, assembly of the complex, and is required for transcriptional elongation of its target genes. Experiments evaluating the

contribution of *MLL*-deficient embryonic stem cells in chimeric animals found an absence of lymphoid and myeloid populations derived from the *MLL*-deficient stem cells, demonstrating a requirement for *MLL* in either the specification or expansion of HSCs during development. Conditional knockout of the *MLL* gene in adult mice leads to bone marrow failure within 3 weeks, providing evidence that *MLL* is not only required for definitive hematopoiesis, but is also required for maintenance of HSCs in postnatal hematopoiesis.

Chromosomal translocations involving the *MLL* gene are associated with both AML and ALL leukemias, with more than 50 different translocation partners identified. *MLL* rearrangements are found in 60%–70% of infants with leukemia, regardless of immunophenotype, but are less common in older children and adults. The distribution of translocation partners varies depending on the age of the patient and the immunophenotype of leukemia, with *MLLT3*, *MLLT10*, *MLLT4*, and *ELL* being more frequent in pediatric AML. With the exception of internal partial tandem duplications (PTD) of *MLL* (*MLL*-PTD), the majority of *MLL* rearrangements contain the N-terminus of *MLL* and the C-terminus of the fusion partner gene. Some of the partner genes are nuclear proteins with transcription modulation activity that lead to activation of *MLL* target loci, while others are either cytoplasmic or membrane bound with diverse functions but share in common the presence of dimerization/oligomerization domains. Oligomerization promotes enhanced recruitment of transcription cofactors as well as stabilization of the large multiprotein transcriptional complex.

Fig. 62.2 PATHOGENESIS OF ACUTE MYELOID LEUKEMIA. Leukemic blasts contain mutations that collectively lead to enhanced self-renewal, a block in differentiation, decreased apoptosis, proliferation, and a growth advantage. Many of the acute myeloid leukemia-associated fusion genes as well as point mutations and small insertion/deletions in genes lead to a block in differentiation of hematopoietic progenitor cells, resulting in an immature phenotype. Cooperating mutations in genes that activate kinase signaling pathways are often present that enhance proliferation and lead to robust cytokine-independent growth, providing a survival advantage. Examples of mutations conferring these characteristics are shown.

In addition to the recruitment of transcriptional transactivators by these fusion proteins, several have been shown to recruit hDOT1L, a histone methyltransferase that methylates H3 lysine residues (H3K79). hDOT1L recruitment is ubiquitously coupled with active transcription and is responsible for H3K79 methylation in the proximal part of a given gene. A global loss of H3K79 methylation significantly affects heterochromatin formation; therefore the aberrant recruitment of hDOT1L by MLL fusions and the resulting H3K79 methylation are thought to affect gene expression by altering chromatin accessibility.

Leukemias with *MLL* translocations show increased expression of multiple *HOX* genes, including *HOXA4*, *HOXA5*, *HOXA9*, and *HOXA10* regardless of their immunophenotype. *HOX* genes encode transcription factors whose deregulated expression is identified in multiple cancers, although the mechanisms by which they contribute to carcinogenesis are extremely varied. All hematopoietic progenitors express a characteristic pattern of *HOX* genes dependent on their lineage and stage of differentiation. Overexpression of individual *HOX* genes results in disturbance of stem cell pools and differentiation patterns, some of which lead to myeloproliferation and even overt AML in mice. *HOXA9*, in particular, leads to increased self-renewal of hematopoietic progenitors and overexpression in AML patients has been frequently described, specifically in patients with *MLL* gene rearrangements. In multiple models, *HOXA9* is required for *MLL*-mediated leukemogenesis, although this does not hold true

in *MLL-MLLT3* transgenic mice. Although *HOXA9* was not specifically required for *MLL-MLLT3*-mediated leukemogenesis, multiple other *HOX* genes are upregulated in this model and it was proposed that due to functional redundancy within members of a given Hox cluster, a “Hox code,” as defined by upregulation of multiple *HOX* genes, is sufficient for the development of leukemia as opposed to one specific gene.

In contrast to CBF leukemias, where cooperating genetic lesions providing a proliferative signal have been described, analysis of *MLL*-rearranged leukemia suggests that very few additional mutations are present in this subset of patients. CNAs in *MLL*-rearranged cases average only 1.33 for pediatric AML and 1 for pediatric ALL in two studies. Next-generation sequencing of *MLL*-rearranged leukemias has confirmed a paucity of cooperating mutations, although approximately 50% carry an activating tyrosine kinase mutation in this pathway, providing the so-called *second hit* for leukemogenesis. However, cases exist that lack additional genetic alterations, and the kinase mutations for those samples that contain them are typically subclonal and often absent at relapse. These data confirm the strength of the *MLL* fusion genes and suggest targeting of cooperating mutations will not result in a therapeutic benefit.

Partial Tandem Duplications of MLL (MLL-PTD)

Tandem duplication of the 5′ end of the *MLL* gene was initially observed in AML with a normal karyotype or trisomy 11. The duplications are in-frame repetitions of exons and lead to a potentially translatable sequence. In patients with a normal karyotype, the PTD is only present on one allele; similarly, in trisomy 11 patients only one allele is mutated while the other two are unchanged. In contrast to *MLL* fusion genes, the C-terminal portion of MLL is retained.

Interestingly, pediatric *MLL*-PTD cases failed to cluster with other *MLL* gene rearrangement cases in gene expression profiling. When *MLL*-PTD was considered as a subgroup and compared to other subtypes of AML, no class-discriminating genes could be identified, suggesting that this subtype is not only distinct from other *MLL*-rearranged cases, but also is heterogeneous. In addition, unique to *MLL*-PTD is the absence of the wild-type *MLL* gene transcript. AML cases with the *MLL-MLLT3* translocation retain expression of the normal *MLL* allele, and this coexpression is required for leukemogenesis in murine hematopoietic cells. The wild-type *MLL* transcript is absent in *MLL*-PTD; however, antisense oligodeoxynucleotides against *MLL*-PTD result in reexpression of the wild-type transcript, suggesting *MLL*-PTD is silencing transcription at the wild-type locus. In addition to antisense oligodeoxynucleotides, the silencing could also be reversed by DNA methyltransferase and histone deacetylase inhibitors. Reexpression of the wild-type allele was associated with increased cell death and reduced proliferation, indicating that the repression of wild-type *MLL* contributes to transformation.

Despite expression array data suggesting *MLL*-PTD is a distinct biologic entity, experiments have shown that the mechanism of *MLL*-PTD-mediated leukemogenesis shares many similarities with other *MLL* fusion proteins. *MLL*-PTD is able to induce strong transactivation in a *MYC*-luciferase reporter assay similar to a dimerized *MLL* fusion gene construct. The duplication of the N-terminal domains may therefore allow dimerization, leading to altered gene expression and malignant transformation. A mouse knock-in model in which exons 5–11 of murine *Mll* were targeted to intron 4 of the endogenous locus resulted in upregulated *HoxA9* gene expression, increased CFU replating capacity, and enhanced proliferation, similar to *MLL* fusion proteins.

Acute Promyelocytic Leukemia

APL is morphologically identified as AML-M3 by the FAB classification and is characterized by a balanced reciprocal translocation between chromosomes 15q22 and 17q1221. In the late 1970s, it was discovered that leukemia cells could be forced to differentiate in vitro

when exposed to retinoic acid. Based on this observation, Zhen-Yi Wang treated a 5-year-old girl with refractory APL who was in a critical condition with all-*trans*-retinoic acid (ATRA). With single-agent ATRA, she achieved a complete remission (CR) and remains disease free to this day. Wang and colleagues subsequently treated 24 patients with APL and were able to improve the CR rate to 96% with ATRA alone. In addition to high CR rates, ATRA has improved long-term outcomes, with 5-year EFS rates as high as 85% in adults and 91% in children. This remarkable response rate to ATRA was specific for APL, leading researchers to explore the retinoic acid receptor (RAR) in this population. In the early 1990s, several groups simultaneously demonstrated that the translocation that characterizes this malignancy encodes a chimeric protein fusing the *PML* gene with the RAR (*RARA*) gene. In contrast to the expected paradigm, whereby molecular biology leads to the development of a targeted agent, ATRA was found to be effective prior to the understanding of the mechanism. In studying the response of APL to this agent, much of the biology of APL has come to light, demonstrating the constant interplay that exists between science and medicine.

Greater than 98% of patients with APL carry t(15;17)(q22;q1221), which fuses the *PML* gene with the *RARA* gene to create the chimeric oncogene *PML-RARA*. Retinoid signaling is relayed by two families of nuclear receptors, the RARs and the retinoid X receptor, that together form heterodimers. In the absence of retinoic acid, these heterodimers bind to target gene promoters and repress transcription through the recruitment of NCoR, SMRT, and HDAC corepressors. When retinoic acid binds, a conformational change allows the recruitment of coactivators and histone acetyltransferases, resulting in activation of transcription. *RARA* is highly expressed in myeloid cells, and activation of its transcriptional targets promotes granulopoiesis. *PML-RARA* expression impairs normal responses to retinoic acid as the fusion protein binds to transcriptional corepressors and histone deacetylases with a higher affinity than wild-type *RARA*.

In addition to the effects on transcription, the fusion gene alters localization of PML. In wild-type cells, PML is localized in discrete nuclear subdomains, called *nuclear bodies*, which likely play a role in senescence, growth control, telomere lengthening, and DNA repair. These nuclear bodies are disrupted by PML-RARA in a manner that is reversible by treatment, suggesting that they are important in apoptosis and growth control. PML is in fact a p53 target gene, and regulates p53 stability by sequestering Mdm2, a negative regulator of p53, to the nucleolus, thus providing a mechanism for this phenotype. PML contains a sumoylation site that is present on the PML-RARA chimeric protein and is required for leukemic transformation.

The mechanism whereby retinoic acid induces differentiation of APL cells carrying *PML-RARA* was delineated following the demonstration of its clinical efficacy. Retinoic acid binds to the hormone-binding site of PML-RARA, inducing a conformational change that triggers co-repressor release and co-activator recruitment, opening up the chromatin structure and relieving the transcriptional repression. Global transcription and protein alterations following treatment with retinoic acid are significant for a large number of genes involved in granulocyte differentiation, such as CEBPs, cytokines, cytokine receptors, and molecules downstream of cytokine signaling. Another effect of ATRA is to induce proteasome degradation of the chimeric oncogene.

ATRA is not the only targeted agent for APL. Ai-ling 1, a Chinese remedy historically used to treat a variety of illnesses, was tested by a group from Harbin Medical University in the 1970s in more than 1000 patients with different cancers and was found to induce remissions in approximately two-thirds of patients with APL. Zhu Chen, a scientist in Shanghai, collaborated with the Harbin team in 1994 to demonstrate that the effective component of this remedy was arsenic (III) trioxide. Importantly, arsenic was able to induce remissions in patients who had failed ATRA and conventional chemotherapy. Subsequently, many groups confirmed these findings and the mechanism of action has been under study ever since. At high concentrations, arsenic induces apoptosis of APL, while low doses promote maturation and differentiation. Arsenic treatment causes

PML to be localized to the nuclear matrix where it becomes sumoylated and subsequently degraded by proteasomes. When global transcription and protein patterns affected by arsenic were compared to those altered by ATRA, it was found that while arsenic regulated a significant number of genes also regulated by ATRA, the total number of affected genes was much less. Arsenic altered a more significant change in protein patterns than ATRA, suggesting that its main mechanism was through protein alterations as opposed to gene expression modulation.

Acute Megakaryocytic Leukemia

AMKL is a subtype of AML characterized by abnormal megakaryoblasts that express platelet-specific surface glycoprotein. Bone marrow biopsy frequently demonstrates extensive myelofibrosis, often making aspiration in these patients difficult. AMKL is rare in adults, occurring in only 1% of AML patients, but comprises between 4% and 15% of childhood AML cases. In pediatrics, the disease is divided into two major subgroups: AMKL in patients with Down syndrome (DS-AMKL) and AMKL in patients without Down syndrome (non-DS-AMKL). AMKL is the most frequent type of AML in children with Down syndrome, and the incidence in these patients is 500-fold higher than in the general population. Somatic mutations in *GATA1* are found in almost all cases of DS-AMKL and precede the development of leukemia, as indicated by their presence in patients with transient myeloproliferative disease (TMD) in the neonatal period. Pediatric non-DS-AMKL is a heterogeneous group of patients, a significant proportion of which carry chimeric oncogenes including *RBM15-MKL1*, *CBFA2T3-GLIS2*, *NUP98-KDM5A*, and *MLL* gene rearrangements.

DS-AMKL is associated with a hematologic disorder in infancy, termed TMD. In this disorder, a clonal population of megakaryoblasts accumulates in the peripheral blood. These blasts are phenotypically indistinguishable from AMKL leukemic blasts, and in the majority of cases remission is spontaneous within 3 months in the absence of treatment. In approximately 20% of TMD cases patients will develop MDS or AMKL. TMD is felt to originate in utero, as mutations in *GATA1*, the genetic lesion associated with TMD, have been found to be present at birth in patients that suffered from TMD. Exome sequencing of TMD has revealed that nonsilent mutations in these blasts are primarily limited to the *GATA1* gene. In contrast, AMKL blasts carry a higher burden of mutations, with additional lesions in epigenetic and kinase-signaling genes leading to progression of the disease. Collectively, these findings support a model whereby TMD blasts arise secondary to *GATA1* mutations, acquiring this so-called *first hit* and persist in the bone marrow. Additional lesions can then occur, providing the cooperating events that are necessary for full blown leukemia to develop.

The GATA proteins are transcription factors, three of which are expressed principally in hematopoietic cells (*GATA1*, *GATA2*, and *GATA3*). *GATA1* is required for the development of erythrocytes, megakaryocytes, eosinophils, and mast cells. Mutations detected in DS patients with AMKL consist of short deletions, insertions, and point mutations within exon 2 that introduce a premature stop codon. This shorter mutant protein retains the ability to bind DNA and interact with its cofactor, but lacks the transcriptional activation domain and hence has reduced transactivation potential. *GATA1* is able to activate lineage specific genes and repress progenitor maintenance genes depending on the cofactors present. Deregulation of these targets contributes to the differentiation arrest seen with the truncated *GATA1* that is no longer able to transactivate transcription of lineage-specific genes. Given that only 20% of TMD progresses to leukemia, what then are the subsequent events or alterations that promote the preleukemic state to that of a fully transformed malignancy? Exome and targeted sequencing of 46 genes has provided insight to this question, identifying recurrently mutated genes in three major categories: cohesin, epigenetic regulators, and signaling molecules. These include the cohesin complex genes *STAG2*, *RAD21*, *SMC3*, *SMC1A*, *NIPBL* and *CTCF*; PRC2 complex genes *EZH2* and

SUZ12; as well as kinases such as *JAK1*, *JAK2*, *JAK3*, *MPL*, *KRAS*, and *NRAS*.

t(1;22), which is seen exclusively in infants with AMKL, fuses *RBM15* and *MKL1*. *MKL1* is a transcriptional coactivator for serum response factor (SRF), a transcription factor that regulates the expression of genes involved in cell growth, proliferation, and differentiation, as well as genes that control the actin cytoskeleton. In unstimulated cells *MKL1* associates with G-actin monomers and is retained in the cytoplasm. Following stimulation and Rho-mediated actin polymerization, G-actin pools are depleted and *MKL1* translocates to the nucleus, associating with SRF to activate gene transcription. *RBM15* encodes a protein containing three N-terminal RNA recognition motifs that bind to nucleic acids and a Spen paralogue and orthologue C-terminal (SPOC) domain that is thought to interact with the SMRT and NCoR corepressor complexes, as well as RBPJ, a transcription factor downstream of Notch signaling. The fusion of *MKL1* to *RBM15* deregulates the normal intracellular localization of *MKL1* such that it becomes constitutively localized to the nucleus, resulting in SRF activation even in the absence of stimuli. In addition to the SRF transcriptional program, the fusion also aberrantly activates RBPJ transcriptional targets. While both transcription programs have been shown to be deregulated by the fusion gene, the degree to which they contribute to transformation is still unclear.

Until recently, with the exception of the *RBM15-MKL1* fusion, the genetic etiology of non-DS-AMKL had remained elusive. Transcriptome sequencing of a small cohort identified a cryptic inversion on chromosome 16 [inv(16)(p13.3q24.3)] in half of the patients that resulted in the joining of *CBFA2T3*, a member of the ETO family of nuclear corepressors, to *GLIS2*, a member of the GLI family of transcription factors. The gene expression profile of *CBFA2T3-GLIS2* AMKL was distinct from that of AMKL cells lacking this chimeric transcript, and from other genetic subtypes of pediatric AML. Furthermore, the *CBFA2T3-GLIS2* fusion gene conferred a poor prognosis, a finding that has since been confirmed. Expression of *CBFA2T3-GLIS2* in *Drosophila* and murine hematopoietic cells induces bone morphogenic protein (BMP) signaling, a pathway not previously implicated in AML, and results in a marked increase in the self-renewal capacity of hematopoietic progenitors. *CBFA2T3-GLIS2*-expressing cells remained growth factor dependent in vitro and fail to induce leukemia in mice, consistent with a requirement for cooperative mutations. Overall, the total burden of somatic mutations in *CBFA2T3-GLIS2*-expressing cases is low; however, several have been found to carry lesions in either a Janus kinase (JAK) gene and/or a somatic amplification of the Down syndrome critical region on chromosome 21.

In addition to *CBFA2T3-GLIS2*, approximately 8% of pediatric non-DS-AMKL cases carry the *NUP98-KDM5A* fusion. *NUP98*, a nucleoporin family member with transactivation activity, fused to *KDM5A*, an H3K4me3-binding PHD finger, was initially described in adult AML. When introduced into murine bone marrow, this fusion oncogene induces a myeloid differentiation arrest and mice develop AML with an average latency of 69 days. Wang and colleagues demonstrated this fusion to be bound to H3K4me3 mononucleosomes, showing the PHD finger plays a role in targeting the fusion to the genome. Interestingly, microarray analysis identified several polycomb proteins carrying H3K4me3 marks to be transcriptionally upregulated in response to the fusion, while housekeeping genes with constitutive H3K4me3 marks remained unchanged. Affected polycomb targets confirmed by chromatin immunoprecipitation include genes upregulated in *MLL*-rearranged leukemia such as *HOXA5*, *HOXA7*, *HOXA9*, *HOXA10*, *MEIS1*, and *PBX1*. Furthermore, the authors demonstrate a block in PRC2 binding, the complex that antagonizes polycomb proteins through transcriptional repression of target genes. Therefore, the *NUP98-KDM5A* fusion is able to prevent silencing of critical transcription factors that play a role in maintaining hematopoietic progenitor status, similar to *MLL* gene rearrangements. It is perhaps not surprising then, that *MLL-AF9* and *MLL-AF10* fusion events have also been detected in non-DS-AMKL. As these lesions are also found in other subtypes of AML,

there are likely additional factors contributing to the development of megakaryoblastic disease. Cooperating mutations, the target cell, and the microenvironment all have the potential to direct lineage during the process of transformation.

Cytogenetically Normal AML

Approximately 20%–25% of pediatric AML cases lack chromosomal aberrations and are prognostically defined as intermediate risk. To understand the underlying lesions driving this form of AML and to use this information to further refine risk stratification of these patients, efforts have been made by a number of groups to identify the genetic lesions within this AML subtype. Identified genetic lesions have included mutations within the genes *FLT3*, *NPM1*, *IDH*, *RAS*, and *CEBPA*. More recent whole-genome sequencing analysis of cytogenetically normal adult AML has identified these previously described mutations, as well as the mutation of a number of other genes including *DNMT3A*, which are thought to contribute to tumorigenesis. Below we discuss the most frequent somatic mutations identified within pediatric AMLs with a normal karyotype.

Nucleophosmin

Nucleophosmin (*NPM*) is often mutated in cytogenetically normal AML and is unique in that it has both oncogenic and tumor suppressor functions. The protein shuttles between the nucleus and cytoplasm, taking part in many cellular processes including regulation of ribosomal RNA transcription/processing, transport of preribosomal particles to the cytoplasm, DNA-histone and nucleosome assembly, as well as regulating the activity and stability of tumor suppressors such as p53 and ARF. Alterations of *NPM* in cancer include its overexpression in a variety of epithelial cancers; involvement in chromosomal translocation in several hematological malignancies including the t(2;5)[*NPM-ALK*] in anaplastic large-cell lymphoma (ALCL), t(3;5)[*NPM-MLF1*] in myelodysplastic syndrome and AML and t(5;17)[*NPM-RARA*] in variant APL; and point mutations that alter its C-terminus resulting in the creation of a new nuclear export signal. Each of these genetic alterations result in alteration of the normal shuttling of *NPM* between the cytoplasm and nucleus, resulting in constitutive cytoplasmic localization. Mutations in *NPM* are found in 35% of cytogenetically normal adult AMLs but only between 2% and 12% of pediatric AMLs with normal cytogenetics.

The tumor suppressor function of *NPM* in hematologic malignancies is attributed to its role in maintenance of genomic stability and in the regulation of the ARF-p53 tumor suppressor pathway. Wild-type *NPM* forms a complex with ARF and HDM2, which stabilizes ARF and prevents HDM2-mediated p53 degradation. More recently, it has also been shown that in the absence of *NPM* or in the presence of an *NPM* mutant, cells express increased protein levels of the MYC proto-oncogene due to a loss of degradation by the *NPM*-stabilized ubiquitin ligase, FBW7G. Given that mutations in *NPM* are able to suppress the ARF-p53 tumor suppressor pathway and enhance the oncogenic MYC pathway, it is perhaps not surprising that the mutation occurs in the context of cytogenetically normal AML with a minimal number of secondary lesions.

Isocitrate Dehydrogenase and TET2

Isocitrate dehydrogenase 1 (*IDH1*) was initially identified as a target of cancer-associated mutations in a study that performed whole-exome sequencing on glioblastoma multiforme (GBM). Subsequent analyses revealed *IDH1* or *IDH2* mutations in up to 16% of adult and about 7% of pediatric AMLs with normal cytogenetics. The mutations in both GBM and AML have been heterozygous and restricted to arginine 132 in exon 4 of *IDH1*, or to either the homologous residue in *IDH2*, R172, or to a second arginine, R140, also located in its substrate binding pocket. Although the distribution of specific *IDH1/IDH2* mutations varies between GBM and AML, each results in a loss of the enzyme's ability to catalyze the oxidative carboxylation of isocitrate to α -ketoglutarate (α -KG), coupled with a

gain of function to catalyze the NADPH-dependent reduction of α -KG to 2-hydroxyglutarate (2-HG). The altered activity of the enzyme leads to an increase in the level of 2-HG, which has pleiotropic effects including the inhibition of the enzymatic activity of the α -KG-dependent enzyme TET oncogene family member 2 (TET2), responsible for catalyzing the conversion of 5-methylcytosine to 5-hydroxymethylcytosine. Loss-of-function mutations of *TET2* have also been identified in a variety of hematopoietic malignancies including MDS, myeloproliferative neoplasms and AML. Interestingly, mutations in *IDH1/2* and *TET2* appear to be mutually exclusive, confirming a common downstream effect of these lesions. Alterations of the enzymatic activity of TET2, either through direct mutations or mutation of *IDH1/2*, lead to enhanced self-renewal of hematopoietic progenitors and an expansion of the stem cell and progenitor cell compartment, and thereby directly contribute to leukemogenesis.

FMS-like Tyrosine Kinase 3

FMS-like tyrosine kinase 3 (FLT3, FLK2) is a class III receptor tyrosine kinase that is normally expressed in early hematopoietic progenitors that are CD34⁺/c-Kit⁺. When bound by its ligand (FLT3 ligand or FL) the receptor dimerizes, leading to activation of the receptor's intrinsic tyrosine kinase activity. The activated kinase signals through a variety of pathways including the phosphatidylinositol 3-kinase (PI3K) and RAS signal-transduction cascades through phosphorylation of cytoplasmic substrates. Two major classes of FLT3-activating mutations have been identified in AML, internal tandem duplication (ITD) in the juxtamembrane domain and point mutations in the tyrosine kinase domain (TKD). Both classes of mutations result in ligand-independent constitutive activation of the receptor's kinase activity and induce factor-independent growth of the murine pro-B-cell line Ba/F3. *FLT3* mutations are frequent cooperating lesions, being found not only in cytogenetically normal AML, but in APL, CBF AML, and *MLL*-rearranged leukemia as well.

The *FLT3*-ITD mutation results from a fragment of the juxtamembrane-domain coding sequence that is duplicated and inserted, the length of which varies from 3 to 400 bp. The juxtamembrane domain is a negative regulator of the kinase activity and the ITD leads to a disruption of this autoinhibitory activity. As a result of the disruption of this domain, the mutant *FLT3*-ITD undergoes ligand-independent dimerization and tyrosine autophosphorylation, and this constitutively active tyrosine kinase activates the downstream targets that are normally regulated by the native receptor. Transplantation of bone marrow cells transduced with *FLT3*-ITD into mice leads to a myeloproliferative disorder but not leukemia, underscoring the importance of cooperative mutations in *FLT3*-ITD-positive malignancy. In a study of 144 cases of newly diagnosed adult AML, 24 out of 28 *FLT3*-ITD-positive cases had second mutations/alterations, the most frequent of which were mutations of *NPM1*, *MLL*-PTD, *CEBPA*, and *PML-RARA*.

FLT3-TKD mutations occur in the activation loop of the kinase domain, leading to constitutive activation. In a wild-type setting, ligand-induced activation of FLT3 causes an active configuration to form, allowing kinase activity. The TKD mutations interfere with the inhibitory loop and thus are similar to ITD in disrupting the regulation of signaling, but differ in that they do not require dimerization for constitutive activation. While both mutations lead to constitutive activation of AKT and extracellular signal-related kinase (ERK)1/2 from the PI3K and RAS signaling cascades, respectively, data suggest that strong signal transducer and activator of transcription (STAT5) activation is only observed in *FLT3*-ITD cells.

RAS

RAS proteins couple receptor activation with downstream effector pathways, altering proliferation, differentiation, and apoptosis. Overall, approximately 30% of cancers express a mutant or so-called *oncogenic* RAS. Three RAS genes are encoded in the human genome: *HRAS*, *KRAS*, and *NRAS*, and the frequency of mutations for these genes vary significantly between cancer types. In myeloid leukemia, *NRAS* mutations predominate, followed in frequency by *KRAS*, while *HRAS* mutations have not been reported. RAS proteins cycle between

an inactive GDP-bound state and an active GTP-bound state. Somatic mutations occur at amino acid residues, which impair their intrinsic GTPase activity and also confer resistance to GTPase-activating proteins leading to persistence of a GTP-bound (and therefore active) state. Active RAS mediates effects through a multitude of downstream effector pathways including RAC, PI3K, RAF, RAL, and PKC, all of which confer abnormal functional properties in cancer cells. These pathways affect cell cycle progression, promote survival, and stimulate actin reorganization and vesicle trafficking, all of which have been shown in various model systems to contribute to RAS-induced tumorigenesis. In AML, cooperating lesions found in *NRAS* mutant cases include *NPM1*, *C/EBPA*, *PML-RARA*, *MLL* rearrangements, *RUNX1-ETO*, and *CBFB-MYH11*. In a pediatric cohort of 111 AML cases, activating mutations in *NRAS* were found in 45%, 44%, and 24% of *RUNX1-ETO*, *CBFB-MYH11*, and *MLL* rearranged cases, respectively.

CCAAT Enhancer-Binding Protein Alpha

CCAAT enhancer-binding protein alpha (C/EBP α) is a transcription factor that contains two N-terminal transcriptional activation domains (TAD1 and TAD2) and a C-terminal DNA-binding basic region followed by a leucine zipper domain that mediates homo- and hetero-dimerization with other CEBP family members. DNA binding requires dimerization and is critically dependent on the distance between the leucine zipper domain and the DNA-binding basic region. *CEBPA* encodes an mRNA that contains alternative translation initiation sites resulting in two major protein isoforms: the fully translated C/EBP α (p42), and an N-terminally truncated protein (p30) lacking the N-terminal transactivation domain TAD1. In the hematopoietic system, *CEBPA* is expressed in myeloid progenitors and granulocytes but not macrophages, and has been shown to regulate the expression of many myeloid genes. Conditional knockout of *Cebpa* in adult mice blocks the transition from common myeloid progenitors to the more differentiated granulocyte monocyte progenitor, leading to an accumulation of myeloid blasts.

Mutations that reduce the transcriptional activity of C/EBP α occur in between 5% and 14% of AML patients, and are primarily seen in FAB-M1/2 AMLs with a normal karyotype. Two classes of *CEBPA* mutations have been defined: mutations that occur within the first 300 bp of the *CEBPA* gene and result in frame-shifts or stop codons that eliminate expression of the p42 isoform but have no effect on the translation of p30; and mutations in the 3' end of the gene that result in in-frame insertions or deletions that disrupt the relationship of the basic and leucine zipper domains and alter DNA-binding activity. The most frequent pattern seen in patients is a combination of the two types of mutations, one on each allele. Knock-in mice that eliminate p42 translation while allowing expression of p30 have been generated, and these mice uniformly die of AML by 60 weeks of age, providing direct evidence that *Cebpa* mutations contribute to the process of leukemogenesis.

CLINICAL AND LABORATORY MANIFESTATIONS AND DIAGNOSIS

Most children with AML have signs and symptoms of bone marrow failure, including pallor, fatigue, bleeding, bruising, and infection. Hepatosplenomegaly, lymphadenopathy, and bone pain are common, but usually less prominent than in children with ALL. Because of the acute nature of the process, weight loss and other signs of chronic disease are rare. In some cases, the predominant clinical signs result not from bone marrow disease, but from extramedullary myeloid tumors, referred to as *chloromas* or *granulocytic sarcomas*, which most often arise in the orbital or spinal regions. Other clinical manifestations include gingival hypertrophy, commonly seen in AML cases with a monocytic component, and skin or subcutaneous nodules. Cutaneous lesions may be single or multiple violaceous papules or nodules, are most common in infants, and may be mistaken for the

blueberry muffin lesions that are associated with congenital infection. Skin nodules sometimes develop before bone marrow involvement and may regress spontaneously. Patients with elevated leukocyte counts (hyperleukocytosis) may also present with central nervous system (CNS) symptoms (seizure or stroke) or pulmonary symptoms related to hyperviscosity.

Among children with AML, the median leukocyte count at diagnosis is approximately $20 \times 10^9/L$, with a median hemoglobin concentration of approximately 9 g/dL and a median platelet count of $60 \times 10^9/L$. Although about 10% of children with AML do not have morphologically detectable circulating blasts, careful examination of the peripheral blood smear will reveal leukemic cells in most cases. Prolonged prothrombin, thrombin, and partial thromboplastin times, as well as decreased fibrinogen levels, are seen in the majority of patients with APL and about 5% of other AML cases. Abnormalities of serum chemistries may include hyperuricemia, although this is less common and less severe than hyperuricemia associated with ALL. The presence of hypokalemia, a rare finding in patients with ALL, suggests a diagnosis of monoblastic leukemia.

Among patients who present with circulating blasts, the differential diagnosis is generally limited to various types of leukemia, including AML, ALL, and juvenile myelomonocytic leukemia (JMML). For patients who do not have blasts in their blood at the time of presentation, the differential diagnosis is determined by signs and symptoms and may include aplastic anemia, autoimmune or inflammatory disease, infection, and solid malignancies. In most cases, the diagnosis of AML is made by bone marrow examination. A bone marrow aspiration should be performed for morphologic examination, immunophenotyping, genetic, and molecular studies, whereas a bone marrow biopsy is used to assess cellularity. A diagnosis of AML is confirmed when 20% or more of nucleated bone marrow cells are blasts of myeloid origin or when the blasts contain AML-specific genetic lesions, regardless of blast percentage. When a diagnosis of AML is confirmed, most investigators classify each case according to the World Health Organization criteria (Table 62.1). Since AML may involve the CNS, examination of the cerebrospinal fluid (CSF) should also be performed as part of the workup of all patients. Although CNS leukemia is traditionally defined as the presence of at least five leukocytes/ μL of CSF with leukemic blast cells present, the significance of lower levels of CNS involvement is not known. The diagnosis of CNS involvement may also be based on the presence of cranial nerve palsies or radiologic evidence of leukemic infiltration.

Prognostic Factors

Genetic features, some of which can be identified by conventional karyotyping and others that require molecular techniques, are strongly associated with outcome (Table 62.2). An equally important predictor of outcome is response to therapy, which can be assessed by morphologic, immunophenotypic, or molecular examination of the bone marrow before and after each course of chemotherapy.

Investigators from almost all study groups consider children whose leukemic blasts contain the $t(8;21)(q22;q22)/RUNX1-RUNX1T1$, $inv(16)(p13.1;q22)/CBF\beta-MYH11$, or $t(16;16)(p13.1;q22)/CBF\beta-MYH11$ (collectively referred as *CBF leukemia*) to have low-risk AML. In contemporary clinical trials, the overall survival (OS) rates are approximately 90% for this group of patients. Although *KIT* mutations confer an inferior prognosis in adults with CBF leukemia, their prognostic significance in children is not clear. Thus, most clinical trials classify children with CBF leukemia as having low-risk disease, regardless of other genetic abnormalities.

Mutations of the *NPM1* gene are seen primarily in AML cases with normal karyotypes, with or without internal tandem duplications of the *FLT3* gene (*FLT3*-ITD). Children whose blasts contain *NPM1* mutations, normal karyotypes, and wild-type *FLT3* appear to have an excellent prognosis, although the data to support their classification as low-risk patients are not as strong as that for children with CBF leukemia. Similarly, biallelic mutations of *CEBPA* are

 $t(1;22)(p13;q13)/RBM15-MKL1$

associated with normal karyotypes and a favorable outcome in adults with AML, but occur in less than 5% of childhood AML cases. Nevertheless, they are likely to be associated with a favorable outcome and are included as a low-risk feature in many treatment protocols.

Genetic abnormalities, for which there is strong evidence of an association with a high risk of relapse, include monosomy 7 and *FLT3*-ITD. The outcome of patients with *FLT3*-ITD is especially poor in cases with high ratios of *FLT3*-ITD to wild-type *FLT3*. Translocations that create chimeric fusion genes and likely confer a poor prognosis include the $t(6;11)(q27;q23)/MLL-MLLT4$, $t(10;11)(p12;q23)/MLL-MLLT10$, $t(10;11)(p11.2;q23)/MLL-ABI1$, $t(5;11)(q35;p15.5)/NUP98-NSD1$, $t(6;9)(p23;q34)/DEK-NUP214$, $t(8;16)(p11;p13)/MYST3-CREBBP$, $t(16;21)(q24;q22)/RUNX1-CBFA2T3$, and $inv(16)(p13.3;q24.3)/CBFA2T3-GLIS2$. The prognostic impact of other lesions, such as mutations of *WT1*, *IDH1*, *IDH2*, *RUNX1*, *TET2*, or *DNMT3A*, is not known. However, because they are associated with a high risk of relapse among adults with AML, it is likely that they also confer a poor outcome in children.

Response to therapy reflects features specific to the leukemia (genetic alterations and inherent sensitivity to chemotherapy), characteristics of the patient (pharmacogenomics and drug metabolism), as well as the intensity and components of therapy, and is therefore a key predictor of outcome. However, morphologic examination of the bone marrow, especially during periods of brisk hematopoietic recovery after intensive chemotherapy, is subjective and lacks the sensitivity and specificity required to accurately assess response. Methods that rely on leukemia-specific features that distinguish residual leukemia cells from normal hematopoietic precursors can provide more precise estimates of MRD. Techniques applicable to AML include RNA-based PCR analysis of leukemia-specific gene fusions, quantitative analysis of *WT1* expression, deep sequencing to detect leukemia-specific mutations, and flow cytometric detection of aberrant immunophenotypes. Although PCR detection of fusion transcripts is sensitive to a level of 0.01%–0.001%, it can be applied to only about 50% of cases. In addition, the significance of persistence

AIEOP, Associazione Italiana di Ematologia e Oncologia Pediatrica; BFM, Berlin-Frankfurt-Münster Study Group; COG, Children's Oncology Group; CR, complete remission; EFS, event-free survival; GO, gemtuzumab ozogamicin; Ida, idarubicin; JCACSG, Japanese Childhood AML Cooperative Study Group; L-DNR, liposomal daunorubicin; MRC, Medical Research Council; NOPHO, Nordic Society of Paediatric Haematology and Oncology; OS, overall survival; SJCRH, St Jude Children's Research Hospital.

of fusion transcript expression is not consistent across subtypes of AML. For example, persistent expression of *PML-RARA* is associated with a high risk of relapse among patients with APL, whereas the *RUNX1-RUNX1T1* and *CBFβ-MYH11* transcripts can be detected in patients with CBF leukemia who are in long-term remission. In contrast, the sensitivity of flow-based MRD assays is only 0.1%–0.01%, but this technique can be applied to more than 90% of cases and has been used successfully by investigators from the Children's Oncology Group (COG), the Berlin-Frankfurt-Münster (BFM) study group, St. Jude Children's Research Hospital (SJCRH), and the Dutch Childhood Oncology Group (DCOG). For example, among children with AML who were treated in the St. Jude AML02 trial, the 3-year cumulative incidence of relapse was 17% for patients without detectable MRD, 39% for those with >0.1% MRD, and 49% for patients with MRD levels >1%. It is clear, however, that better methods are needed to identify patients who are MRD negative by current techniques, but who still suffer relapse of their disease.

THERAPY

CR and OS rates are now greater than 90% and 60%, respectively, for children with AML (Table 62.3). Most induction regimens are based on the combination of cytarabine and daunorubicin, first developed in the 1970s. Attempts to improve remission induction rates have included the addition of other nucleoside analogues (cladribine or fludarabine), dose-intensification of cytarabine, the replacement of daunorubicin with idarubicin, mitoxantrone, or liposomal daunorubicin, and the addition of gemtuzumab ozogamicin (GO). Although all these interventions were found to be safe, randomized clinical trials demonstrated similar remission rates regardless of the dose of cytarabine, the addition of other nucleoside analogues, the substitution of daunorubicin with another anthracycline, or the addition of GO. It is likely that the increases in CR rates are largely due to improvements in supportive care, rather than to the development of better chemotherapy.

Clinical trials conducted during the 1980s and 1990s demonstrated that intensive postremission therapy, administered as intensive chemotherapy or HSCT, significantly improves outcome and is an essential component of therapy for all children with AML. By contrast, low-dose maintenance therapy may actually lower the survival rates. Trials performed during the past 20 years (Table 62.3) have sought to determine the optimal duration of postremission therapy, the benefit of new agents, the value of MRD monitoring, and the role of HSCT. However, like the interventions used to improve

remission induction rates, many of the postremission interventions have had only modest effects on survival.

Examples of large, well-designed randomized trials that have produced excellent results despite the lack of major differences between treatment arms include the AML-BFM 2004 and the COG AAML0531 trials. In the BFM trial, 521 children with AML were randomly assigned to receive liposomal daunorubicin (80 mg/m²/day for 3 days) or idarubicin (12 mg/m²/day for 3 days) in combination with cytarabine and etoposide during induction therapy. Results were similar between the liposomal daunorubicin and idarubicin treatment arms: OS, 76% versus 75%; EFS, 59% versus 53%, and cumulative incidence of relapse, 29% versus 31%. Subgroup analyses suggested that patients with t(8;21) may benefit from the use of liposomal daunorubicin. In the COG trial, 1022 patients were randomly assigned to receive standard chemotherapy with or without the addition of three doses of GO. Although the incorporation of GO was associated with a better EFS (53% vs. 47%), there was no difference in OS between arms (69% vs. 65%). In this trial, GO had the greatest impact among patients with favorable karyotypes and had no effect on the outcome of high-risk patients. These trials illustrate the difficulties encountered when performing randomized studies of non-specific agents in a heterogeneous disease with small subgroups.

Attempts to improve the results obtained with chemotherapy have included the use of autologous and allogeneic HSCT. Although autologous transplantation is rarely recommended for patients with AML, allogeneic HSCT is a reasonable option, as many studies have demonstrated that HSCT is associated with lower rates of relapse compared with chemotherapy. However, because HSCT is accompanied by higher rates of treatment-related mortality and morbidity than chemotherapy, the indications for performing HSCT in first remission remain controversial.

In general, study groups in the United States recommend HSCT in first remission for a larger proportion of patients than do European investigators, who often reserve the use of HSCT for patients who are in second remission. However, improvements in supportive care, more comprehensive HLA typing, and the selection of killer inhibitory receptor (KIR)-mismatched donors, have led to fewer short- and long-term side effects and greater benefits. In recent trials the outcomes are similar regardless of donor type. For example, among children with high-risk AML who were treated in the St. Jude AML02 trial and underwent HSCT at our institution, the 5-year OS rates were 68%, 74%, and 77% for patients who received matched sibling donor, matched unrelated donor, and haploidentical donor transplants in first remission, respectively. In addition, the 5-year OS estimate was 67% for patients who had detectable disease (0.01%–5%)

Fig. 62.3 EVENT-FREE SURVIVAL (A) AND OVERALL SURVIVAL (B) FOR PATIENTS WITH ACUTE MYELOID LEUKEMIA TREATED ON ST. JUDE TRIALS.

at the time of transplant, indicating that even though MRD is an important predictor of posttransplant outcome, it is not a contraindication to HSCT (Fig. 62.3).

Children with Down syndrome and AML have a favorable prognosis, with OS rates greater than 90%, and should be treated in cooperative group trials that are designed to minimize toxicity while maintaining high cure rates. The excellent outcome has been at least partly attributed to increased levels of cystathionine- β -synthetase, a high frequency of cystathionine- β -synthetase polymorphisms, and decreased levels of cytidine deaminase in the blasts of patients with Down syndrome, all of which result in altered metabolism of cytarabine. Approaches to the diagnosis, supportive care measures, and treatment of childhood APL are similar to those in adults with APL, including the immediate initiation of all-*trans* retinoic acid (ATRA) followed by the continued use of ATRA and arsenic trioxide, with or without the addition of conventional chemotherapy.

SUPPORTIVE CARE

Supportive care is an essential component of the management of children with AML. Initial leukocyte counts greater than 100,000/ μ L

are associated with risks of intracranial hemorrhage and respiratory insufficiency secondary to leukostasis. Therefore, all patients with hyperleukocytosis, as well as those with symptoms of leukostasis regardless of leukocyte count, should immediately receive interventions to reduce the leukemic burden, such as leukapheresis, exchange transfusion, hydroxyurea, or low-dose cytarabine (100–200 mg/ m^2 /day).

Infectious complications are a major cause of morbidity and mortality in children with AML. In fact, the cumulative incidence of documented infection is greater than 60% among AML patients who do not receive prophylactic antibiotics. Randomized, controlled trials conducted in adults with AML demonstrated that prophylactic antibiotics, such as oral levofloxacin, are effective at reducing the incidence of bacterial infection, but similar studies have not yet been completed in children. However, nonrandomized trials performed in pediatric patients with AML have shown that the use of prophylactic antibiotics, such as cefepime alone or the combination of vancomycin and ciprofloxacin, dramatically reduce the incidence of bacterial infection and decrease the length of hospital stay compared with historical controls. Although the emergence of drug-resistant bacteria is a concern, we believe that the benefits of prophylactic antibiotics outweigh this potential risk (Box 62.2).

BOX 62.2 Prophylactic Antimicrobials

As a result of prolonged periods of neutropenia secondary to myelosuppressive therapy, patients with acute myeloid leukemia (AML) are at high risk of bacterial and fungal infections. Prior to our implementation of prophylactic antibiotics 10 years ago, we observed documented bacterial infections, most commonly caused by viridans group streptococci, in approximately two-thirds of AML patients. We subsequently demonstrated that the use of prophylactic antibiotics, such as cefepime alone or the combination of vancomycin and ciprofloxacin, dramatically reduced the incidence of bacterial infection, decreased length of hospital stays, and could be safely administered by caregivers in the outpatient setting. Although the emergence of drug-resistant bacteria is a concern, we believe that the benefits of prophylactic antibiotics outweigh this potential risk. To further address the risks and benefits of prophylactic antibiotics, the Children's Oncology Group is currently evaluating prophylactic levofloxacin in children with leukemia who are at high risk of infection. Because disseminated fungal infections are also common in children with AML, we recommend that all patients receive antifungal prophylaxis with micafungin, caspofungin, voriconazole, or posaconazole. Micafungin and caspofungin provide excellent coverage for infections caused by *Candida* species, but are less active than voriconazole and posaconazole against *Aspergillus* species. Our use of prophylactic voriconazole has been associated with a decrease in the incidence of *Aspergillus* infections, but we have seen the emergence of other molds, such as *Fusarium*, *Mucor*, and *Rhizopus*. Although we have successfully treated these infections with posaconazole, we must be wary of the development of posaconazole resistance.

Disseminated fungal infections, most commonly caused by *Candida* and *Aspergillus* species, are also frequently seen in children with AML. Because several randomized, controlled trials demonstrated the benefits of prophylactic antifungal therapy in adults with cancer, many pediatric oncologists recommend antifungal prophylaxis for children with AML. Available agents include fluconazole, itraconazole, voriconazole, posaconazole, micafungin, and caspofungin. Among the azoles, fluconazole and itraconazole are not ideal because they are less active against *Aspergillus* species than voriconazole and posaconazole. Although the latter agents are both active against *Aspergillus* species, posaconazole has greater activity against other molds, such as *Fusarium*, *Mucor*, and *Rhizopus*. Micafungin and caspofungin are not as broadly active as voriconazole and posaconazole, but their ease of administration (daily intravenous infusion), compatibility with other drugs, and less variable pharmacokinetic properties suggest that they are reasonable choices as well.

FUTURE DIRECTIONS**Tyrosine Kinase Inhibitors**

AML cells commonly possess aberrant receptor tyrosine kinase activity as a result of genetic alterations, such as *FLT3*-ITD. These alterations are seen in approximately 15% of pediatric and 30% of adult AML cases, and are associated with a poor outcome, particularly in cases with high ratios of *FLT3*-ITD to wild-type *FLT3*. Evidence that *FLT3* mutations are driver lesions suggests that they are rational targets to which inhibitors should be tested. Recent studies have demonstrated that sorafenib, sunitinib, and other *FLT3* inhibitors are highly active in patients with *FLT3* mutations, but that prolonged use of these agents is associated with the development of resistance, most commonly caused by the acquisition of point mutations in the kinase domain. Crenolanib, a novel tyrosine kinase inhibitor, is active in sorafenib-resistant AML mouse models that contain the *FLT3* D835 or F691 mutations, suggesting that this agent may extend clinical benefit. Further studies are needed to determine the optimal dose, schedule, and combination of inhibitors that are required to improve the long-term outcome of patients with *FLT3* mutations. Although tyrosine kinase inhibitors represent a distinct approach to

AML therapy, target validation is slow and new therapeutic strategies are needed.

Epigenetic Agents

Abnormal regulation of epigenetic modification, such as histone acetylation and DNA methylation, is likely a key factor in the pathogenesis of AML. A central role for epigenetic dysfunction in AML is supported by the observation of mutations and translocations in genes involved in these processes, such as *TET2*, *DNMT3*, *IDH1*, *IDH2*, and *MLL*. These findings suggest that histone deacetylase inhibitors and demethylating agents may be active, either alone or in combination with chemotherapy, in AML. The histone deacetylase inhibitor vorinostat as well as the DNA hypomethylating agents decitabine and 5-azacytidine have shown promising activity and are currently being tested in combination with chemotherapy. A related epigenetic target in childhood AML is the DOT1L histone methyltransferase, which is required for transformation by *MLL* fusion proteins. A DOT1L inhibitor (EPZ-5676) is now in phase I trials for adults and children with relapsed *MLL*-rearranged leukemia. Recently, the bromodomain and extraterminal (BET) family of proteins (BRD2, BRD3, BRD4, and BRDT), which bind acetylated lysines in histone tails and regulate gene expression by recruiting multiprotein complexes such as *MLL* to super enhancer regions, have also been explored as drug targets in AML. Preclinical models show that BET inhibitors are active against a variety of malignancies, including AML, and at least four such inhibitors are in early clinical trials.

Antibody-Based Therapies

Most antibody-directed therapies for AML have focused on CD33, which is expressed on the surface of leukemia blasts in greater than 90% of cases. GO, a humanized anti-CD33 antibody conjugated to calicheamicin, was approved by the United States Food and Drug Administration in 2000, but was later withdrawn from the market because of concerns of toxicity. However, the results of randomized trials that were completed after the withdrawal of GO suggest that the addition of GO to conventional chemotherapy reduces the risk of relapse and improves event-free survival. Metaanalyses demonstrate that the benefit of GO was greatest among low-risk patients, with only modest benefits seen in intermediate-risk patients and no benefits in patients with high-risk disease. Recently, a novel anti-CD33 conjugate (SGN-CD33A), in which calicheamicin is replaced with a synthetic pyrrolbenzodiazepine, was shown to be more potent than GO at inducing apoptosis in AML in preclinical models, and is now being evaluated in Phase I clinical trials.

An alternative approach to enhancing the efficacy of CD33-directed therapy is through the development of CD33/CD3-directed bispecific T-cell engager (BiTE) antibodies. By bridging CD33 with T-cell receptors (TCRs), BiTE antibodies can direct T-cell effector functions to AML cells. In preclinical models, the CD33/CD3 BiTE AMG 330 was able to recruit T cells, resulting in potent CD33-dependent cytotoxicity. Analogous to BiTE antibodies, bispecific killer cell engagers (BiKE) target CD16 on natural killer (NK) cells and tumor-specific antigens, such as CD33. A CD33/CD16 BiKE has recently been shown to induce NK cell function and eliminate CD33⁺ AML cells in preclinical models. It is likely that BiTE and BiKE antibodies will soon be tested in clinical trials for patients with relapsed AML (Box 62.3).

Natural Killer Cell Therapy

The beneficial effects of KIR-mismatched donor NK cells in the setting of allogeneic HSCT for AML has led to interest in the use of allogeneic NK cells in the non-HSCT setting. We performed a pilot study that demonstrated that infusions of haploidentical NK

BOX 62.3 Treatment of Relapsed Acute Myeloid Leukemia

The treatment outcome for patients with acute myeloid leukemia (AML) who have suffered relapse of their disease is poor. On a recent international trial for patients with refractory disease or in first relapse, the complete remission and overall survival rates were only 64% and 38%, respectively. For patients in second or later relapse, the outcome is even worse, indicating that these patients are candidates for experimental approaches. Such approaches include the use of novel tyrosine kinase inhibitors, epigenetic therapy, and immunotherapy. Patients with *FLT3*-mutated relapsed AML should be enrolled on clinical trials that incorporate second- or third-generation *FLT3* inhibitors, such as crenolanib, especially if they have previously received sorafenib. For patients who do not have activating kinase mutations, epigenetic strategies may be appropriate and may include the use of azacitidine, decitabine, vorinostat, or panobinostat. The DOT1L inhibitor EPZ-5676 should be considered in patients with *MLL* gene rearrangements. Although immunotherapeutic options are limited at this time, it is likely that clinical trials of antibody therapy (SGN-CD33A, AML 330) or chimeric antigen receptor–modified T-cell therapy will soon be available for children with AML. Other promising areas of investigation include bromodomain and extraterminal inhibitors, B-cell lymphoma 2 inhibitors, selective inhibitors of nuclear exports, and proteasome inhibitors. Because it is imperative to study new agents in scientifically rational and clinically safe trials, we believe that efforts should be made to enroll all patients with relapsed AML on research protocols.

cells in patients with AML were well tolerated and associated with transient engraftment, expansion of donor NK cells, minimal toxicity, and no graft-versus-host disease. Although these results suggest that treatment with haploidentical mismatched NK cells is a safe and potentially valuable approach to reduce the risk of relapse in patients with AML, clinical trials are required to investigate its benefits. In addition, it is likely that enhancement of NK cell activity will be required to provide optimal antileukemic effects. Potential methods to increase NK cell activity include the expansion of activated NK cells, the addition of lineage-specific antibodies, the use of anti-KIR antibodies to block inhibitory KIRs, and the depletion of host regulatory T cells, which may inhibit the proliferation of donor NK cells.

Chimeric Antigen Receptor-Modified T Cells

T cells can be redirected to target cells of interest through the use of chimeric antigen receptors (CARs), which link a target cell ligand-recognition domain to signaling regions from the TCR. First-generation CARs typically incorporated the TCR ζ cytoplasmic domain, but it was later demonstrated that tandem signaling domains incorporating the TCR along with costimulatory or coreceptor signals provided more robust stimulation and enhanced the survival, expansion, and activity of CAR-modified T cells. The clinical effectiveness of CAR-modified T cells was first established in B-cell malignancies using a CD19-41BB- ζ CAR, originally developed by Imai and Campana at St. Jude.

A major challenge to extending the success achieved with CD19-specific CARs to AML is identifying the proper recognition domain, because effective therapy will require eradication of the leukemic initiating cells as well as their more mature descendants. The widespread expression of CD33 on leukemic cells and the absence of downmodulation after GO treatment indicate that it is a robust target. Preclinical studies performed in NOD-SCID mouse models suggest that CD33 CAR-modified T cells should be investigated. However, the potential depletion of normal hematopoietic precursors or committed myeloid progenitor cells may cause unacceptable long-term neutropenia. In addition, the absence of CD33 expression on leukemic stem cells in some cases may limit the efficacy of such therapy. Future clinical trials and additional modifications of CD33 CARs will address these important issues.

CONCLUSION

Recent studies of the genetics and biology of AML have identified new therapeutics targets and have led to the development of novel therapies, many of which are now in early-phase clinical trials. We hope that these efforts will lead to the development of more effective and less toxic treatments in the near future. However, the evaluation of these treatment strategies will require collaboration between cooperative groups to ensure that adequate numbers of patients to which each therapy is directed can be studied.

MYELOYDYSPLASTIC SYNDROMES AND MYELOPROLIFERATIVE NEOPLASMS IN CHILDREN

Franklin O. Smith, Christopher C. Dvorak, and Benjamin S. Braun

The myelodysplastic syndromes (MDS) and myeloproliferative neoplasms (MPN) are a heterogeneous group of clonal stem cell disorders that result in ineffective hematopoiesis and an increased risk of developing acute myeloid leukemia (AML). In children, MDS and MPN are now classified into three main groups: MDS, juvenile myelomonocytic leukemia (JMML), and transient abnormal myelopoiesis (TAM) in children with Down syndrome. Whereas in MDS, ineffective hematopoiesis results in progressive cytopenias, in MPN, at least initially, ineffective hematopoiesis leads to excessive proliferation frequently characterized by increased peripheral blood counts. MDS and MPN are rare in children. Chronic myeloid leukemia (CML), characterized by the Philadelphia chromosome (*BCR/ABL* positive) is seen in both children and adults, but other forms of MPN (polycythemia vera [PV], essential thrombocythemia [ET], primary myelofibrosis, chronic neutrophilic leukemia, chronic eosinophilic leukemia, chronic basophilic leukemia, chronic myelomonocytic leukemia, systemic mastocytosis [SM], and stem cell leukemia–lymphoma syndrome) are exceedingly rare in children. Readers interested in CML and disorders that are predominantly found in adults are referred to in [Chapters 67–70](#). In contrast, two MPNs are uniquely pediatric: JMML and Down syndrome–associated TAM.

MYELOYDYSPLASTIC SYNDROMES

The MDS are a heterogeneous group of clonal disorders characterized by ineffective hematopoiesis, impaired maturation of hematopoietic cells, progressive cytopenias, and dysplastic changes in the bone marrow (BM).

Epidemiology

MDS is a common malignancy of adults with an incidence of 50 cases per million in people older than the age of 60 years.¹ In contrast, MDS accounts for only 3%–7% of all hematologic malignancies in children, with an unknown true incidence, owing in part to the inclusion of children with Down syndrome in some estimates. Several population-based studies have been performed with reported incidences of 4.0 cases per million in Denmark,² 3.1 per million in British Columbia (Canada),³ and 1.35 per million in the United Kingdom.⁴ The median age of presentation is 6.8 years with an equal sex distribution.^{4–6} However, in a study of children with advanced or high-risk MDS, the median age of presentation was older at 10.7 years with a 2:1 male to female ratio.⁷

Pathobiology

As in adults, MDS in children can be considered as primary (de novo) or secondary. In adults, two predominant patterns of primary, de novo MDS have been observed. In the first of these patterns, the disease is indolent in nature and is characterized by prolonged survival, little accumulated genetic damage, and a low probability of progression to AML. This group of diseases is best exemplified by the

5q– syndrome, an entity not seen in children. Far more common in adults is a disease characterized by the accumulation of genetic damage, progression to BM failure, and a high probability of developing AML. This form of the disease is characterized as a mutator phenotype.⁸ The primary MDS seen in children appear to share this mutator phenotype.

As in adults, secondary MDS in children can also arise as sequelae from exposure to chemotherapy and radiation, and from genetic conditions including monosomy 7 syndrome, Down syndrome, paroxysmal nocturnal hemoglobinuria (PNH), neurofibromatosis, Bloom syndrome, and Li-Fraumeni syndrome. However, MDS in children may often result from inherited constitutional BM failure syndromes including Fanconi anemia (FA), severe congenital neutropenia, Shwachman-Diamond syndrome, congenital amegakaryocytic thrombocytopenia, dyskeratosis congenital, Diamond-Blackfan anemia, and MonoMAC syndrome. Unlike de novo MDS in the elderly, the true incidence of de novo MDS in children may become less frequently diagnosed as genetics and inherited constitutional BM failure syndromes (IBMFS) causes of secondary MDS are increasingly identified in children.

Ongoing studies are now defining the molecular pathogenesis and interrelationships among MDS, MPN, and AML.^{9–11} Accumulating data suggest that aberrant signal transduction resulting from acquired somatic mutations encoding proteins leading to hyperactivation of the Ras pathway may stimulate proliferation without concomitant differentiation.¹⁰ This has been clearly demonstrated in CML (*BCR-ABL*).^{12,13} A number of other putative pathogenetic mutations have been identified in other myeloproliferative disorders, including *JAK2* V617F mutations in PV, ET, and primary myelofibrosis¹⁴; *KIT* D816V mutations in SM¹⁵; *FIPL1-PDGFR α* in chronic eosinophilic leukemia-SM¹⁶; *ZNF198-FGFR1* mutations in stem cell leukemia–lymphoma syndrome¹⁷; *RAS/NF1/PTPN11* mutations in JMML^{18–20} (Fig. 63.1); and *GATA1* mutations in TAM.²¹

AML is the result of cooperating mutations in genes that confer a proliferative and survival advantage (e.g., activating mutations in receptor tyrosine kinases [FLT3, c-kit]) and genes that impair differentiation and apoptosis (e.g., loss-of-function mutations in transcription factors [CBF, AML/ETO]) (Fig. 63.2). This multistep model for the pathogenesis of AML is supported by murine models,^{22,23} the analysis of leukemia in twins,^{24–27} and the analysis of patients with familial platelet disorder with a propensity to develop AML (FDP/AML syndrome).²⁸

Recent advances in sequencing techniques and a rapidly evolving understanding of the biology of epigenetics (global methylation and histone modification) and mRNA splicing machinery have transformed our understanding of oncogenic driver mutations in adult MDS.^{29–32} In adults with MDS, approximately 50% of patients have recurrent mutations in a splicing factor (*SF3B1*, *U2AF1*, *SRSF2*, *ZRSR2*), a novel class of cancer-associated genes that was only recently recognized to be important in MDS. Similarly, the same percent of adult patients have at least one mutated epigenetic regulator (*TET2*, *ASXL1*, *DNMT3A*, *EZH2*, *IDH1*, and *IDH2*), whereas approximately 25% of adults will have mutations in both splicing factors and epigenetic regulators. Karyotypic abnormalities (5/5q–, 7/7q–, 3q, 20q) alone occur in approximately 5% of adults. Approximately 15% of adult patients have mutations in other genes (without associated mutations

Fig. 63.1 OVERVIEW OF RAS SIGNALING WITH MOLECULES HARBORING MUTATIONS IN PATIENTS WITH MYELOID MALIGNANCIES. *AML*, Acute myeloid leukemia; *CML*, chronic myeloid leukemia; *CMML*, chronic myelomonocytic leukemia; *ET*, essential thrombocythemia; *GDP*, guanosine diphosphate; *GTP*, guanosine triphosphate; *JAK*, Janus-activated kinase; *JMML*, juvenile myelomonocytic leukemia; *MDS*, myelodysplastic syndromes; *MPD*, myeloproliferative disorder; *PV*, polycythemia vera.

in mRNA splicing genes or DNA methylation genes) including transcription factors (*RUNX1*, *ETV6*, *PHF6*, *GATA2*), kinase signaling genes (*NRAS*, *KRAS*, *JAK2*, *CBL*), and cohesion genes (*STAG2*, *SMC3*, *RAD21*). Finally, approximately 10% of adult patients have no mutations detectable.³² This remarkable improvement in the understanding of the genetic events underlying adult MDS is leading to improved methods of risk-group stratification and prognosis (e.g., *TP53* mutations are associated with adverse disease features and outcomes).^{33–35}

The patterns of genetic and karyotypic abnormalities in children with MDS are increasingly distinctive from that of adults. Although a few karyotypic abnormalities are shared (e.g., 7/7q–), many that are common in adults are only rarely found in children (e.g., 5q–). Importantly, mutations in mRNA splicing genes and other genes are only rarely found in children with de novo and secondary MDS.^{36–39} Mutations in epigenetic genes that control DNA methylation and histone function are also only rarely identified in children, making their role in MDS uncertain. For example, although mutations in *TET2* are identified in 20%–25% of adults with MDS, only one out of 19 children with refractory cytopenia of childhood (RCC) had a mutation in *TET2*.⁴⁰ Instead, the genetic abnormalities in children with MDS are most often those associated with inherited BM failure syndromes and other genetic disorders (*FANC* member genes, *DKC*, *TERT*, *TREC*, *WAS*, *GATA-2*, *SBDS*, etc.).

Finally, three exceedingly rare familial forms of MDS/AML are associated with mutations in *RUNX1/AML1* (familial platelet disorder with a predisposition to AML), *CEBP α* (familial AML), and *GATA-2*.^{39,41–43}

Classification

Until recently, MDS in children was poorly defined, characterized, classified, and reported. In fact, MDS was not included in the International Classification of Childhood Cancer until 2005.⁴⁴ Also contributing to this lack of information was the use of classification and prognostic systems designed for adults that have had limited

applicability to children. A number of classification systems for children and adults have now been proposed. Taken together, it may be useful to think about childhood MDS as primary or secondary in nature, with secondary MDS arising either from a known inherited BM failure syndrome, prior acquired aplastic anemia, or as a complication from prior chemotherapy or radiation therapy. A diagnosis of primary MDS would then apply to all other cases.

Historically, one of the most commonly used classification systems was the French-American-British (FAB) system, originally proposed in 1982.⁴⁵ This classification system recognized five forms of MDS in adults: refractory anemia (RA), refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess of blasts (RAEB), refractory anemia with excess of blasts in transformation (RAEB-T), and CMML. Using this system, whereas RAEB and RAEB-T were commonly reported in children, RA and RARS were thought to be rare in children. However, a population-based study in the United Kingdom showed 25% of childhood MDS cases to be RA or RARS, suggesting inaccurate diagnosis or reporting of these subtypes in other pediatric studies. CMML has only rarely been reported in children.

Additional subtypes of MDS are now recognized that do not fit well into the FAB system, including hypoplastic MDS, therapy-related MDS, refractory cytopenias with trilineage dysplasia, MDS associated with myelofibrosis, and MDS associated with inherited disorders (congenital neutropenias, Shwachman-Diamond syndrome, FA), Down syndrome, neurofibromatosis type 1, and mitochondrial cytopathies.^{46,47} Therefore the World Health Organization (WHO) proposed changes to the FAB criteria to account for many of these subtypes.^{48,49} Importantly, whereas adults commonly present with RA without cytopenias in the myeloid or platelet lineages, this is very rare in children since they more often have cytopenias in more than one cell line. Therefore children with low-grade MDS are classified as having refractory cytopenia as opposed to RA. Thus in 2008 the WHO classification of pediatric MDS included the provisional category of RCC based on persistent cytopenia with less than 5% blasts in the bone marrow and less than 2% blasts in the peripheral blood.⁵⁰ Under this classification, it is recommended that children with refractory cytopenia with multilineage dysplasia (RCMD) be classified as RCC until it is clarified whether the number of lineages involved is an important prognostic discriminator in childhood MDS. Under the 2016 revision of the WHO classification of myeloid and neoplasms and acute leukemia, RCC remains a provisional entry.⁵¹

Clinical Manifestations

Signs and symptoms of MDS are nonspecific and are usually attributable to pancytopenia (fever, infections, pallor, fatigue, bruising, and petechiae). Lymphadenopathy, hepatomegaly, and splenomegaly are uncommon presenting signs in children with MDS.

Laboratory Manifestations

Commonly accepted minimal diagnostic criteria for pediatric MDS include the absence of common de novo AML karyotypic abnormalities and at least two of the following: (1) sustained, unexplained anemia; neutropenia or thrombocytopenia; dysplastic morphology in the erythroid; granulocytic or megakaryocytic lineages (at least bilineage), and (2) an acquired, sustained clonal cytogenetic abnormality and 5% or more blasts in the BM.^{8,52} Almost half of all children with MDS in one series presented with refractory cytopenia, most notably neutropenia and thrombocytopenia.⁵³

Morphologically, the BM may be hypocellular, normocellular, or hypercellular. A diagnosis of MDS is made based on the presence of dysplastic changes in at least two cell lineages. The dysplastic changes in the granulocytes (hypogranulation, nuclear hyposegmentation, megaloblastoid maturation, and a left shift with an increased number of myeloblasts), megakaryocytes (micromegakaryocytes, abnormal megakaryocyte nuclei), monocytes (increase in BM monocytes, abnormal granulation with persistence of azurophilic granules,

hemophagocytosis, abnormal nuclei, and giant forms), or erythroid lineages (megaloblastoid maturation, nuclear budding and multinucleated forms, and ringed sideroblasts) can be multiple and varied. Similar dysplastic changes can occur in the peripheral blood for each of these lineages. Although dysplastic changes in the BM are a common feature of MDS, it is important to remember that dysplasia, unto itself, is not diagnostic of MDS because dysplastic features are associated with other conditions and can be found in normal BM donors.⁵⁴

Flow cytometric analysis can serve as a useful addition to histopathology and to quantitate the number of blasts based on aberrant cell surface antigen expression. It is also helpful in detecting populations of PNH-like cells^{55,56}. However, although beneficial, flow cytometric findings are not generally diagnostic of MDS.

Cytogenetic abnormalities are seen in approximately half of children diagnosed with de novo MDS. Karyotypic abnormalities most commonly seen are -7 , $7q-$, and $+8$. Abnormalities in chromosomes 6, 9, 11, 12, and 13 are rare in children. Specific abnormalities seen in adults, including -5 , $5q-$, and $-Y$, are very rarely seen in children.

Differential Diagnosis

Although the history, physical examination, evaluation of the BM and peripheral blood, and cytogenetic analysis often make the diagnosis of MDS, other diseases should be considered. Congenital disorders such as Down syndrome, FA, Shwachman-Diamond syndrome, Diamond-Blackfan anemia, congenital dyserythropoietic anemias, and hereditary sideroblastic anemia should be considered. The differential should also include AML with a low blast count, mitochondrial cytopathies such as Pearson syndrome, rheumatic diseases including juvenile idiopathic arthritis, and myeloproliferative disorders. Specifically, PNH, although rare in children, should be considered. Deficiencies of vitamin B₁₂ and folate can cause megaloblastic changes that resemble the dysplastic changes seen in MDS. Other nutritional deficiencies, including copper, iron, thiamine, riboflavin, and pyridoxine, should be considered. Infections caused by human immunodeficiency virus, parvovirus, Epstein-Barr virus, cytomegalovirus, and human herpes virus 6 can cause changes that resemble MDS. Finally, the differential diagnosis should include toxins (insecticides, chemotherapy agents, and arsenic), as well as cytokine exposure and radiation.

Hypoplastic MDS (RCC) can be difficult to distinguish from severe aplastic anemia and inherited bone marrow failure syndromes, especially when no chromosomal aberrations are detected. One interesting area of research that may help in differentiating between these diagnoses is the use of cytokine-based programs. In one preliminary study, thrombopoietin and IL-17 levels were useful in differentiating hypoplastic MDS from aplastic anemia.⁵⁷ When the diagnosis is unclear, prospective monitoring and serial BM examinations may serve as useful aids in making an accurate diagnosis.

Therapy

Although MDS is a heterogeneous, clonal disease of hematopoietic stem cells (HSCs) that can manifest different clinical courses, it is not readily curable by conventional chemotherapy and requires allogeneic hematopoietic cell transplantation (HCT) for cure in most cases. Some children with RCC and RCMD who do not have life-threatening neutropenia and who do not require transfusions may only require close observation (see box on [Treatment Overview for Children With MDS](#)). Although children with this disease may eventually develop progressive disease requiring HCT, they may have long periods when minimal treatment is required.⁵³ The use of AML-like chemotherapy for patients with RCMD with excess blasts (RCMD-EB) is controversial but may serve to “debulk” patients with a high percentage of blasts before HCT.^{6,58,59} However, this potential benefit may be offset by toxicities associated with AML-like

Treatment Overview for Children With MDS

A multitude of agents have been studied for the treatment of myelodysplastic syndromes (MDS) in adults, but only rarely in children. These include low-dose chemotherapy (cytosine arabinoside, melphalan, hydroxyurea, etoposide, topotecan, 6-mercaptopurine, and busulfan), hormones (glucocorticoids and androgens), differentiating agents (13-*cis*-retinoic acid, all-*trans* retinoic acid), hematopoietic growth factors (granulocyte-macrophage colony-forming factor, granulocyte colony-forming factor, and erythropoietin), demethylating agents (decitabine, 5-azacytidine), proteasome inhibitors, antiangiogenic agents, and arsenic.^{60–75} This has resulted in three drugs (lenalidomide, azacitidine, and decitabine) that are now approved by the US Food and Drug Administration for the treatment of MDS in adults. However, as there are currently no safety or efficacy data to support the use of these agents in children with MDS, these drugs are not approved for MDS in children.

In addition, a large number of agents are being tested in clinical trials in the broad categories of kinase inhibitors, deacetylase inhibitors and DNA methyltransferase inhibitors, altered cell metabolism, cytotoxics, cell cycle inhibitors, immunomodulators and immunosuppressive agents, apoptosis modulators, and others.⁷⁶

The difficulty in assessing the safety and efficacy of new agents in children with MDS is illustrated by the Children's Oncology Group's recent prospective study of amifostine.⁷⁷ This prospective Phase II cooperative group study was unable to be completed because of lack of accrual. As a result, the safety and efficacy of amifostine in children with MDS remains uncertain. Despite a lack of successful prospective clinical trials in children with MDS, there are limited retrospective data on the use of the hypomethylating agent azacytidine in children with newly diagnosed MDS, and in the palliative setting, children with relapsed MDS. These children had RCC, advanced and secondary MDS,⁷⁸ and prior to allogeneic hematopoietic cell transplantation (HCT).⁷⁹ These retrospective reviews suggest that azacytidine is tolerable and responses are possible, although the safety and efficacy in these various clinical settings have not been demonstrated in prospective clinical trials in children.

Most children with MDS require allogeneic HCT for curative therapy. Although children have been included in published HCT studies for MDS that are largely focused on adult patients, several studies focus specifically on children.^{80–85} Taken together, these studies suggest a probability of disease-free survival in about 50% of patients undergoing human leukocyte antigen–matched related donor HCT. The Center for International Blood and Marrow Transplant recently published results for 118 children with MDS who underwent unrelated donor HCT.⁸⁴ Forty-six children had refractory cytopenia, 55 with RAEB and 17 with RAEB-T. Relapse of disease was most likely in children with RAEB and RAEB-T, with transplant-related mortality highest in recipients of human leukocyte antigen–mismatched grafts. The 8-year probabilities of disease-free survival for children with refractory cytopenia, RAEB, and RAEB-T were 51%, 35%, and 29%, respectively (Fig. 63.3).

HCT has also been reported in children and young adults with secondary MDS and secondary AML after aplastic anemia,⁸⁶ and as a salvage, second transplant procedure after relapse or graft failure.⁸⁷ Current areas of investigation include the predictive value of Wilms tumor 1 expression prior to HCT,⁸⁸ monosomal karyotype at the time of diagnosis or time of HCT⁸⁹ and hematopoietic chimerism after transplantation.⁹⁰

chemotherapy. Finally, patients with advanced MDS (RAEB-T or t-MDS) should be treated like those with AML.

Prognosis

Although a number of methods have been developed to predict the outcome of adults with MDS, the systems now most commonly used in adults are the International Prognostic Scoring System⁹¹ that uses percentage bone marrow blasts, karyotype, and number of cytopenias to assign a score that is then used to predict outcome, and the WHO classification-based prognostic scoring system (WPSS) that includes more recently identified prognostic factors (e.g., transfusion dependency and multilineage dysplasia).⁹² A recent study demonstrated

Fig. 63.3 (A) The 8-year probabilities of DFS after bone marrow transplantation (BMT): 57% for patients who received matched BMT (matched at human leukocyte antigen A, B, C, DRB1) and 33% for patients who received mismatched BMT. (B) The 8-year probabilities of disease-free survival after BMT: 51% when transplantation was performed for RC, 35% when transplantation was performed for RAEB, and 29% when transplantation was performed for RAEB-T. DFS, Disease-free survival; RAEB, refractory anemia with excess of blasts; RAEB-T, refractory anemia with excess of blasts in transformation; RC, refractory cytopenia. (Reproduced with permission from Woodard P, Carpenter PA, Davies SM, et al: Unrelated donor bone marrow transplantation for myelodysplastic syndrome in children. *Bio Blood Marrow Transplant* 17: 723, 2011.)

that both systems “well represent” the prognostic risk for patients whose MDS is defined by the WHO classification criteria.⁹³ Although these are effective tools for adults, their value for children is very limited.⁹⁴

Secondary Myelodysplastic Syndrome

Secondary MDS can develop in both children and adults after exposure to chemotherapy and radiation. Alkylating agents used to treat Hodgkin disease, non-Hodgkin lymphoma, and Ewing sarcoma are particularly concerning in children.^{95–107} Interestingly, there is also evidence to suggest that the cardioprotectant dexrazoxane, a topoisomerase II inhibitor with a mechanism of action that is different from etoposide and doxorubicin, may have increased the incidence of secondary MDS and AML in children treated for Hodgkin disease.¹⁰⁸

Treatment options for children with secondary MDS are limited. Although AML-like chemotherapy can induce a period of remission and reduction in BM blasts, it is not curative. Allogeneic HCT has curative potential, but outcomes remain poor, with only 20%–30% of children surviving in reported series.^{106,109,110} However, as noted earlier, recent data from the Center for International Blood and Marrow Transplant demonstrate that treatment failure with unrelated donor HCT is not higher compared with primary MDS.⁸⁴

TABLE 63.1 Diagnostic Criteria for Juvenile Myelomonocytic Leukemia

Category 1	Category 2	Category 3
All of the Following:	At Least 1 of the Following:	At Least 2 of the Following:
- Splenomegaly^a - AMC >1000/μL - Blasts in PB/BM <20% - Absence of the t(9;22) <i>BCR/ABL</i> fusion gene	- Somatic mutation in <i>RAS</i> or <i>PTPN11</i> - Clinical diagnosis of NF1 or <i>NF1</i> gene mutation - Homozygous mutation in <i>CBL</i> - Monosomy 7	- Circulating myeloid precursors - WBC >10,000/μL - Increased Hgb F for age - Clonal cytogenetic abnormality excluding monosomy 7 - GM-CSF hypersensitivity

The diagnosis of juvenile myelomonocytic leukemia is made if a patient meets all of the Category 1 criteria and one of the Category 2 criteria without needing to meet the Category 3 criteria. If there are no Category 2 criteria met, then the Category 3 criteria must be met.

^aFor the 7%–10% of patients without splenomegaly, the diagnostic criteria must include all other features in Category 1 AND one of the parameters in Category 2 OR no features in Category 2 but two features in Category 3.

AMC, Absolute monocyte count; BM, bone marrow; GM-CSF, granulocyte-macrophage colony-stimulating factor; Hgb F, fetal hemoglobin; NF1, neurofibromin type 1; PB, peripheral blood; PTPN11,; WBC, white blood cell.

MYELOPROLIFERATIVE NEOPLASMS

Juvenile Myelomonocytic Leukemia

JMML is classified by the WHO as an overlap of MDS and MPN. It is an aggressive myeloid malignancy of young children with poor outcomes to conventional therapies. The diagnostic criteria are complex (Table 63.1), but recent advances in elucidating the molecular genetics of the disorder demonstrate that approximately 85% of children will harbor an alteration in one of five genes. Thus there is now international agreement on the diagnostic criteria¹¹¹ (see Table 63.1), with an emphasis on incorporating these molecular genetic criteria, as well as a recent definition of common response criteria.¹¹²

Epidemiology

The incidence of JMML in the United States has been estimated as 0.69–1.2 per million.^{4,113} There is a male predominance with a median age of diagnosis of 1.8 years. The apparent incidence and demographic distribution may change in coming years because of refinement of diagnostic techniques such as molecular testing. In particular, mutation analysis may identify patients with less aggressive disease or at a younger age.

Pathogenesis

Early clonality studies suggested that JMML arose at the level of at least an immature myeloid precursor cell.^{111,114–118} More recent data suggest that JMML may arise in a pluripotent stem cell with involvement of the myeloid, erythroid, and megakaryocyte lineages, as well as B lymphocytes and T lymphocytes.^{111,119–122} This is supported by finding pathogenic mutations in immature hematopoietic cells identified by flow cytometry.¹²³

Somatic mutations that augment signaling through the Ras pathway occur in approximately 85% of JMML patients. These include biallelic inactivation of *NF1* (15%),¹²⁴ activating mutations

in *NRAS* or *KRAS* (25%),^{125–127} mutations in the *PTPN11* gene (see Fig. 63.1) (35%), and mutations in *CBL* (10%–15%).^{128–131} This synopsis reflects decades of research, beginning with the seminal observation that JMML is associated with neurofibromin type 1 (NF1). A rough comparison of incidence rates suggests that NF1 carries a 500-fold increased risk of acquiring JMML. At a molecular level, these children inherit a defective allele of the *NF1* gene, which encodes a negative regulator of Ras named *neurofibromin*. In JMML, the normal allele is lost as a somatic event in the initiating cell, most often by loss of heterozygosity in which the overall copy number remains unchanged (uniparental isodisomy). This completely ablates neurofibromin and thereby increases Ras activity.

Such interplay of inherited and somatic mutations is also relevant to the other JMML genes. Germline mutations in *PTPN11* cause Noonan syndrome (NS), a common genetic condition that overlaps phenotypically with NF1 and sometimes includes a mild JMML-like myeloproliferative syndrome. This finding led directly to the discovery of somatic *PTPN11* mutations in sporadic JMML, a lesion now recognized as the most common pathogenic mutation in this disease. Furthermore, rare germline mutations in *KRAS* have also been associated with related genetic syndromes including NS and cardiofaciocutaneous syndrome.^{132–137} The *PTPN11* and *KRAS* mutations present in the germline generally have less severe biochemical consequences than those in sporadic cases. This suggests that strong signal activation is not tolerated during development. Accordingly, the most common NS-associated *PTPN11* alleles have relatively weak effects on signal transduction, and the myeloproliferative syndrome in these patients is usually transient.^{138–140} However, a more recent and comprehensive analysis has suggested that a cohort of NS patients may inherit more deleterious mutations and develop fatal neonatal JMML.¹⁴¹ Thus cytoreductive therapy or HCT may be considered for select NS patients with severe disease.

Similar to *NF1*, mutations in *CBL* are heterozygous in the germline, with subsequent reduction to homozygosity in hematopoietic cells. This contrasts with the lesions described in adults.¹³⁰ The heterozygous germline mutations appear to cause a genetic syndrome with features that can overlap with NS, termed *CBL syndrome* or *Noonan syndrome-like disorder with or without juvenile myelomonocytic leukemia*. The phenotypic manifestations of NSLL are variable and incompletely penetrant, and they include cryptorchidism, hearing loss, and skeletal abnormalities. Importantly, major vascular abnormalities have been described in patients with *CBL*-mutant JMML, and this could also reflect an NSLL phenotype. As expected for a heterozygous mutation, transmission is autosomal dominant, although 50% of cases arise spontaneously.^{129,131,142–145} In contrast to the loss of function mutations in *NF1*, the mutations in *CBL* selectively inactivate the ubiquitin ligase activity of the Cbl protein while leaving the molecule otherwise intact. When homozygous, this alteration eliminates the negative regulatory activity of Cbl while sparing positive signaling functions.¹³⁰

It has been speculated that the 15% of patients without mutations in the five major JMML genes have heretofore undetected mutations that also activate Ras signaling. In recent genomic studies, rare mutations in *SH2B3*, *RRAS*, *RRAS2*, *RAC2*, or *JAK3* seem to be consistent with this idea.^{146–148} Collectively, these data support the idea that hyperactive Ras is essential for initiation of JMML, but suggest that initiating mutations beyond the five major genes will be diverse and infrequent.

These so-called *Ras pathway* or *driver* mutations are largely mutually exclusive, supporting the idea that each provides a similar function in JMML. However, patients with two such lesions or duplication of the mutant allele have been reported, typically co-occurring in the same cells.^{146,147} This likely reflects clonal evolution and positive selection for increased Ras signaling even beyond that provided by the initiating mutation. Growing evidence demonstrates that negative feedback prevents the Ras pathway from being fully activated by a single lesion, leading to a dosage effect of mutant alleles on signaling outputs.¹⁴⁹ Consistent with predictions from model systems, cases with multiple Ras pathway mutations have a more aggressive clinical course.¹⁴⁷

Genomic studies have also begun to address the question of whether mutations outside the Ras pathway contribute to the pathogenesis of JMML.^{123,146–148} A wide variety of so-called secondary mutations have now been recognized. They are primarily associated with relapse of JMML after HCT, or with transformation to AML. However, they often can be detected at a low level in the blood or bone marrow when JMML is first diagnosed. This suggests that clonal evolution selects for chemotherapy resistance and eventually leukemic transformation. This is supported by the striking observation that secondary mutations of any kind have a major prognostic impact, even when they are present in a very small proportion of hematopoietic cells at diagnosis.

In the few JMML cases in which clonal history has been inferred, mutations appear to be acquired sequentially, beginning with a Ras pathway lesion. This linear evolutionary path contrasts with the highly branched patterns typical of high-grade neoplasms. Thus despite the discovery of a variety of secondary mutations in JMML, it remains a disease with much less genetic complexity than most cancers. This may have important implications for therapy, as any individual patient is likely to harbor a relatively small number of distinct subclones that need to be eradicated to achieve cure.

The cellular function of cooperating mutations in JMML is under active investigation. Most can be categorized into three groups. Some amplify signaling beyond the level provided by the initial Ras pathway mutation. As described earlier, some second mutations directly alter core Ras pathway genes. Janus-activated kinase (JAK)/signal transducer and activator of transcription (STAT) signaling is enhanced by activating mutations in *JAK3* or loss-of-function mutations in *SH2B3*, which encodes the negative regulatory adaptor protein LNK. Mutations in *RRAS*, *RRAS2*, and *RAC2* represent a novel signaling complex in JMML that is implicated in regulating the PI3K/Akt pathway.¹⁴⁷ Dominant point mutations in *SETBP1* remain somewhat unexplored, but may augment signal transduction by inhibiting the phosphatase PP2A or regulate gene transcription and strengthen self-renewal programs. Other secondary lesions have broad effects on gene expression, through inactivation of the PRC2 polycomb repressor complex or alteration of spliceosome components. Many of these genes and cellular functions are also implicated in the pathogenesis of other myeloid neoplasms such as CMML or AML.

Model Systems

Genetically engineered mouse models of JMML have been based on directed mutation of *Nf1*, *Kras*, *Nras*, *Ptpn11*, and *c-Cbl*. These are reviewed in detail elsewhere.^{150,151} In general terms, these mice reproduce many key features of JMML, but penetrance and severity of disease vary across these models. In an alternative approach, induced pluripotent stem cells have recently been generated from germline and neoplastic cells from JMML patients.¹⁵² These can be differentiated into myeloid progenitors that also recapitulate signal transduction and cell biology phenotypes characteristic of JMML. Together, these systems provide a robust set of tools for investigating the biology of JMML and also enable preclinical testing of novel therapeutic strategies.

Cell Biology of JMML

Hematopoiesis in JMML is altered in a distinctive way that is much more subtle than in acute leukemias, although nonetheless usually fatal if not corrected. A consensus has emerged that the disease initiates with a somatic Ras pathway mutation, presumably in a single HSC. This implies that the mutation imparts a competitive advantage over normal stem cells. This is supported by evidence from multiple mouse models.^{153–156} Interestingly, however, *Nf1*^{−/−} HSCs fail to cause an overt disease when mixed with wild-type cells, suggesting a limit to the advantage imparted by *Nf1* loss. Furthermore, there is also evidence that excessive signaling in Ras or phosphatidylinositol 3-kinase (PI3K) induces substantial stress in HSCs.^{153,157–162}

More overt effects are seen in myeloid and erythroid progenitor cells, as manifested clinically by the circulation of immature erythroid and myeloid forms in the peripheral blood. In normal hematopoiesis, proliferative myeloid precursors are only present in the bone marrow and are strictly dependent on exogenous cytokines. By contrast, myeloid colonies arise from cultures of either blood or bone marrow from JMML patients, and they often do not require additional cytokines.¹⁶³ Importantly, they uniformly demonstrate a hypersensitive dose-response curve to the cytokine granulocyte-macrophage colony-forming factor (GM-CSF). Finally, aberrant differentiation generates excessive monocytes and insufficient mature erythrocytes. Although the mechanisms underlying abnormal hematopoiesis in JMML remain under investigation, both cell-intrinsic and cell-extrinsic mechanisms are likely to contribute.

Similarly, the precise biochemical signaling events responsible for the MDS/MPN phenotype are poorly understood. Ras proteins potentially signal through a wide variety of effector proteins,¹⁶⁴ but cancer is most closely linked to the Raf/MEK/ERK and PI3K/Akt pathways. Evidence from model systems suggests that each of these plays an important role in directing the abnormal growth and differentiation that defines JMML. Inhibitors of MEK cause substantial improvements in MDS/MPN in *Kras* or *Nf1* mutant mice.^{165,166} Similarly, attenuation of PI3K signaling counteracts the effects of mutant *Ptpn11* and *Kras* alleles in mice.^{167–169} The relevant downstream targets of these signaling networks in JMML are poorly characterized, but several studies have implicated specific hematopoietic transcription factors that integrate aberrant upstream signals to alter hematopoietic cell fate decisions.^{170,171}

JAK/STAT signaling is also implicated in JMML. The GM-CSF receptor requires the nonreceptor tyrosine kinase Jak2 to initiate signaling. Therefore JAK2 is upstream of Ras as well as STAT5 in this context. STAT5 phosphorylation in myeloid progenitors from JMML patients is hypersensitive to GM-CSF, mirroring the abnormal colony forming activity of these cells.¹⁷² The acquisition of *JAK3* or *SH2B3* mutations in advanced JMML also implies involvement of this pathway in JMML pathogenesis.

Clinical Manifestations

Children with JMML typically present with signs and symptoms attributable to a heavy burden of organ-infiltrating cells that results in hepatosplenomegaly, lymphadenopathy, and skin rash. As a result of the association with neurofibromatosis, patients may also have café-au-lait spots or juvenile xanthogranulomas. Death is usually the result of organ dysfunction caused by infiltrating cells, infection, or bleeding. Approximately 10%–20% of children progress to a blast-like phase consistent with AML.

Laboratory Manifestations

Laboratory abnormalities may include an elevated white blood cell count with absolute monocytosis, anemia, and thrombocytopenia (Figs. 63.4 and 63.5). Monocytes, either circulating in the peripheral blood or in the BM, frequently appear dysplastic. The peripheral smear shows leukoerythroblastic changes, and there are often circulating nucleated red blood cells. Fifty percent of patients may also present with elevated fetal hemoglobin levels and hypergammaglobulinemia, which is of interest given that there are patients recently described with autoimmune lymphoproliferative syndromes who also harbor *RAS* mutations (see later). International criteria mandate that the BM have fewer than 20% blast cells at diagnosis. Other findings typical in the BM may include micromegakaryocytes.

Differential Diagnosis

Traditionally, establishing a diagnosis of JMML was not easy because its clinical and laboratory presenting features can also be associated

Fig. 63.4 JUVENILE MYELOMONOCYTIC LEUKEMIA: BLOOD, BONE MARROW, LUNG, AND SPLEEN. The illustrations are from the case of a 3-year-old boy who was diagnosed with neurofibromatosis at birth. At 1 year of age, he presented with leukocytosis (58 K/ μ L). The peripheral blood (A and B) showed left-shifted granulocytes and increased monocytes (16%). A bone marrow biopsy (C and D) was hypercellular as a result of increased granulocytic and monocytic cells that could also be appreciated on the aspirate (E). Blasts accounted for only 4% of the bone marrow elements. A combined esterase reaction (F) illustrated the increased monocytes (α -naphthol butyrate esterase reaction positive; orange/brown) in the background of granulocytes (chloroacetate esterase reaction positive; blue). Cytogenetic analysis revealed monosomy 7. At age 2 years, the patient presented with respiratory distress, and a lung biopsy (G and H) demonstrated a monocyte infiltrate (lysozyme stain, I) consistent with involvement by juvenile myelomonocytic leukemia. This is not uncommon in such patients. At age 3 years, his blast count began to rise, and he underwent a splenectomy (which showed a marked infiltrate of immature and mature monocytes and granulocytic cells [J and K; lysozyme stain, L]). After the splenectomy the patient underwent a successful stem cell transplant.

Fig. 63.5 JUVENILE MYELOMONOCYTIC LEUKEMIA: SKIN AND GASTROINTESTINAL TRACT. Patients with juvenile myelomonocytic leukemia sometimes present with or develop skin nodules, which on biopsy show a myelomonocytic infiltrate in the upper and lower dermis (A). Involvement can also be seen in the gastrointestinal tract (B). (The case was kindly provided by Dr. Elizabeth Hyjek, University of Chicago.)

with other disorders, including Wiskott-Aldrich syndrome,¹⁷³ infantile osteopetrosis,¹⁷⁴ infections (Epstein-Barr virus, cytomegalovirus, human herpesvirus 6, histoplasmosis, mycobacterium, and toxoplasmosis), class I Langerhans cell histiocytosis, hemophagocytic lymphohistiocytosis, FA, Kostmann syndrome, Shwachman syndrome, and Down syndrome. However, with a positive molecular mutation, patients who exhibit the category 1 features are now more easily diagnosed.

Recently, the term “Ras associated lymphoproliferative disorder (RALD)” has been coined to describe patients with autoimmunity and lymphoid proliferation with activating *RAS* mutations in the blood.¹⁷⁵ These mutations were initially thought to be in the germline but later were established to be somatically acquired in the bone marrow. These patients also exhibit splenomegaly and monocytosis, and they tend to meet clinical diagnostic criteria for JMML. At this time, there is no accepted method for distinguishing JMML from RALD, except to note that patients diagnosed with RALD have less fulminant myeloid disease and relatively more prominent immune dysregulation. Further study is needed to determine whether these diagnoses represent distinct clinicopathologic entities or rather represent the spectrum of hematologic phenotypes specified by Ras pathway mutations. Along with reports of rare JMML patients who survive without chemotherapy despite persistent Ras pathway mutations, this idea has raised the controversial question as to whether select patients can be monitored without definitive therapy. However, given the difficulty of prospectively diagnosing RALD, its extremely low incidence, and the strong tendency of JMML to become more aggressive over time, most patients meeting JMML criteria should be treated as such.

Therapy

Children with JMML can have a variable course, with rare patients having a spontaneous remission and long-term survival without

treatment but others having a rapidly fatal course despite aggressive treatment.^{176,177} The patients likely to do well without HCT are those with somatic *NRASG212S* or *KRASG12V* mutations, or germline mutations in *CBL*.^{178–180} Older age, lower platelet count, and elevated hemoglobin F levels have been used to predict a more aggressive clinical course for patients.^{181–185} Currently, the most adverse prognostic factor for outcome is the presence of >20% blasts or an AML-like gene expression profile,^{181,184} which have survival rates of <10% even with allogeneic HCT.

A wide variety of agents have been used to treat children with JMML, including AML-like chemotherapy,^{59,186–191} low-dose chemotherapy,^{192,193} interferon- α (IFN- α),¹⁹⁴ and 13-*cis*-retinoic acid. Tipifarnib, a farnesyl transferase inhibitor, was tested in a Phase II window by the Children's Oncology Group (COG) where it produced some responses, but did not appear to impact long-term survival.¹⁹⁵ Perhaps because the evaluation of these treatment regimens has been complicated by small patient numbers, a prior lack of consistent response criteria, and until recently, lack of assays to measure the burden of clonogenic JMML stem cells, the utility of chemotherapy prior to HCT is unclear. One report showed no difference in univariate post-HCT outcomes in patients who did or did not receive AML-like chemotherapy, but this was limited by the inclusion of patients with AML and the lack of multivariate analysis.¹⁸¹ Several newer reports show trends towards better post-HCT outcomes in patients who either received AML-like chemotherapy (without mention of response)¹⁸² or who had normalization of WBC count and organomegaly prior to HCT.¹⁹⁵ With the advent of uniform response criteria¹¹² and the ability to follow molecular disease burden in patients with mutations in *PTPN11*, *NRAS*, and *KRAS*,¹⁹⁶ more definitive data on the role of pre-HCT chemotherapy may soon be forthcoming. For most children with JMML, allogeneic HCT offers the only known potential for cure, with about half of transplanted children surviving disease free.^{182,197,198} Rapid withdrawal of immunosuppression appears to be important in this disease, as mounting evidence supports a graft-versus-leukemia effect.^{199,200} A number of issues related to HCT for JMML remain uncertain. Among these are the value of pretransplant splenectomy and the optimal conditioning regimen and graft-versus-host disease prophylaxis. Splenectomy, a procedure not without long-term risks, had a trend towards improved outcomes in patients undergoing umbilical cord blood transplant,¹⁸² but no benefit in those getting transplants from other donors.^{181,195} Radiation-containing preparative regimens, which have significant long-term risks in small children, have not shown benefit when compared with other published reports,¹⁹⁵ although they did decrease the risk of rejection in patients undergoing cord blood transplant.¹⁸² The most common cause of death after HCT is recurrent disease, but a second HCT can be lifesaving for some children.^{181,201,202} Donor leukocyte infusions have variable response rates.^{200,203}

Down Syndrome–Associated Transient Abnormal Myelopoiesis

Epidemiology

Down syndrome is one of the most common congenital disorders, affecting approximately one in every 800–1000 live births. It has been demonstrated in a recent population-based study that children with Down syndrome have a 10–20-fold overall increased risk of developing leukemia,²⁰⁴ a 150-fold increased risk of developing AML, and a 500-fold increased risk of acute megakaryocytic leukemia. The median age of diagnosis of myeloid leukemia of Down syndrome (ML-DS), as defined by the WHO classification system, in children with Down syndrome is 2 years.²⁰⁵ TAM, also known as *transient myeloproliferative disorder* (TMD) and *transient leukemia*, is thought to occur in at least 10% of children with trisomy 21 Down syndrome, although 7%–16% of TAM cases have mosaic trisomy 21. It has also been suggested that when cases of TAM that develop and resolve in utero or result in death before

delivery are taken into account, the incidence may be as high as 20%.²⁰⁶ Currently, it is estimated that approximately 20%–30% of children with TAM subsequently develop AML, usually by 3 years of age. This estimate was validated in a recent prospective study conducted by the COG.²⁰⁷ In this study, AML developed in 16% of Down syndrome children who had TAM at a median of 441 days (118–1085 days).

Pathobiology

The molecular pathogenesis of TAM and ML-DS in children with Down syndrome is now providing valuable insights into myeloid leukemogenesis.²¹ Current research suggests that the development of TAM and subsequent progression to ML-DS are the result of a three-step process: perturbation of fetal hematopoiesis by trisomy 21; an acquired *GATA1* mutation; and the acquisition of additional oncogenic mutations.^{208,209}

It is increasingly clear that trisomy 21 results in genome-wide changes in gene expression that affect, directly or indirectly, most chromosomes.²¹⁰ This results in perturbed hematopoiesis with increased numbers and clonality of HSCs, increased frequency of megakaryocyte and erythroid progenitors, and reduced numbers of granulocyte- and macrophage-committed progenitor cells.^{211,212}

Recent studies have shown that virtually all patients with TAM and most patients with ML-DS harbor mutations in exon 2 and occasionally in exon 3 of the hematopoietic transcription factor *GATA1*.^{213–217} *GATA1* is a double-zinc finger DNA-binding transcription factor expressed primarily in hematopoietic cells. It is required for the development of red blood cells, megakaryocytes, mast cells, and eosinophils. A number of different mutations in *GATA1* have been identified, including insertions, deletions, missense mutations, nonsense mutations, and splice site mutations. All of these mutations lead to a block in the expression of the full-length 50-kd isoform of *GATA1* but allow for the expression of a smaller, 40-kd isoform (*GATA1s*).²¹⁸ This smaller isoform lacks the N-terminal transactivation domain but retains both zinc fingers involved in DNA binding as well as interactions with its cofactor, friend of *GATA1* (*FOG1*).²¹³ Recent studies have shown that mutations that alter *GATA1-FOG1* binding in the N-terminal zinc finger or result in the expression of the *GATA1s* isoform uncouple megakaryocyte growth and differentiation.^{219–221} Similar studies in cell lines derived from children with ML-DS have demonstrated that expression of *GATA1* led to erythroid differentiation whereas expression of *GATA1s* did not alter the characteristics of the cell line.²¹⁷ Taken together, current data suggest that the loss of *GATA1* and expression of *GATA1s* directly contribute to leukemogenesis.

Although mutations in *GATA1* may be sufficient to cause TAM, these mutations are not sufficient for the development of ML-DS, as evidenced by the latency period between resolution of TAM and the development of ML-DS, as well as the observation that not all children with TAM and *GATA1* mutations will ultimately develop ML-DS. Therefore a multistep pathogenesis model is proposed in patients with Down syndrome in whom ML-DS develops in clones with *GATA1* mutations and additional cooperating mutations. A large number of potential target genes have been proposed and are the subject of ongoing investigation.²²² Among this long list of candidate targets are mutations in the gene for *JAK3*, a member of the JAK family of nonreceptor tyrosine kinases. Several gain-of-function mutations^{223,224} and loss-of-function mutations in *JAK3*²²⁵ have been identified in both TAM and ML-DS patient samples. Although mutations in *JAK3* might indeed represent an additional “hit” in this three-step model, the finding of mutations in TAM patients who have not progressed to ML-DS may argue against *JAK3* as a cooperating mutation.

Another particularly important area of investigation is the interaction between *GATA1* and chromosome 21. Identification of critical interactions between *GATA1* and relevant genes on chromosome 21 will serve to further inform us about the pathogenesis of leukemia in children with Down syndrome.

Clinical Manifestations

Patients with Down syndrome typically present with TAM within 3 months after birth, although TAM can be manifest at birth. Some of these children present with hydrops fetalis secondary to anemia and cardiac dysfunction. Although some patients may be asymptomatic, others can have myeloblast infiltration of the heart, liver, and spleen that can result in hepatosplenomegaly; hepatic fibrosis; pleural, pericardial, and peritoneal effusions; and disseminated intravascular coagulopathy. In some cases, organ dysfunction can be severe, with failure of the liver, heart, kidneys, and lungs. In the COG's recently published prospective study, death occurred in 21% of patients, although only 10% died as a result of TAM-associated problems.²⁰⁷

Laboratory Manifestations

The complete blood count in infants with TAM typically demonstrates an elevated white blood cell count with myeloblasts present (see Fig. 63.6). The percentage of circulating myeloblasts exceeds the percentage of BM myeloblasts. Rarely, a neonate without stigmata of Down syndrome will present with similar features—in these cases, workup for either trisomy 21 mosaicism or a *PTPN11* mutation should be pursued. Flow cytometric analysis of the myeloblasts from TAM patients and ML-DS associated with Down syndrome show many similarities between these disorders as well as patterns of cell surface antigen expression that is distinct from other types of AML in children.²²⁶ Specifically, all TAM and ML-DS blasts express CD45, CD38, and CD33, but the majority of cases express CD36 and CD34. CD41 and CD61 also are expressed, consistent with megakaryocyte differentiation. CD14 and CD64 are usually negative. Most cases have aberrant expression of CD7, a T-lineage antigen.

Therapy

The treatment of infants with TAM is generally supportive. Patients without significant organ dysfunction can be followed closely without medical intervention. In the COG's prospective study, peripheral blood blasts and TAM-associated symptoms resolved in 36 and 49 days, respectively, for observation patients.²⁰⁷ In infants with significant organ impairment, a number of therapeutic approaches aimed at reducing the burden of myeloblasts are routinely used, including exchange transfusion, leukapheresis, and chemotherapy. According to reports using cytosine arabinoside in children with Down syndrome and ML-DS,^{227,228} cytosine arabinoside is the chemotherapeutic agent now most commonly used in infants with TAM. The

efficacy of very low doses of cytosine arabinoside is being tested in prospective clinical trials. Several additional questions related to the treatment of infants with TAM are also the subject of ongoing clinical trials. Among these is the identification of high-, intermediate-, and low-risk populations, with treatment stratified on the basis of risk group and a determination of whether treatment with very low-dose cytosine arabinoside will prevent progression of TAM to ML-DS and hepatic fibrosis.

Prognosis

Recent data from the COG reporting the results of the POG-9481 prospective clinical trial offer insights into the natural history of TAM and the identification of prognostic factors.²²⁹ This study followed 48 children with TAM. Eighty-nine percent of infants achieved a spontaneous remission, 74% had a normalization of peripheral blood counts, and 64% maintained a clinical remission. Seventeen percent of infants had an early death. Factors associated with early death included a high white blood cell count ($p < .001$), increased bilirubin and liver function test values ($p < .005$), and a failure to normalize blood counts ($p < .001$). Nineteen percent of patients had a progression to ML-DS at a median of 20 months. The greatest risk factor for progression to leukemia was the presence of karyotypic abnormalities in addition to trisomy 21 in blasts cells.

The COG's more recent A2971 study identified three groups of children with different outcomes based on the presence or absence of hepatomegaly and life-threatening symptoms.²⁰⁷ Children with neither hepatomegaly nor life-threatening symptoms were at low risk of death (overall survival [OS], 92%); children with hepatomegaly alone had an intermediate risk of death (OS, 77%), and children with both hepatomegaly and life-threatening symptoms were at high risk of death (OS, 51%).

OTHER MYELOPROLIFERATIVE NEOPLASMS

Essential Thrombocythemia

ET has an estimated incidence of 1–1.25 cases per million in adults but is even rarer in children, with an estimated incidence of 0.09 cases per million.^{230–234} ET is a genetically heterogeneous disease. Mutations in *JAK2* have been reported in adults with *BCR-ABL*-negative MPNs, including ET, PV, and idiopathic myelofibrosis (IM). It has been proposed that ET consists of several subtypes, with some children and adults having monoclonal disease but others having polyclonal disease. Further investigation into the mutational status of *JAK2* V617F also demonstrates mutation-positive (roughly 55%) and mutation-negative patients.^{231,235} Another cause of ET was recently demonstrated to be mutations in *CALR* (calreticulin).²³⁶ Studies suggest that a similar proportion of children and adults with somatic ET display polycythemia rubra vera-1 (PRV-1) RNA overexpression, *JAK2* V617F mutations, and monoclonal disease.²³⁷ Rare cases of familial ET have been shown to be caused by dominant activating mutations in both *c-MPL*²³⁷ and in *JAK2*.²³⁸

Patients with ET have thrombocythemia with an increased number of megakaryocytes in the BM. Platelet clumps on peripheral blood smears are common. Some patients have a concomitant increase in the number of peripheral blood granulocytes. The differential diagnosis includes familial ET, other forms of MPS, and increased platelets as a reactive process.

Although the clinical course can be uncomplicated, patients can develop thromboembolic complications, including deep venous thrombosis, and arterial thrombosis such as transient cerebral ischemia and peripheral vascular ischemia. The clinical course for children is typically less aggressive than in adults, with fewer thrombotic episodes.^{237,239} Adult patients have a median survival of at least 10 years, with most deaths caused by thrombosis.^{240,241} Progression to AML has been reported in adult patients, usually those with a prior exposure to chemotherapy agents.

Fig. 63.6 TRANSIENT ABNORMAL MYELOPOIESIS AND TRANSIENT LEUKEMIA OF DOWN SYNDROME. The patient was a premature newborn girl with trisomy 21 and a white blood cell count of 195,000/ μ L with 67% blasts (A). The blasts were CD34⁺, CD33⁺, and CD117⁺, and a portion exhibited CD41, a megakaryocyte marker. Morphologically, some of the blasts appeared to be megakaryoblasts (B), sometimes with slight differentiation toward megakaryocytes (C).

Asymptomatic children do not require treatment. There is no clear association with platelet count and thrombotic events. As such, there is not a clear role for treatment with aspirin, which can increase the risk of paradoxical bleeding episodes.²⁴² Risk factors for thrombosis include leukocytosis and presence of a *JAK2* V617F mutation.²⁴³ A number of treatment approaches aimed at controlling thrombocytosis have been attempted for symptomatic patients, including hydroxyurea, IFN- α , and anagrelide.^{244–246} The JAK inhibitor ruxolitinib may benefit some patients with ET, especially those with *JAK2* V617F mutations, although pediatric-specific data with this agent are lacking. The successful use of allogeneic HCT has been reported for a number of adult patients with ET, especially after transformation to myelofibrosis or AML.^{247–249} Younger patients, and those with matched related donors, did especially well, suggesting that allogeneic transplant should be considered in pediatric patients with ET.

Idiopathic Myelofibrosis

IM is very rarely diagnosed in children²⁵⁰ and should be differentiated from acute megakaryocytic leukemia; metastatic neoplasms; and connective tissue, metabolic, and bone diseases. It is characterized by BM fibrosis, megakaryocytes with bizarre morphology, splenomegaly, anemia, and extramedullary hematopoiesis. IM is a clonal disorder, with approximately half of adult patients having mutations in *JAK2* V617F.²⁵¹ Recent studies have suggested that angiogenic cytokines produced by megakaryocytes and monocytes and their receptors (platelet-derived growth factor receptors, vascular endothelial growth factor receptor-2, and fibroblast growth factor receptor) may be involved in the pathogenesis of the myelofibrosis.²⁵²

Numerous treatment approaches have been attempted with variable degrees of success. These include splenectomy, splenic radiation, transfusions, androgens, corticosteroids, hydroxyurea, and IFN- α .^{253–255} More recently, based on preliminary studies about the potential role of angiogenic cytokines and their receptors, newer approaches have been tested, including the tyrosine kinase inhibitor imatinib^{256,257} and the antiangiogenic agent thalidomide.^{258,259} Selective JAK inhibitors have been successfully used in patients with IM with a dramatic improvement in the quality of life but without generalized reduction of the *JAK2* V617F burden allele.²⁶⁰ In 2011, the United States Food and Drug Administration granted approval to the first of these agents, ruxolitinib, for adults with IM. However, the safety and efficacy of ruxolitinib in children is still unknown. Further trials are investigating the combination of JAK inhibition in combination with other therapeutic modalities, such as PI3K inhibition, mammalian target of rapamycin inhibition, histone deacetylase inhibition, and antifibrotic agents.²⁶¹ Finally, allogeneic transplantation is the only potentially curative option for IM, with resolution of BM fibrosis in donor-engrafted patients but high rates of transplant-related complications.^{248,262–265} The survival in children is unknown, with a median survival in adults of 4 years.

Polycythemia Vera

PV has an incidence of three cases per 100,000 in adults but is very rarely seen in children, with fewer than 0.1% of PV patients diagnosed before 20 years of age.²⁶⁵ PV in children is far more often the result of congenital or acquired causes of an increased red blood cell mass. These include primary familial polycythemia (characterized by specific mutations in the erythropoietic receptor gene)²⁶⁶ and secondary polycythemias caused by abnormal hemoglobins, cardiac and pulmonary disease, excessive erythropoietin, and a relative polycythemia that is the result of decreased plasma volume.

PV in children and adults is associated with clonal hematopoiesis,²⁶⁷ *JAK2* V617F mutations (in 95% of patients; with mutations in *JAK2* exon 12 representing 2%–4%),^{237,268–273} overexpression of PVR-1 RNA,^{274,275} and endogenous erythroid colony growth.^{276,277} In contrast to adults, children with PV may be less likely to have *JAK2*

V617F mutations and endogenous erythroid colony growth,^{237,278} such that the proposed revision to WHO's diagnostic criteria,²⁷⁹ may be less helpful in the diagnosis of PV in children, although other reports suggest that the proposed WHO criteria are equally applicable to children.²⁸⁰ The proposed criteria include: (1) a hemoglobin >16.5 g/dL in men or >16.0 g/dL in women; (2) a BM biopsy showing trilineage myeloproliferation and pleomorphic megakaryocytes; and (3) either a *JAK2* mutation or a serum erythropoietin level below the normal reference range.²⁸¹ Although the pathogenesis is currently unclear, patients also have abnormalities in tissue factor, endogenous anticoagulants mechanisms, hyperhomocysteinemia, and acquired von Willebrand syndrome.

Children with PV may present with signs and symptoms associated with an increased red blood cell mass such as headache, dizziness, fatigue, pruritus, night sweats, and a ruddy complexion. Mild splenomegaly may be present, but massive hepatosplenomegaly is rare. As a result of hyperviscosity of the blood, elevated platelet counts, and coagulation abnormalities, patients can develop thromboses and CNS ischemia, although the incidence of thrombotic events may be lower than that reported in adults.^{237,278}

Many different agents have been used to treat patients with PV, including chlorambucil,²⁸² melphalan,²⁸³ 6-thioguanine,²⁸⁴ uracil mustard,²⁸⁵ busulfan,²⁸⁶ carboquone,²⁸⁷ anagrelide,²⁸⁸ imatinib,²⁸⁹ hydroxyurea,²⁹⁰ radioactive phosphorus,²⁹¹ and IFN.²⁹² Despite these efforts, the best approach to patients with PV remains unclear. Therefore the British Committee for Standards in Haematology formulated recommendations for the initial management of PV.²⁹³ Recommendations include phlebotomy to maintain a hematocrit level less than 45%;²⁹⁴ low-dose aspirin unless contraindicated; and cytoreduction if there is poor tolerance to phlebotomy, symptomatic or progressive splenomegaly, evidence of disease progression, or thrombocytosis. For patients younger than 40 years of age, pegylated IFN was the recommendation for first-line cytoreduction, with hydroxyurea as second line. However, the JAK inhibitor ruxolitinib was recently found to have excellent results in controlling the hematocrit and splenomegaly with minimal side-effects in an open-label phase III trial.²⁹⁵ This may eventually supplant IFN and hydroxyurea as front-line therapy once pediatric-specific dosing is available. Finally, allogeneic transplantation has been successfully used to treat some adult patients,^{247–249} especially those with progression to myelofibrosis or AML. Younger patients, and those with matched related donors, did especially well, suggesting that allogeneic transplant should be considered in pediatric patients with PV.

FUTURE DIRECTIONS

Although a clearer understanding of the biologic mechanisms underlying MDS in children is slow in coming, dramatic progress has been made in our understanding of the genetic and biologic mechanisms contributing to TMD, JMML, PV, ET, and IM. There exists a potential for targeted therapeutics for many of these disorders, with the first targeted agents now receiving approval for use in adults. However, the use of these approved agents in children remains investigational.

Progress for both MDS and MPN in children will require international cooperation. The rarity of these disorders and limitations in resources for pediatric cooperative cancer groups make clinical trials within each individual cooperative group increasingly difficult.

PATHOBIOLOGY OF ACUTE LYMPHOBLASTIC LEUKEMIA

Melissa Burns, Scott A. Armstrong, and Alejandro Gutierrez

Normal lymphoid precursors undergo somatic recombination at their immunoglobulin (Ig) or T-cell receptor (TCR) gene loci,¹ and the successful completion of V(D)J recombination, with the resultant formation of a functional Ig or TCR, is required for the survival of lymphocyte precursors. Positive and negative selection steps ensure that only lymphocytes with Ig or TCRs that function appropriately within the context of an individual's immune microenvironment are allowed to proceed through the proliferation and differentiation steps required for the development of mature lymphocytes. This developmental process generates a repertoire of mature lymphocytes with unique variations in the antigen-recognition portions of the Ig or TCR genes; together these form the foundation of the adaptive immune system that can recognize a countless variety of foreign antigens. The acquisition of mutations of oncogenes or tumor suppressors during this developmental process, which can be mediated by off-target activity of the V(D)J recombination machinery,^{2,3} can lead to the dysregulated proliferation and differentiation arrest that are characteristic of acute lymphoblastic leukemia (ALL). Many of these genetic alterations have prognostic significance and are used in modern ALL treatment protocols to adjust the intensity of therapy. Although the incidence of specific genetic alterations in ALL varies according to patient age (Fig. 64.1), evidence suggests that the pathogenesis underlying malignant transformation in molecularly defined subsets of ALL is similar across age groups.^{4,5}

CLONAL ORIGIN OF LEUKEMIC LYMPHOID CELLS

The clonal origin of leukemia was first suggested by the identification of the Philadelphia (Ph) chromosome in chronic myeloid leukemia (CML).⁶ Subsequently, numerous lines of evidence have provided additional support for this theory, which is now generally accepted. Uniform structural and numerical chromosomal abnormalities are frequently demonstrated in all leukemic lymphoblasts from an individual patient. Identical rearrangements of Ig or TCR genes, which are somatic in origin, have been demonstrated in ALL cell populations.^{7,8} Additionally, identical patterns of X-chromosome inactivation have been demonstrated within all cells of individual patients with ALL by allelic analysis of the glucose-6-phosphate dehydrogenase gene on the X chromosome.⁹ Moreover, the methylation patterns of restriction fragment length polymorphisms in X-linked genes, as detected by Southern blot analysis, have been used to show that even rare ALL cases with two completely different cytogenetic clones probably arise by clonal evolution from a single transformed progenitor.¹⁰

LINEAGE-SPECIFIC FEATURES OF LEUKEMIC LYMPHOBLASTS

Malignant lymphoblasts share many of the features of normal lymphoid progenitors.^{11,12} Thus, ALL cells rearrange their Ig and TCR genes and express components of antigen receptor molecules and other differentiation-linked cell-surface glycoproteins in ways that correspond to features of developing normal B and T lymphocytes. In many cases, leukemic cells appear to represent the clonal expansion of a lymphoid progenitor that has arrested its development at an early stage of B- or T-cell differentiation.¹³ However, in many cases of ALL,

the blast cell phenotypes differ from those of normal lymphocyte progenitors, which is likely a result of aberrant regulation of gene expression. Still the general concept that leukemic cells should be classified according to their "normal" developmental stage remains an important one, providing a basis for the study of immunophenotype-specific genetic changes.

Mature B-Cell Acute Lymphoblastic Leukemia

The diagnosis of mature B-cell ALL, also termed *Burkitt leukemia*, is based on the detection of surface Ig on leukemic blasts. This rare phenotype accounts for only 2%–3% of ALL cases, and the lymphoblasts generally have distinctive morphology, with deeply basophilic cytoplasm containing prominent vacuoles; this morphologic pattern is designated L3 in the French-American-British (FAB) system.^{14–16} Mature B-cell ALL is a disseminated form of Burkitt lymphoma, as these conditions share common cytogenetic, molecular, phenotypic, and clinical features.¹⁷ Mature B-cell ALL does not respond well to chemotherapy traditionally used for childhood ALL. However, good outcomes have been obtained with treatments designed for Burkitt lymphoma, which involve relatively brief but intensive regimens that emphasize cyclophosphamide and the rapid rotation of antimetabolites in high dosages.^{18–22} Thus, mature B-cell leukemia was the first form of ALL to be recognized as a distinct clinical entity based on immunophenotypic and cytogenetic features, and the first to be treated by separate protocols designed specifically for the leukemia's unique features.

Precursor B-Cell Acute Lymphoblastic Leukemia

Approximately 80% of ALL patients have lymphoblasts with phenotypes corresponding to those of B-cell progenitors.^{16,23} These cases can be identified on the basis of cell surface expression of CD19 and at least one other recognized B lineage-associated antigen: CD20, CD24, CD22, CD21, or CD79.^{16,23} The most common subtype of precursor B-cell ALL, termed *common precursor B-cell ALL*, also expresses CD10. These lymphoblasts may also express nuclear terminal deoxynucleotidyl transferase (TdT) or CD34. About one-fourth of precursor B-cell ALL cases express cytoplasmic Ig μ heavy-chain proteins and are designated *pre-B ALL*.

DNA rearrangement of Ig genes occurs before heavy-chain gene expression in B-cell development, providing a genetic marker of B-lymphocyte ontogeny. Korsmeyer and coworkers pioneered the use of heavy- and light-chain gene rearrangements to support an early B-lineage origin of most ALL blasts.^{24,25} However, Ig heavy-chain gene rearrangements have also been documented in about 15% of T-cell ALL cases and in a similar percentage of acute myeloid leukemia (AML) cases.^{26–28} Thus, caution must be exercised when assigning cell lineage on the basis of studies of Ig gene rearrangement.

The identification of specific immunophenotypic, genetic, and clinical features that predict response to therapy in patients with B-lineage ALL, and the incorporation of these predictors into clinical decision making, are now widespread in modern ALL treatment protocols. This ability to predict outcome has been closely tied to the remarkable improvements in therapy for children with this disease, which 50 years ago was universally fatal. However, many subgroups

Fig. 64.1 FREQUENCY OF THE MAJOR CYTOGENETIC ABERRATIONS IN PEDIATRIC (A) AND ADULT (B) ACUTE LYMPHOBLASTIC LEUKEMIA. The Ph-like (also known as BCR-ABL1-like) acute lymphoblastic leukemia subtype comprises a number of chromosomal translocations and mutations in oncogenic kinase and cytokine receptor pathways, which are shown in the *insert*.

of pediatric and adult patients face a much poorer prognosis, and much progress remains to be made.

T-Cell Acute Lymphoblastic Leukemia

Lymphoblasts with a T-cell phenotype comprise approximately 15% of cases of ALL. These cases can be classified according to the sequence of expression of T-cell-associated surface antigens during normal thymocyte ontogeny.^{29,30} Numerous investigators, using a battery of monoclonal antibodies specific for T-cell surface glycoproteins, have confirmed the close relationship between the recognizable patterns of surface antigen expression on leukemic T cells and the normal stages of thymocyte development.^{31–34} T-cell ALL is often associated with distinctive clinical features that include high circulating leukocyte counts, a male predominance, CNS involvement, and a radiographically evident thymic mass in many cases at presentation. Historically, patients with T-cell ALL had an adverse prognosis compared with patients with B-lineage ALL, but this gap has narrowed with the intensification of therapy for these patients.^{35,36} In marked contrast to precursor B-cell ALL, in which the availability

of a wide range of clinical and genetic prognostic markers has allowed the development of treatment protocols tailored to an individual patient's risk of relapse, robust pretreatment prognostic markers had been lacking in T-cell ALL³⁷ until the recent identification of biomarkers of differentiation arrest at the earliest stages of T-cell development.^{38,39}

Recent work has identified a subset of T-cell ALL cases at particularly high risk of treatment failure, which are characterized by differentiation arrest at the earliest identifiable stages of T-cell development. These cases are defined either by absence of biallelic TCR γ deletion (ABD), indicating differentiation arrest prior to the completion of T-cell receptor (TCR) gene rearrangement, or by expression of a characteristic "early T-cell precursor" (ETP) phenotype.^{38,39} In addition to harboring oncogenic lesions typical of T-cell ALL, ETP cases also harbor gene mutations that are characteristic of AML or myelodysplastic syndrome, including *DNMT3A*, *IDH1/2*, and *EZH2*,^{40,41} suggesting that the cell of origin of ABD/ETP T-cell ALL may be a multipotent hematopoietic stem or progenitor cell rather than a committed T-cell progenitor. ETP appears to comprise 8%–15% of pediatric T-cell ALL but may account for a much higher fraction of T-cell ALL in adults,⁴¹ thus providing one possible

B

Fig. 64.1, cont'd

explanation for the significantly inferior outcomes of adults versus children with T-cell ALL.

Mixed-Lineage Leukemia

Acute mixed-lineage leukemia (MLL) is defined by blast cells that coexpress markers of both the lymphoid and myeloid lineages. Two distinct forms of these leukemias are recognized: biphenotypic leukemia, which accounts for the majority of MLLs and can be the result of cells with lymphoid morphology coexpressing myeloid-associated antigen,^{42,43} or those with myeloid morphology and reactivity to myeloperoxidase staining that coexpress cell-surface antigens normally restricted to lymphoid cells, and bilineal leukemia, in which there are two distinct population of cells (generally one lymphoid and one myeloid). The origin of MLLs has not been established. One possibility is malignant transformation of pluripotent hematopoietic stem or progenitor cells that retain the ability to differentiate in both the myeloid and lymphoid lineages; another is immortalization of rare progenitor cells that normally coexpress features of both lineages; and a third is aberrant gene expression caused by specific genetic alterations.⁴⁴ Despite initial controversy, coexpression of myeloid antigens in ALL, or of lymphoid markers in AML, does not appear to have significant prognostic value in the setting of contemporary treatment regimens.^{45–47}

GENETIC BASIS OF ACUTE LYMPHOBLASTIC LEUKEMIA

An in-depth analysis of the genetics of ALL is beyond the scope of this chapter, but we present here an overview of select genetic lesions that have provided key insights into the mechanisms of leukemogenesis. Mutations are classified based on their predominant cellular consequences, which is an imperfect classification scheme because some mutations can induce more than one type of cellular aberration. Nevertheless, we believe this provides a useful conceptual framework for understanding the molecular pathogenesis of ALL.

Aberrant Activation of Oncogenic Transcriptional Programs

Dysregulated activation of oncogenic transcriptional programs is a central theme in the pathogenesis of ALL. Many of the proto-oncogenes recurrently activated by genetic lesions are transcription factors that regulate proliferation and differentiation during the development of various embryonic tissues. Thus, co-option of normal developmental pathways plays a central role in human leukemogenesis. Transcription factors are commonly activated by chromosomal translocations in ALL, but the consequences of translocations tend to vary according to the ALL subtype. In mature B-cell ALL and in T-cell ALL, these genetic lesions often lead to the aberrant expression

of structurally intact genes. By contrast, the chromosomal translocations that often occur in precursor B-cell ALL generally lead to the expression of chimeric fusion proteins.

Activation of Structurally Intact Transcription Factors

MYC in Mature B-Cell Acute Lymphoblastic Leukemia

The vast majority of cases of mature B-cell ALL (Burkitt leukemia) are characterized by a translocation that places one allele of *MYC* from chromosome 8 under the control of the regulatory elements of an *Ig* gene, either the heavy-chain gene on chromosome 14q32 or the κ or λ light-chain genes on chromosomes 2 and 22, respectively. These translocations are oncogenic because they result in lineage-specific overexpression of *MYC*, a prototypical basic helix-loop-helix oncogenic transcription factor.^{48–56} The mechanisms through which the MYC oncoprotein exerts its potent oncogenic effects have been the subject of intense investigation. MYC has been estimated to regulate the expression of 15% of the genome,⁵⁷ and leads to the transcriptional activation of a large number of genes involved in cell division, growth, metabolism, adhesion, and motility.⁵⁸ MYC also exerts posttranscriptional effects on gene expression by regulating microRNA expression and ribosome biogenesis.^{59–62} MYC exerts its transcriptional activity via the formation of heterodimers with its DNA-binding partner protein MAX. MYC-MAX heterodimers bind to canonical hexameric E-box DNA sequences (5'-CACGTG-3'), where they activate transcription.⁶³ MAX can also heterodimerize with other basic helix-loop-helix proteins, including MAD,⁶⁴ MXI-1 (MAD2),⁶⁵ and MNT.⁶⁶ Whereas transcriptional activation by MYC-MAX complexes promotes proliferation, binding by MAD-MAX and other MAX heterodimers produce opposite effects. For example, MAD inhibits MYC function both by competing with MYC for binding to MAX and by directly inhibiting transcription.

Recent work has revealed that a major consequence of *MYC* overexpression is the global amplification of gene expression. Investigation of transcriptional regulation mechanisms has revealed two distinct steps in the regulation of gene expression by transcription factors. First, RNA polymerase II and its associated transcriptional apparatus are loaded onto a gene promoter by one set of transcription factors,^{67,68} but RNA polymerase is often initially “paused” near the proximal promoter.^{69–71} Subsequent release from transcriptional pause is a distinct and highly regulated step in the control of gene expression. Unexpectedly, recent studies have revealed that a major consequence of *MYC* overexpression is the release of transcriptional pause at genes that were already loaded with RNA polymerase, rather than the recruitment of RNA polymerase to new target genes.^{72–74} These findings support a model in which *MYC* overexpression functions to amplify the expression of genes that are already being transcribed, thus “locking in” a cell’s existing transcriptional program. The acquisition of a *MYC*-activating lesion in a cell with a highly proliferative gene expression program that is normally transient, such as an immature B-cell progenitor, can lock this cell in this highly proliferative state, thus providing one mechanism to explain *MYC*-driven oncogenesis.

TAL1 and LMO Genes in T-Cell Acute Lymphoblastic Leukemia

In leukemia with a T-cell phenotype, the breakpoints of recurrent chromosomal translocations consistently juxtapose TCR gene regulatory elements, which are highly active in committed T-cell progenitors, to the protein-coding sequence of oncogenic transcription factors, which then become aberrantly overexpressed as a result of these translocations. The best characterized of the oncogenic transcription factors involved is TAL1 (; also known as SCL). *TAL1* is overexpressed as a result of the recurrent t(1;14) translocation or intrachromosomal deletions in approximately one-fourth of

childhood T-cell ALL cases.^{75–80} However, *TAL1* is aberrantly expressed in the leukemic cells of 60% of children and 45% of adults with T-cell ALL, implicating additional pathogenic mechanisms leading to *TAL1* overexpression. One such recently described mechanism is an activating mutation of a noncoding gene-regulatory element, which is described later in this chapter. TAL1 acts as a master regulatory protein during early hematopoietic development and is required for the generation of all blood cell lineages.^{81,82} However, it does not seem to be required for the generation and function of hematopoietic stem cells (HSCs) during adult hematopoiesis.⁸³ *TAL1* is a bona fide T-cell ALL oncogene, as its aberrant expression in murine T-cell progenitors induces T-cell ALL.^{84,85}

TAL1 binds DNA in complex with other transcription factors including TCF3 (also known as E2A), HEB, LMO1/2, GATA3, RUNX1 and MYB.^{86–88} TAL1 binding can activate or repress expression of its target genes, and a number of these targets have been implicated in T-cell transformation.^{89,90} In murine T-cell progenitors, *TAL1* expression inhibits TCF3 transcriptional activity,⁹¹ and loss of TCF3 function induces T-cell leukemias in mice,^{92,93} supporting a role for TAL1-mediated inhibition of TCF3 function in leukemogenesis. The TAL1 complex binds and upregulates expression of several of its own core components, including TAL1, GATA3, RUNX1, and MYB, thus forming a positive-feedback loop that reinforces activity of this oncogenic transcriptional complex.^{88,90} TAL1 also upregulates expression of *TRIB2*, a gene whose overexpression in mouse bone marrow cells induces myeloid leukemia,⁹⁴ and whose expression is required for the survival of *TAL1*-overexpressing T-cell ALL.⁹⁰ Furthermore, TAL1 also upregulates expression of the microRNA mir223, which promotes leukemic cell survival by downregulating expression of the FBXW7 tumor suppressor.⁹⁵

The LIM-only domain genes, *LMO1* and *LMO2*, are also involved in recurrent chromosomal translocations in T-cell ALL.^{96–98} These genes encode transcription factors that interact with *TAL1* in erythroid cells and in T-cell leukemias.^{99–101} Homozygous disruption of *LMO2* in mice phenocopies the hematopoietic defect of *TAL1* knock-outs, suggesting that these proteins function together during hematopoietic development.^{102,103,104,105} In addition, overexpression of *LMO1* or *LMO2* in murine thymocytes leads to T-cell transformation^{106–110} and accelerates the onset of leukemias in *TAL1* transgenic mice.¹⁰¹

Homeobox Genes

The homeobox gene *TLX1* (also known as *HOX11*) is the founding member of a family of homeobox genes that includes *TLX2* (*HOX11L1*) and *TLX3* (*HOX11L2*), each of which plays key roles in embryonic development.^{111–114} *TLX1* was originally isolated from the recurrent t(10;14) translocation in T-cell ALL,^{27,115–117} and is aberrantly expressed in 5% of pediatric and approximately 25% of adult T-cell ALL cases.^{118–120} *TLX3* is also involved in a recurrent t(5;14) (q35;q32) translocation,¹²¹ and is overexpressed in approximately 25% of pediatric but only 5% of adult T-cell ALL.^{118,120,122–124} *TLX1* and *TLX3* encode very similar proteins, suggesting they have similar oncogenic mechanisms. Overexpression of *TLX1* or *TLX3* induces differentiation arrest at a cortical stage of T-cell development, an effect that is mediated by *TLX*-induced transcriptional repression of the pre-T-cell receptor alpha, whose expression is required for progression beyond this stage in normal T-cell development.^{125,126} *TLX1* expression in murine T-cell progenitors induces T-cell ALL, and these tumor cells have a defective mitotic checkpoint due to transcriptional repression of the checkpoint kinase *CHEK1*.¹²⁷ These findings, together with the previous observation that *TLX1* binds the catalytic subunits of the phosphatases, PP2A and PP1, and disrupts the G2/M checkpoint,¹²⁸ thus provide a mechanistic explanation for the association of *TLX1/TLX3* overexpression with aneuploidy, which is otherwise rare in human T-cell ALL.¹²⁷ *RUNX1*, which is directly bound and repressed by *TLX1* and *TLX3*, has been implicated as a downstream mediator of the oncogenic function of these transcription factors in T-cell ALL.¹²⁹

The cluster of *HOXA* genes on chromosome 7 is affected by a recurrent chromosomal inversion that places it in the vicinity of TCR beta gene regulatory elements, leading to aberrant expression of the entire *HOXA* cluster in approximately 5% of cases of T-cell ALL.^{130,131} Many of these cases also carry cooperating oncogenic lesions consisting of *NOTCH1* gene mutations and deletions of 9p21.¹³² This new translocation that directly activates *HOXA* gene expression provides additional evidence for the role of aberrant *HOXA* activation in leukemogenesis and in the pathogenesis of *MLL*- and *CALM-AF10*-rearranged leukemias, as reviewed in more detail later.

Chimeric Transcription Factor Oncogenes

Chromosomal translocations resulting in the formation of chimeric proteins represents a second mechanism for aberrant transcription factor activation, which is more prevalent in precursor B-cell ALL. These translocations juxtapose exons that encode the DNA-binding and protein-binding domains of different genes, resulting in expression of a chimeric fusion protein. The generation of such fusions is facilitated by the modular structure of transcription factor genes, in which discrete exons encode particular functional domains. This feature of gene structure facilitates organismal evolution, but is commonly co-opted during oncogenesis.

TCF3-PBX1 Fusion Genes in Precursor B-Cell Acute Lymphoblastic Leukemia

A well-known example of an oncogenic chimeric transcription factor is the *TCF3-PBX1* (also known as *E2A-PBX1*) rearrangement, which results from the t(1;19)(q23;p13) chromosomal translocation present in about 5% of all B-lineage ALLs and in 25% of cases with a pre-B (cytoplasmic Ig-positive) phenotype.^{133,134} This translocation fuses the two N-terminal transactivation domains of the *TCF3* transcription factor on chromosome 19 to the DNA-binding domain of the homeobox gene *PBX1*, leading to the expression of hybrid *TCF3-PBX1* oncoproteins.^{135–140} The transforming potential of *TCF3-PBX1* was first demonstrated by the rapid induction of AML in lethally irradiated mice repopulated with hematopoietic progenitors transduced with *TCF3-PBX1* genes.¹⁴¹ This fusion has also been shown to transform NIH-3T3 fibroblasts and induce T-cell lymphomas in transgenic mice.^{142,143} Additional studies have shown that deletion of one of the *TCF3* activation domains diminishes its transforming activity, but deletion of the *PBX1* homeodomain has no effect.^{143,144} The presence of the *TCF3-PBX1* translocation was originally associated with a poor prognosis.¹⁴⁵ However, this translocation no longer imparts an adverse prognosis in the setting of modern risk-adjusted protocols for childhood ALL.^{134,146–148}

TCF3-HLF Fusion Genes in Early Pre-B Acute Lymphoblastic Leukemia

The t(17;19) is a rare recurrent chromosomal translocation that fuses the N-terminal transactivation domains of *TCF3* to the C-terminal DNA-binding and dimerization domains of *HLF*,^{149,150} a basic leucine zipper domain transcription factor. Although the *TCF3-HLF* fusion protein can bind DNA either as a homodimer or as a heterodimer with *HLF* and related proteins, no other PAR proteins are expressed in hematopoietic cells, and the *TCF3-HLF* fusion binds DNA as a homodimer in cells harboring the t(17;19). Similar to *TCF3-PBX1*, *TCF3-HLF* can transform NIH-3T3 fibroblasts, a process that requires the *HLF* leucine zipper domain and the *TCF3* transactivation domains.¹⁵¹ *TCF3-HLF* can also induce lymphoid tumors in transgenic mice.^{152,153} A major consequence of *TCF3-HLF* expression in lymphoid precursors is inhibition of apoptotic cell death. In normal pro-B lymphocytes, expression of *TCF3-HLF* blocks apoptosis induction by either interleukin (IL)-3

or p53.¹⁵⁴ In *TCF3-HLF*-expressing human ALL cells, inhibition of *TCF3-HLF* function by expression of a dominant-negative form of *TCF3-HLF* results in apoptosis induction.¹⁵⁴ *HLF* is the mammalian homologue of the worm protein *ces-2*, a transcription factor that is necessary for the death of two specific nerve cells during *Caenorhabditis elegans* development.^{154–156} This pathway, which is evolutionarily conserved, is inhibited by the *TCF3-HLF* fusion. Thus, in contrast to the proapoptotic role of the wild-type *HLF* homolog (*ces-2*) in worms, *TCF3-HLF* blocks apoptosis by inducing the expression of *SLUG*, a transcription factor that blocks DNA damage-induced apoptosis in hematopoietic cells.^{157–160} The t(17;19) is seen in less than 1% of ALL cases, but is associated with characteristic clinical features including adolescent age, disseminated intravascular coagulation and hypercalcemia at diagnosis.

CALM-AF10 Fusion Gene in T-Cell Acute Lymphoblastic Leukemia

The t(10;11)(p13;q14) is detected in approximately 3%–10% of T-cell ALL cases and in occasional AML cases. This translocation results in the fusion of *CALM* (also known as *PICALM*), encoding a protein with high homology to the murine clathrin assembly protein ap3, with *AF10*, a gene identified as an *MLL* partner in the *MLL-AF10* fusion resulting from the t(10;11)(p13;q23).¹⁶¹ Expression of the *CALM-AF10* fusion transcript has been associated with early arrest in T-cell development and to differentiation into the gamma-delta lineage in T-cell ALL.¹⁶² Additionally, aberrant upregulation of *HOX* gene expression appears to be involved in *CALM-AF10*-mediated leukemogenesis, at least in AML cells that carry this translocation.¹⁶³ Interestingly, analysis of a mouse model of *CALM-AF10*-induced AML suggests that the leukemic stem cell in this model has lymphoid characteristics, and cells from human patients with AML can be identified that have similar characteristics to the disease-propagating cell in this animal model.¹⁶⁴ More recent evidence has demonstrated a dependence of *CALM-AF10*-mediated leukemogenesis on the H3K79 methyltransferase DOT1L, thus implicating targeted therapy with DOT1L inhibitors in this ALL subtype.^{165,166}

ETV6-RUNX1 (*TEL-AML1*) Fusions in Precursor B-Cell Acute Lymphoblastic Leukemia

Although most t(12;21) translocations are not detectable by standard cytogenetic analysis, this translocation is detectable by molecular techniques in approximately 25% of childhood B-lineage ALL, which makes this the most common translocation in pediatric ALL (see Fig. 64.1). The *ETV6-RUNX1* translocation often arises prenatally and is likely to be the initiating mutation in at least a subset of ALL, as evidenced by the identification of identical *ETV6-RUNX1* translocations in identical twins with concordant ALL, and in retrospectively analyzed neonatal blood specimens of children who were diagnosed with ALL many years later.^{167,168} However, *ETV6-RUNX1* alone is not sufficient for leukemogenesis because the incidence of detectable *ETV6-RUNX1* fusions in the blood of normal newborns is about 100-fold greater than the incidence of leukemia.¹⁶⁹

The molecular mechanisms mediating *ETV6-RUNX1*-induced leukemogenesis remain poorly understood. This fusion gene encodes a chimeric protein that contains the helix-loop-helix (HLH) domain of *ETV6* fused to nearly all of *RUNX1* (also known as *AML1* or *CBF2A2*), including both the transactivation domain and the DNA- and protein-binding Runt homology domains. Both of these genes are found in other leukemia-related translocations, and both are essential for normal hematopoiesis. *ETV6* was first identified in the t(5;12) in chronic myelomonocytic leukemia, where it is fused to the platelet-derived growth factor receptor gene (*PDGFRB*), and is also fused to *ABL*, *MN1*, and *EVII* in AML and to *JAK2* in T-cell ALL.¹⁷⁰ *ETV6* is required for fetal hematopoiesis in the mouse. Interestingly, the inactivation of *Etv6* in adult mice leads to the selective loss of

HSCs from adult bone marrow, but hematopoiesis is sustained by committed precursors.¹⁷¹ Most *ETV6-RUNX1* leukemias show loss of the normal *ETV6* allele, suggesting that the leukemogenic effect of *ETV6-RUNX1* may be mediated in part by loss of wild-type *ETV6* function.^{172–175} Interestingly, germline loss-of-function *ETV6* mutations have been recently identified in patients with familial thrombocytopenia and a predisposition to hematologic malignancies including ALL,^{176,177} further implicating wild-type *ETV6* as an ALL tumor suppressor.

RUNX1 is the DNA-binding component of the RUNX1-CBF β transcription factor complex disrupted by the t(8;21), t(3;21), and inv(16) in AML. RUNX1 is a transcription factor that is required for the expression of several hematopoietic genes involved in myeloid and lymphoid development, including *PU.1* and *IL-3*, although it can also act as a transcriptional repressor in some settings.¹⁷⁸ Homozygous disruption of the murine *Runx1* or *CBFB* genes results in the lack of definitive hematopoiesis, indicating that genes regulated by RUNX1 are essential for normal hematopoietic development.^{179,180} Additionally, rare familial mutations in the *RUNX1* DNA-binding domain lead to familial platelet disorder and predisposition to both myeloid and lymphoid malignancies.^{177,181}

The presence of the *ETV6-RUNX1* translocation is associated with an excellent prognosis, with event-free survival rates of approximately 90% in a variety of studies.^{182–184} However, *ETV6-RUNX1* may not represent an independent predictor of prognosis when age and white blood cell count at the time of diagnosis are taken into account in multivariate analysis.¹⁸⁴ Nevertheless, this translocation identifies a large subset of children with precursor B-cell ALL who appear to represent good candidates for less intensive therapy.

Activating Point Mutations of Oncogenic Transcription Factors

NOTCH1 in T-Cell Acute Lymphoblastic Leukemia

The *NOTCH1* gene was originally discovered as a partner gene in an exceedingly rare t(7;9) chromosomal translocation in T-cell ALL, in which *NOTCH1* is truncated and placed under the control of the *TCR β* locus.¹⁸⁵ Despite the rarity of *NOTCH1* translocations, a search for point mutations within the *NOTCH1* gene revealed activating mutations in more than 50% of cases of T-cell ALL.¹⁸⁶ *NOTCH1* plays several critical roles during T-cell development,^{30,187–189} and its overexpression in murine hematopoietic cells potently drives T-cell ALL.¹⁹⁰ NOTCH1 is a transmembrane protein that is proteolytically processed during its transit to the cell surface, where it exists as a heterodimer consisting of extracellular and transmembrane subunits (Fig. 64.2). Upon ligand binding, the transmembrane subunit undergoes additional proteolytic cleavage within the plasma membrane, which leads to the release of its intracellular domain, known as ICN1 (intracellular domain of NOTCH1), into the cytosol. ICN1 subsequently translocates into the nucleus, where it is active as a transcription factor. Activating *NOTCH1* mutations in T-cell ALL can occur as either missense mutations in the heterodimerization domain, which allow constitutive proteolytic activation of the ICN1 domain,^{186,191} or as frameshift or stop codon mutations that lead to truncation of the PEST domain. The PEST domain regulates proteasomal degradation of the protein, and these PEST-inactivating mutations result in aberrant stabilization of ICN1 protein.^{186,192} Mutations in both regions are often found on the same allele in cases of T-cell ALL, and are synergistic in increasing *NOTCH1* transcriptional output.¹⁸⁶ Additionally, the *NOTCH1* oncoprotein can also be stabilized by inactivating mutations of tumor suppressor genes involved in its proteasomal degradation, including *FBXW7* and *Cyclin C*, as discussed later in this chapter.^{193,194} *MYC* is an important transcriptional target of *NOTCH1*, and it mediates many of the leukemogenic properties of *NOTCH1* in human T-cell ALL cells.^{195–198} However, *NOTCH1* also has *MYC*-independent oncogenic activity, as evidenced by its ability to induce T-cell ALL in zebrafish, where *NOTCH1* does not upregulate *MYC* expression.¹⁹⁹

Fig. 64.2 THE NOTCH1 ONCOGENIC SIGNALING PATHWAY. Binding of the NOTCH1 cell surface receptor with δ serrate ligand (DSL) stimulates proteolytic cleavage of NOTCH by metalloproteases and γ -secretase. This leads to the release of the intracellular domain of NOTCH1 (ICN), which translocates to the nucleus, where it acts as a transcription factor to regulate gene expression. (Adapted from Armstrong SA, Look AT: *Molecular genetics of acute lymphoblastic leukemia*. J Clin Oncol 23:6306, 2005, with permission.)

Additional *NOTCH1* targets implicated in T-cell ALL pathogenesis include the *IL7R* interleukin receptor,²⁰⁰ and the long noncoding RNA *LUNARI*, which is upregulated by *NOTCH1* and functions to upregulate expression of the insulin-like growth factor 1 receptor (*IGF1R*).²⁰¹

Small-molecule inhibitors of γ -secretase impair the proteolytic activation of NOTCH1 (see Fig. 64.2), and these drugs were previously developed due to the role of this enzyme in Alzheimer's disease. More recently, SERCA calcium channel inhibitors have also emerged as an alternative approach to target oncogenic NOTCH1 signaling. Small-molecule SERCA inhibitors induce endoplasmic reticulum (ER) stress, impair NOTCH1 maturation in the ER, and effectively inhibit NOTCH1 signaling with a preference for mutant rather than wild-type alleles.²⁰² SERCA inhibition also has activity in human T-cell ALL xenograft models.²⁰²

The clinical experience with NOTCH1 inhibitors to date has been limited to γ -secretase inhibitors. Although these drugs have activity in vitro in a subset of T-cell ALL cell lines,¹⁸⁶ early clinical trial results have been disappointing.^{203,204} In part, this reflects the fact that prolonged systemic NOTCH inhibition is intolerable due to development of severe secretory diarrhea. This is an on-target toxicity of NOTCH inhibition, which drives intestinal epithelial cells to a secretory goblet cell fate.^{205,206} Interestingly, dexamethasone has been shown to mitigate the intestinal toxicity of γ -secretase inhibitors, and this is an especially appealing therapeutic combination because NOTCH1 inhibition can simultaneously reverse resistance to dexamethasone.²⁰⁷ In vivo preclinical data support the utility of this combination,²⁰⁸ which awaits testing in human clinical trials.

Investigation of mechanisms of resistance to NOTCH1 inhibition has revealed several potential strategies for therapeutic intervention. Activation of the phosphatidylinositol 3-kinase (PI3K)-AKT pathway, which commonly results from loss of its negative regulator *PTEN* in T-cell ALL,²⁰⁹ provides one mechanism for resistance to NOTCH1 inhibition.²¹⁰ The PTEN-PI3K-AKT pathway also mediates resistance to MYC inhibition in this disease.²¹¹ However, work in a murine model of Kras-induced T-ALL, where leukemias commonly acquire activating *NOTCH1* mutations and are sensitive to PI3K inhibitors, revealed that the development of resistance to PI3K inhibition was unexpectedly associated with loss of oncogenic NOTCH1 signaling.²¹² This finding thus raises the possibility that dual PI3K-NOTCH1 inhibition may actually promote the emergence of drug resistance. Additional studies are needed to define the

optimal strategy for clinical application of NOTCH1 and PI3K inhibition in patients with T-cell ALL.

Recent work has also revealed that some T-cell ALL cases in which the bulk cell population is sensitive to NOTCH1 inhibition harbor minor populations of so-called “persister” cells that are resistant to NOTCH1 inhibitors. This “persister” state is not driven by genetic mutations, but is instead a reversible cellular state characterized by chromatin compaction.²¹³ These NOTCH1 inhibitor-resistant cells maintain expression of *MYC*, a crucial downstream target of *NOTCH1*, despite effective inhibition of NOTCH1 activity.^{213,214} However, the survival of these cells is specifically dependent on BRD4,^{213,214} a transcriptional regulator whose ability to bind acetylated chromatin can be specifically inhibited using small molecules.²¹⁵ Combination therapy with inhibitors of both BRD4 and NOTCH1 can block emergence of this resistance mechanism, and this approach has promising in vivo activity in preclinical models.^{213,214}

MYC Mutations in Mature B-Cell Lymphoblastic Leukemia

As reviewed previously in this chapter, mature B-cell ALL is characterized by chromosomal translocations that place the *MYC* coding sequence under the control of *Ig* gene-regulatory elements. Although the *MYC* coding region is not structurally altered by these translocations in most cases, point mutations of *MYC* commonly arise in these tumors at codons 58 or 62.^{216–218} These codons encode phosphorylation sites that regulate the activity and proteasomal degradation of *MYC*.²¹⁹ These mutations lead not only to the aberrant stabilization of *MYC* protein,^{220–222} but also inhibit the ability of *MYC* to activate apoptosis, while its ability to stimulate proliferation remains intact.²²³

Mutations of Histone-Modifying Enzymes

DNA exists in cells in complex with histone proteins and other molecules in a complex known as chromatin. Posttranslational modifications of histone proteins play prominent roles in the regulation of chromatin structure. Chromatin structure at individual loci can be broadly categorized as euchromatin, or “open” chromatin, where transcription factor binding sites in DNA are readily accessible to the transcriptional machinery, or heterochromatin, where chromatin is compacted and DNA is generally not accessible to the transcriptional machinery. Alternations in chromatin structure can have profound effects on the gene expression program activated by transcription factors. Several enzymes that catalyze covalent histone modifications are recurrently mutated in ALL, highlighting a central role for dysregulation of chromatin structure in human leukemogenesis.

MLL Fusion Genes

Translocations involving the *MLL* gene (also known as *KMT2A*) on chromosome 11q23 occur in approximately 80% of infant ALL cases, 5% of AML cases, and 85% of secondary AML cases that occur in patients treated with topoisomerase II inhibitors.¹⁸² *MLL* is the human ortholog of the *Drosophila* trithorax gene.^{224–227} Trithorax proteins are positive regulators of homeobox gene expression and act antagonistically to polycomb proteins.²²⁸ Wild-type *MLL* positively regulates *HOX* gene expression and is required for both primitive and definitive hematopoiesis.^{229–231} Wild-type *MLL* is a member of a large transcriptional regulatory complex, together with histone deacetylases and members of the SWI/SNF chromatin-remodeling complex.²³²

The *MLL* protein undergoes proteolytic processing by Taspase1, a specialized protease that cleaves the *MLL* protein into N-terminal (*MLL*^N) and C-terminal (*MLL*^C) fragments that remain associated through intramolecular protein–protein interaction domains.^{233–235} *MLL*^N contains several DNA-binding domains, including AT-hook domains that nonspecifically bind the minor groove of DNA, a methyltransferase homology region (CxxC domain) that specifically

binds unmethylated DNA, four plant homeodomain zinc fingers with an embedded bromodomain, and a transcriptional repression domain.²²⁸ The C-terminal fragment *MLL*^C contains a transcriptional activation domain that recruits the histone acetyltransferase cAMP response element-binding protein (CBP) and a SET domain that is responsible for its histone 3 lysine 4 (H3K4) methyltransferase activity.²³⁵

Wild-type *MLL* encodes a H3K4 lysine methyltransferase, and H3K4 methylation is associated with transcriptional activation. Strikingly, the H3K4 methyltransferase domain is invariably lost in *MLL* fusion oncoproteins. *MLL* fusion oncogenes result from translocations whose breakpoints cluster between exons 5 and 11 of *MLL*, and the resultant fusion proteins retain the N-terminal region of *MLL*, including the AT-hook and CxxC domains that bind DNA in a sequence-nonspecific manner.²³⁶ By contrast, the C-terminal domains that mediate the association of wild-type *MLL* with its endogenous chromatin remodeling complex and its H3K4 methyltransferase activity are invariably lost from oncogenic *MLL* fusion proteins. Instead, the C-terminus of *MLL* fusion proteins is provided by one of more than 60 different translocation partners, with common translocations such as the t(4;11), t(9;11), and t(11;19)(q23;p13.3) resulting in the in-frame fusion of *MLL* to *AF4*, *AF9*, and *ENL*, respectively. The unrelated t(11;19)(q23;p13.1) translocation results in fusion of *MLL* to *ELL*, the RNA polymerase II elongation factor.^{237,238}

Formal proof that *MLL* fusions play a critical role in the development of leukemias has come from the generation of murine models of *MLL*-induced leukemias. Chimeric mice harboring a *MLL*-*AF9* fusion gene generated by homologous recombination developed leukemias with a latency of 4–12 months.²³⁹ Retroviral transduction of *MLL*-*ENL*, *MLL*-*ELL*, and *MLL*-*CBP* fusion genes in hematopoietic precursors induces transformation upon transplantation into recipient mice.^{240–242} Similar results were obtained with a model in which chromosomal translocations involving the *MLL* locus are induced by directed interchromosomal recombination in mice, a strategy that experimentally reproduces the initiating events in the pathogenesis of *MLL*-rearranged leukemias.²⁴³ Interestingly, the introduction of *MLL*-*AF9* into committed granulocyte-macrophage progenitors in the mouse leads to the reactivation of a subset of genes normally expressed only in HSCs, and transforms these committed precursors into AML leukemic stem cells by imparting the properties of self-renewal,²⁴⁴ suggesting that the leukemogenic lesion in *MLL*-rearranged leukemia might occur in a committed progenitor rather than in a pluripotent HSC.

MLL-rearranged B-lineage leukemias have a characteristic gene-expression signature that includes the upregulation of several *HOX* genes and the expression of numerous myeloid markers.^{245–247} Both early B- and T-cell ALLs with *MLL* rearrangements showed a characteristic upregulation of specific *HOX* genes, including *HOXA9*, *HOXA10*, and *HOXC6*, and the *HOX* gene regulator *MEIS1*.^{245–247} These results, together with the demonstration that *HOXA9* plays important roles in the transformation of hematopoietic precursors by *MLL* fusion oncogenes in murine leukemia models,^{248,249} emphasize the central role of *HOX* gene dysregulation in the pathogenesis of *MLL*-rearranged leukemias. Additionally, as discussed later in this chapter, overexpression or activating mutations of the *FLT3* receptor tyrosine kinase are frequent in *MLL*-rearranged leukemias.^{245,246,250,251}

Until recently, the precise mechanisms mediating the oncogenic activity of *MLL* fusion proteins were unclear, because *MLL* translocation partners have no sequence similarity. However, recent work has shown that several distinct *MLL* translocation partners are functionally linked through their association in protein complexes that regulate transcriptional elongation (Fig. 64.3).²⁵² Oncogenic *MLL* fusion proteins have been implicated in the DOT1L, SEC, and PAFc transcriptional complexes. The DOT1L complex consists of DOT1L, a H3K79 methyltransferase, and multiple *MLL* fusion partners, including *AF9*, *ENL*, and *AF10*.^{253–258} The SEC (also known as p-TEFb or AEP) complex consists of a CDK9 and cyclin T heterodimer (known as p-TEFb) that phosphorylates RNA polymerase II,

Fig. 64.3 TRANSCRIPTIONAL ACTIVATION COMPLEXES IN MIXED-LINEAGE LEUKEMIA-REARRANGED ACUTE LYMPHOBLASTIC LEUKEMIA. Mixed-lineage leukemia (MLL) can be fused to several distinct translocation partners with little sequence similarity, but many of the MLL translocation partners have been found to be functionally related via roles in multimeric protein complexes that regulate transcriptional elongation and activation, some of which are shown here. The DOT1-like histone lysine methyltransferase (DOT1L) complex has drawn particular interest given the requirement for this enzyme for leukemogenesis driven by MLL fusions. Small molecule DOT1L inhibitors have promising activity in pre-clinical models of *MLL*-rearranged leukemia. SEC, Super elongation complex; PAFc, polymerase-associated factor complex; P-TEFb, positive transcription elongation factor complex. (Adapted from Deshpande, AJ, Bradner J, Armstrong SA: *Chromatin modifications as therapeutic targets in MLL-rearranged leukemia*. Trends Immunol 33:563, 2012, with permission.)

interacts with several MLL fusion partners, including ENL, ELL, AF4, and AF5, and copurifies with several MLL fusion proteins.^{259,260} PAFc regulates RNA polymerase II and associates with the N-terminus of both wild-type MLL and MLL fusions.²⁶¹

The observation that DOT1L interacts with multiple MLL translocation partners suggests that MLL fusion proteins may drive ectopic gene expression through recruiting excessive DOT1L activity to their target loci, implicating the DOT1L complex as a potential therapeutic target. DOT1L encodes a histone H3K79 methyltransferase, and many of the target genes directly upregulated by oncogenic MLL fusions are characterized by aberrant histone H3 lysine 27 (H3K27) methylation, including the 5' *HOXA* cluster genes and *MEIS1*.^{262–264} Interestingly, the DOT1L methyltransferase is required for transformation of murine bone marrow progenitors by MLL fusion oncoproteins, but it plays a less prominent role in normal hematopoiesis, thus suggesting a therapeutic window for therapeutic targeting of DOT1L in *MLL*-driven leukemias.^{166,257,265–269} Indeed, small-molecule inhibitors of DOT1L have recently been developed and demonstrate promising activity against *MLL*-rearranged leukemia cells in vitro and in vivo, with little toxicity in murine models.^{270–273} The antileukemic activity of DOT1L inhibition is mediated, at least in part, by the recruitment of SIRT1, a histone deacetylase that induces chromatin compaction and silences gene expression. Moreover, the combination of DOT1L inhibitor with a pharmacologic SIRT1 activator demonstrates significantly better therapeutic activity than DOT1L inhibition alone.²⁷⁴

The oncogenic activity of MLL fusions also requires their physical interaction with Menin, the tumor suppressor protein encoded by the multiple endocrine neoplasia 1 (*MEN1*) gene. Menin binds an N-terminal domain of *MLL* that is conserved in all MLL fusion proteins.^{275,276} Moreover, abrogating the interaction of Menin with MLL, either by deleting Menin or by mutating the Menin-binding domain of *MLL*, impairs both transcriptional and oncogenic functions of MLL fusions.^{275,277} These findings spurred the development of small-molecule inhibitors of the MLL–Menin interaction, and one such inhibitor has demonstrated promising activity in preclinical models, both in vitro and in vivo.²⁷⁸

The presence of *MLL* rearrangements is associated with dismal outcomes despite aggressive chemotherapy in most cases of B-precursor ALL.^{16,279–281} Although bone marrow transplantation (BMT) in first remission does not appear to improve outcomes for all infants with *MLL*-rearranged ALL,^{281,282} a recent comprehensive study revealed significantly improved outcomes with BMT in infants with *MLL*-rearranged ALL who have particularly high-risk features.²⁸³ Recent data demonstrating the therapeutic utility of small-molecule inhibitors of DOT1L and of the MLL–Menin interaction have generated considerable enthusiasm for the application of these novel therapeutic strategies for patients with *MLL*-rearranged leukemias.

PRC2 Mutations in T-Cell ALL

The polycomb repressive complex 2 (PRC2) is a transcriptional repressor complex best known as a “writer” of H3K27 methylation, a chromatin mark associated with transcriptional repression. Up to 25% of T-cell ALL cases harbor inactivating mutations of core components of the PRC2, including *EZH2*, *SUZ12*, and *EED*.^{40,284,285} *EZH2* deficiency is sufficient to initiate T-cell leukemogenesis in murine models,²⁸⁵ implicating PRC2 as a tumor suppressor in this disease. Genome-wide analysis of NOTCH1 occupancy and histone methylation patterns have revealed that NOTCH1 binding is associated with loss of the repressive histone mark placed by the PRC2 complex, H3K27 trimethylation.²⁸⁴ Recent work has revealed that the H3K27 “eraser” demethylase JMJD3 (also known as *KDM6B*) is a component of the NOTCH1 transcriptional complex.²⁸⁶ These data thus support a model in which NOTCH1 recruits the H3K27 “eraser” demethylase JMJD3 to its target genes, where it antagonizes the activity of the H3K27 “writer” PRC2. Thus, one pathogenic consequence of PRC2 inactivation in T-cell ALL may be the release of inhibition of oncogenic NOTCH1 signaling. Interestingly, a small-molecule inhibitor whose effects include inhibition of JMJD3 function has therapeutic activity in T-cell ALL,²⁸⁶ thus suggesting the need to investigate JMJD3 inhibition as a potential therapeutic strategy for patients with PRC2-mutant T-cell ALL.

Focal Activating Mutations of Non-coding Gene Regulatory Elements

Activating mutations of *cis*-acting gene-regulatory elements are common events in ALL pathobiology. This mechanism was first revealed through investigation of recurrent translations that juxtapose the protein-coding sequences of *MYC* with *Ig* enhancer elements in mature B-cell ALL (Burkitt leukemia), as discussed earlier in this chapter. However, monoallelic oncogene overexpression often occurs in the absence of identifiable chromosomal translocations, suggesting the existence of unrecognized mutations of *cis*-acting gene regulatory elements. However, our ability to identify pathogenic mutations of nonprotein-coding elements has been hampered by the difficulty of distinguishing pathogenic “driver” mutations from nonspecific “passenger” events that represent nonspecific consequences of genetic instability, which are much more common in cancer genomes. Two recent studies provide experimental paradigms for the identification of such pathogenic mutations of gene-regulatory elements, based on colocalization of genetic lesions with markers of active gene-regulatory elements.

Fig. 64.4 ONCOGENIC SUPERENHANCER IN T-CELL ACUTE LYMPHOBLASTIC LEUKEMIA. Noncoding insertion mutations upstream of *TAL1* create binding sites for the myeloblastosis (MYB) transcription factor, which then recruits its H3K27 acetylase binding partner CBP (CREB-binding protein) leading to the recruitment of core components of a major leukemogenic transcriptional complex containing *RUNX1*, *GATA3*, and *TAL1*, and to the formation of a de novo superenhancer that drives expression of the *TAL1* oncogene in a subset of T-cell ALL. (Adapted from Hnisz D, Abraham BJ, Lee TI, et al: Super-enhancers in the control of cell identity and disease. *Cell* 155:934, 2013.)²⁸⁷

TAL1 Super-Enhancer Mutations in T-Cell ALL

Advances in the ability to map transcription factor occupancy and chromatin modifications genome-wide have revealed the presence of unusually dense clusters of enhancer elements at select genomic locations. These elements have been termed *super-enhancers* (also stretch enhancers or locus control regions), and are characterized by dense and broad occupancy by core components of the transcriptional machinery, such as Mediator, as well as histone marks associated with active enhancer elements, including H3K27 acetylation. Super-enhancers have been implicated in the expression of genes responsible for cellular identity in normal and malignant cells.^{287–291}

Recent work has revealed the presence of focal mutations affecting a specific hotspot in a noncoding locus 23 kb upstream of the *TAL1* oncogene in 5% of T-cell ALL cases.²⁹² These mutations uniformly introduce a binding motif for the MYB transcription factor, and this occurs at a locus that already harbors binding motifs for core components of the TAL1 complex, including TAL1 itself, RUNX1 and GATA3. These mutations lead to the discovery that the *MYB* oncogene is a core component of the TAL1 complex. Indeed, the introduction of this novel MYB binding site is sufficient to recruit the entire TAL1 transcriptional complex to this locus (Fig. 64.4), which leads to the generation of an aberrant super-enhancer that drives aberrant overexpression of *TAL1* specifically from the mutated allele.⁸⁸

Duplications of the NOTCH1-Driven Enhancer of MYC in T-Cell ALL

Aberrant NOTCH1 activation is pathogenic, at least in part, due to NOTCH1-driven overexpression of *MYC*, as reviewed earlier in this chapter. Recent work has revealed an enhancer element downstream of *MYC* that is highly bound by NOTCH1, and is affected by recurrent somatic duplications in 3% of human T-cell ALL.²⁹³ This enhancer forms a looping interaction with the *MYC* proximal promoter, and it drives NOTCH1-dependent overexpression of *MYC*. Mice in which this enhancer element has been deleted have a defect in T-cell development that specifically mimics that seen in mice with T-cell-specific *MYC* inactivation. Moreover, murine bone marrow cells lacking this enhancer element are completely resistant to leukemic transformation by NOTCH1. Finally, duplication of this enhancer element drives increased gene expression in a reporter assay, suggesting that this enhancer duplication is pathogenic because it potentiates signaling through the oncogenic *NOTCH1-MYC* axis.^{293,294}

Aberrant Growth Factor Signaling

BCR-ABL1 in B-Cell Acute Lymphoblastic Leukemia

The Ph chromosome, which arises from the t(9;22)(q34;q11), was originally identified in patients with CML; however, it is also found in about 2% of childhood cases and 20% of adult cases of ALL, which are almost always of the precursor B-cell subtype.¹⁸² The t(9;22) generates a *BCR-ABL1* fusion gene, consisting of 5' (upstream) sequences from *BCR* and 3' (downstream) sequences of *ABL1*. The t(9;22) breakpoints on the distal tip of the long arm of chromosome 9 are scattered over a distance of nearly 200 kb within the first intron of the *ABL1* proto-oncogene, upstream of the tyrosine kinase domain.^{295–297} The breakpoints in the *BCR* gene on chromosome 22 cluster in two separate regions of that gene, known as the *major breakpoint cluster region* (*M-BCR*) or *minor breakpoint cluster region* (*m-BCR*). In two-thirds of cases of Ph-positive ALL, the breakpoint in the *BCR* gene occurs in the minor breakpoint cluster region (*m-BCR*), but in all cases of CML and about one third of cases of ALL, the breaks occur in the major breakpoint cluster region (*M-BCR*).²⁹⁸ The fusion transcript more commonly present in ALL (*m-BCR*) encodes a 190-kd protein (p190), whereas the transcript found in CML and in some cases of ALL (*M-BCR*) encodes a 210-kd hybrid protein (p210).^{299–302} Both types of fusions generate chimeric oncoproteins that are activated as a tyrosine-specific protein kinase, similar to the v-abl protein.^{303–305}

The ABL1 tyrosine kinase is localized both in the nucleus and in the cytoplasm of proliferating cells. It is normally activated by DNA damage downstream of *ATM* and appears to promote p53-mediated growth arrest.^{306–309} Mice deficient in *Abl1* develop a wasting syndrome and die soon after birth.^{310,311} In contrast to the nuclear and cytoplasmic distribution of normal ABL1, the BCR-ABL1 fusion oncoprotein has a cytoplasmic location and shows increased tyrosine kinase activity.^{312,313} When expressed in murine hematopoietic precursors, both p190 and p210 transform hematopoietic cells in vitro and induce a syndrome similar to CML in mice.^{314–317} Transformation by the BCR-ABL1 oncoprotein involves activation of the RAS–mitogen-activated protein kinase (MAPK) pathway, PI3K and JUN kinase, c-CBL and CRKL, JAK-STAT, nuclear factor kappa-B (NFκB), SRC, and cyclin D1.^{318–325} The BCR-ABL1 oncoprotein affects multiple aspects of cell homeostasis, including apoptosis, differentiation, and cell adhesion. An important cellular effect of BCR-ABL1 is the induction of cellular resistance to DNA damage agents such as cytostatic drugs and irradiation. After DNA damage, BCR-ABL1 extends the duration of the G2/M cell cycle checkpoint and facilitates DNA repair. It also upregulates the antiapoptotic *BCLXL* gene, contributing to the suppression of apoptotic cell death.³²⁶

The presence of the Ph chromosome has historically been associated with an extremely poor prognosis in ALL patients despite treatment with intensified chemotherapeutic regimens.^{327–329} These patients have been shown to have particularly good responses to allogeneic BMT in first remission, whether from matched sibling or from unrelated donors.^{330–334} However, the development of imatinib mesylate, a pharmacologic tyrosine kinase inhibitor targeting the BCR-ABL1 oncoprotein, opened novel therapeutic opportunities for the management of Ph-positive ALL. The utility of imatinib as a single agent for Ph-positive ALL is limited by the rapid development of drug resistance.^{335,336} However, the combination of BCR-ABL kinase inhibitors with conventional chemotherapy has led to remarkable improvements in outcome for patients with Ph-positive ALL.^{337–341}

Despite its activity, imatinib resistance remains a barrier to further therapeutic improvements in Ph-positive ALL. Resistance most commonly emerges because of point mutations in the kinase domain of *BCR-ABL1*. As a result, a series of novel BCR-ABL1 kinase inhibitors have been developed that retain activity against many of these mutant oncoproteins.^{342–344} Although not all *BCR-ABL1* mutations that confer resistance can be overcome with newer agents, the potential of these newer BCR-ABL inhibitors with broader

specificity to further improve outcomes is actively being investigated. Additionally, a novel pathway mediating resistance to BCR-ABL1 inhibition has been uncovered in Ph-positive ALL. Upon BCR-ABL1 inhibition, these cells markedly upregulate expression of the *BCL6* transcription factor, a well-known oncogene that is often translocated in diffuse large B-cell lymphomas.³⁴⁵ *BCL6* then blocks activation of the p53 pathway via transcriptional repression of ARF and thus blocks the therapeutic efficacy of monotherapy with imatinib in Ph-positive ALL cells. Importantly, inhibition of *BCL6* activity genetically or using a peptide inhibitor of *BCL6* has demonstrated marked activity in patient-derived BCR-ABL1 xenografts grown in immunodeficient mice, highlighting the therapeutic relevance of these findings.³⁴⁶

BCR-ABL1–Like Acute Lymphoblastic Leukemia

Analysis of the gene expression signatures of patients with ALL has led to the identification of a new subtype of precursor B-cell ALL, termed *BCR-ABL1–like* or *Ph chromosome-like (Ph-like) ALL*. These cases were identified because they lack *BCR-ABL1* translocations, yet are characterized by a gene expression signature nearly identical to that of BCR-ABL1-positive ALL. These patients are at very high risk of treatment failure, mirroring the poor prognosis of BCR-ABL1 ALL.^{347,348} One common genetic feature common to both BCR-ABL and BCR-ABL–like ALL is the deletion of the Ikaros tumor suppressor.³⁴⁸ However, in-depth genomic investigation of BCR-ABL1–like ALL has also revealed that most of these cases harbor chromosomal translocations or point mutations leading to dysregulated activation of growth factor signaling pathways. These include activating translocations of the *ABL1* kinase to “noncanonical” fusion partners, of the cytokine receptor *CRLF2* or the erythropoietin receptor *EPOR*, or activating mutations of the RAS or JAK-STAT pathways.^{349–351} These findings have important clinical implications, as many of these mutated genes are targetable with clinically relevant inhibitors, and clinical trials testing specific targeted agents in genetically defined subsets of the disease are underway.

NUP214-ABL1 in T-Cell Acute Lymphoblastic Leukemia

Although the BCR-ABL1 translocation is rare in T-cell ALL, amplified episomes containing *NUP214-ABL1* fusion genes have recently been described in approximately 6% of children and adults with T-cell ALL.³⁵² These episomes appear to arise via a mechanism in which the genomic region of chromosome 9q34, which contains both the *NUP214* and *ABL1* genes, is circularized in a manner that leads to the fusion of these two genes. The breakpoint in the *ABL1* gene in all of these cases occurs in intron 1, which is the same breakpoint observed in Ph-positive CML and precursor B-cell ALL, but the *NUP214* breakpoints are variable. The wild-type *NUP214* protein is a component of the nuclear pore complex and may contribute oligomerization motifs to the *NUP214-ABL1* fusion oncogene. The *NUP214-ABL1* fusion protein has constitutively activated ABL1 tyrosine kinase activity, which is inhibited by the BCR-ABL kinase inhibitor imatinib.³⁵² The therapeutic potential of imatinib or second-generation tyrosine kinase inhibitors for *NUP214-ABL1*–positive T-cell ALL is of considerable interest.

B-Cell Receptor Signaling in Acute Lymphoblastic Leukemia

Despite its importance in the molecular pathogenesis of mature B-cell lymphomas, the role of B-cell receptor signaling in ALL was poorly understood. However, a recent study has revealed that 10%–15% of cases of ALL are characterized by active signaling through the B-cell receptor.³⁵³ Such B-cell receptor-positive cases were identifiable by expression of the Ig μ heavy chain or of *BCL6* protein on flow

cytometry, and were strongly associated with the presence of the *TCF3-PBX1* rearrangement or 6q21 deletion, but rare in other ALL subsets.^{353,354} Interestingly, the oncogenic *TCF3-PBX1* translocation itself directly binds and upregulates genes encoding key components of the B-cell receptor in these cases.³⁵³ Active B-cell receptor signaling leads to downstream activation of *SRC*, *SYK*, and *PI3K* oncogenic signaling pathways. Importantly, these cases are sensitive to small-molecule inhibitors of kinases that mediate B-cell receptor signaling in preclinical models, thus providing a novel potential therapeutic strategy for these patients.^{353,354}

RAS Gene Mutations

Pioneering studies into the molecular etiology of cancer led to the identification of activated homologs of either *HRAS* or *KRAS* in human tumor DNA.^{355,356} These proto-oncogenes were originally identified on the basis of their homology with viral oncogenes. Gene-transfer methods identified an additional member of the *RAS* gene family, called *NRAS*,^{357,358} that had not been observed as a component of a transforming retrovirus. Proto-oncogenes of the *RAS* family (*HRAS*, *KRAS*, and *NRAS*) encode 21-kDa proteins that are associated with the inner surface of the cytoplasmic membrane and are involved in growth factor receptor signaling.³⁵⁹ *RAS* proteins are guanosine nucleotide-binding proteins (G proteins) that are GTP-bound in their active form and GDP-bound in their inactive form. The *RAS* proto-oncogenes are converted to the status of transforming oncogenes by somatic mutations that most commonly alter the amino acids specified by codons 12, 13, or 61. Mutated *RAS* genes lose their intrinsic GTPase activity, thus accumulating in their active, GTP-bound conformation, even in the absence of growth factor binding to surface receptors. Aberrant *RAS*–mediated signaling contributes to transformation through activation of the *PI3K* and *MAPK* pathways.³⁵⁹

In ALL, mutations of codons 12, 13, or 61 of *NRAS* have been found in approximately 10% of patients, while *KRAS* mutations have been identified in 5%–10% of patients.^{360,361} *RAS* mutations are considerably more common in specific molecular subsets of ALL. Up to 50% of cases of *MLL*–rearranged ALL harbor mutations of *NRAS* or *KRAS*,^{361,362,363} although these mutations can be subclonal and lost at relapse.³⁶³ *RAS* mutations have also been identified in approximately 30% of Down syndrome–associated precursor B-cell ALL and appear to be mutually exclusive of *JAK2* mutations in this setting.³⁶⁴ *RAS* mutations appear to be more frequently found in the setting of relapsed ALL and are associated with a poor prognosis in this setting.³⁶⁵ The development of an effective pharmacologic approach for direct inhibition of *RAS* has been elusive.³⁶⁶ However, recent studies in preclinical models of *RAS*–driven ALL have revealed the therapeutic potential of inhibitors of key downstream effectors of *RAS* signaling in ALL, including MEK and *PI3K*, thus providing a rationale for clinical trials testing such an approach for *RAS*–mutant ALL.^{365,367,368}

PTEN-PI3K-AKT Mutations in T-Cell Acute Lymphoblastic Leukemia

The *PI3K*–*AKT* signal transduction pathway, which is negatively regulated by the *PTEN* tumor suppressor, induces cellular growth and proliferation while inhibiting apoptosis and is aberrantly activated in a range of human cancers.^{369–371} In T-cell ALL, recent work has identified a very high frequency of mutational activation of oncogenic signaling through this pathway, most often via deletions or truncating mutations of *PTEN*, but activating mutations of *PI3K* and *AKT* genes also occur.^{209,210,372,373} Moreover, deletions of *PTEN* have been found to predict treatment resistance in clinical specimens.^{40,209} Studies in zebrafish and patient-derived xenograft mouse models have identified that acquisition of the *PI3K*–*AKT* pathway during clonal evolution of leukemic blasts leads to primary glucocorticoid resistance, an effect mediated by direct phosphorylation of the

glucocorticoid receptor by AKT.^{374,375} In addition, both MYC and the PI3K-AKT pathway have been identified as key suppressors of the proapoptotic factor BIM, which is required for mitochondrial apoptosis in normal T-cell development.^{210,211,376,377} Taken together, these findings thus suggest the potential clinical utility of PI3K-AKT pathway inhibitors in high-risk T-cell ALL, many of which are currently in human clinical trials.³⁷⁸

FLT3 in *MLL*-Rearranged Acute Lymphoblastic Leukemia

FLT3 encodes a receptor tyrosine kinase that is highly expressed in early hematopoietic precursors, where it plays important functional roles.^{379,380} Multiple studies have shown that activating mutations of *FLT3*, which lead to constitutive receptor tyrosine kinase activity even in the absence of ligand, are common in leukemic myeloblasts in patients with AML but are rare in adults with ALL.^{381–383} However, gene expression studies demonstrated high expression of *FLT3* in most cases of ALL that involve *MLL* gene rearrangements or hyperdiploidy.^{245,246,250} Additionally, activating mutations were identified in 18% of infants with *MLL*-rearranged ALL,²⁵¹ in 21%–24% of hyperdiploid ALL cases,^{251,384} and in all three cases of the prothymic CD117/KIT⁺ subtype of T-cell ALL in adults examined.³⁸⁵

In the absence of *FLT3* ligand, wild-type *FLT3* receptors are inactive because of autoinhibition mediated by the juxtamembrane domain of the receptor. Upon binding of *FLT3* ligand, normal *FLT3* receptors homodimerize, become activated by phosphorylation, and lead to the activation of signal-transduction pathways that promote proliferation and cell survival.³⁸⁶ Activating mutations of *FLT3* found in leukemias occur in two separate regions of the gene. In-frame tandem duplications in the juxtamembrane domain lead to loss of the autoinhibition mediated by this domain, with subsequent dimerization and receptor activation in the absence of *FLT3* ligand.³⁸⁷ Alternatively, point mutations or insertions in the second tyrosine kinase domain of the *FLT3* receptor lead to autophosphorylation and activation of downstream signaling in the absence of *FLT3* ligand.^{383,388,389} Small-molecule inhibitors of the *FLT3* kinase lead to apoptosis in AML cell lines in vitro. A phase I study of the *FLT3* inhibitor, quizartinib, demonstrated an acceptable toxicity profile and is currently being investigated in phase II trials, both as monotherapy and in combination with chemotherapy or BMT in adults with AML and MDS.^{390,391} These small-molecule inhibitors are also active against *MLL*-rearranged ALL cell lines,^{250,392} and hold promise as targeted therapies for cases of ALL that rely on aberrant activation of *FLT3*.

CRLF2 and *JAK2* Mutations in Precursor B-Cell Acute Lymphoblastic Leukemia

The *CRLF2* cytokine receptor binds its ligand, thymic stromal lymphopoietin (TSLP), as a heterodimeric complex with the IL-7 receptor subunit (IL-7R). TSLP-*CRLF2* signaling plays physiologic roles during normal B-cell development and in inflammation. Genomic analyses of precursor B-cell ALL patient samples revealed recurrent deletions within the pseudoautosomal region of Xp22.3/Yp11.3 that result in overexpression of the entire coding region of *CRLF2* under the control of gene regulatory elements of P2RY8, a purinergic receptor that is expressed at high levels in ALL cells.^{393–395} In some cases, such rearrangements are also accompanied by a Phe-232Cys point mutation in *CRLF2* that promotes constitutive dimerization and cytokine-independent growth.^{394,395} Interestingly, aberrant *CRLF2* expression very frequently co-occurs with *JAK2*-activating mutations, and these two genetic lesions collaborate to induce ligand-independent activation of downstream signal transduction pathways, suggesting that *CRLF2* may act as a scaffold that is required for activation of oncogenic JAK-STAT signaling by *JAK2* mutations in precursor B-cell ALL.^{393–395} Overall, *CRLF2* rearrangements occur with especially high frequency in patients with Down

syndrome^{323–325} and have been found to portend a poor prognosis in adults³²⁴; however, more recent studies in the pediatric population suggest that *CRLF2* may not be as poor a prognostic indicator as originally thought, suggesting that in the absence of a Ph-like ALL expression profile, *CRLF2* mutations are not an independent poor prognostic indicator.^{396,397}

A number of *JAK2* inhibitors have been developed for the treatment of myeloproliferative syndromes,³⁹⁸ which generated considerable excitement for the application of such inhibitors to *CRLF2*/*JAK2*-mutant precursor B-cell ALL. However, one problem with first-generation (“type 1”) *JAK2* inhibitors that stabilize *JAK2* in its active conformation is that these drugs induce paradoxical hyperactivation of *JAK2*, and these drugs have little therapeutic activity in *JAK2*-mutant ALL.³⁹⁹ Paradoxical *JAK2* phosphorylation following treatment with type 1 *JAK2* inhibitors is mediated by heterodimerization and trans-phosphorylation of *JAK2* by other *JAK* family kinases, including *JAK1* or *TYK2*.⁴⁰⁰ One promising approach to overcome this obstacle is to target the chaperone protein HSP90, which binds and stabilizes both wild-type and mutant *JAK2* proteins. Indeed, treatment with small-molecule HSP90 inhibitors, which are in human clinical trials, triggers *JAK2* degradation and has promising activity in preclinical models.^{399,401} An additional approach has been the development of second-generation (“type 2”) *JAK2* inhibitors that stabilize *JAK2* in its inactive conformation. One such type 2 *JAK2* inhibitor has been shown to have significant activity as a single agent, and to synergize with dexamethasone, both in vitro and in vivo in preclinical models of ALL.⁴⁰² These findings support the need for human clinical trials testing this approach in patients with *CRLF2*-rearranged or *JAK2*-mutant precursor B-cell ALL.

Interleukin-7 Receptor Mutations in T-Cell Acute Lymphoblastic Leukemia

IL7R is required for normal T-cell development, with loss-of-function *IL7R* mutations leading to severe combined immunodeficiency.³²⁷ The IL-7R protein can heterodimerize with either IL2R γ , resulting in the receptor for IL-7, or with *CRLF2* to form the receptor for TSLP.^{403,404} Recently, point mutations in the *IL-7R* have been described in approximately 10% of T-cell ALL cases.^{40,405,406} These point mutations typically introduce a novel cysteine residue in the transmembrane domain of the protein that permits formation of a neomorphic disulfide bond between mutant IL-7R homodimers. This leads to ligand-independent receptor dimerization and activation of downstream oncogenic signal transduction pathways, including JAK-STAT and PI3K-AKT. A potential therapeutic strategy to target oncogenic activation of mutant IL-7R proteins is the reduction of the neomorphic disulfide bond. Indeed, *N*-acetylcysteine, a reducing agent developed clinically for the treatment of acetaminophen overdose, has been shown to reduce the extracellular cysteine bond and inhibit signaling by mutant IL-7R proteins.⁴⁰⁷ Clinical trials testing this approach are under development.

Tumor Suppressor Gene Inactivation

Much attention has been focused on tumor suppressors, whose loss of function via deletion or mutational inactivation leads to malignant transformation. Knudson first proposed that inactivation of both alleles of a single locus is needed to initiate the development of retinoblastoma, basing his hypothesis on the observed frequencies of hereditary and sporadic forms of this disease.⁴⁰⁸ Allelic loss of defined regions of many different chromosomes has been linked to specific types of human tumors. By analogy with the findings in retinoblastoma, a reasonable hypothesis is that each of these regions harbors a tumor suppressor gene whose product is uniquely involved in the inhibition of cell cycle progression and promotion of terminal differentiation of the normal cells that give rise to these different types of tumors.

p53 and *CDKN2A* mutations

p53 (also known as *TP53*) is a classic tumor suppressor gene whose activation induces apoptosis, cell cycle arrest, or senescence in response to distinct stimuli, including DNA damage or aberrant oncogene activation.^{409–411} *p53* is mutated or deleted in a wide variety of human tumors,⁴¹² and occurs as a heritable cause of cancer in families with Li-Fraumeni syndrome.^{413–416} *p53* is inactivated in a variety of hematopoietic malignancies, including mature B-cell ALL, but is mutated or deleted in fewer than 3% of pediatric precursor B-cell or T-cell ALL cases at diagnosis.^{417–419} However, *p53* mutations are seen in approximately 25% of relapsed T-cell ALL cases, as well as in association with early treatment failure, suggesting a role for *p53* inactivation in the development of resistant disease.^{417,418}

Despite the rarity of *p53* mutations in ALL specimens at the time of diagnosis, the *p53* pathway is commonly inactivated by loss-of-function mutations of the *CDKN2A* locus in ALL.^{420–423} *CDKN2A* encodes two distinct tumor suppressor proteins, ARF (also known as p14ARF in humans and p19ARF in mice) and p16INK4a. ARF is induced by oncogene stress, such as acute *MYC* overexpression, and it binds and sequesters mouse double-minute 2 homolog MDM2, leading to *p53* activation. p16INK4a is a cyclin-dependent kinase inhibitor, a family of proteins that also include p15INK4B, p18INK4C, p19INK4D, p21, p27, and p57. These constitute a family of tumor suppressors that negatively regulate the cell cycle by inhibiting CDK phosphorylation of pRB.⁴²⁴ In particular, human leukemia and lymphoma show a high frequency of 9p21 deletions involving both the *p16INK4A/p14ARF* and the *p15INK4B* loci. Epigenetic silencing of these tumor suppressor genes through hypermethylation of their promoter sequences represents an alternative mechanism of gene inactivation. Although *p16INK4A/p14ARF* and *p15INK4B* are homozygously deleted in 20%–30% of precursor B-cell ALL cases and in 70%–80% of T-cell ALL cases, epigenetic silencing of the *p15INK4B* promoter has been observed in 44% of primary B-lineage ALLs.^{382,420–422,425–433}

FBXW7 and Cyclin C in T-Cell Acute Lymphoblastic Leukemia

FBXW7 (also known as *FBW7*) is an E3 ubiquitin ligase that targets the transcriptionally active intracellular form of NOTCH1 (ICN), MYC, and cyclin E for degradation, and this gene is inactivated by mutation or deletion in approximately 10% of T-cell ALL cases.¹⁹³ In T-cell ALL cell lines, *FBXW7* mutation or homozygous deletion leads to resistance of NOTCH1 pathway inhibition by γ -secretase inhibitor therapy, presumably because intracellular NOTCH1 protein levels remain high in the absence of *FBXW7*-mediated degradation despite inhibition of γ -secretase activity. Additionally, tumor-derived *FBXW7* mutations maintain their ability to bind MYC but do not lead to its degradation, and may act as dominant-negative mutants that protect MYC from degradation.¹⁹³ *FBXW7* also targets the antiapoptotic protein MCL1 for proteasomal degradation in T-cell ALL, providing an additional oncogenic consequence resulting from inactivation of the *FBXW7* tumor suppressor.⁴³⁴

Recent work has implicated cyclin C as a key component of the *FBXW7*-dependent pathway that mediates degradation of NOTCH1.¹⁹⁴ Cyclin C, which was originally identified as a growth-promoting cyclin, is involved in recurrent heterozygous deletions in human T-cell ALL. In a murine model, loss of one cyclin C allele accelerates the onset of NOTCH1-induced T-cell ALL, implicating this gene as a tumor suppressor. Mechanistically, cyclin C binds and activates the cyclin-dependent kinases CDK18, CDK8, and CDK3 to phosphorylate the intracellular domain of NOTCH1, and promote its *FBXW7*-mediated proteasomal degradation. Thus, cyclin C deficiency and *FBXW7* are both key components of a degradation pathway that controls physiologic NOTCH1 activity. The model that emerges from these findings is that impaired function of either of these tumor suppressors promotes T-cell oncogenesis by

inducing aberrant nuclear accumulation of transcriptionally active NOTCH1.¹⁹⁴

PAX5 and Other B-Cell Developmental Gene Alterations in Precursor B-Cell Acute Lymphoblastic Leukemia

A high-resolution genome-wide analysis of precursor B-cell ALL cases using single-nucleotide polymorphism arrays identified copy number alterations in a number of genes that play important roles in B-cell development.⁴³⁵ Genes involved in B-cell development were found to be altered by deletion, amplification, mutation, or rearrangement in 40% of cases of precursor B-cell ALL. The most common abnormalities identified were deletions of *PAX5*. Upon further analysis of other cases, other mechanisms that led to inactivation of *PAX5* were identified. These included a number of translocations that led to fusion proteins that maintained the ability to bind to *PAX5* transcriptional targets but lost regulatory ability, thus having dominant-negative activity, and inactivating point mutations that altered the transcriptional activity of *PAX5*. More recently, a recurrent germline *PAX5* mutation affecting Gly183 in the octapeptide domain of the gene has been identified in two unrelated kindreds, thus implicating *PAX5* in an autosomal dominant leukemia predisposition syndrome.⁴³⁶ Deletions were also detected in the *TCF3*, *EBF1*, *LEF1*, *IKZF1*, and *IKZF3* genes, all of which play important roles in B-cell development.

Ikaros Mutations in High-Risk Precursor B-Cell Acute Lymphoblastic Leukemia

Ikaros is a DNA-binding transcription factor that is required for the development of all lymphoid lineages, and expression of a dominant-negative Ikaros mutation in mice was shown to lead to T-cell lymphomas.^{437,438} However, the role of Ikaros in human leukemias was not appreciated until genomic analyses of precursor B-cell ALL patient samples revealed Ikaros (*IKZF1*) deletions in 29% of pediatric samples.⁴³⁵ Ikaros deletions are strongly associated with *BCR-ABL*-positive ALL, and are characteristically acquired at transformation of CML to ALL (lymphoid blast crisis), as well as with Ph-like ALL.⁴²³ Ikaros deletions predict a very high risk of treatment failure that appears to be independent of *BCR-ABL1*, with patients with Ikaros-deleted, *BCR-ABL1*-negative ALL faring as poor as those with *BCR-ABL1*-positive ALL.³⁴⁸ Interestingly, recent work has implicated mutational activation of a variety of kinases or cytokine receptors in Ikaros-deleted, *BCR-ABL1*-negative ALL,^{349,351,439} as reviewed earlier in this chapter. Given the remarkable clinical activity of imatinib in high-risk *BCR-ABL1* ALL, these findings strongly support the need for clinical trials testing specific targeted inhibitors for patients with such targetable oncogenic alterations.

Inactivation of *LEF1* in T-Cell Acute Lymphoblastic Leukemia

The *LEF1* transcription factor, a member of the lymphoid enhancer binding factor/T-cell specific transcription factor (*LEF/TCF*) family of DNA-binding transcription factors, is best known for its role as a positive mediator of β -catenin transcriptional activity, a well-established oncogene.⁴⁴⁰ Recent genomic analyses have identified mono- and biallelic deletions and truncating mutations of *LEF1* in 18% of primary T-cell ALL patient samples, unexpectedly implicating *LEF1* as a T-cell ALL tumor suppressor.³⁷ *LEF1* inactivation is associated with a very young age at diagnosis, T-cell differentiation arrest at an early cortical stage of T-cell development, and activating *NOTCH1* mutations. Moreover, T-cell ALL cases with *LEF1* inactivation are characterized by very high expression of *MYC* mRNA, a surprising finding given that *LEF/TCF* transcription factors transactivate *MYC* expression when bound to β -catenin.^{441,442} In

addition to their well-established functions as transcriptional activators, *LEF/TCF* transcription factors can also act as transcriptional repressors when bound to Groucho/TLE family members in the absence of β -catenin activation.⁴⁴³ Although the precise mechanisms responsible for the pathogenic effect of *LEF1* inactivation in T-cell ALL have not yet been established, one potential explanation is that *LEF1* may actively repress *MYC* in T-cell ALL cells lacking β -catenin activation, and that *LEF1* inactivation in this context may promote maximal *MYC* overexpression downstream of other oncogenic lesions that drive *MYC* overexpression, such as *NOTCH1* mutations.

BCL11B Inactivation in T-Cell Acute Lymphoblastic Leukemia

The *BCL11B* transcription factor is required for normal T-cell development. In murine T-cell progenitors, inactivation of *BCL11B* leads to developmental arrest at double-negative stages, acquisition of natural killer-like features, and aberrant self-renewal activity.^{444–447} Monoallelic *BCL11B* deletions or point mutations have recently been identified in 9%–16% of primary T-cell ALL patient samples.^{127,448} The point mutations identified typically occur within the DNA-binding domains of *BCL11B* and are predicted to disrupt their ability to bind DNA. Moreover, previous work in murine models has shown that *BCL11B* suppresses T-lymphoblastic malignancies induced by *p53* haploinsufficiency, radiation, or the *BCR-ABL1* oncogene,^{449,450} and *BCL11B* inactivation is a particularly common cooperating lesion in murine T-cell ALL induced by the *TLX1* oncogene or by *ATM* deficiency.^{127,451} In human T-cell ALL, recurrent cryptic t(5;14) (q35;q32) translocations juxtaposing *BCL11B* and *TLX3* have been described, which result in *BCL11B* gene regulatory elements driving overexpression of *TLX3*.^{121,452,453} These translocations were long thought to be pathogenic because of the resultant overexpression of the *TLX3* oncogene. However, these recent findings indicate that both *BCL11B* inactivation and *TLX3* oncogene overexpression are important pathogenic consequences of this translocation, thus representing two oncogenic events from a single genomic lesion. *BCL11B* has recently been implicated as a core component of the SWI/SNF chromatin remodeling complex, a key tumor suppressor in diverse human malignancies. Thus, SWI/SNF complex inactivation provides one potential mechanism to explain the pathogenic consequences of *BCL11B* in T-cell ALL.⁴⁵⁴

PHF6 Mutations in T-Cell Acute Lymphoblastic Leukemia

T-cell ALL has a conspicuous male predominance, suggesting the potential involvement of tumor suppressors on the X-chromosome. Targeted mutational analysis of the X chromosome revealed one such candidate tumor suppressor, *PHF6*, which is a nucleolus ribosomal RNA (rRNA) promoter-associated protein that directly interacts with upstream binding factor through its PHD1 domain and suppresses rRNA. Germline mutations of *PHF6* were first described in association with Borjeson-Forssman-Lehmann syndrome (OMIM 301900), which is associated with severe mental retardation and facial dysmorphisms but until recently had not been associated with T-cell ALL. Ferrando and colleagues identified somatic nonsense and frameshift mutations leading to loss of *PHF6* expression in 16% of pediatric and in 38% of adult T-cell ALL patient samples, and which were associated with overexpression of the *TLX1* or *TLX3* oncogenic transcription factors.⁴⁵⁵ The pathogenic consequences of *PHF6* inactivation in T-cell ALL are not fully understood and remain an area of ongoing investigation. However, recent work has suggested that *PHF6* plays a role in cell proliferation, and that loss of *PHF6* leads to arrest at the G₂/M checkpoint and increased DNA damage at the ribosomal locus. Thus, it is postulated that *PHF6* acts as a tumor suppressor with a regulatory role in rRNA synthesis and genome maintenance.⁴⁵⁶

Ribosomal Protein Gene Mutations in T-Cell Acute Lymphoblastic Leukemia

Mutations in ribosomal proteins that lead to impaired ribosome biogenesis and function are well characterized in disorders of normal hematopoiesis, such as Diamond-Blackfan anemia and in 5q- myelodysplastic syndrome; however, until recently they were not known to be associated with the development of ALL. Using whole-exome sequencing, recurrent mutations in *RPL5* and *RPL10* have been identified in pediatric T-cell ALL.⁴⁵⁷ Moreover, gene expression analysis of pediatric T-cell ALL samples has identified monoallelic focal deletions of *RPL22*, a ribosomal gene that is required for the development of normal T-cell progenitors.⁴⁵⁸ While functional studies investigating ribosomal proteins in T-cell ALL have revealed a role in transformation and cell proliferation, the exact mechanism through which this may provide an advantage to the lymphoblasts remains unknown.^{457,458}

Abnormalities of Leukemia Cell Ploidy

Abnormalities of chromosome number, which generally occur in the absence of specific chromosomal translocations, have important prognostic and biologic implications in childhood ALL.

Hyperdiploidy

Found in 25%–30% of childhood ALL cases, high hyperdiploidy, defined as the presence of 51–65 chromosomes in the leukemic clone, is a powerful favorable prognostic indicator in childhood ALL.¹⁸³ Trisomies of chromosomes 4, 10, and 17 impart a particularly good prognosis, while high hyperdiploidy in the absence of these trisomies is less of a favorable prognostic factor.⁴⁵⁹ Near triploid (68–80 chromosomes) and near tetraploid ALL (>80 chromosomes) appear to be biologically distinct entities with less prognostic significance. Patients with high hyperdiploidy can expect favorable long-term outcomes, and typically present with favorable prognostic indicators, such as age between 2 and 10 years, a low white blood cell count, and precursor B-cell immunophenotype.^{460–462} The mechanisms accounting for the favorable outcome of patients with hyperdiploid ALL remain elusive but may reflect an increased sensitivity to antimetabolite therapy⁴⁶³ and a greater propensity to undergo apoptosis.¹⁵²

Hypodiploidy

In marked contrast to the favorable outcomes associated with hyperdiploidy, the occurrence of hypodiploidy (<45 chromosomes) carries an extremely poor prognosis.^{183,464} A recent large-scale genomic study has revealed that hypodiploid ALL comprises two molecularly distinct biologic entities.⁴⁶⁵ Near-haploid ALL (24–31 chromosomes) commonly harbors activating mutations in the *RAS* pathway, with activating mutations of *RAS* genes or loss-of-function mutations of its negative regulator *NFI* being particularly common. By contrast, low hypodiploid ALL (32–39 chromosomes) has an exceptionally high frequency of *p53* mutations, which are otherwise very rare in ALL. Strikingly, nearly half of these cases had *p53* mutations identified in remission DNA, strongly suggesting these patients have germline *p53* mutations. Despite the differences in underlying genetic alterations, both near haploid and low hypodiploid ALL are associated with activation of *RAS* and *PI3K* signaling pathways, and preclinical data support the potential therapeutic utility of *PI3K* pathway inhibitors for these patients.⁴⁶⁵

Polysomy 21

Gains of additional copies of chromosome 21 are the most common somatic aneuploidy in precursor B-cell ALL, and patients with

germline trisomy 21 (Down syndrome) are at increased risk of this disease.^{466,467} Additionally, chromosome 21 is never lost in ALL cases with hypodiploidy,⁴⁶⁵ highlighting the role of additional copies of chromosome 21 in ALL pathobiology.

In addition to whole-chromosome 21 gains, 1%–2% of precursor B-cell ALL cases are characterized by amplification of material from an approximately 5-Mbp region of chromosome 21 that includes *RUNX1*, the so-called *intra-chromosomal amplification of chromosome 21* (iAMP21).^{468,469} Interestingly, iAMP21 is 2700-fold more common in individuals with a germline Robertsonian translocation involving chromosomes 15 and 21. These translocations result in the fusion of the long arms of chromosomes 15 and 21 into a single chromosome. Both of these chromosomes are acrocentric with little genetic material on their short arms, thus little genetic material is lost and heterozygous carriers are phenotypically normal. Whole-genome sequencing analysis of ALL cases with iAMP21 has revealed highly complex structural and copy number rearrangements within the amplified region.⁴⁷⁰ Interestingly, reconstruction of the evolution of this lesion strongly suggests that the initiating event for this lesion is chromothripsis, or the shattering of a chromosome in a single catastrophic event,⁴⁷¹ followed by additional amplification via breakage-fusion-bridge cycles.⁴⁷⁰ These data strongly suggest that the abnormal structure of the Robertsonian chromosome predisposes it to focal genomic instability involving chromosome 21, possibly because it is prone to mitotic segregation errors,^{472,473} thus providing a potential mechanism linking germline chromosome 21 Robertsonian translocations and iAMP21. Children with iAMP21 ALL are often older at presentation with a mean age of 9 years and have a low white blood cell count. Several studies have demonstrated increased risk of relapse and overall worse outcomes with this chromosomal aberration; however, more recent studies have shown improved outcomes with intensification of therapy for patients with iAMP21.⁴⁷⁴

Until recently, the molecular mechanisms linking trisomy 21 to B-cell leukemogenesis were unknown. Recent work with a murine model harboring triplication of 31 genes that are orthologous to a segment of chromosome 21q22⁴⁷⁵ revealed that chromosome 21q22 triplication leads to aberrant self-renewal and differentiation arrest of B-cell progenitors.⁴⁷⁶ Moreover, chromosome 21q22 triplication accelerates the onset of B-ALL induced by either *BCR-ABL1* or the combination of *CRLF2* and activated *JAK2*. Polysomy 21 was found to induce loss of the repressive histone mark H3K27 trimethylation, indicating suppression of activity of the PRC2. This effect was mediated, at least in part, by overexpression of the histone remodeling gene *HMGNI*, a gene encoded on the triplicated region of chromosome 21q22.⁴⁷⁶ These findings thus formally prove that polysomy 21 is oncogenic in the B-cell lineage, and provide a molecular mechanism linking this chromosomal lesion to B-cell pathobiology.

CHEMOTHERAPY RESISTANCE MECHANISMS AND NOVEL THERAPEUTIC TARGETS

Apoptosis Resistance and Mitochondrial Apoptosis

Despite the clinical application of conventional cytotoxic chemotherapy for more than 50 years, the molecular determinants of chemotherapy response have received relatively little attention. Recent work has implicated a major role for resistance to cell death through the mitochondrial pathway. The mitochondrial pathway of apoptosis is regulated by the relative activity of pro- and antiapoptotic BCL2 family members, which converge at the mitochondrial outer membrane. When survival signals predominate, the BAX and BAK1 effector proteins are in an inactive conformation. However, induction of mitochondrial apoptosis culminates in the activation of BAX and BAK1, which oligomerize to form pores in the mitochondrial outer membrane.⁴⁷⁷ This step triggers mitochondrial depolarization, cytochrome c release, and subsequent caspase activation, and is generally considered the point of irreversible commitment to cell death. Recent work using an assay to measure the ability of a fixed proapoptotic stimulus to trigger mitochondrial depolarization has

revealed that a tumor cell's sensitivity to mitochondrial apoptosis is a major determinant of chemotherapy response. Indeed, resistance to mitochondrial apoptosis can predict clinical outcome for patients with a wide range of tumors, including ALL.⁴⁷⁸ Investigation of the dependence of ALL cells on specific antiapoptotic factors revealed that most cases of precursor B-cell ALL and of ETP ALL are dependent on the antiapoptotic BCL2 protein, whereas "typical" T-cell ALL cases are most often dependent on a distinct antiapoptotic protein, BCL-XL. Small-molecule inhibitors of both of these proteins are under preclinical development and demonstrate promising activity in preclinical models.⁴⁷⁹ There is considerable interest in the clinical application of these antiapoptotic inhibitors for the treatment of ALL.

NT5C2 Nucleosidase Gene Mutations in Acute Lymphoblastic Leukemia

Genomic analyses of relapsed ALL clinical specimens have revealed activating point mutations in the cytosolic 5'-nucleotidase II gene (*NT5C2*), occurring in approximately 20% of relapsed T-cell ALL cases and in 3% of relapsed precursor B-cell ALL.^{480,481} *NT5C2* encodes a 5'-nucleotidase enzyme that metabolizes and inactivates nucleoside analog chemotherapeutics, including 6-mercaptopurine and 6-thioguanine. Point mutations within *NT5C2* lead to increased enzyme activity in vitro, and their expression is sufficient to induce resistance to 6-mercaptopurine and 6-thioguanine in ALL cells. Patients with *NT5C2* mutations presented with early relapse, defined as within 36 months of achieving remission, and had a uniformly poor prognosis.^{480,481} These findings highlight the need for alternative therapeutic strategies for these patients.

Pharmacologic PP2A Activation in T-Cell Acute Lymphoblastic Leukemia

A small-molecule screen in a zebrafish model of MYC-induced T-cell ALL revealed that perphenazine has activity against zebrafish and human T-cell ALL.⁴⁸² Perphenazine is a US Food and Drug Administration-approved antipsychotic best known as an inhibitor of dopaminergic signaling, but its antileukemic activity could not be explained by any of its known molecular targets. Using a mass spectrometry-based approach, PP2A was identified as a novel target of perphenazine. Perphenazine was found to bind and activate the phosphatase activity of PP2A, leading to dephosphorylation and inactivation of several oncoproteins with well-known roles in leukemogenesis, including MYC and AKT.⁴⁸² Despite its key role as a tumor suppressor, PP2A-inactivating mutations have not been described as a recurrent event in T-cell pathobiology. This is likely because each subunit of PP2A is encoded by multiple redundant genes, making it easier for a tumor cell to inactivate PP2A function by overexpression of a negative regulator, such as the *TLX1* oncogene.¹²⁸ Although the dopaminergic neurotoxicity of perphenazine is an obstacle to immediate clinical translation of these findings, the development of more potent and specific PP2A activators could have important therapeutic applications for patients with T-cell ALL and other cancers driven by hyperphosphorylated PP2A substrates.

FUTURE DIRECTIONS

The immediate applications of the emerging molecular information include a redefinition of risk-classification schemes to emphasize the roles of somatically acquired genetic abnormalities that carry a defined prognosis and likelihood of therapeutic failure. Currently, patients are assigned to treatment according to their initial clinical features and, increasingly, the genetic and biologic properties of their leukemic cells. We are now in a position to view ALL as a group of heterogeneous diseases defined by discrete molecular lesions. As these lesions have been systematically analyzed in larger numbers of patients, it

has been possible to devise new classification schemes for ALL that reflect prognosis with precision. The development of new drugs based on the molecular biology of ALL, whose promise is highlighted by the early success of imatinib in BCR-ABL1-positive ALL, is clearly a priority for the future and will likely take the form of compounds developed to specifically interfere with oncoprotein function and other prosurvival mechanisms specific to each patient's leukemic blasts. Additionally, the discovery that enzymes such as kinases and histone methyltransferases play important roles in ALL pathogenesis has provided new opportunities for targeted drug development. The opportunity is now at hand to improve therapy through randomized trials coordinated on a nationwide or even worldwide scale that focus on key subsets of patients with acute leukemia whose lymphoblasts harbor specific genetic abnormalities.

CLINICAL MANIFESTATIONS AND TREATMENT OF CHILDHOOD ACUTE LYMPHOBLASTIC LEUKEMIA

Sima Jeha and Ching-Hon Pui

INTRODUCTION

Serial risk-directed clinical trials have optimized the combination of chemotherapeutic agents and, along with advances in supportive care, have led to current cure rates of childhood acute lymphoblastic leukemia (ALL) exceeding 85% compared with those of less than 10% in the 1960s.¹ However, because ALL is the most common cancer in children, relapsed ALL remains a leading cause of death from a disease in this age group. Over the last decade, minimal residual disease (MRD) has become the most important determinant in risk stratification. Prophylactic cranial irradiation has been successfully omitted from virtually all patients in several frontline protocols, and the Abelson (ABL) tyrosine kinase inhibitors imatinib and dasatinib have revolutionized the treatment of patients with Philadelphia chromosome (Ph)-positive ALL. Significant advances in biotechnology, such as next generation sequencing (NGS), have led to a deeper understanding of the molecular pathways involved in ALL, which in turn helped identify new ALL subtypes and their driver mutations.² Precision medicine ALL strategies based on inherited and leukemia-specific genomic features, host pharmacogenomics, and targeted molecular and immunologic treatment approaches are increasingly implemented to improve cure rates and reduce toxicity.

EPIDEMIOLOGY

ALL accounts for approximately 75% of all cases of childhood leukemia, and is the most common pediatric cancer, representing 23% of cancer diagnoses among children younger than 15 years of age. About 3600 children and adolescents are diagnosed with ALL each year in the United States, with an annual rate of 30 to 40 per million. The peak incidence of ALL occurs around 3 to 5 years of age. This young age peak historically has been associated with major periods of industrialization in many countries, suggesting a causative role for environmental changes. Recent studies disclosed that hyperdiploid (>50 chromosomes) and *ETV6-RUNX1* (also known as *TEL-AML1*) ALL account for more than half of the cases in this peak age group, and are associated with specific germline genetic polymorphisms. In fact, the differences in the prevalence of specific germline genetic polymorphisms can largely explain the racial or ethnic differences in the incidence and proportion of genetic subtypes of ALL. ALL, especially T-cell subtype, occurs more frequently in boys than in girls.³

Certain inherited genetic and acquired factors are associated with the development of ALL, but most patients have no recognized risk factors. Children with constitutional trisomy 21 (Down syndrome) are up to 15 times more likely to develop leukemia than children without Down syndrome. Genetic instability and DNA repair disorders (e.g., Bloom syndrome, ataxia-telangiectasia, Fanconi anemia) are also associated with an increased risk of developing ALL.⁴ Among identical twins, if one is diagnosed with ALL during the first year of life, the risk that the other twin will develop ALL is over 70%, approaching 100% in twins with a single monozygotic placenta. The extraordinarily high concordance rate in monozygotic infant twins compared with dizygotic infant twins or nontwinned siblings results from the metastasis of leukemic cells from one twin to the other through shared placental circulation. Highest in infancy, this

risk diminishes with increasing age. If the first twin develops ALL by 5 to 7 years of age, the risk to the second twin is approximately twice that in the general population, regardless of zygosity.⁵ After the age of 7 years, the risk to the unaffected twin is similar to that for persons in the general population. The majority of infants with ALL have a chromosome translocation that results in the fusion of the *MLL* gene at 11q23 with a variety of partner genes, the most common of which is *AF4*. Identical twin infant pairs with concordant ALL share the same acquired *MLL* gene rearrangements.

The most common chromosome translocation in childhood ALL, t(12;21), results in *ETV6-RUNX1* fusion. In contrast to *MLL*-rearranged ALL, *ETV6-RUNX1* leukemias present after infancy and have a concordance rate of only 10% in identical twins. *ETV6-RUNX1* fusion can be found in as many as 1% of cord blood samples of normal newborn babies, a frequency 100 times higher than the prevalence of this subtype of leukemia, suggesting that additional postnatal mutations are necessary for malignant transformation. Analysis of Guthrie cards of 2- to 6-year-old children with ALL showed that most did have detectable, clonotypic *ETV6-RUNX1* sequences at birth. In addition, identical *ETV6* and *RUNX1* breakpoints were present in each of the twin pairs with a very asynchronous diagnosis supporting the requirement for one or more additional postnatal events following in utero initiation. This interpretation suggests that *ETV6-RUNX1* initiates leukemogenesis but is insufficient for overt disease, and further genetic alterations are required. *ETV6* deletions on chromosome 12p, the most frequent additional genetic abnormalities described in cases of ALL with *ETV6-RUNX1*, appear to be subclonal in fluorescence in situ hybridization (FISH) analysis of leukemic cells from nontwin patients. These findings indicate that *ETV6* deletion is a secondary or later event in leukemogenesis, and suggest that leukemia might be initiated in utero but requires at least an essential second postnatal event (two hits).⁶ Indeed, recent next generation studies show that virtually all cases of ALL, with the exception of *MLL-AP4*-positive ALL, have 8 to 12 cooperative mutations.

Several genetic, dietary, and environmental factors have been proposed to modify the risk of leukemia initiation. Children with various congenital immunodeficiency diseases, including Wiskott-Aldrich syndrome, congenital hypogammaglobulinemia, and ataxia-telangiectasia, have an increased risk of developing lymphoid malignancies, as do patients undergoing chronic treatment with immunosuppressive drugs. The loss of cellular immune surveillance capability for tumor antigens and the inability to self-regulate lymphoproliferative processes may contribute to malignant transformation in these patients. Absence of exposure to common infections in the first year of life is associated with a higher risk of developing *ETV6-RUNX1*-positive or hyperdiploid ALL (>50 chromosomes) in older children. A possible explanation is that in the absence of infection-driven modulation of the naive immune network in infants, subsequent infectious exposures could result in a highly dysregulated response to infections in older children contributing to leukemogenesis. Exposure to ionizing radiation and certain toxic chemicals could also facilitate the development of acute leukemia. The high incidence of leukemia among survivors of atomic bomb explosions in Japan during World War II is well documented. Among survivors of the atomic bomb, there was no increase in the incidence of leukemia in

children exposed to radiation in utero. This experience contrasts with other reports of an increased incidence of ALL in children exposed to medical diagnostic radiation both in utero and in childhood. Other evidence linking most environmental exposures to risk of childhood ALL has largely been inconsistent. Causation pathways are likely to be multifactorial and it is probable that the risk of ALL from environmental exposure is influenced by germline genetic variations through the co-inheritance of multiple low-risk variants.

PATHOBIOLOGY

Acute leukemias comprise a group of clonal disorders of maturation at an early phase of hematopoietic differentiation. ALL subtypes are a heterogeneous group of malignancies with distinctive immunophenotype and molecular pathogenesis that result in varying clinical characteristics and response to therapy. Accurate pathobiologic diagnosis is not only important for prognostic stratification, but can also help define patient-specific therapeutic approaches.⁷

Lymphoblastic leukemias can arise from either B- or T-cell mutant hematopoietic progenitor cells capable of indefinite self-renewal. T-cell ALL can be classified into several distinct genetic subgroups that correspond to specific T-cell development stages, and is frequently associated with translocations of T-cell receptor genes on chromosome 14q11 or 7q34 with other gene partners. Early T-cell precursor (ETP) ALL comprises 12% to 15% of T-ALL and is characterized by immature genetic and immunophenotypic features (CD1a-negative, CD8-negative, and CD5-weak and the coexpression of stem-cell or myeloid markers), and gene expression reminiscent of double-negative 1 thymocyte that retains the ability to differentiate into both T-cell and myeloid, but not B-cell lineages. The discovery of its mutational spectrum recapitulated that of acute myeloid leukemia (AML) by whole genome sequencing and global transcription profile similar to that of normal hematopoietic stem cells, and granulocyte macrophage precursors suggest that this subtype of leukemia is a stem-cell leukemia. The prevalence of mutations in genes regulating cytokine receptor and RAS signaling, and histone modification further suggests that the addition of targeted therapy might improve the outcome of this subtype.⁸ Most B-lineage leukemias are early precursor B cells, expressing CD19 and CD10 (or cALLa, the common acute leukemia antigen) but lacking surface or cytoplasmic immunoglobulin. The mature B-cell ALL, or Burkitt cell leukemia, are stratified separately and not included in this chapter.

Recent advances in global genome analysis have enabled the identification of recurring alterations in genes and pathways with key roles in cell growth and tumorigenesis. Several observations suggest that multiple lesions are acquired subsequent to founding translocations to induce leukemogenesis. A single nucleotide polymorphism (SNP) array demonstrated substantial differences in the frequency of copy number abnormality (CNA) among various ALL subtypes. *MLL*-rearranged cases had less than one CNA per case, suggesting that *MLL* is a potent oncogene that requires very few cooperating lesions to induce leukemia transformation, especially in infants, while other subtypes such as *ETV6-RUNX1* and *BCR-ABL1* leukemias have over eight lesions per case.

Deletion or sequence mutation of the *IKZF1*, a gene that encodes the early lymphoid transcription factor IKAROS, is present in over 80% of Ph-positive (*BCR-ABL1*-positive) ALL and is common in Ph-like ALL that has a gene expression profile similar to that of Ph-positive ALL but lacks *BCR-ABL1* fusion. The Ph-like ALL constitutes around 10% of B-ALL in children, its prevalence increases among young adults, and it is more common in patients with Hispanic ethnicity and Native American genetic ancestry with germline *GATA3* polymorphism.⁹ Approximately half of the Ph-like cases have rearrangements of the cytokine receptor-like factor 2 gene *CRLF2*, with concomitant Janus kinase (JAK) mutations in one-third of the *CRLF2*-rearranged cases. This genotype is associated with increased risk of relapse. Remarkably, *CRLF2* alterations occur in approximately 50% of the cases with Down syndrome. JAK inhibitors have not yet been studied in patients with Down syndrome ALL, and could

be of therapeutic interest given the increased toxicity with standard chemotherapy in this patient population. Genome sequencing of other Ph-like cases identified structural alterations and mutations activating kinase and cytokine receptor signaling, including *EBF1-PDGFRB*, *NUP214-ABL1*, *RANBP2-ABL1*, *BCR-JAK2*, *STRN3-JAK2*, and activating mutations of *IL7R* or *FLT3*. Importantly, preclinical studies showed that primary leukemic cells harboring *PDGFRB* or *ABL1* fusion responded to ABL1 tyrosine kinase inhibitors, and those harboring *BCR-JAK2* or mutated *IL7R* responded to JAK2 inhibitor, suggesting that these patients would benefit from the targeted therapy.¹⁰

Historically, association studies of ALL based on the candidate gene approach have implicated a few genes involved in the metabolism of carcinogens, folate metabolism, protection of DNA from carcinogen-induced damage, and cell-cycle regulation in the development of ALL. However, none of these genes can be confirmed by the recent genome-wide association studies that instead have identified polymorphic variants in several other genes (including *ARID5B*, *CEBPE*, *GATA3*, *CDKN2A*, *BM11-PIP4K2A*, and *IKZF1*) that are associated with an increased risk of ALL or specific ALL subtypes.¹¹ Rare germline mutations in *PAX5* and *ETV6* are linked to familial ALL.¹² In addition to identifying common, low-penetrance susceptibility alleles, these data provide insights into disease causation by identifying risk variants annotating genes involved in transcriptional regulation and differentiation of B-cell progenitors.

CLINICAL MANIFESTATIONS

Children with ALL present with nonspecific symptoms and signs reflecting the degree of disruption in bone marrow (BM) function and the extent of extramedullary infiltration. The most common presenting symptoms are fever, fatigue, pallor, petechiae, bruising, bleeding from mucosal surfaces, and pain. Patients, especially young children, may present with bone pain, arthralgia, or refusal to walk due to leukemic infiltration of the bone or joint, or to expansion of the marrow cavity by leukemic cells (Table 65.1). The evolution of

TABLE 65.1 Clinical Presentation of ALL

Symptoms/Signs	Etiology	Management
Fever	Disease or infection	Always conduct fever work up and provide broad antimicrobial coverage until infectious etiology is ruled out
Fatigue, pallor	Anemia (ALL infiltrating bone marrow)	Packed red blood cell transfusion (slow if anemia is severe, avoid in hyperleukocytosis)
Petechiae, bruising, bleeding	Thrombocytopenia (ALL infiltrating bone marrow)	Transfuse with platelets
Pain	Leukemia infiltrating bones/joints, or expanding marrow cavity	Establish diagnosis and start chemotherapy
Respiratory distress/superior vena cava syndrome	Mediastinal mass	Avoid sedation in presence of tracheal compression. Establish diagnosis as soon as possible and start chemotherapy

ALL, Acute lymphoblastic leukemia.

Fig. 65.1 CENTRAL NERVOUS SYSTEM (CNS), TESTICULAR, AND SUBCUTANEOUS INVOLVEMENT IN CHILDHOOD ACUTE LYMPHOBLASTIC LEUKEMIA (ALL). CNS disease identified in the cerebrospinal fluid (CSF) by screening lumbar puncture at the time of diagnosis in a 12-year-old boy with high-risk precursor B-cell ALL. The total count of the CSF specimen was 6131/ μ L with 6076 white blood cells/ μ L and 98% blasts. (A, B) The cytospin preparation shows mostly blasts, slightly altered morphologically by the preparation. In (B), there is a small lymphocyte (*middle*) for comparison with the blasts. (C, D) Testicular disease noted at relapse in a 13-year-old boy with precursor B-cell ALL. Note the infiltrate of blasts in the parenchyma of the testes, surrounding the seminiferous tubules. Immunostaining (not shown) demonstrated that the blasts were CD19+, CD10+, and TdT+. (E, F) Cutaneous disease at diagnosis. The patient was an 8-year-old boy with a scalp lesion for 2 months that was initially treated with antibiotics. (F) On biopsy there was much crush artifact, but deep in the specimen there was an infiltrate of blasts separating fibers shown to be B-cell lineage. Interestingly, the patient had a normal complete blood count, but bone marrow was packed with blasts that had a precursor B-cell phenotype and a hyperdiploid karyotype.

symptoms may proceed over a few days, weeks, or months. Less common presenting symptoms include headache, visual complaints, vomiting, respiratory distress, oliguria, and anuria. Occasionally, patients present with life-threatening infection or bleeding.

On physical examination, fever, pallor, petechiae, and ecchymoses may be present. The lymphoproliferative nature of the disease may be manifested as lymphadenopathy, splenomegaly, or hepatomegaly. Overt central nervous system (CNS) involvement is uncommon at presentation, but leukemic cells can be detected by screening lumbar puncture (Fig. 65.1A,B) in as many as 20% of children with ALL, especially those with high-risk disease who are asymptomatic at the time of the puncture. Papilledema, retinal hemorrhages, and cranial nerve palsies may be present. CNS involvement usually is restricted to leptomeninges, and parenchymal mass lesions are uncommon. Epidural spinal cord compression is a rare but serious presenting finding and requires immediate chemotherapy including high-dose glucocorticoid therapy. Laminectomy or radiotherapy is generally not necessary because leukemias are very sensitive to chemotherapy at diagnosis. Overt testicular involvement occurs in only 2% of boys and usually presents as painless, asymmetric enlargement that can be distinguished from hydrocele by ultrasonography (Fig. 65.1C,D). Less common presenting features include ocular involvement, subcutaneous nodules (leukemia cutis) (Fig. 65.1E,F) and enlarged salivary glands (Mikulicz syndrome). Approximately 55% of T-cell cases present with an anterior mediastinal mass. A bulky mediastinal mass can compress the great vessels and trachea, resulting in superior vena cava syndrome and respiratory distress. Patients with large mediastinal mass generally present with cough, dyspnea, orthopnea, dysphagia,

stridor, cyanosis, facial edema, increased intracranial pressure, and sometimes syncope. When significant tracheal compression is present, general anesthesia should be avoided and procedures should be performed under local anesthesia. Immediate diagnosis and initiation of steroids and chemotherapy is essential to prevent respiratory failure. Lumbar puncture and intrathecal therapy can be delayed for a few days, allowing the relief of airway compression and decrease in circulating blasts, without compromising ultimate clinical outcome.

Clinical laboratory data often reveal a broad spectrum of abnormal findings. Various degrees of anemia and thrombocytopenia are usually present at diagnosis. The presenting leukocyte counts range widely from 0.1 to $1500 \times 10^9/L$. Leukemic blasts may not be appreciated morphologically in the peripheral blood smear in 10% of the patients. Approximately 45% of children have leukocyte counts less than $10 \times 10^9/L$, and 15% present with hyperleukocytosis ($>100 \times 10^9/L$). Patients with hyperleukocytosis are at increased risk of CNS disease, tumor lysis syndrome, and leukostasis. Leukostasis may manifest as dyspnea, chest pain, alteration in mental status, cranial nerve palsies, or priapism. The majority of childhood ALL cases are B cell in derivation with approximately 12% to 15% of children with ALL having a T-cell immunophenotype. T-cell ALL usually occurs in patients older than 9 years of age with elevated leukocyte count, and is associated with CNS involvement. Coagulopathy, usually mild, can occur in T-cell ALL and is only rarely associated with severe bleeding. Elevated serum uric acid and lactate dehydrogenase levels are common in patients with a large leukemic cell burden. Patients with massive renal involvement can have increased levels of creatinine, urea nitrogen, uric acid, and phosphorus; intrathecal methotrexate should be

delayed for a few days to avoid undue delay in methotrexate clearance resulting in systemic toxicity in these patients. Approximately 0.5% of patients have hypercalcemia at diagnosis, attributable to the release of parathyroid hormone–like protein from lymphoblasts and leukemic infiltration of bone; these patients tend to be in the older age group and present with low blast cell count; and this complication generally resolves rapidly with hydration and chemotherapy. The chromosomal rearrangement t(17;19), observed in less than 1% of precursor B-ALL, has been associated with hypercalcemia, coagulopathy, and dismal outcome. Liver dysfunction due to leukemic infiltration occurs in 10% to 20% of patients, is usually mild, and has no prognostic consequences. Because vincristine and daunorubicin are metabolized primarily through biliary excretion, modifications of the dosage of these agents are recommended if direct bilirubin level is elevated.

Abnormalities of the bone, such as metaphyseal banding, periosteal reactions, osteolysis, osteosclerosis, or osteopenia, can be demonstrated by radiographic studies in one-half of the patients, especially those with low presenting leukocyte counts. Routine bone surveillance is not necessary because these findings have no clinical or prognostic implication. Vertebral compression fracture that can be found in 2% of the cases in routine chest x-ray to detect mediastinal mass, is usually associated with low leukocyte count and hyperdiploidy (>50 chromosomes), and is not associated with adverse prognosis.

DIFFERENTIAL DIAGNOSIS

Children with ALL present with a variety of nonspecific symptoms that may mimic other conditions. Pancytopenia and fever are also presenting symptoms for aplastic anemia. Failure of a single cell line, as in transient erythroblastic anemia, idiopathic thrombocytopenic purpura, and congenital or acquired neutropenia, sometimes produces a clinical picture that is difficult to distinguish from ALL. Routine BM aspiration is not necessary for patients with severe thrombocytopenia and no other hematologic or physical evidence of leukemia. However, BM aspiration should be performed to exclude leukemia in patients who require glucocorticoid treatment. Children with infectious mononucleosis or other acute viral illnesses may present with fever, adenopathy, splenomegaly, lymphocytosis, or pancytopenia. Fever, arthralgia, or a limp may frequently be confused with juvenile rheumatoid arthritis, which can also be associated with anemia, leukocytosis, and mild splenomegaly. Children with prominent bone pain frequently have nearly normal blood counts, a finding that can contribute to a delay in diagnosis. Immunostains and molecular studies help differentiate ALL from AML and other small blue cell malignancies that invade the BM including neuroblastoma, rhabdomyosarcoma, Ewing sarcoma, and retinoblastoma. Infants may present with subcutaneous nodules (leukemia cutis) that look clinically like Langerhans cell histiocytosis.

PROGNOSIS

Contemporary regimens have abolished the prognostic impact of many clinical and biologic features, demonstrating that the single most important prognostic factor in childhood ALL is appropriate risk-directed therapy (Table 65.2). Accurate assessment of relapse hazard is an integral part of ALL therapy, so that only high-risk patients are treated aggressively, with less toxic therapy reserved for cases at lower risk of failure.

To facilitate comparison of treatment results among different clinical trials, participants in a 1993 workshop sponsored by the United States National Cancer Institute adopted a uniform risk classification based on age and leukocyte. Two-thirds of the patients who were 1 to 9 years old with precursor B-cell ALL and a leukocyte count less than $50 \times 10^9/L$ were considered to be at standard risk of relapse, while the other third were classified as high risk. This classification proved to be of limited prognostic value because up to a third of

patients designated as standard-risk may relapse, and this criterion cannot be applied to T-cell ALL. Moreover, the prognostic impact of age and, to a lesser extent, leukocyte count is largely due to their association with specific genetic abnormalities. For example, the overall poor prognosis of infants less than 12 months of age can be explained by the very high frequency of *MLL* rearrangements (70% to 80%) in this age group, and the overall favorable outcome of patients aged 1 to 9 years is related to the preponderance of cases (70%) with hyperdiploidy (>50 chromosomes) or *ETV6-RUNX1* fusion, both favorable genetic features. Thus a more reasonable strategy would be to develop clinical prognostic risk categories based on their major immunophenotypic features and genetic characteristics. As discussed below, the most important prognostic factor is the early response to remission induction treatment, as determined by MRD level.

B-ALL, lacking immunoglobulin synthesis, is the most common form of acute leukemia in children, and can be further divided into several subtypes based on the stage of differentiation. The high-risk features previously ascribed to pre-B ALL (presence of cytoplasmic IgM) are closely associated with the presence of the t(1;19) translocation with *E2A (TCF3)-PBX1* fusion. Prognostic distinctions among ALL immunophenotypes, including the negative prognostic impact once associated with T-cell ALL and pre-B ALL with *E2A-PBX1* fusion, have been abolished by recent improvements in risk-directed treatment. Aberrant expression of myeloid-associated antigens has been observed with certain genetic subtypes. CD15, CD33, and CD65 are expressed in ALL cases with a rearranged *MLL* gene, and CD13 and CD33 are expressed in cases with the *ETV6-RUNX1* fusion. Once associated with a poor outcome in some studies, myeloid-associated antigen expression has no prognostic impact in contemporary risk-directed treatment programs.

ALL can be classified according to modal chromosomal number (ploidy) and specific genetic abnormalities of the leukemia stem line. Hyperdiploidy (>50 chromosomes per cell) occurs in 25% to 30% of children with pre-B ALL and is associated with an age of 1 to 10 years, a lower median leukocyte count, increased sensitivity to anti-metabolite agents, and a favorable prognosis. In contrast, a hypodiploid karyotype (<44 chromosomes per cell) occurs in 2% to 3% of children with pre-B ALL and predicts a poor outcome among those who respond poorly to remission induction. Low hypodiploidy (30 to 39 chromosomes) is associated with the presence of *TP53* mutations that are frequently inherited, and is a manifestation of the Li-Fraumeni syndrome.¹³ Molecular analysis can identify prognostically and therapeutically relevant subgroups that cannot be identified by karyotyping. *ETV6-RUNX1*, the most common specific genetic rearrangement in childhood ALL, has been associated with the most favorable prognosis. With the exception of T-cell ALL with the t(11;19), 11q23/*MLL* rearrangements are generally associated with higher risk of relapse.

Genetic features do not entirely account for treatment outcome and their prognostic impact also depends on the treatment efficacy. As many as 15% of patients with hyperdiploidy >50 or *ETV6-RUNX1* fusion and poor response to induction may suffer recurrences of their leukemia. On the other hand, 70% or more of the patients with the t(9;22) and *BCR-ABL1* fusion, once associated with dismal prognosis, can be cured with chemotherapy and ABL tyrosine kinase inhibitor without the need of allogeneic hematopoietic cell transplantation if they can achieve a solid remission with no detectable MRD.^{14,15} Among patients with *MLL-AF4* fusion, infants and adults have a worse prognosis than children. Interindividual variability in the pharmacokinetics and pharmacodynamics of many antileukemic agents also contributes to the heterogeneity in treatment response among patients with specific genetic abnormalities.

The degree of reduction of the leukemic cell clone early during remission induction therapy is determined by leukemic cell genetics, microenvironment, and host pharmacogenetics and pharmacodynamics, and has shown greater prognostic strength than any other individual biologic or host-related feature.¹⁶ Measurements of MRD, by flow-cytometric detection of aberrant immunophenotypes or by polymerase chain reaction (PCR) of clonal antigen-receptor gene

TABLE 65.2 Prognostic Factors in ALL

Factor	Prognosis	Clinical Application
Age		
<1 year	MLL ⁺ (70–80% infants) poor outcome; MLL [−] same outcome as older children	MLL [−] do well on standard ALL therapy Potential role for FLT3 inhibitors, proteasome inhibitors, histone deacetylase inhibitors, and hypomethylating agents for MLL ⁺
1–9 years	Lower (standard) risk	ALL biology may change risk
>9 years	Higher risk	ALL biology may change risk
WBC		
<50 × 10 ⁹ /L	Lower (standard) risk	ALL biology may change risk
≥50 × 10 ⁹ /L	Higher risk	ALL biology may change risk
CNS		
CNS3	Higher risk of CNS and bone marrow relapse	Therapy intensification
CNS2	Higher risk of CNS relapse	CNS directed therapy intensification
Traumatic lumbar puncture with blasts		
Testicular	Higher risk	Therapy intensification
Immunophenotype		
T cell	Higher risk	Poor outcome abolished with current therapy
pre-B (cIgM+)	Standard risk	Poor outcome abolished with current therapy
Early pre-B	Standard risk	Genetics may change risk
Early T-cell precursor	Adverse prognosis	Ongoing studies exploring targeted therapies
Ploidy		
>50 (DI > 1.16)	Low risk	Good response to antimetabolites
<44	Higher risk	Therapy intensification
Genetic Alterations		
t(9;22)/ <i>BCR-ABL1</i>	Higher risk	ABL TKI
t(4;11)/ <i>MLL-AF4</i>	Higher risk	Potential role for FLT3 inhibitors, proteasome inhibitors, histone deacetylase inhibitors, and hypomethylating agents
t(1;19)/ <i>E2A-PBX1</i>	Higher risk of CNS relapse	Improved outcome with current therapy
t(12;21)/ <i>ETV6-RUNX1</i>	Low risk	
<i>IKZF1</i>	Poor prognosis. Present in 80% Ph+ and also in Ph-like ALL	Potential role for tyrosine kinase, JAK inhibitors
<i>NUP214-ABL1</i>	High risk	Potential benefits from TKI
<i>CRLF2</i>	In half of Ph-like cases, associated with Hispanic/Latino, poor outcome	Potential role for JAK inhibitors
<i>CREBBP</i>	Associated with drug resistance and relapse	Potential benefit from histone deacetylase inhibitors
MRD		
Day 15 <0.01%	Excellent outcome	No benefit from 2nd delayed intensification
Slow early responders	Higher MRD = higher risk of relapse	Benefit from augmented delayed intensification
End of induction >1%	Dismal prognosis	Transplantation in first CR
4 months after diagnosis >0.01%	Dismal outcome	Transplantation in first CR

ALL, Acute lymphoblastic leukemia; CNS, central nervous system; CR, complete remission; DI, DNA index; JAK, Janus kinase; MRD, minimal residual disease; TKI, tyrosine kinase inhibitor; WBC, white blood cell.

rearrangements and more recently by next generation deep sequencing, provides a level of sensitivity and specificity that cannot be attained by traditional morphologic assessment of early treatment response. Patients who achieve an immunologic or molecular remission, defined as leukemic involvement of less than 10^{−4} nucleated BM cells on completion of remission induction, have a much more favorable prognosis than do those who do not achieve this status. Patients who are in morphologic remission but have a postinduction MRD level of 1% or more, fare as poorly as those who do not achieve clinical remission by conventional criteria (≥5% blasts). About half of all patients show a disease reduction to 10^{−4} or lower after only 2 weeks of remission induction, and they appear to have an exceptionally good treatment outcome.¹⁶ The persistence of MRD (≥0.01%)

beyond 4 months from diagnosis was associated with an estimated 70% cumulative risk of relapse. Patients with 0.1% MRD or more at 4 months had an especially dismal outcome. Most contemporary clinical trials have incorporated MRD detection into the risk-classification system. Although MRD positivity is strongly associated with known presenting risk features, it has independent prognostic strength, and is increasingly used in risk stratification of ALL in contemporary regimens.

Currently, pediatric patients with ALL are typically classified into three risk groups: low-, intermediate-, and high-risk (also referred to as standard-, high-, and very high-risk) categories based on age, leukocyte count at diagnosis, blast cell immunophenotype and genotype, as well as early treatment response. More recently, genome-wide

Minimal Residual Disease

The rapidity of response to induction therapy is an important independent predictor of outcome. There is strong concordance between the assessment of MRD by flow cytometry and by PCR methods. We monitor MRD primarily using the flow cytometry method because it is simple and rapid, and we reserve the PCR method for the few patients (less than 5%) whose leukemic cells lack a suitable immunophenotype. About half of all patients show a disease reduction to 10^{-4} or lower after only 2 weeks of remission induction, and these patients appear to have an exceptionally good treatment outcome. Persistence of MRD of 10^{-4} or more at 4 months from diagnosis is associated with an especially dismal outcome. The adverse prognosis of high-risk slow early responders can be improved with intensification of induction and consolidation. Low-risk cases may be spared the increased risk of early morbidity and mortality from intensive induction provided that they receive postinduction intensification therapy. Novel approaches at measuring MRD using deep sequencing are being evaluated.

Consolidation Therapy

The importance of a consolidation phase following remission induction is undisputed, but the treatment regimen and duration varies in the different childhood ALL studies. Commonly used strategies include high-dose methotrexate plus mercaptopurine, frequent pulses of vincristine and corticosteroid plus high-dose asparaginase for 20 to 30 weeks, and re-induction treatment with the same agents given during initial remission induction. Re-induction treatment has become an integral component of contemporary protocols. In one randomized study, double re-induction further improved treatment outcome in patients with intermediate-risk ALL, while additional pulses of vincristine and prednisone after a single re-induction course was not beneficial, suggesting that the increased dose intensity of other drugs, such as asparaginase, was responsible for the observed improvement. An “augmented” regimen including additional doses of vincristine and asparaginase during periods of myelosuppression, improved outcome of patients with a slow early response to therapy.

analyses with SNP array and especially NGS have discovered many nonrandom genetic abnormalities, several of which have already been found to have prognostic and therapeutic implications.

THERAPY, INCLUDING STEM CELL TRANSPLANTATION

In contrast to Burkitt leukemia, which is treated with short-term intensive chemotherapy, therapy for B-ALL or T-ALL is administered over 2 to 3 years. Treatment starts with a 4- to 6-week remission-induction phase aiming at eradicating the initial leukemic cell burden and restoring normal hematopoiesis. The induction phase typically includes the administration of a glucocorticoid (prednisone or dexamethasone), vincristine, and at least a third drug (asparaginase or anthracycline, or both). A three-drug induction regimen appears sufficient for most low-risk cases, provided they receive intensified postremission therapy. The benefit in long-term survival of using four or more drugs during induction is widely accepted in higher risk patients but less clear in lower risk patients. With this approach, 98% to 99% of patients can attain remission, as defined by $<5\%$ blasts in the marrow and a return of neutrophil and platelet counts to near normal levels. Intrathecal chemotherapy is usually initiated at the start of treatment but may be delayed in selected patients, as mentioned earlier.

Following remission induction, consolidation (or intensification) is given to eradicate drug-resistant residual leukemic cells. Therapy is tailored to the leukemia subtype and risk group. All patients benefit from a delayed intensification (or delayed re-induction), consisting of using drugs similar to those used in remission induction therapy after a 3-month period of a less intensive, interim maintenance chemotherapy. Double-delayed intensification with a second re-induction at week 32 of treatment improves outcome in patients with intermediate-risk leukemia but does not benefit patients with rapid early response. An augmented intensification regimen consisting of the administration of additional doses of vincristine and asparaginase during the myelosuppression period following delayed intensification has improved the outcome of intermediate- and high-risk patients.

After completion of induction and consolidation, patients receive a 2- to 2.5-year continuation (or maintenance) phase consisting of low intensity metronomic chemotherapy designed to eradicate any residual leukemic cell burden. Weekly low-dose methotrexate and daily oral mercaptopurine form the backbone of most continuation regimens. Many groups add regular pulses of vincristine and corticosteroids to this regimen, although the benefit of these pulses and their optimal duration and frequency of administration in the context of contemporary therapy have not been established.¹⁷ Adjusting chemotherapy doses to maintain white cell count between 2 and $3 \times 10^9/L$ and neutrophil counts between 0.5 and $1.5 \times 10^9/L$ has been associated with a better clinical outcome. Overzealous use of mercaptopurine, to

the extent that neutropenia necessitates chemotherapy interruption, reduces overall dose intensity and is counterproductive. The optimal duration of therapy remains unknown. Attempts to shorten therapy duration from 24 months to 12 or 18 months have resulted in a significant increase in relapses. Several studies showed no advantage to prolonging treatment beyond 3 years. A small number of patients with particularly poor prognostic features may undergo allogeneic hematopoietic cell transplantation during first remission.

Radiation therapy was the first modality successfully used to prevent CNS relapse. The effectiveness of cranial radiation as preventive therapy was offset by substantial late effects in long-term survivors, including learning disabilities, multiple endocrinopathies, and an increased risk of second malignancies. Subsequent trials demonstrated that, in the context of optimal systemic and intrathecal therapy, cranial irradiation can be omitted in all patients but reserved for a few patients who developed subsequent CNS relapse.¹⁸ A recent collaborative group study showed that prophylactic cranial irradiation failed to improve outcome of any high-risk subgroups and in fact was associated with poor survival in several subgroups. Patients with high-risk genetic features, T-lineage ALL, and leukemic cells in the cerebrospinal fluid (CSF) even from iatrogenic introduction from a traumatic lumbar puncture at diagnosis, require more intensive CNS-directed therapy to reduce CNS relapse.¹⁸ Studies have successfully used early triple intrathecal therapy with methotrexate, hydrocortisone, and cytarabine or intrathecal methotrexate alone. Systematically administered agents including high-dose methotrexate, dexamethasone, and asparaginase also contribute to prevention of extramedullary relapse.

Based on reports of more potent in-vitro antileukemic activity and better CNS penetration, dexamethasone has replaced prednisone in many continuation regimens. Prednisone remains the preferred glucocorticoid during induction because of the relative increased toxicity associated with dexamethasone use.¹⁹ Polyethylene glycol-conjugated asparaginase, a long-acting and less allergenic form, is progressively replacing the native *Escherichia coli* asparaginase, and is being increasingly administered intravenously instead of intramuscularly. Asparaginase derived from *Erwinia chrysanthemi* has a short half-life and its use is currently limited to patients who are allergic to the *E. coli* formulations.²⁰ The dose schedule for asparaginase should take into account the variability in the pharmacokinetic profile and potency among the different preparations. Intensifying asparaginase therapy during the early phase of treatment benefits high-risk patients, particularly those with T-cell disease. Significant improvement was also reported in the outcome of patients receiving early intensification consisting of intermediate- or high-dose antimetabolite therapy.²¹ The optimal dose of methotrexate depends on the leukemic cell genotype and phenotype, as well as host pharmacogenetic and pharmacokinetic parameters. Methotrexate at 2.5 g/m^2 is adequate for most patients with standard-risk B-ALL, but a higher dose (5 g/m^2) may benefit those with T-cell or high-risk B-ALL. This

observation is consistent with the finding that T-lineage blast cells accumulate methotrexate polyglutamates less avidly than do B-lineage blast cells. The increased ability of hyperdiploid ALL blasts cells to accumulate methotrexate polyglutamate could partially explain the excellent outcome of children with hyperdiploid >50 ALL treated on regimens based on low-intensity antimetabolites. Leucovorin rescue is necessary after treatment with high-dose methotrexate; however, overzealous rescue might counteract the antileukemic activity of methotrexate. While the intensive asparaginase and high-dose methotrexate treatment has significantly improved the outcome for patients with T-cell ALL, the emergence of specific therapy like the purine nucleoside analog nelarabine will likely increase the tendency to assign patients with T-cell ALL to a specific treatment protocol or stratum.

About 10% of the population inherit one wild-type gene encoding thiopurine methyltransferase (TPMT) and one nonfunctional variant allele, resulting in intermediate enzyme activity, while 1 in 300 people inherit two nonfunctional variant alleles and are completely deficient of this enzyme that catalyzes the *S*-methylation of mercaptopurine to its inactive metabolite. Patients with heterozygous and especially homozygous deficiency of TPMT are at high risk of severe myelosuppression. Patients with poor tolerance to antimetabolite treatment should be tested for TPMT genotype or activity for selective dose reduction of mercaptopurine. Recently, *NUDT15* polymorphism was found to account for the poor tolerance of Asian and to a lesser degree Hispanic populations to mercaptopurine. Substituting thioguanine for mercaptopurine during continuation therapy was associated with a high incidence of profound thrombocytopenia and hepatic venoocclusive disease. Thioguanine use has therefore been limited to short pulses administered during consolidation therapy in some trials, and some patients who develop mercaptopurine-induced pancreatitis.

As optimizing the administration of existing therapies is reaching its limit, further improvements in outcome will require the development of therapeutic approaches directed against rational therapeutic targets. The expanded understanding of the biologic, immunologic, and genetic heterogeneity of ALL has enabled development of several novel therapeutic strategies. Various monoclonal antibodies, bispecific T-cell engager antibody (blinatumomab), and autologous CD19 chimeric antigen receptor (CAR) T cells are showing promise in early clinical trials and may be incorporated into ALL regimens in the future.²²

Autologous transplantation has failed to improve the outcome in ALL. Comparisons between allogeneic hematopoietic cell transplantation and intensive chemotherapy for high-risk patients have yielded inconsistent results due to the small number of patients studied and differences in case selection criteria. It is generally accepted that allogeneic transplantation is a treatment modality for patients with ALL who are predicted to respond poorly to intensive chemotherapy.²³ At present, patients with refractory leukemia (failure to enter morphologic remission after 4 to 6 weeks of induction therapy), high level of MRD (>1%) after remission induction, persistent MRD after consolidation treatment, and early hematologic relapse are candidates for allogeneic transplantation. It is crucial to reduce residual disease to, or close to, undetectable levels as the outcome is superior if MRD

is undetectable prior to transplantation, and worsens with increasing MRD levels at time of transplant. Whether CAR T-cell therapy can replace transplantation in selected patients will need to be tested in prospective clinical trials.

Treatment approaches for adolescents and young adults with ALL have evolved considerably with the widespread adoption of pediatric-based protocols that appears to have significantly improved survival and decreased the need for transplantation in this age group. The benefit of allogeneic transplantation in infants with t(4;11) ALL remains controversial, and should be evaluated in the context of emerging molecular therapies such as FLT3, DNA methyltransferase, proteasome, and histone deacetylase inhibitors. Patients with the recently identified ETP ALL and Ph-like ALL may benefit from molecularly targeted therapy that will improve their outcome without relying on transplantation. Matched unrelated-donor or cord blood transplantation has yielded outcomes comparable to those obtained with matched related-donor transplantation, and should be considered reasonable alternatives if a matched donor is not available. Many advances have been made in stem cell transplantation, such as prevention of graft-versus-host disease, expansion of the pool of suitable unrelated or related donors, donor selection and tissue typing, acceleration of engraftment, enhancement of the graft-versus-leukemia effect, and supportive care. Because improvements in transplantation tend to parallel those in chemotherapy, the indications for transplantation in newly diagnosed and relapsed patients should be re-evaluated periodically. For example, the presence of the Philadelphia chromosome is no longer a clear indication for transplantation with the advent of ABL tyrosine kinase inhibitors.

ACUTE LYMPHOBLASTIC LEUKEMIA RELAPSE

Most relapses occur during treatment or within the first 2 years after its completion, although relapses have been reported as late as 10 years after initial ALL diagnosis. The most common site of relapse is the BM.²⁴ Relapse in extramedullary sites, such as the CNS and testes, has decreased to less than 3% and 1%, respectively. Leukemia relapse occasionally occurs at other sites, including the eye, ovary, uterus, bone, muscle, tonsil, kidney, mediastinum, pleura, and paranasal sinus. Extramedullary relapse in children with ALL frequently presents as an isolated clinical finding. However, in studies that included the MRD assay, many extramedullary recurrences were associated with MRD in the BM. A small fraction of patients experience a recurrence of acute leukemia with an immunophenotype different from that determined at diagnosis. Some of the cases represent relapse of original leukemic clones with a shift in immunophenotype, but others are secondary malignancies caused by the mutagenic effects of leukemia treatment, especially from epipodophyllotoxin. Patients with isolated BM relapse generally fare worse than those with isolated extramedullary relapse or combined BM and extramedullary relapse.²⁵ Factors indicating an especially poor prognosis are short initial remission and T-cell immunophenotype. The presence of MRD at the end of second remission induction is also a strong adverse prognostic indicator. While chemotherapy may secure a prolonged second remission in children with ALL who experience late relapse (defined as more than 6 months after cessation of therapy), allogeneic transplantation is the treatment of choice for patients who experience

Dose Schedule

The biologically equivalent doses among the different formulations of corticosteroids, thiopurines, and asparaginase are not clear. Trials comparing such agents should be cautiously interpreted taking into account the dose schedule and route of administration, and the effect of variability in the pharmacokinetic profile and potency among the agents involved. Simple modification of dose, schedule, or route of administration may result in significant differences in efficacy and toxicity. Also, when comparing regimens containing high-dose intravenous methotrexate, the dose schedule of leucovorin rescue should not be ignored as it plays a crucial role in modulating the activity and toxicity of methotrexate.

Therapeutic Innovations Being Incorporated Into Contemporary Personalized ALL Therapy

1. Targeting genetic alterations that drive high-risk Ph-like ALL with ABL tyrosine kinase inhibitors and JAK inhibitors
2. Immunotherapeutic approaches with bispecific T-cell engager antibodies and chimeric antigen receptor (CAR) T cells
3. Proteasome inhibitors
4. Histone deacetylase inhibitors

hematologic relapse during therapy or shortly thereafter and for those with T-cell ALL. Patients with late-onset isolated CNS relapse who had not received cranial irradiation as initial CNS-directed therapy have a very high remission retrieval rate, with long-term prognosis approaching that of newly diagnosed patients.

Genome-wide studies using paired diagnosis and relapse samples from the same patients are exploring the genetic basis of relapse. Although 90% of the cases exhibit differential gaining or losing genetic lesions from diagnosis to relapse, most relapse samples are clonally related to diagnosis samples. Relapse clones could be present as minor populations at diagnosis and selected during treatment to emerge in the predominant clone at relapse, displaying alterations of genes that have been implicated in treatment resistance. Almost 20% of relapsed cases have sequence or deletion mutations of *CREBBP*, which impair histone acetylation and transcriptional regulation of *CREBBP* targets, suggesting that the mutations may confer drug resistance and raising the possibility of using drugs to reverse the aberrant epigenetic programs, such as histone deacetylase inhibitors.²⁶ The next generation of deep sequencing technologies promises to unravel many more, if not the full repertoire of genetic alterations in leukemia.

SUPPORTIVE CARE

Stringent supportive care significantly contributes to a favorable ALL outcome, and should be initiated at diagnosis as remission induction is associated with an increased risk from cardiovascular, metabolic, and infectious complications. All febrile patients with or without documented infection should be given broad-spectrum intravenous antibiotics until an infectious disease can be excluded. Rapid turnover of leukemia cells before and immediately after the initiation of chemotherapy leads to metabolic disturbances including hyperkalemia, hyperuricemia, hyperphosphatemia, and secondary hypocalcemia. Patients with high levels of uric acid are at risk for the development of acute kidney injury secondary to uric acid deposition in the kidneys. All patients require intravenous hydration to prevent or treat hyperuricemia and hyperphosphatemia. Allopurinol, a xanthine oxidase inhibitor, can prevent uric acid formation. Rasburicase, a recombinant urate oxidase that breaks down uric acid to allantoin (a readily excretable metabolite with 5- to 10-fold higher solubility than uric acid), is more effective than allopurinol but is associated with methemoglobinemia or hemolytic anemia in patients with glucose-6-phosphate dehydrogenase deficiency because hydrogen peroxide is a byproduct of the uric acid breakdown.²⁷ Phosphate binders should also be used to prevent or treat hyperphosphatemia. Transfusions should be administered slowly in patients with severe anemia to prevent congestive heart failure. In patients with extreme hyperleukocytosis, prompt diagnosis can be established on peripheral blood, and chemotherapy should be urgently initiated (usually steroids with gradual introduction of other agents to achieve adequate response while avoiding massive tumor lysis). Packed red blood cell transfusion should be delayed until after the leukocyte count is decreased to prevent complications of leukostasis, but platelet transfusion should be administered to prevent bleeding. All blood products should be irradiated in patients who are receiving immunosuppressive therapy to prevent graft-versus-host disease. Patients should avoid foods that may be contaminated with pathogens and reduce salt intake, which could induce hypertension and resultant seizure in patients receiving glucocorticoids during induction. Adolescents, obese individuals, and patients with Down syndrome are at increased risk of hyperglycemia and other complications. Prophylactic use of trimethoprim-sulfamethoxazole (or pentamidine or atovaquone in patients with poor tolerance to trimethoprim-sulfamethoxazole) successfully prevents *Pneumocystis jirovecii* (formerly *carinii*) pneumonia. Dental evaluation at diagnosis and meticulous oral hygiene during chemotherapy minimizes the oral complications of leukemia and its treatment. It is important to distinguish between herpes simplex viral infection and chemotherapy-induced oral mucositis. Occasionally, patients have nausea and substantial pain on swallowing because

Drug Interactions

We have not yet reached a full understanding of the contribution of genetic polymorphisms to interindividual differences in drug effects that allows us to translate this new knowledge into clinical practice. However, by simply avoiding drug interactions, one can prevent increased toxicity or reduced efficacy of chemotherapy. Phenytoin and phenobarbital induce the activity of cytochrome P450 enzymes, significantly increasing the systemic clearance of several antileukemic agents that may adversely affect treatment outcome. We substitute these anticonvulsants with gabapentin or levetiracetam in patients receiving antileukemic therapy. On the other hand, azole compounds (e.g., fluconazole, itraconazole, ketoconazole, posaconazole) can inhibit cytochrome P450 enzymes and increase the toxicities of various antileukemic agents, especially vincristine.

of esophageal herpes simplex viral infection, candidiasis, or both. Oral candidiasis occurs frequently, especially in young children. Azole compounds (e.g., fluconazole, itraconazole, ketoconazole) are frequently used to treat fungal infections. It should be recognized that they can inhibit cytochrome P450 enzymes and increase the toxicities of various antileukemic agents, especially vincristine. On the other hand, concomitant administration of anticonvulsants that induce cytochrome P450 enzymes (e.g., phenytoin, phenobarbital, carbamazepine) increases the systemic clearance of several antileukemic agents and may adversely affect treatment outcome. Anticonvulsants that are less likely to induce the activity of cytochrome P450 enzymes (e.g., levetiracetam [Keppra]) are recommended in patients receiving chemotherapy. Photosensitive skin rash can occur during antimetabolite therapy. The rashes are erythematous, maculopapular, similar to atopic eczema, and most prominent on the face. Topical administration of simple emollients or a weak steroid preparation, and avoidance of external exposure to sunlight, should improve the skin condition. Patients with Down syndrome tolerate methotrexate poorly, and appropriate dose adjustment is indicated in them. During each clinic visit, a thorough review of all drugs should be undertaken because of potential adverse interactions among them. In fact, chemotherapy can also interact with various food (e.g., grapefruit) and supplements (e.g., St. John's wort, folic acid).²⁸

LATE EFFECTS OF TREATMENT

The most problematic late effects of contemporary ALL therapy include neuropsychologic impairments, bone morbidity, and obesity.²⁹ While neuropsychologic deficits are well-recognized side effects of cranial irradiation, intrathecal and systemic chemotherapy (especially methotrexate) can also cause brain atrophy and spinal cord dysfunction and contribute to the development of neurocognitive toxicities. Severe CNS toxicity has been attributed to cranial irradiation at doses of 2400 cGy or higher, but lower doses have also been associated with long-term neuropsychologic impairments, especially in younger children. Obesity, most prevalent among female survivors of childhood ALL, may be related to metabolic syndrome caused by treatment with cranial radiation and corticosteroids. Osteopenia, fractures, and osteonecrosis have been observed in up to 30% of survivors of childhood ALL. Osteonecrosis, which can lead to significant pain, loss of function, and total joint replacement, has been reported in approximately 8% of children with ALL, with the highest frequency observed in those diagnosed in adolescence. Testicular function (in boys treated with less than 6 g/m² cumulative dose of cyclophosphamide) and especially ovarian function are relatively unaffected by antileukemic therapy. Offspring of patients successfully treated for childhood ALL are generally expected to be as normal as the general population. However, recent studies showed that about 5% of patients with ALL inherit major cancer predisposing genes, some of which (such as TP53) have important clinical implication to the immediate family members.³⁰ Second malignant neoplasms, including malignant

gliomas, meningiomas, and myeloid malignancies, occur with increased frequency in patients treated with regimens that included irradiation, epipodophyllotoxins, or alkylating agents.³¹

FUTURE DIRECTIONS

As the cure rate approaches 90%, treatment response assessed by MRD measurements of submicroscopic leukemia has emerged as a powerful and independent prognostic indicator for gauging the intensity of ALL therapy. Children at high risk of relapse may now benefit from early intensification of therapy. The next goal is to reduce the intensity of therapy in children at very low risk of relapse, hence avoiding undue toxicity. The successful elimination of preventive cranial irradiation indicates that treatment reduction is feasible if done with caution and appropriate substitution with less toxic alternatives. Global genome analysis, in addition to refining leukemia classification, is helping identify potential molecular targets for therapy. Expanding the application of pharmacogenomics, a science that aims to define the genetic determinants of drug effects, will allow further personalized therapy in the future.

ACUTE LYMPHOBLASTIC LEUKEMIA IN ADULTS

Shira Dinner, Sandeep Gurbuxani, Nitin Jain, and Wendy Stock

Acute lymphoblastic leukemia (ALL) is a heterogeneous group of diseases characterized by clonal proliferation of lymphoid progenitors (lymphoblasts). Improved diagnostic tools permit accurate and prompt diagnosis, and aid in evaluation of minimal residual disease (MRD). There have been significant advances in the past decade toward understanding disease pathogenesis, refinement of prognostic groups, and the development of exciting new therapies directed towards specific disease subsets. These molecular targeted and immunotherapeutic approaches are transforming the treatment strategies for adults with ALL and are beginning to result in significant improvements in survival.

EPIDEMIOLOGY

It is estimated that in the year 2015, approximately 6250 new cases of ALL will be diagnosed and 1440 deaths will occur due to the disease in the United States. ALL is primarily a cancer of childhood; the peak incidence (7.7 in 100,000) occurs between the ages of 1 and 4 years, and approximately 60% of the patients are diagnosed before the age of 20 years. The incidence of ALL begins to decline with increasing age after the first decade of life. A second upward trend starts to emerge in the sixth decade of life, and a much smaller peak is seen in patients older than 85 years of age (1.8 in 100,000). Men have a slightly higher incidence of ALL than women (male-to-female ratio, 1.4:1). The overall age-adjusted rate of ALL has increased from 0.93 in 100,000 in the year 1975 to 1.47 in 100,000 in the year 2008. Similar increases in the incidence of ALL have also been reported in Scandinavia, the United Kingdom, and Italy. Although most investigators agree that this increase in the incidence is beyond what might be expected from better reporting, the actual cause(s) of this increased incidence remains largely speculative.

ETIOLOGY

A small minority of ALL cases (<5%) are associated with predisposing inherited syndromes such as Down syndrome, Bloom syndrome, ataxia telangiectasia, and Nijmegen breakage syndrome. However, the underlying etiology is not known in most cases. Although parental tobacco or alcohol use, exposure to pesticides or solvents, and cigarette smoking have all been implicated, only ionizing radiation has been significantly linked to increased risk of developing ALL. The vast majority of literature that attempts to identify causative agents for ALL is at best correlative; most of it borders on pure speculation and conjecture. Only recently has it been appreciated that the interaction between genetic predisposition and environmental factors involved in leukemogenesis is complex and may be different for different subtypes of ALL. Epidemiologic studies designed to identify environmental agents involved in leukemogenesis will therefore have to take into account the biologic subsets defined by morphology, immunophenotype, karyotype, and the molecular abnormalities, and consider the possibility that for each of these subtypes the causative agent may well be different. To adequately investigate these issues, future studies will require collaborative efforts studying large patient populations.

Despite the limitations described, it is relevant to review some of the recent advances in our understanding of the etiology of ALL.

Greaves and colleagues have used DNA obtained from neonatal blood spots to demonstrate that ALL-associated chromosomal translocations (and hence a preleukemic clone) can be demonstrated in neonatal blood spots that are acquired in utero. Furthermore, these are present at 100-fold higher rate than the incidence of leukemia. These investigators hypothesize that overt leukemia evolves as a consequence of an abnormal lymphoid proliferation that occurs in response to exposure to an as yet unidentified infectious agent(s). Supporting this hypothesis are data that suggest that day care attendance associated with early exposure to common infectious agents is associated with a lower incidence of ALL. Similarly, industrialization associated with improved socioeconomic status and exposure to common infectious agents later in life has been postulated to result in abnormal and excessive lymphoid proliferation and leukemic transformation. Finally, an infectious etiology can also be evoked to explain leukemic clusters that occur when a previously unexposed community is exposed to infectious agents brought into the community by a large influx of residents, as happens during urbanization of rural communities. However, it needs to be reiterated that all of these studies are at best correlative and not supported by direct experimental evidence. Furthermore, the infectious or environmental agent(s) responsible for this abnormal lymphoid proliferation remains elusive.

CLINICAL MANIFESTATIONS

The clinical presentation of ALL encompasses a wide spectrum of symptoms that correlate with the degree of bone marrow (BM) involvement and the resultant cytopenias, as well as the leukemic cell burden. Typical symptoms include fatigue, anorexia, night sweats, pallor, shortness of breath, bone pain, fever, and bleeding diathesis. Involvement of extramedullary sites may present with lymphadenopathy, hepatomegaly, or splenomegaly. Less commonly, ALL can involve the central nervous system (CNS), leading to headache, vomiting, lethargy, and cranial nerve palsies. Other extramedullary sites of involvement include the testis, tonsils, adenoids, breast, and gastrointestinal tract. Precursor T-cell ALL often presents with a large mediastinal mass with associated respiratory distress or possible signs of superior vena cava syndrome. Burkitt leukemia/lymphoma is frequently associated with CNS involvement and bulky adenopathy.

CLINICAL AND LABORATORY EVALUATION

The initial workup for patients with suspected ALL is detailed in Table 66.1. All patients should undergo a detailed history and physical examination. Family history should be ascertained. Laboratory evaluation should include complete blood count (CBC) with differential; comprehensive metabolic panel, including liver function tests, lactate dehydrogenase (LDH), and uric acid. Coagulation profile should also be obtained, although coagulation parameters are frequently normal at diagnosis. Human leukocyte antigen (HLA) testing should be obtained for patients who are potential candidates for allogeneic stem cell transplantation (aSCT).

All patients should undergo BM aspiration and biopsy for confirmation of diagnosis, and for cytogenetic and molecular genetic evaluation. It is particularly important to send an aspirate (or peripheral

TABLE 66.1 Initial Evaluation of a Patient With Acute Lymphoblastic Leukemia

blood if lymphoblasts are present) to the molecular oncology diagnostic laboratory to evaluate for the presence of the *BCR-ABL* fusion transcript using reverse-transcriptase polymerase chain reaction because these patients will receive frontline therapy that includes a tyrosine kinase inhibitor (TKI).

A lumbar puncture should be performed at diagnosis to determine CNS involvement. In the event of increased risk of bleeding caused by severe thrombocytopenia or risk of cerebrospinal fluid contamination caused by high peripheral blood blasts, the lumbar puncture should be performed by an experienced operator. It is prudent to administer intrathecal chemotherapy at the time of the diagnostic lumbar puncture after obtaining the necessary samples.

APPROACH TO DIAGNOSIS

While evaluation of morphology and immunophenotype are sufficient for making the diagnosis, current risk stratification relies on additional cytogenetic and molecular genetic information. Data from these tests is therefore an important adjunct to the initial diagnostic work up.

Initial laboratory evaluation starts with a CBC and morphologic evaluation of a Giemsa-stained peripheral blood smear. An abnormality of at least one of the CBC parameters is detected in more than 90% of ALL patients at the time of diagnosis. Anemia and thrombocytopenia are common. The anemia is usually a normochromic, normocytic anemia accompanied by reticulocytopenia. The hemoglobin levels range from 30–174 g/L, and almost 50% of the patients have hemoglobin levels below 100 g/L. The median platelet count at presentation is approximately $55\text{--}60 \times 10^9/\text{L}$, and almost 60% to 70% of patients have platelet counts below $100 \times 10^9/\text{L}$. Although the total white blood cell (WBC) count may be low, normal or elevated, neutropenia is commonly present. In a Cancer and Leukemia Group B (CALGB) study, the median WBC count at presentation was $19.3 \times 10^9/\text{L}$. Almost one-third of the patients are likely to present with WBC count greater than $30 \times 10^9/\text{L}$. Blasts account for a variable proportion of the circulating WBCs, and the percent blast population can range from 0% to 100%. A leukoerythroblastic picture can sometimes be seen. In an extreme form, immature myeloid precursors and myeloblasts constitute the vast majority of cells in the peripheral blood. This should be kept in mind when attempting to make a diagnosis exclusively from peripheral blood. Eosinophilia as a presentation of ALL is extremely uncommon and is seen in association with specific chromosomal abnormalities, including *t*(5;14)(q31;q32) or, even less frequently, with 8p11-associated ALL. Eosinophilia associated with *t*(5;14) is reactive and due to overexpression of interleukin-3 on chromosome 5 driven by the immunoglobulin H (IgH) promoter on chromosome 14. The eosinophilia can be extremely pronounced and mask the blast population in this subset of patients.

Several metabolic abnormalities are present at the time of diagnosis and frequently reflect tumor burden. For example, LDH levels are frequently elevated, and almost 50% of the patients have levels between 300 and 1000 U/L. Elevated serum levels of calcium, potassium, and phosphorous have been noted. More importantly, elevated serum uric acid levels are frequently present and reflect tumor burden. Hyperuricemia needs to be carefully monitored and aggressively corrected to avoid renal failure, especially at the time of starting induction therapy.

MORPHOLOGY

Romanowsky-based stains such as Wright Giemsa and Giemsa provide the greatest cytoplasmic detail for evaluation of cytomorphology of the cells in the peripheral blood smear, BM aspirate smear, and touch imprints (Fig. 66.1). Most frequently, lymphoblasts are small to intermediate in size and have scant, agranular cytoplasm. B lymphoblasts are morphologically indistinguishable from T lymphoblasts, and this distinction relies on immunophenotyping. The nuclei are usually round, with uniformly dispersed “smudgy” chromatin and inconspicuous nucleoli (see Fig. 66.1C). However, variations in morphology are common, and larger cells with abundant bluish gray cytoplasm, larger, somewhat irregular nuclei, and variably prominent nucleoli can be frequently seen (see Fig. 66.1D). Even though the nuclear chromatin of these cells can be fine, it is never as finely dispersed as in a myeloblast. At the other end of the morphologic spectrum are smaller cells with uniformly condensed, mature lymphocyte-like chromatin (see Fig. 66.1E), and distinction from mature B-cell malignancies relies on immunophenotyping. Coarse azurophilic granules (see Fig. 66.1F) can be seen in a subset of blasts in 5% to 8% of childhood ALLs and even more frequently in adult ALL patients. These have been reported in association with Philadelphia chromosome-positive (Ph⁺) ALL and in ALL in Down syndrome patients. The granules are coarser than the granules seen in myeloblasts and are invariably myeloperoxidase negative (see later discussion of *cytochemistry*). Morphologic distinction between the L1 and L2 category recommended in the French–American–British (FAB) classification has proven to be poorly reproducible and of little prognostic value. It has been abandoned in the current World Health Organization (WHO) classification.

Cytoplasmic vacuolation (see Fig. 66.1H) can be seen in as many as 28% of childhood ALL patients. These lymphoblasts can be distinguished from leukemic presentation of BL (see later discussion) based on other morphologic features such as a smaller cell size, lack of deep blue cytoplasm, and less coarse chromatin. However, when morphology is confounding, the distinction relies on immunophenotyping of the malignant cells. In contrast to BL cells, ALL blasts are precursor B cells that express terminal deoxynucleotidyl transferase (TdT) and lack surface immunoglobulin (Ig) expression (see later discussion).

The trephine biopsy sections show hypercellular BM (Fig. 66.2). The sections are evaluated after staining with hematoxylin and eosin. The BM is usually packed with a relatively uniform population of small round blasts with round to oval nuclei. Less frequently, the blasts can be more pleomorphic, with indented, convoluted, and variably sized nuclei. The chromatin is described as being finely dispersed or stippled and the nucleoli are usually not conspicuous. Brisk mitotic activity is almost always present. The effacement of the BM space is almost complete and uniform at the time of initial presentation. Minimal residual hematopoiesis is present; in most instances this is represented by a few megakaryocytes and some erythropoiesis. Normocellular or even hypocellular BMs at presentation have been described but are uncommon. Rarely, the initial presentation of ALL can be with an aplastic or markedly hypocellular BM. Making the diagnosis in this hypocellular context can be particularly challenging because of a paucity of material available for supporting studies such as cytogenetics and immunophenotyping.

BM biopsy can show partial or complete necrosis (see Fig. 66.2C). When extensive necrosis is present, making a diagnosis can be

Fig. 66.1 MORPHOLOGIC FEATURES OF ACUTE LYMPHOBLASTIC LEUKEMIA IN THE BLOOD AND BONE MARROW ASPIRATE. (A) In acute lymphoblastic leukemia (ALL), the peripheral blood count can be low, normal or high, although frequently it is high and composed of mostly blasts. (B) A similar range in cellularity is true regarding the bone marrow. Typically, lymphoblasts are small to intermediate in size and have round nuclei with dispersed chromatin and indistinct nucleoli. (C) They have scant pale blue cytoplasm. A small lymphocyte (C, *middle, left*) is useful for comparison. (D) In many cases, the lymphoblasts are monotonous, but in some cases, the lymphoblast morphology is varied with some large cells, some cells with abundant cytoplasm, and other cells with prominent nucleoli. In the older French–American–British classification, these two patterns were referred to as ALL-L1 and ALL-L2, respectively, although they have been shown not to have any clinical significance. Other cytologic variants of lymphoblasts are shown in (E–H). These include (E) lymphocyte-like blasts, (F) blasts with azurophilic granules, (G) blasts with “hand-mirror” morphology, and (H) blasts with vacuoles. The small lymphocyte-like blasts can be difficult to distinguish from chronic lymphocytic leukemia cells in the blood, making flow immunophenotyping important in the distinction. Lymphoblasts with granules can be misleading as they can be mistaken for myeloblast or monoblasts. The hand-mirror cells appear to be an artifact because they can be seen only focally on a smear. Vacuoles in the blasts can make the blasts difficult to distinguish from Burkitt cells (see also Fig. 66.7). However, flow cytometry can easily distinguish the immature ALL blasts from the mature B cells seen in a leukemic presentation of Burkitt lymphoma.

Fig. 66.2 MORPHOLOGIC FEATURES OF ACUTE LYMPHOBLASTIC LEUKEMIA IN THE BONE MARROW BIOPSY. (A) The findings in the bone marrow (BM) biopsy in acute lymphoblastic leukemia are varied, but frequently the biopsy is 100% cellular and packed with blasts. Sometimes there is some residual hematopoiesis with sparing of megakaryocytes as shown. (B) A high power of the lymphoblasts is shown, illustrating the fine, dispersed, and “blastic” chromatin pattern of the cells. Sometimes the BM can be hypocellular (not shown); however, the majority of the cells in such cases are blasts. (C) Sometimes there is necrosis. The necrotic cells are referred to as “ghost” cells. They may retain some of their antigen expression as identified by immunostains; however, if the entire biopsy shows necrosis, a diagnosis should be made from the findings in the blood or a repeat BM may be necessary. Other tumors can present with BM necrosis.

challenging or almost impossible. A repeat BM biopsy should be attempted and will usually provide diagnostic material. Some increase in reticulin fibrosis is present in 60% to 70% of ALL patients. When fibrosis is extensive, an aspirate cannot be obtained, limiting material available for ancillary studies such as flow cytometry and cytogenetics.

For these patients, the immunophenotyping can be performed by immunoperoxidase immunohistochemistry on the bone core biopsy. A second core can be obtained and submitted without fixation to the cytogenetic laboratory; evaluation can be performed from cells obtained from the disaggregation of the core.

Fig. 66.3 CYTOCHEMISTRY IN ACUTE LYMPHOBLASTIC LEUKEMIA. (A) The blasts in acute lymphoblastic leukemia are always myeloperoxidase reaction negative. (B) Compare the blasts with a single positively reactive granulocyte with a black–blue reaction product. Evaluating for nonspecific esterase reactivity (α -naphthyl acetate esterase, or α -naphthyl butyrate esterase) might also be performed when the blasts are difficult to distinguish from monoblasts.

Organs other than the BM can be frequently involved. Extramedullary or lymphomatous presentation is more common with T-acute lymphoblastic leukemia (T-ALL) than B-acute lymphoblastic leukemia (B-ALL). The cytomorphology of the malignant cells in extramedullary disease is similar to that described in the bone core biopsy. Lymph node involvement is usually diffuse but can be partial with sparing of the follicles.

CYTOCHEMISTRY

The use of cytochemistry to assign lineage has been largely replaced by flow cytometry evaluation of the leukemic blast immunophenotype. However, when available, the myeloperoxidase reaction (Fig. 66.3A and B) permits a rapid distinction from acute myeloid leukemia (AML). The reaction detects the myeloperoxidase enzyme in the primary granules of myeloblasts and is specific for the myeloid lineage. An acute leukemia in which 3% or more of the cells are myeloperoxidase positive is considered myeloid. There is excellent concordance between the myeloperoxidase reaction detected by cytochemistry and the myeloperoxidase molecule detected by flow cytometry. A block-like positivity has been described with the periodic acid-Schiff reaction that detects glycogen in almost 50% of ALL cases.

IMMUNOPHENOTYPE

Based on large cooperative group studies in Europe and the United States, the incidence of B-ALL ranges from 75% to 80% and T-ALL from 15% to 25%. B lymphoblasts cannot be distinguished from T lymphoblasts by morphology. Extensive immunophenotypic characterization is therefore required for the appropriate classification of ALL and indeed distinction from certain subtypes of AML. When adequate material is available, immunophenotyping should be performed using multicolor flow cytometry so that multiple antigens can be detected simultaneously on the lymphoblasts (Fig. 66.4). When interpreting the immunophenotypic data, it is important to remember that no single antigen is specific for any given lineage and multiple antigens need to be evaluated to establish the correct diagnosis. The panel of antibodies used for flow cytometry of a new leukemia and the pattern of expression seen in B-ALL and T-ALL are shown in Table 66.2. In addition, the combination of markers expressed on the

^aAntigens are listed approximately in order of frequency.

^bAlmost always positive.

^cMost specific for B lineage but can be positive in t(8;21) acute myeloid leukemia.

^dAltered expression provides leukemia associated phenotype crucial for detection of minimal residual disease.

^eRarely present.

^fOnly marker considered lineage specific.

^gFrequently coexpressed.

^hAlong with CD5¹⁰, CD1a⁺, CD8⁺, the expression of these antigens is helpful in identifying early T-cell precursor acute lymphoblastic leukemia. For prognostic significance, please refer to discussion in text.

B-ALL, B-acute lymphoblastic leukemia; c, cytoplasmic; s, surface; T-ALL, T-acute lymphoblastic leukemia.

B or T lymphoblasts can be reflective of the stage of development at which the transformation happened (Table 66.3). Of note, expression of myeloid antigens is seen frequently in B-ALL and T-ALL, as is the expression of T-cell antigens in B-ALL and B-cell antigens in T-ALL. Expression of individual myeloid antigens should not be a deterrent to making the diagnosis of ALL. Of particular significance is the subgroup of T-ALL that lack CD1a, CD8, and CD5 but show expression of one or more myeloid or stem cell markers and have been recently designated as *early T-cell precursor ALL*. While these leukemias can have a gene expression profile and spectrum of genetic mutations that overlaps significantly with biphenotypic leukemia, most recent studies suggest improved outcomes using T-ALL therapy. It is therefore best to recognize this type of ALL as a type of T-ALL rather than mixed lineage leukemia. The criteria for diagnosis of acute leukemias of ambiguous lineage, which would include mixed phenotype acute leukemia, have been extensively revised in the current WHO classification.

CYTOGENETICS AND MOLECULAR GENETICS

Chromosomal abnormalities can be detected in almost 80% of B-ALLs and 70% of T-ALLs. Cytogenetic classification remains the single most important prognostic factor in both pediatric and adult ALL. Numerical abnormalities as well as structural abnormalities that disrupt the function of transcription factors involved in hematopoietic development and differentiation are common. These genetic abnormalities define the biology of the disease and have an impact

Fig. 66.4 AN EXAMPLE OF FLOW CYTOMETRIC EVALUATION IN A CASE OF B-ACUTE LYMPHOBLASTIC LEUKEMIA. Selected histograms from a panel of markers used in the evaluation of acute lymphoblastic leukemia by flow cytometry are illustrated. The blasts are first identified by weak CD45 expression and low side scatter (*left histogram, circled population*). This is a useful gating strategy because it allows for an easy identification of the blast population and its separation from lymphocytes (with bright CD45) and nucleated red blood cells (with absent CD45 expression). Because no single antigen is specific for a lineage, multiple antigens are evaluated using multicolor flow cytometry. The phenotype illustrated is that of a common precursor B-acute lymphoblastic leukemia. In this case, the blasts are CD34⁺, HLA-DR⁺, TdT⁺, CD19⁺, CD10⁺, CD20⁻, cyCD79a⁺, κ^- , λ^- , and cyIgM⁻. There is weak and partial expression of the myeloid marker CD33.

on treatment outcome. In addition, specific cytogenetic or molecular abnormalities are associated with unique phenotypic characteristics and are amenable to targeted therapy. Although Ph⁺ ALL is the first subset of ALL to use a molecularly targeted TKI therapy as frontline treatment, it is likely that more genetically-defined entities will be targeted for specific therapy. This was recognized in the 2008 WHO classification with a specific discussion on lymphoblastic leukemia/lymphoma with recurrent cytogenetic abnormalities ([Table 66.4](#)).

The ongoing revision of the WHO classification will build upon the framework established in 2008 to incorporate subsequent discoveries on molecular genetics of ALL in order to potentially identify groups of ALL likely to benefit from specific targeted therapy (see discussion on [Philadelphia chromosome-like ALL \(Ph-like ALL\)](#) later).

Hyperdiploidy, defined by the presence of more than 50 chromosomes, is seen in almost 25% of pediatric patients and 4% to 5% of adult ALL patients. In addition to routine karyotyping or fluorescence

TABLE 66.4 Significant Features of B-Acute Lymphoblastic Leukemia With Recurrent Cytogenetic Abnormalities in the 2008 World Health Organization Classification

Cytogenetic Abnormality	Phenotype	Clinical Correlates	Incidence #
t(9;22)(q33;q11.2)	CD19 ⁺ , CD10 ⁺ , CD25 ⁺ ; frequent expression of myeloid antigens	Seen more frequently in adults; traditionally associated with extremely poor outcome; improved early event-free survival with targeted therapy	19% of all adult ALL patients; incidence increases with age
t(v;11q23) Common fusion partners include AF4 (4q21) and ENL (19p13)	CD19 ⁺ , CD10 ⁺ ; aberrant expression of myeloid antigen CD15	Frequent presentation with high WBC count, CNS involvement	9% of Ph ⁻ adult ALL
t(12;21)(p13;q22) Cryptic translocation; requires FISH	CD19 ⁺ , CD10 ⁺ ; aberrant expression of myeloid antigen CD13	Sensitive disease with favorable outcome on standard therapy	2% to 3% of Ph ⁻ adult ALL
Hyperdiploidy Chromosome number >50, <66 Extra copies of nonrandom chromosomes, most frequently 21,X,14, and 4	CD19 ⁺ , CD10 ⁺ ; no distinctive phenotype	Sensitive disease with favorable outcome on standard therapy	10% of Ph ⁻ adult ALL
Hypodiploidy Chromosome number <46	CD19 ⁺ , CD10 ⁺ ; no distinctive phenotype	Poor prognosis	4% of Ph ⁻ adult ALL
t(5;14)(q31;q32)	CD19 ⁺ , CD10 ⁺ ; no distinctive phenotype	Reactive eosinophilia driven by IL-3 overexpression driven by the translocation; blasts may be <20% in the BM and undetectable in peripheral blood	Rare in adults
t(1;19)(q23;p13.3)	CD19 ⁺ , CD10 ⁺ ; cytoplasmic μ^+	No significant association with response to therapy on current protocols	3% of Ph ⁻ adult ALL

ALL, Acute lymphoblastic leukemia; BM, bone marrow; CNS, central nervous system; FISH, fluorescent in situ hybridization; IL-3, interleukin-3; Ph, Philadelphia chromosome; WBC, white blood cell.

Data from Moorman AV, Harrison CJ, Buck GA, et al, Adult Leukaemia Working Party, Medical Research Council/National Cancer Research Institute: Karyotype is an independent prognostic factor in adult acute lymphoblastic leukemia (ALL): analysis of cytogenetic data from patients treated on the Medical Research Council (MRC) UKALLXII/Eastern Cooperative Oncology Group (ECOG) 2993 trial. *Blood* 109:3189, 2007; and Pui CH, Relling MV, Downing JR: Acute lymphoblastic leukemia. *N Engl J Med* 350:1535, 2004.

in situ hybridization (FISH) analysis, hyperdiploid DNA content can be determined by flow cytometry using DNA-binding fluorescent dyes and corresponds to a DNA content between 1.16 and 1.6. However, some studies have demonstrated that hyperdiploidy resulting from duplication of specific chromosomes (4, 10, and 17) is a better indicator of a favorable prognosis than the actual ploidy or the DNA content. Careful analysis of the specific pattern of chromosomal gains and losses or flow cytometry peaks for DNA content is required to distinguish true hyperdiploid cases from near-haploid cases that have undergone endoreplication (vide infra). In contrast to hyperdiploidy, a hypodiploid karyotype is associated with an adverse prognosis. Hypodiploid ALL with near-diploid chromosome numbers (44–45) is associated with somewhat distinct biology (loss of sex chromosome, dicentric chromosomes, presence of recurrent cytogenetic abnormalities such as ETV6-RUNX1) and is associated with a better outcome. In contrast, presence of hypodiploidy with chromosome numbers less than 44 is invariably associated with poor outcome. The most common chromosome complements within the hypodiploid group are near haploid (24–31 chromosomes) and low hypodiploid (32–39 chromosomes), and are both associated with a poor outcome. Of note, low-hypodiploid ALL is frequently associated with germline *TP53* mutations and at least in a subset of cases appears to be a manifestation of Li–Fraumeni syndrome. Both near-haploid and low-hypodiploid ALL have activation of phosphatidylinositol 3-kinase (PI3K)/mammalian target of rapamycin (mTOR) and MEK-ERK signaling that can potentially be targeted by PI3K inhibitors.

A structural abnormality seen commonly in the pediatric age group but extremely rarely in the adult age group is a cryptic translocation, the t(12;21)(p13;q22) (*ETV6-RUNX1*). When present, it is associated with a favorable prognosis. Leukemias that harbor rearrangements of the mixed-lineage leukemia (*MLL*) gene at chromosome 11q23, most notably t(4;11)(q21;q23), present with high WBC counts and frequent CNS involvement, and are associated with poor clinical outcomes. Ph⁺ ALL associated with t(9;22)(q34;q11.2) is seen

in 25% of adults diagnosed with ALL. The translocation results in *BCR-ABL1* fusion and the resulting leukemia has a poor outcome without the inclusion of TKIs into frontline treatment. Intrachromosomal amplification of chromosome 21 (iAMP21) is defined as a gain of at least three copies of regions of chromosome 21 that include *RUNX1*. The abnormality seen in 2% of B-ALL patients is associated with an older age at diagnosis and poor outcome with standard-risk therapy. iAMP21 is usually the sole cytogenetic abnormality but can be seen in patients with Ph-like ALL (see later). In addition, use of technology to assess copy number variation has identified submicroscopic genomic alterations that have significant impact on the biology of B-ALL. These involve transcription factors such as *IKZF1* (Ikaros), *EBF*, and *PAX5*. The role of these transcription factors in B-cell development and the biology of B-ALL are discussed in greater detail in Chapter 64.

One of the most critical and clinically relevant discoveries with respect to ALL has been the description of high-risk ALL with a gene expression profile similar to that of Ph⁺ ALL but without the *BCR-ABL1* fusion gene. This subtype of leukemia is referred to as *Ph-like ALL* and the kinase-activating alterations are a result of a diverse group of genetic lesions that result in dysregulated cytokine receptor and tyrosine kinase signaling. The lesions can be grouped into a surprisingly small number of broad categories. The most frequent category involves *CRLF2* rearrangements that account for almost 50% of Ph-like ALLs. The rearrangements involve either translocation of *IGH2* at locus on chromosome 14q32 to *CRLF2* on Xp22.3/Yp11.3 (pseudoautosomal region 1), or a 320-kb interstitial deletion centromeric of *CRLF2* resulting in *P2RY8-CRLF2* fusion. *CRLF2* overexpression is frequently associated with activating mutations of *JAK1/JAK2*, *IL7R*, or deletion of the JAK-STAT negative regulator *SH2B3*, resulting in activation of JAK-STAT signaling. JAK-STAT signaling activation also occurs in a second category of Ph-like ALL with *JAK2/EPOR* rearrangements. The third broad category of Ph-like ALL involves *ABL1*, *ABL2*, *CSF1R*, and *PDGRB*, described

Fig. 66.5 ALGORITHM TO EVALUATE FOR PHILADELPHIA CHROMOSOME-LIKE ACUTE LYMPHOBLASTIC LEUKEMIA. Initial evaluation includes standard karyotype analysis to exclude cases with *BCR-ABL1*, *MLL*, *TCF3-PBX1*, *ETV6-RUNX1* rearrangements. Flow cytometry for *CRLF2* can identify as many as 50% of Philadelphia chromosome-like (Ph-like) acute lymphoblastic leukemia. In the remaining cases FISH analysis can be used to identify recurrent rearrangements that contribute to a Ph-like gene expression profile. However, some cases will require additional analysis by next-generation sequencing. *B-ALL*, B-acute lymphoblastic leukemia; *FISH*, fluorescence in situ hybridization; (Modified from Roberts KG, Li Y, Payne-Turner D, et al: Targetable kinase-activating lesions in Ph-like acute lymphoblastic leukemia. *N Engl J Med* 371:1005, 2014.)

together as *ABL1* class rearrangements. In addition, other kinases such as *NTRK3*, *PTK2B*, and *TYK2* have also been shown to be involved in rearrangements in sporadic cases. As preclinical studies as well as case reports continue to document dramatic responses to targeted therapy for this group of patients, it is imperative that these lesions be identified prospectively. Because a wide variety of lesions result in a Ph-like phenotype, the laboratory diagnosis of Ph-like ALL remains a challenge. One approach to work-up of Ph-like ALL is highlighted in Fig. 66.5.

Similar to B-ALL, translocations involving transcription factors are common in T-ALL. The most commonly involved genes include *HOX11* and *HOX11L2*. Other genes that have been described to be involved in T-ALL are *MYC*, *TAL1*, *LMO2*, and *LYL1*. Similar to t(12;21), translocations involving the *TAL1* gene are cryptic and require detection by molecular techniques. Activating mutations of the *NOTCH1* gene are detected in almost 50% of ALL patients. Although activating mutations of *NOTCH1* appear to be associated with disease pathogenesis, they do not appear to be associated with an adverse prognosis in the majority of studies; in fact, some pediatric studies suggest that *NOTCH1*-mutated T-ALL may have a relatively favorable response to current treatment regimens. Deletions of the *CDKN2A* gene on chromosome 9p are also particularly frequent as are mutations in the *FBXW7* gene, but neither has clear prognostic significance as single abnormalities. The significance of these mutations remains an area of active research.

DIFFERENTIAL DIAGNOSIS

ALL blasts can be easily distinguished from the reactive lymphocytes seen in viral infections because of the precursor phenotype of these cells. Low to weak expression of CD45 and expression of one or more precursor antigens such as TdT or CD34 is useful. In addition, precursor T-ALL cells express only cytoplasmic CD3 and no surface CD3, and B-ALLs frequently lack expression of CD20 while being CD19 positive. As mentioned previously, ALL cells can have some

cytoplasmic vacuolation and need to be distinguished from leukemic presentation of Burkitt lymphoma (BL). Unlike ALL, BL cells are mature B cells with bright surface Ig expression, very strong CD20 expression, and no expression of CD34. Diagnosis of BL is confirmed by the presence of an *MYC* translocation using FISH or cytogenetics. Other entities that require distinction from ALL depend on the age of presentation. In the pediatric age group, ALL blasts need to be distinguished from hematogones. Hematogones are normal B-cell precursors present within the BM. These are more abundant in childhood and decrease with increasing age. Hematogones may also be increased during hematopoietic regeneration, particularly after chemotherapy or BM engraftment after stem cell transplant. Hematogones possess a distinct pattern of antigen expression that recapitulates progressive B-cell maturation. This is reflected in progressive loss of antigens such as CD34, TdT, and CD10 and acquisition of CD20 and surface Ig expression (Fig. 66.6). Other diseases that need to be morphologically distinguished from ALL include small blue cell tumors, including Ewing sarcoma, neuroblastoma, and medulloblastoma. Ancillary studies, including immunophenotyping and cytogenetics, are helpful in making the distinction. In older adults, entities that can morphologically mimic ALL include blastoid mantle cell lymphoma, chronic lymphocytic leukemia, and prolymphocytic leukemia. These latter are all mature B-cell malignancies that can be distinguished from ALL based on the mature B-cell phenotype, including consistent expression of CD20 and surface Igs.

PROGNOSIS

Prognostication based on clinical and biologic risk factors has been useful in making informed decisions about postremission treatment options. Established risk factors for a poor prognosis with current chemotherapeutic approaches include age older than 60 years, elevated WBC count at diagnosis (>30,000/ μ L for B-cell ALL; >100,000/ μ L for T-cell ALL), pro-B-cell or early T-cell immunophenotype, and cytogenetics (t(4;11)[q21;q23] and other *MLL* rearrangements, hypodiploidy, or a complex karyotype). The presence of the Philadelphia chromosome, t(9;22)(q34;q11.2) resulting in the *BCR-ABL* fusion gene, was previously associated with very poor treatment outcomes. Recent addition of ABL kinase inhibitors (molecularly targeted therapy), discussed in detail later, has improved the prognosis for these patients. Time to achievement of complete remission (CR) longer than 4 weeks has also been associated with a poor clinical outcome (Table 66.5).

Although different study groups have used slightly different variations of these risk factors, the presence of any one of the following is generally accepted as high risk (HR): high WBC count at diagnosis (>30,000/ μ L in B-cell ALL or >100,000/ μ L in T-cell ALL); cytogenetic abnormalities [hypodiploidy, t(4;11), t(9;22)]; age older than 60 years; pro-B-cell phenotype; and time to remission longer than 4 weeks. All other patients are considered standard risk (SR).

Nevertheless, despite being labeled as SR, up to 40% to 50% of these adults eventually relapse. Thus, there is a need for refinement of prognostic markers for ALL patients. Recently, an early T-cell phenotype, the expression of CD20⁺ and several recently described genetic mutations (*IKAROS*, *CRLF2*, and *JAK2*; reviewed earlier in this chapter) have been identified as being associated with adverse outcomes from retrospective analyses.

MINIMAL RESIDUAL DISEASE

The identification and measurement of MRD (below the level of morphologic disease detection) using leukemia clone-specific quantitative polymerase chain reaction (PCR) and flow cytometry is an independent prognostic factor that is now being used to guide postremission therapies in many pediatric and some adult ALL treatment studies. In a study that directly compared MRD detection by PCR and flow cytometry in 1375 samples from 227 patients, the results were consistent in 97% of cases. In general, these techniques have

Fig. 66.6 HEMATOGENES AND FLOW CYTOMETRIC EVALUATION OF MINIMAL RESIDUAL DISEASE. Hematogones are nonmalignant immature precursor B cells that are present in the bone marrow (BM). They are more commonly seen in pediatric patients but can be seen in adults during BM regeneration or associated with other conditions. (A) They can be difficult to distinguish morphologically from malignant lymphoblasts because the cytologic features overlap significantly. (B) Unlike malignant lymphoblasts, hematogones exhibit a spectrum of maturation that can be seen, for example, by analyzing CD10 and CD20 expression on CD19⁺ cells (*left histogram*). Hematogones are CD10⁺, but as CD20 is expressed, CD10 is diminished. Lymphoblasts, on the other hand, frequently exhibit maturation arrest and over- or underexpression of markers. They can also exhibit aberrant markers. In the *middle histogram*, the B lymphoblasts from the initial diagnosis specimen can be seen (*red*), and the CD10 and CD20 expression is outside the normal hematogone range, with overexpression of CD10 and absence of CD20. This pattern can be used to identify minimal residual disease (*right histogram*) and distinguish regenerative hematogones (*black*) from residual or recurrent blasts (*red*) after therapy. Multiple markers and parameters are usually used to study posttherapy specimens in this way. *B-ALL*, B-acute lymphoblastic leukemia.

TABLE 66.5 Markers for Poor Prognosis in Adult Acute Lymphoblastic Leukemia

Established Risk Factors	
Age	>60 years
Presenting WBC count	>30,000/ μ L (B-cell ALL); >100,000/ μ L (T-cell ALL)
Immunophenotype	Pro-B cell; early T cell ^a
Cytogenetics	t(4;11)(q21;q23) and other <i>MLL</i> rearrangements t(9;22)(q34;q11.2) – Philadelphia chromosome Hypodiploidy (<44 chromosomes) Complex (>5 abnormalities)
Therapy response	Time to complete remission >4 weeks
MRD	$\geq 0.01\%$ at 3–6 months after initiation of therapy ^b
Emerging Risk Factors	
Immunophenotype	CD20
Molecular	BAALC FUS ERG IKZF1 ^c Ph-like ALL

^aInitial report characterizing ETP ALL showed a poor outcome. However, subsequent studies have shown variable association with response to therapy.

^bDifferent studies have used different time points for MRD assessment.

^cFocal deletions in IKZF1 are present in up to 70% of Ph-like ALL. However, IKZF1 deletions are associated with adverse outcome irrespective of association with Ph-like phenotype.

ALL, Acute lymphoblastic leukemia; ETP, early T-cell precursor; MRD, minimal residual disease; Ph, Philadelphia chromosome; WBC, white blood cell.

not yet been widely standardized; however, the majority of studies demonstrate that MRD detection during early postremission therapy is a reliable and independent predictor of relapse. Recently, pediatric studies have confirmed that achieving lower levels of MRD also have prognostic significance, with rates of relapse being higher in those with MRD greater than 0.01% by PCR (calculated using a ratio of the clone-specific IgH or T-cell receptor gene rearrangement/control gene such as glyceraldehyde 3-phosphate dehydrogenase) compared to those with MRD of less than 0.01%. The optimal time point for outcome prognostication based on MRD measurements varies from study to study; undoubtedly, some of this variability is the result of differences in the PCR technique used, the sensitivity of detection of MRD of the individual assay, the treatment intensity, and the population being studied. While MRD assessment after induction has been the primary time point for prognostication and allocation of risk-adapted postremission therapy in pediatric ALL (and to a lesser degree in adults), more recent data suggest that additional MRD assessments during postremission therapy at weeks 16–22 can further refine prognostic information and help to delineate further therapy. In a study of 142 adult ALL patients, those with MRD greater than 0.01% after consolidation were eligible for transplant and those with MRD less than 0.01% received maintenance therapy. The 5-year overall survival (OS) rate was significantly higher for patients with MRD less than 0.01% or negative status postconsolidation (75% versus 33%). A subsequent GMALL study incorporated autologous hematopoietic stem cell transplant (aHSCT) for all patients with molecular disease after consolidation. For patients that remained MRD positive after consolidation, the subgroup who underwent aHSCT achieved significantly higher rates of CR at 5 years (66% versus 12%), and this trended towards higher rates of OS (54% versus 33%) compared with those that did not undergo aHSCT. Based on these findings, the majority of studies indicate that MRD detection anywhere from 4–20 weeks from initiation of treatment is highly predictive of relapse. Thus current studies are using novel approaches to try to eradicate MRD during early remission or stratifying

MRD-positive patients to early intensification with aSCT to try to improve survival for these patients at very HR for relapse. Recent data from the ALL-SCT-BFM 2003 study showed that MRD can also be reliably assessed after aHSCT as a predictor for relapse. Further data from these studies will help elucidate the optimal timing of MRD assessments and the appropriate management response.

TREATMENT OF ACUTE LYMPHOBLASTIC LEUKEMIA

Combination chemotherapy is the cornerstone of ALL management. In the 1960s, investigators at the National Institutes of Health designed multidrug chemotherapy regimens given over many different courses for pediatric ALL patients. A similar approach was then introduced for adults with ALL. The Berlin–Frankfurt–Muenster (BFM) group in the 1980s conducted pioneering studies and showed that an intensive multidrug induction and consolidation chemotherapy followed by delayed intensification led to improvement in survival in the majority of children. These regimens combine drugs with varying mechanisms of action at different doses, often in complex schedules, which have largely evolved empirically. Only a few of these drugs have been tested individually in randomized clinical trials in adults with ALL; therefore, the relative contribution of each of the drugs in a multidrug regimen to the overall outcome is difficult to assess. Because there is an increased propensity for CNS involvement in ALL patients, all treatment regimens must also include CNS prophylaxis with intrathecal chemotherapy with or without cranial radiation.

The therapy for ALL is typically divided into three phases: (1) the remission induction phase, (2) remission consolidation or intensification, and (3) the maintenance (or continuation) phase. The remission induction and consolidation phases typically involve blocks of monthly treatment for 6–8 months followed by long-term maintenance, which is given for up to 3 years; thus the treatment of ALL is long and challenging, and requires tremendous attention to detail, compliance, and support. Because of these challenges and the relative rarity and biologic heterogeneity of the disease, it is recommended that patients are referred to larger academic centers for evaluation and treatment to ensure the best possible survival rates. In the ensuing sections, the various components of treatment are reviewed. Special attention to the treatment of certain disease subsets are addressed because treatment of ALL is becoming increasingly based on its heterogeneity and the ability to adapt therapy to each of these subsets.

Effective chemotherapy regimens must be supplemented with adequate supportive care measures to obtain the best patient outcomes. Given the highly immunosuppressive nature of ALL treatment regimens, prophylaxis for *Pneumocystis carinii* with trimethoprim-sulfamethoxazole should be initiated early during treatment and continue throughout the consolidation and maintenance phases of chemotherapy. It is also reasonable to consider antifungal and antiviral prophylaxis during periods of neutropenia. Consideration may be given to antibacterial prophylaxis during periods of neutropenia. Fluoroquinolones such as levofloxacin are the preferred agent, although the optimal antibiotic choice should depend on local bacterial resistance patterns. Neutropenic fever in this group of patients must be treated as a medical emergency with immediate institution of intravenous (IV) antibiotics after obtaining the necessary cultures.

In an attempt to decrease the duration of neutropenia and improve remission rates, several groups have studied the role of granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF) during induction therapy. In the CALGB 9111 trial, 198 adults with untreated ALL were randomized to receive G-CSF (beginning 4 days after the start of induction until neutrophil recovery) versus placebo. The median time to neutrophil recovery ($\geq 1000/\mu\text{L}$ for 2 days) significantly shortened to 16 days in the G-CSF arm compared with 22 days in the placebo arm. The duration of hospitalization was also significantly shorter in the G-CSF arm. There was a trend toward increased CR rate in the G-CSF arm. However, the infectious complications, disease-free

survival (DFS), and OS were similar in the two arms. Thomas and colleagues randomized 236 ALL patients treated on the LALA-94 trial to receive G-CSF, GM-CSF, or no CSF. Use of G-CSF was associated with a significant decrease in time to neutrophil recovery, duration of hospitalization, and infections that were grade 3 or higher. Thus use of G-CSF can allow for faster hematopoietic recovery, especially in older adult patients, and may decrease infectious complications; however, the prophylactic use of G-CSF has not been uniformly adopted, and many studies simply follow standard guidelines for use of growth factors in the setting of neutropenic fever.

All patients should be monitored carefully for tumor lysis syndromes, especially those with risk factors such as elevated WBC counts, renal dysfunction, and elevated LDH at presentation. Patients must be provided adequate hydration and prophylaxis or treatment for hyperuricemia with allopurinol for the first week of induction. Rasburicase, a urate oxidase, can be considered for the treatment of hyperuricemia in cases with high proliferation rates.

REMISSION INDUCTION

The aim of induction therapy is to achieve maximal reduction of the leukemic burden to result in morphologic remission ($<5\%$ blasts with trilineage hematopoiesis) and normalization of the blood counts, with as little toxicity as possible. This is typically achieved using combination chemotherapy consisting of four or five systemically administered drugs and intrathecal chemotherapy over a period of approximately 3–4 weeks. Most current ALL induction regimens in adults are modeled after pediatric regimens, and include a prolonged course of oral corticosteroid (prednisone or dexamethasone), weekly vincristine, and either weekly or pulsed anthracycline (doxorubicin, daunorubicin, or mitoxantrone). Many groups (CALGB, French Group for Research in Adult Acute Lymphoblastic Leukemia [GRAALL] 2003, and BFM) have also used twice-weekly L-asparaginase as part of induction therapy and some have added cyclophosphamide (MD Anderson, GRAALL 2003, and GMALL 07/2003, CALGB 8811, and CALGB 19802). With the current treatment regimens, very high CR rates in adults with ALL have been achieved in the range of 84% to 94% (Table 66.6). There have been few randomized comparisons between these different induction regimens; therefore the choice of the regimen should depend on the treating physician's experience with a particular regimen. Most ALL regimens are designed to optimally deliver a variety of chemotherapeutic agents; thus an entire treatment program should be selected at the time of diagnosis based on the patient's performance status and biologic risk factors. Whenever possible, these patients should be referred to centers that offer expertise in the treatment of ALL and where enrollment into clinical trials is available. Once a specific regimen has been selected, the goal (and challenge) is for both the medical team and the patient to adhere to the recommended treatments, which are arduous and lengthy in duration.

Traditionally, prednisone was the corticosteroid of choice during induction therapy for ALL trials. Studies in pediatric patients have shown lower relapse rates but higher toxicity (more sepsis, higher incidence of osteonecrosis) with dexamethasone. Dexamethasone penetrates the blood–brain barrier effectively and therefore may offer more direct CNS protection than prednisone. Comparative studies of prednisone versus dexamethasone have not been performed in adults, and some groups have incorporated prednisone (CALGB 10403, GRAALL 2003, and BFM); others have incorporated dexamethasone (CALGB 10102, MD Anderson, and GMALL 07/2003) during the induction cycle. Anthracyclines form an important part of induction therapy. In an early trial from the CALGB (7612), patients were randomized to receive vincristine, prednisone, and L-asparaginase with or without daunorubicin. Significant improvements in CR rates and remission duration were noted with the addition of daunorubicin; anthracyclines have since become standard components of induction chemotherapy in adult and pediatric ALL. Different anthracyclines (doxorubicin, daunorubicin, and mitoxantrone) are thought to be clinically equivalent and, to date, dose

TABLE 66.6**Clinical Trials With Various Chemotherapy Regimens for Adult Acute Lymphoblastic Leukemia**

Trial	Patients (<i>n</i>)	Age in Years, Median (Range)	CR Rate (%)	Disease-Free Survival	Overall Survival	Comments
CALGB 8811 ¹	197	32 (16–80)	85	46% at 3 years	36 months (median)	Five-drug induction regimen based on pediatric trials with earlier and more intensive L-asparaginase
CALGB 9111 ²	198	35 (16–83)	85	40% at 3 years	23 months (median)	Patients randomized to G-CSF vs. placebo; G-CSF significantly decreased time to neutrophil recovery and CR rate with no effect on DFS, OS, or toxicities
MDACC hyper-CVAD ³	288	40 (15–92)	92	38% at 5 years	32 months (median)	Long-term follow-up results of hyper-CVAD regimen; regimen does not include asparaginase
GMALL 05/93 ⁴	1163	35 (15–65)	83		35% at 5 years	
GMALL 07/2003 ⁵	713	34 (15–55)	89		54% at 5 years	Risk-adapted SCT for HR and very HR groups
LALA 94 ⁶	922	33 (18–79)	84	30% at 5 years	23 months (median)	CR rate similar between IDA and DNR arms; significantly higher TRM with IDA; improved DFS for the IDA arm for patients receiving only chemotherapy; for SR patients, intensive consolidation did not affect outcomes
JALSG ALL-93 ⁷	263	31 (15–59)	78	30% at 6 years	33% at 6 years	Doxorubicin dose intensity did not improve outcomes; during maintenance phase, early sequential intensification compared with intermittent intensification did not affect DFS
JALSG ALL-97 ⁸	404	38 (15–64)	74	33% at 5 years	32% at 5 years	Induction and maintenance based on CALGB 8811; dose-intensive doxorubicin during consolidation did not improve outcomes
GIMEMA 0288 ⁹	778	28 (12–60)	82	33% at 9 years	29% at 9 years	Addition of cyclophosphamide to induction did not influence CR rate or survival; responders to prednisone pretreatment had favorable outcomes
MRC UKALLXII/ECOG E2993 ¹⁰	1646 (Ph ⁻)	(15–64)	90		43% at 5 years	Largest ALL trial to date; in a donor vs. no-donor analysis, those with a donor had improved OS and lower relapse rate; ASCT cannot replace consolidation or maintenance chemotherapy in any risk group
PETHEMA ALL-93 ¹¹	222 high-risk ALL	27 (15–50)	82	35% at 5 years	34% at 5 years	Did not show beneficial effect of aSCT compared with ASCT or chemotherapy
GRAALL-2003 ¹²	225 Ph ⁻ ALL	31 (15–60)	94	59% at 3.5 years	60% at 3.5 years	Pediatric-inspired treatment regimen; in a historical comparison, significant increases in CR, EFS, and OS rates compared with LALA-94 trial; OS was improved for patients younger than 45 years only

ALL, Acute lymphoblastic leukemia; aSCT, allogeneic stem cell transplantation; ASCT, autologous stem cell transplantation; CALGB, Cancer And Leukemia Group B; CR, complete remission; CVAD, cyclophosphamide, vincristine, adriamycin, and dexamethasone; DFS, disease-free survival; DNR, daunorubicin; G-CSF, granulocyte colony-stimulating factor; HR, high risk; IDA, idarubicin; OS, overall survival; Ph, philadelphia chromosome; SCT, stem cell transplantation; SR, standard risk; TRM, transplant-related mortality.

intensification of anthracycline during induction has been tested in a variety of prospective clinical trials but has not been shown to definitely improve already high CR rates or to result in significant benefits in DFS. Addition of pulsed cyclophosphamide to induction chemotherapy has been studied with conflicting results. In the CALGB 8811 trial, addition of cyclophosphamide to the induction regimen was shown to lead to improved responses compared with historical control participants. However, in a prospective, randomized Italian GIMEMA 0288 study, the addition of cyclophosphamide did not influence CR rate or survival.

L-asparaginase (asparaginase) is also an important component of ALL therapy and has been incorporated into most ALL trials beginning with induction. ALL cells are unable to produce asparagine and are dependent on plasma levels of this amino acid for protein synthesis. Depletion of asparagine results in inhibition of protein synthesis and subsequent apoptotic leukemic cell death. Traditionally, native enzyme derived from *Escherichia coli* has been used. However, this preparation can be immunogenic, leading to hypersensitivity reactions and development of cross-reacting antibodies; this preparation, while still used elsewhere, is no longer available for administration in the United States. Polyethylene glycosylated (PEG)–asparaginase, formed by covalently attaching PEG to the native *E. coli* enzyme, has been developed and offers lower immunogenicity and a longer half-life. Douer and colleagues treated 25 newly diagnosed adult ALL patients (median age: 27 years; range: 17–55 years) with the adult ALL BFM protocol in which 14 injections of *E. coli* asparaginase were replaced by a single dose of pegaspargase (2000 IU/m² IV) on day 16 of induction therapy. After the single dose, asparagine deamination was complete in all patients after 2 hours and in 100%, 81%, and 44% on days 14, 21, and 28, respectively. No allergic reactions or pancreatitis was observed, and a CR was achieved in 24 of the 25 patients. The CALGB 9511 trial used pegaspargase (2000 IU/m² subcutaneously, two doses during induction and two during first intensification) as part of the five-drug induction regimen. Of the 85 evaluable patients, those with effective asparagine depletion (defined by enzyme levels >0.03 U/mL plasma for 14 consecutive days after pegaspargase administration) had improved DFS and OS compared with those without effective asparagine depletion. Thus, use of pegaspargase is generally safe and effective in adults, and has replaced native L-asparaginase as the agent for asparagine depletion. In 2011 the Food and Drug Administration (FDA) approved Erwinase (asparaginase *Erwinia chrysanthemi*) to treat ALL patients who develop a hypersensitivity reaction to *E. coli*-derived asparaginase and pegaspargase. 25,000 u/m² of erwinia asparaginase given every 48 hours for six doses (for every one dose of pegaspargase) has demonstrated safety and results in effective asparagine depletion in pediatric ALL. Patients receiving *Erwinia* asparaginase are still at risk for known toxicities of asparaginase, including bleeding, clotting, transaminitis, and pancreatitis. To avoid systemic toxicities, a novel preparation of L-asparaginase in which L-asparaginase is encapsulated within red blood cells (GRASPA [erythrocytes encapsulating L-asparaginase]) has been developed and is in early clinical development in Europe.

One of the regimens that is widely used in the United States and that also results in high CR rates of approximately 90% is the hyper-CVAD (cyclophosphamide, vincristine, adriamycin, and dexamethasone) regimen developed at the MD Anderson Cancer Center. The hyper-CVAD regimen differs from the pulsed weekly therapy developed by the pediatric groups and consists of four cycles of intensive infusional cyclophosphamide, vincristine, doxorubicin, and dexamethasone alternating with four cycles of high-dose methotrexate and high-dose cytarabine for a total of eight intensive treatment cycles.

Because CD20 is expressed on 20% to 40% of pre-B lymphoblasts and has been noted to be associated with adverse prognosis, the investigators at MD Anderson subsequently added rituximab to a modified hyper-CVAD regimen for patients with CD20 expression greater than or equal to 20%. In younger patients (≤60 years of age), rituximab improved 3-year OS to 75% compared with 47% in the historical control participants; however, no difference was seen for older adults. The GMALL has substantiated these results and rituximab is now routinely used with these regimens.

Some groups have also instituted a 5–7-day steroid prophase before starting the induction therapy. This results in gentle cyto-reduction and reduces the risk of tumor lysis. The achievement of rapid cytoreduction during this steroid prophase has also been shown to be of prognostic value in several studies.

In summary, although all of the currently employed induction regimens in adults with ALL now routinely result in very high CR rates of 80% to 90%, none of them has yet translated into the 80% to 85% DFS rates that are routinely achieved in pediatric ALL. In adult ALL, DFS generally has been reported to be at 40% to 45% at 3 years and 30% to 35% at 5 years (see Table 66.6). Thus the main problem with the current treatment programs in adult ALL is disease relapse from the emergence of resistant disease and not in the failure to achieve CR.

POSTREMISSION THERAPY

As mentioned earlier, 80% to 90% of adults with previously untreated ALL achieve CR with induction chemotherapy. However, all patients relapse if no further chemotherapy is given. This underscores the need for effective postremission management strategies for these patients in first CR (CR1). As described earlier, adult patients with ALL have traditionally been stratified into SR or HR.

The type of recommended postremission strategy is to be based on the risk (risk-adapted approach), which implies more aggressive therapeutic approaches for HR groups compared with the SR group. There have been three tested approaches for postremission therapies: (1) postremission chemotherapy modules followed by long-term maintenance chemotherapy; (2) alloSCT; and least frequently, (3) autologous stem cell transplantation (ASCT). Studies using these postremission strategies are reviewed later.

The optimal postremission strategy for SR adult patients is not clear. Conventionally, consolidation and maintenance chemotherapy has been the recommendation for this group of patients, given lower potential for toxicities and up to 40% to 60% survival at 5 years with this approach. Postremission chemotherapy typically consists of a variety of non-cross-resistant chemotherapeutic agents administered in treatment “modules” for a total of 6–8 months after achievement of remission. The postremission modules are typically 4–6 weeks in length and are modeled after successful pediatric regimens and often consist of consolidation module(s), interim maintenance modules that often focus on CNS prophylaxis (described in more detail below), and a late intensification module(s), which is often quite similar to the induction chemotherapy course. The specific drugs and the sequence or combinations in which they used are different for each protocol but typically include cyclophosphamide, L-asparaginase (or pegaspargase), methotrexate, cytarabine, 6-mercaptopurine, vincristine, and doxorubicin. Many of these protocols have evolved empirically with few randomized trials evaluating the impact of any of the modifications that have been developed (see Table 66.6).

A different approach to postremission therapy has been taken by the MD Anderson Cancer Center, which have reported long-term results of the hyper-CVAD regimen (also listed in Table 66.6). As described earlier in the induction section, patients received alternating cycles of hyperfractionated cyclophosphamide, vincristine, adriamycin, and dexamethasone hyper-CVAD (courses 1, 3, 5, and 7) alternating with high-dose methotrexate and cytarabine (courses 2, 4, 6, and 8) followed by maintenance therapy for 2 years with 6-mercaptopurine, methotrexate, vincristine, and prednisone (POMP). They identified the following factors to be independent poor prognostic factors for survival: older age, Ph⁺ disease, leukocytosis, thrombocytopenia, poor performance status, and hepatomegaly. The 5-year OS for the good-risk (risk score: 0–1), intermediate risk (risk score: 2–3), and poor-risk groups (risk score: ≥4) were 62%, 34%, and 5%, respectively.

In summary, despite attempts to intensify postremission therapy with high doses of cytarabine and anthracycline, the OS rate of patients in all of the studies published in the past decade is

Fig. 66.7 CEREbroSPINAL FLUID AND CENTRAL NERVOUS SYSTEM DISEASE. Blasts in the cerebrospinal fluid can be identified on a cytospin preparation. (A) They have similar cytologic features as the blasts in the blood or bone marrow aspirate. Histologic section of the brain is illustrated from a patient with acute lymphoblastic leukemia and leukemic meningitis. (B) The sections show blasts within the leptomeninges (higher power, C).

approximately 30% to 50%, depending on risk factors and treatment approach. Notably, adults older than the age of 60 years have uniformly fared poorly with an OS below 10%. Table 66.6 summarizes the major treatment questions, therapeutic approach, and results of several of the recent large prospective cooperative group trials in the United States and Europe.

CENTRAL NERVOUS SYSTEM DISEASE: PROPHYLAXIS AND TREATMENT

Involvement of the CNS (Fig. 66.7) is uncommon at the time of diagnosis, with most series reporting it at less than 10%. However, because many patients with CNS involvement may not be referred for clinical trial enrollment, this may be an underestimate of the true rate. In the MRC UKALL XII/ECOG E2993 trial, of the 1508 eligible patients, 77 (5%) had CNS involvement at diagnosis. Similarly, the French group reported a 7% (104 out of 1493 patients) incidence of CNS disease at diagnosis. Risk factors for CNS disease at diagnosis have varied in different studies. In the French trial (LALA-87 and LALA-94), risk factors included mediastinal mass associated with precursor T-cell immunophenotype, lymphadenopathy, higher hemoglobin level, and absence of the Philadelphia chromosome. In the MRC trial, the risk factors included a higher WBC count, precursor T-cell immunophenotype, and mediastinal mass. The presence of CNS disease at diagnosis has been shown not to affect the CR rate. The French group also reported no significant difference in the OS in patients with and without CNS disease at diagnosis. However, in the MRC trial, the OS at 5 years was lower in the CNS disease group (29% versus 38%; $p = .03$), and they also reported that patients with CNS disease at diagnosis were twice as likely to relapse in the CNS. In the French study, younger age (<30 years), male gender, absence of the Ph chromosome, achievement of CR with one course, and use of transplant as postremission therapy had favorable impact on OS for patients presenting with CNS disease at diagnosis.

Induction therapy of ALL usually includes lumbar punctures with introduction of intrathecal chemotherapy during the first weeks of therapy. For those presenting with CNS disease at diagnosis or in whom CNS disease develops later in the course of the treatment, immediate intensified CNS treatment is imperative. These patients should receive intrathecal chemotherapy (intrathecal methotrexate alone or together with cytarabine and steroid [triple intrathecal therapy]) twice weekly until clearing of cerebrospinal fluid along with initiation of systemic chemotherapy. Cranial irradiation (1800 cGy given in 10 daily fractions of 180 cGy per fraction) is considered necessary for the successful treatment of CNS disease with cranial nerve involvement.

CNS prophylaxis is an essential component of therapy for all patients given the high incidence (30% to 40%) of CNS relapse if

the CNS prophylaxis is omitted. Now with the universal adoption of CNS prophylaxis in the treatment regimens, the rates of CNS relapse have decreased substantially. CNS prophylaxis is typically administered by multiple rounds of intrathecal chemotherapy that are staggered over the entire treatment duration. In addition, the use of high-dose methotrexate and cytarabine also provides for CNS prophylaxis because both agents penetrate the blood–brain barrier. The intensive use of high-dose systemic methotrexate and frequent intrathecal therapy has often replaced the more traditional combination of CNS irradiation and intrathecal therapy that were the hallmarks of the earlier ALL regimens. This non–radiation-containing approach has resulted in effective CNS protection, with rates of CNS relapse now routinely reported as occurring in fewer than 5% to 10% of cases. Adolescents and young adults (AYAs) treated on pediatric regimens with more intensive CNS prophylaxis have reported CNS relapse rates as low as 1%. The omission of cranial irradiation may prevent neurocognitive damage in adults. Although this has not been demonstrated in adult studies, definitive evidence from pediatric studies indicates that avoidance of cranial irradiation may prevent declines in cognitive function.

MAINTENANCE THERAPY

The goal of maintenance treatment is to prevent disease relapse by elimination of leukemia clones by long-term exposure to cytotoxic drugs. One of the commonly used regimens uses daily 6-mercaptopurine and weekly oral methotrexate with monthly vincristine and prednisone (POMP regimen). Some groups replaced prednisone with dexamethasone. The duration of maintenance treatment is generally 2–3 years (2 years for women and 3 years for men). Similar to the other components of adult ALL regimens, the adoption of long-term maintenance therapy is based upon the benefit of maintenance therapy that has been demonstrated in pediatric trials.

Although the benefit of maintenance therapy in adult trials has not been demonstrated in randomized trials, it has been shown that omission of maintenance treatment leads to worse clinical outcomes. In a CALGB study, 164 newly diagnosed ALL patients were randomized to receive daunorubicin or mitoxantrone during induction followed by four cycles of consolidation. No maintenance therapy was planned. There were significantly more relapses noted in this study, with median remission duration of only 10–12 months. The study was stopped earlier than planned because remission duration was shorter than in historical control participants who had received maintenance therapy. Similar results were obtained by the Dutch–Belgian Haemato-Oncology Cooperative Group (HOVON), which treated 130 ALL patients with induction followed by three cycles of consolidation. No maintenance therapy was given. The estimated 5-year OS and DFS were only 22% and 28%, respectively. Pediatric

regimens routinely incorporate CNS prophylaxis during the maintenance phase. Pediatric studies have also reported favorable impact on DFS of achieving adequate myelosuppression with the chemotherapy drugs during the maintenance phase. Thus, it appears that careful adjustment of the doses of the oral agents used during maintenance therapy to achieve optimal yet safe myelosuppression improves treatment outcomes.

ALLOGENEIC STEM CELL TRANSPLANT IN FIRST COMPLETE REMISSION

Despite attempts to improve DFS in adult ALL, OS with the standard chemotherapy regimens described earlier has been “fixed” at about 35% to 45% for the past decade. Thus, several groups have evaluated the role of treatment intensification with transplant (both aSCT and ASCT) as postremission therapy and compared the outcomes with the traditional chemotherapy approaches described previously. Conventionally, an aSCT has been reserved as the standard recommendation for only HR patients in CR1. In one of the earliest randomized trials to investigate the role of allogeneic transplant, the French LALA-87 study, patients in CR1 were assigned to a donor group (if they had an HLA-matched related donor); the remaining patients (no-donor group) were randomized to ASCT versus chemotherapy. In this study, patients with HR ALL (defined as the presence of Philadelphia chromosome, or null leukemia [defined by a CD10, CD20-immunophenotype], undifferentiated leukemia, or common leukemia with at least one adverse prognosis factor such as age older than 35 years, WBC count greater than 30,000/ μ L, or time to CR longer than 4 weeks) benefitted from aSCT. For the HR group, 5-year OS was 44% in the donor arm ($n = 41$), which was significantly better than the 20% in the no-donor arm ($n = 55$; $p = .03$). The outcome of the SR group was not improved with aSCT (5-year OS of 51% in the donor arm versus 45% in the no-donor arm). Similar results were seen in a follow-up of LALA-94 trials with benefit of aSCT in the HR group. In contrast, the Program Español de Tratamiento en (PETHEMA) ALL-93 trial failed to show benefit of aSCT in HR ALL patients.

In the MRC UKALLXII/ECOG E2993 trial, all patients (age <50 years or <55 years after 2003) in CR1, irrespective of risk status, were assigned to aSCT if they had an HLA-compatible sibling donor. All other patients were randomized to consolidation or maintenance therapy, or to an ASCT. In this largest adult ALL trial to date, 1646 Ph-negative patients were enrolled; 1484 (90%) achieved CR1. After excluding patients who were older than 55 years of age and those without available HLA-typed siblings, 1031 CR1 patients (55% SR; 45% HR) were HLA typed. In a “genetic randomization” approach using donor ($n = 443$) versus no-donor ($n = 588$) analysis, OS benefit was seen for the donor arm when all patients were considered (5-year OS, 53% versus 45%; $p = .01$). In a subgroup analysis, the survival benefit of transplant was restricted to patients who were younger than 35 years of age. For patients older than 35 years of age or with adverse cytogenetics, OS was not better than with standard chemotherapy because of transplant-related toxicities, which resulted in early deaths.

In a report by the Dutch–Belgian HOVON group, patients younger than 50–55 years in CR1 were offered an aSCT. In a donor ($n = 96$) versus no-donor ($n = 161$) analysis for all patients, 5-year OS was 61% for the donor arm compared with 47% in the no-donor arm ($p = .08$). In subset analysis, the survival benefit of transplant was restricted to SR patients, which were those without any of the following HR features: presence of a high WBC count at diagnosis (>30,000/ μ L in B-ALL or >100,000/ μ L in T-ALL), cytogenetic abnormalities (t[4;11], t[1;19], t[9;22]), pro-B-cell immunophenotype, and CR achievement longer than 4 weeks from start of induction.

A meta-analysis of seven studies (with 1274 patients) that prospectively assessed OS using genetic randomization based on donor availability reported significantly better OS in the donor group versus the no-donor groups (hazard ratio: 1.29; $p = .037$), which was more pronounced in patients with HR features.

Alternative Stem Cell Sources; Alternative Preparative Regimens for Allogeneic Stem Cell Transplantation

Matched sibling donors (MSDs) remain the preferred modality for the stem cell source (Table 66.7). For patients lacking an MSD, a matched unrelated donor (MUD) or an alternative donor source (e.g., umbilical cord blood [UCB]) should be pursued. In a Center for International Blood and Marrow Transplant Research (CIBMTR) registry study, outcomes of 169 patients with ALL in CR1 who underwent unrelated donor (URD) transplants between 1995 and 2004 were analyzed. A total of 41% were HLA well matched, 41% partially HLA matched, and 18% HLA mismatched. The majority (93%) of the patients had at least one HR feature. One-year transplant-related mortality (TRM) was high at 36%, and TRM at 5 years was 42%. The relapse rate at 5 years was 20%, with 5-year DFS and OS of 38% and 39%, respectively. Factors associated with worse survival included WBC greater than 100×10^9 /L, time to CR1 longer than 8 weeks, cytomegalovirus seropositivity, HLA mismatching, and T-cell depletion. The Minnesota group recently reported outcomes of myeloablative aSCT for ALL patients transplanted at their center and compared retrospectively the outcomes with respect to different donor sources. In an analysis restricted to 91 adult patients who received aSCT in CR1 or CR2 from 1990 to 2005, there was no difference between the allogeneic donor sources (matched related donor versus matched URD versus UCB donor) for OS, DFS, or TRM. Similarly, in the ALL-SCT-BFM 2003 study of children and adolescents, no difference was observed between matched related donor sources and at least 9 out of 10 MUD sources.

Because the majority of older adults are not candidates for a myeloablative aSCT, reduced-intensity conditioning (RIC) approaches have been explored in this patient population (Table 66.8). The Seattle group recently reported outcomes of aSCT using nonmyeloablative conditioning in 51 patients with ALL (median age: 56 years), half of whom were Ph positive. For the Ph-negative group, the 3-year OS for those transplanted in CR1 was 52%. The incidence of chronic graft-versus-host disease, however, was high at 44%. A recent registry study examined the efficacy of RIC in 93 ALL patients and compared it with 1428 ALL patients receiving myeloablative conditioning for aSCT using either a sibling or unrelated donor in CR1/CR2. Interestingly, the TRM at 3 years was similar between the RIC and myeloablative regimens (32% versus 33%, respectively). The relapse rate at 3 years was slightly higher in the RIC arm, although this was not statistically significant (35% versus 26%; $p = .08$). The OS at 3 years was similar between the two groups (38% for RIC arm versus 43% for myeloablative arm, $p = .39$). This was a retrospective registry study; however, it provides evidence that RIC regimens can lead to similar survival in adults with ALL as aSCT with a more intensive, myeloablative conditioning regimen. This is particularly compelling because the median age was significantly older for those receiving RIC (median age in RIC arm: 45 years versus 28 years for myeloablative arm). The group from Minnesota has also reported encouraging results with UCB donor transplantation using a RIC regimen. Eighteen adults (median age: 49 years; range: 24–68 years) with high-risk ALL (majority Ph⁺ ALL) received a cord blood transplant using a RIC conditioning regimen and reported 3-year OS, TRM, and relapse rates of 49%, 28%, and 33%, respectively. Notably, patients in CR1 had a TRM of only 8% with no events after 6 months. These results with UCB donor transplantation are promising and compare favorably to conventional aSCT with relatively low TRM in this high-risk population. Thus RIC-based aSCT regimens with alternative donor sources should be considered for older adults in prospective clinical trials.

In summary, aSCT is a curative option for patients with ALL and can be considered the standard recommendation for patients with a good performance status but with adverse disease risk factors in CR1. There have been significant improvements in transplantation techniques (better supportive care, refinement of preparative regimens, and uses of alternative donors as a source of stem cells) that are

TABLE 66.7**Clinical Trials Evaluating Role of Myeloablative Allogeneic Stem Cell Transplant in Acute Lymphoblastic Leukemia**

Trial	Patients (n)	Age in Years, Median (Range)	Conditioning Regimen/Donor	TRM	DFS/OS	Comments
GOELAL02 ¹³	41 (HR)	34 (15–52)	Etoposide/ cyclophosphamide/ TBI (12 Gy in six fractions) MSD	15%	DFS: 75% at 6 years; OS: 75% at 6 years	Shown improved survival with aSCT compared with ASCT
LALA 94 ⁶	100 (HR ALL excluding Ph ⁺ ALL)	33 (15–55) for the entire study cohort of 922 patients	Cyclophosphamide/ TBI (10 Gy as a single dose or 12 Gy in six fractions) MRD	18% at 3 years	3-year DFS: 47%	For HR ALL, aSCT was superior to an ASCT
PETHEMA-93 ¹¹	222 HR patient underwent MSD (if available); if not, randomized to ASCT vs. chemotherapy	27 (15–50)	Cyclophosphamide/ TBI (12 Gy in six fractions) MSD		5-year OS: 35%	No benefit of an MSD transplant for HR patients (compared with ASCT or chemotherapy only approach)
MRC UKALLXII/ ECOG E2993 ¹⁰	Patients assigned to aSCT if an MSD available (donor group); those without donors randomized to ASCT vs. chemotherapy	15–64	Etoposide/TBI (13.2 Gy in six fractions) MSD	NRM HR (36% donor; 14% no-donor); SR (20% donor; 7% no donor)	5-year OS: HR (41% donor, 35% no donor) SR (62% donor vs. 52% donor)	Beneficial effect of all-SCT limited to SR group only; relapse rate decreased with aSCT in both HR and SR groups
HOVON ¹⁴	ALL in CR1 according to sibling donor vs. no-donor comparison HR: 46 donor; 73 no donor SR: 50 donor; 88 no donor	Donor 31 (16–55)	Cyclophosphamide/ TBI (12 Gy in six fractions) MRD	HR: NRM at 5 years (15% donor vs. 4% no-donor) SR: NRM at 5 years (16% donor vs. 2% no-donor, $p =$.01)	HR: OS at 5 years (53% donor vs. 41% no donor) SR: OS at 5 years (69% donor vs. 49% no donor, $p = .05$)	Similar to the MRC UKALLXII/ECOG E2993 trial, benefit of aSCT seems limited to SR patients

ALL, Acute lymphoblastic leukemia; aSCT, allogeneic stem cell transplantation; ASCT, autologous stem cell transplantation; CR1, first complete remission; DFS, disease-free survival; HR, high risk; MRD, minimal residual disease; MSD, matched sibling donor; NRM, non-relapse mortality; OS, overall survival; Ph, Philadelphia chromosome; SCT, stem cell transplantation; SR, standard risk; TBI, total-body irradiation; TRM, transplant-related mortality.

resulting in greater availability and improved transplant outcomes. At the same time, the TRM and mortality are significant, and aSCT has largely been offered only to patients younger than 60 years of age because of the poor tolerance of older adults to standard myeloablative transplant preparative regimens. Prospective incorporation of MRD evaluation may refine the ability to risk-stratify patients who are at HR of relapse and might benefit from aSCT in CR1. However, the benefit of a SCT for MRD-positive patients remains to be proven and has only been studied prospectively in a single study to date. Conversely, patients who were MRD negative in CR1 may best be treated by chemotherapy alone. Overall, the role of aSCT in CR1 merits further study, and it is important to refer these patients to clinical trials exploring such approaches.

Autologous Stem Cell Transplantation

ASCT in CR1 has also been studied prospectively in several clinical trials. Dhedin and colleagues reviewed the data from the French LALA 85, 87, and 94 trials and compared the outcomes of patients in CR1 who were randomized to chemotherapy versus ASCT. There was no improvement in DFS or OS with the use of ASCT compared with postremission chemotherapy, but there was a lower incidence of

relapse at 10 years (66% versus 78%; $p = .05$). In the MRC UKALLXII/ECOG E2993 trial, 456 patients were randomized to chemotherapy versus ASCT in CR1. Patients randomized to chemotherapy had significantly better 5-year event-free survival (EFS) (41% versus 32%; $p = .02$) and OS (46% versus 37%; $p = .03$). Thus, outside of a clinical trial, an ASCT cannot be recommended for ALL patients.

THERAPY FOR SPECIFIC DISEASE SUBSETS

Philadelphia Chromosome-Positive Acute Lymphoblastic Leukemia

The Philadelphia chromosome [t(9;22)(q34;q11)] is the most common cytogenetic abnormality in adult ALL, and its incidence increases with age. Among patients older than 60 years, 40% to 50% have the Philadelphia chromosome. Before the introduction of molecularly targeted therapy, Ph⁺ ALL was associated with lower remission rates and a very poor prognosis, with a median survival time of only approximately 9 months.

With the introduction of therapy using TKIs targeted to the aberrant BCR-ABL protein, the outcome of Ph⁺ ALL has improved

substantially and has been the major treatment advance for adults with ALL in the past two decades. Imatinib, the first targeted TKI developed for use in Ph⁺ leukemias, has been combined with multi-agent chemotherapy by various groups and this has substantially improved both CR rates and DFS (Table 66.9).

The MD Anderson Cancer Center was the first to report on the combination of imatinib with chemotherapy (hyper-CVAD). They used imatinib 400 mg/day on days 1 to 14 of each of the intensive chemotherapy courses, followed by imatinib at a dose of 600 mg daily during the maintenance phase, with monthly vincristine and prednisone, and then imatinib indefinitely. Thomas and colleagues recently reported long-term results of the Hyper-CVAD–Imatinib trial. The 3-year CR duration and OS rates were significantly superior in the hyper-CVAD–imatinib arm compared with historical control participants treated with hyper-CVAD alone (68% versus 24% and 54% versus 15%, respectively; *p* < .001). The Japanese have also reported impressive improvements compared to their control participants. In the JALSG ALL202 trial, imatinib, 600 mg/day, was added to standard induction followed by alternating cycles of high-dose methotrexate and high-dose cytarabine and single agent imatinib 600 mg/day. Later maintenance therapy with imatinib 600 mg/day with monthly vincristine and prednisone was given. In a recent update, they reported results on 103 patients with Ph⁺ ALL with a 97% CR rate and 3-year OS of 57%, both of which were significantly better than in historical control participants.

Older adults with Ph⁺ ALL have also demonstrated improved survival with the addition of imatinib to reduced-intensity chemotherapy regimens. Ottmann and colleagues reported for the German study group in which older adults (>55 years of age) Ph⁺ ALL patients were randomized to receive induction cycle with imatinib alone (*n* = 28) versus combination chemotherapy (*n* = 27). The CR rate was 96% in the imatinib arm, which was significantly better than the CR rate of 50% in the chemotherapy alone arm. This is the first prospective randomized controlled trial comparing imatinib with chemotherapy and clearly showed the superiority of the imatinib arm. There was no difference in the two arms with respect to DFS and OS, likely due to the fact that all patients received imatinib-based consolidation or maintenance therapy. The Italian GIMEMA group treated 30 Ph⁺ ALL patients (median age: 69 years; range: 61–83 years) with 7-day steroid pretreatment followed by induction treatment with only imatinib (800 mg/day) plus steroids. Impressively, all 29 evaluable patients achieved CR with 1-year DFS and OS of 48% and 74%, respectively.

There is general consensus that early TKI therapy is crucial, and most current treatment protocols include chemotherapy with continuous TKI therapy. In general, the TKI has been started with induction chemotherapy and continues throughout postremission and maintenance therapy.

Despite these significant advances in the treatment of Ph⁺ ALL, relapses are still major challenges. Resistance to imatinib develops and

TABLE 66.9 Clinical Trials With Tyrosine Kinase Inhibitor Plus Chemotherapy for Adult Philadelphia Chromosome-Positive Acute Lymphoblastic Leukemia

Trial	Patients (n)	Age in Years, Median (Range)	CR Rate	Disease-Free Survival	Overall Survival	Comments
MDACC Hyper-CVAD Imatinib ^{22,23}	54	51 (17–84)	93%	68% at 3 years	In de novo patients 40 years of age or younger: 3-year OS was 90% with aSCT (n = 10) vs. 33% without aSCT (n = 6), p = .05	First report of the combination of chemotherapy with a TKI Imatinib 400 mg/day on days 1–14 of induction; 600 mg continuously during courses 2–8; 600 mg during 2 years of maintenance therapy with monthly vincristine–prednisone; then imatinib indefinitely; allo-SCT in CR1 as feasible
JALSG ALL202 ^{24–26}	103	45 (15–64)	97%	For those younger than age 55 years, 54 of 74 patients in CR1 who had aSCT, only 13% relapsed; among the 20/74 patients in CR1 who did not undergo SCT, 90% relapsed	57% at 3 years For patients younger than age 55 years, OS at 3 years was 75.0% for the transplanted group vs. 36.4% for the nontransplanted group	Standard induction plus imatinib 600 mg/day followed by alternating cycles of high-dose methotrexate and high-dose cytarabine and imatinib 600 mg/day; imatinib 600 mg/day with monthly vincristine–prednisone for maintenance
GRAAPH-2003 ^{27,28}	45	45 (16–59)	96%	43% at 4 years	52% at 4 years The 4-year OS in the aSCT, ASCT, and no SCT groups were 55%, 80%, and 25%, respectively	Imatinib was started with consolidation in good early responders (corticosenesitive and chemosensitive ALL) or during the induction course in poor early responders
GMALL ²⁹	47 (alternating imatinib and chemotherapy)	46 (21–65)	NA because only CR patients were eligible	52% at 2 years	36% at 2 years	Coadministration of imatinib with induction cycle 2 led to CR rate of 95% and molecular CR rate of 52% of patients compared with 19% (significantly worse) in patients in the alternating treatment cohort
	45 (concurrent imatinib and chemotherapy starting after induction I)	41 (19–63)	95%	61% at 2 years	43% at 2 years	
GMALL ³⁰	28 (imatinib arm) 27 (chemotherapy arm)	66 (54–79) 68 (58–78)	96% 50% (significantly inferior to imatinib arm)	30% at 1.5 years 35% at 1.5 years	57% at 1.5 years 41% at 1.5 years	Patients older than age 55 years with de novo ALL and not eligible for aSCT; randomized to single-agent imatinib induction versus. multi-agent chemotherapy induction; subsequent consolidation or maintenance with imatinib plus chemotherapy for all patients

NILG protocol 09/00 ³²	59	45 (20–66)	92%	39% at 5 years	38% at 5 years	Imatinib (600 mg/day) was added to each chemotherapy course for 7 consecutive days, starting from day 15 of chemotherapy course 1 and from 3 days before chemotherapy during courses 2 to 8.
UKALLXII/ECOG2993 ³³	175	Not reported	92%	54% at 3 years	42% at 3 years	Outcomes (CR, DFS, and OS) were significantly better compared with the historical preimatinib cohort; for the imatinib group, 3-year OS for patients who received aSCT was 59% vs. 28% for those who did not receive aSCT
PACE ³⁴	32	62	41%	7% at 12 months	40% at 12 months	Ponatinib is active in Ph ⁺ ALL with T315I mutation
EWALL-PH-02 ³⁵	36	66	97%	89% at median follow up of 7 months		
CALGB 10001 ³⁶	58	45	8 patients converted from MMR to CMR after transplant	Median DFS 5.9 months after auto-HSCT	Median OS 4.8 years. 47% OS with allo-HSCT versus 42% OS with auto-HSCT	TRM associated with auto-SCT occurred in one (5%) of 19 patients, while TRM associated with allo-SCT occurred in 3 (20%) of 15 patients

ALL, Acute lymphoblastic leukemia; aSCT, allogeneic stem cell transplantation; ASCT, autologous stem cell transplantation; CMR, complete molecular response; CR, complete remission; CR1, first complete remission; DFS, disease-free survival; HSCT, hematopoietic stem cell transplantation; MMR, major molecular response; NA, not applicable; OS, overall survival; Ph⁺, philadelphia chromosome positive; SCT, stem cell transplantation; TKI, tyrosine kinase inhibitor; TRM, treatment-related mortality.

most frequently results from the emergence of a resistant clone with ABL kinase domain mutations. These kinase domain mutations cause conformational changes in the ABL protein that prevent effective binding. Other potential mechanisms of resistance that have been described include reduced intracellular availability of imatinib and activation of alternative signaling pathways such as the Src-kinase pathways. Second-generation TKIs, dasatinib and nilotinib, are more potent kinase inhibitors and are also effective against many imatinib-resistant mutations (although not the T315I mutation). In addition, dasatinib has been shown to penetrate the CNS and thus may be particularly effective in Ph⁺ ALL.

Dasatinib has been tested in several prospective trials for previously untreated Ph⁺ ALL. MD Anderson Cancer Center investigators evaluated hyper-CVAD plus dasatinib in newly diagnosed Ph⁺ ALL patients. Dasatinib 100 mg/day was given for the first 14 days of each of eight cycles of hyper-CVAD. The study was amended to allow dasatinib 100 mg/day for 14 days during cycle 1, and then 70 mg/day continuously during subsequent cycles. Maintenance chemotherapy consisted of daily dasatinib 100 mg/day with monthly vincristine and prednisone for 2 years followed by dasatinib

indefinitely. The median age of the 35 patients studied was 53 years (range: 21–79 years); 94% achieved CR. Of the patients who achieved CR, 61% of patients achieved complete molecular remission, meaning that there was no detectable MRD using quantitative PCR for *BCR-ABL*. In a recent update to the hyper-CVAD and dasatinib study, the MD Anderson Cancer Center group reported that 24% patients underwent aSCT (16% in CR1; 8% CR2), and 3-year DFS and OS for the entire cohort were 49% and 62%, respectively.

Foa and colleagues reported the results of the GIMEMA LAL1205 study in which dasatinib monotherapy (70 mg twice daily) with steroids was investigated for frontline treatment of 53 adult Ph⁺ ALL patients (median age: 54 years). All patients achieved a complete hematologic response, and there were no induction deaths. BCR-ABL transcript levels decreased rapidly during induction therapy, and the percentage of patients achieving BCR-ABL levels below 0.001% increased from 23% at day 22 to 52% at day 85. aSCT in CR1 was performed in 18 (34%) patients. At 20 months, the OS was 69% and DFS was 51%. BCR-ABL levels of less than 0.001% at day 85 correlated with DFS. These results with dasatinib without any cytotoxic chemotherapy are encouraging but demonstrated

that single-agent dasatinib is not sufficient to cure this disease. In a subsequent trial, the GIMEMA LAL1509, if patients did not achieve complete molecular response after a prolonged 84-day induction with dasatinib and steroids, they received more intensive combination chemotherapy and/or allogeneic transplantation. At day 85, 58 out of 60 (97%) patients achieved a complete hematologic remission; however, only 11 (18.6%) patients achieved a complete molecular remission (CMR) with TKI plus steroid induction, suggesting that dasatinib and steroids are insufficient to achieve a molecular remission in most patients and that additional postremission intensification is needed. Using this stratified treatment approach, the DFS was 62% with 18 months of follow-up and OS was 69%. Nilotinib is also a second-generation TKI that has been evaluated as frontline therapy. In a prospective, single arm phase II trial, induction treatment consisted of vincristine, daunorubicin, oral prednisolone, and nilotinib (400 mg orally twice daily). Patients in CR received either five courses of consolidation followed by 2-year maintenance therapy or an aSCT, depending on donor availability. Nilotinib was administered from day 8 of induction continuously until the end of maintenance or aSCT. Patients achieved a complete hematologic remission in 45 out of 50 (90%) cases. More than 70% of patients received aSCT. Estimated DFS and OS at 2 years were 71% and 66%, respectively, similar to rates observed with other TKIs. A subsequent study, EWALL-PH02, in patients greater than 55 years old evaluated nilotinib as induction therapy with vincristine and dexamethasone followed by consolidation cycles with further chemotherapy added. Patients achieved a CR with induction in 35 out of 36 (97%) cases. In addition, 30% of patients were in a molecular remission after induction. Although these results are similar to other studies with dasatinib, most of the current trials in Ph⁺ ALL have incorporated dasatinib in the frontline therapy because of its potential advantage over nilotinib with respect to CNS penetration.

Ponatinib is a third-generation ABL kinase inhibitor with the ability to inactivate the T315I mutant ABL kinase, which has been the most commonly occurring mutation at time of relapse in Ph⁺ ALL, and is approved for relapsed disease based on data from the PACE trial. In the chronic myeloid leukemia blast phase/Ph⁺ ALL cohort, 37% (11 out of 30) of patients who were resistant or intolerant to second-generation TKIs and 27% (6 out of 22) of patients with T315I mutations achieved a major hematologic remission. Recently the MD Anderson Cancer Center has reported preliminary results from a phase II study of ponatinib with hyperCVAD in newly diagnosed Ph⁺ ALL. Thirty five (95%) patients achieved major molecular remission and 26 (70%) complete molecular remission. The median time to MMR and CMR were 3 and 10 weeks, respectively. Several patients received alternative TKI therapy due to vascular toxicities. Further definition of the incidence of serious vascular events with ponatinib in the frontline treatment setting of Ph⁺ ALL is required; thus at this time the use of ponatinib as initial therapy in Ph⁺ ALL remains investigational.

Role of Transplantation for Philadelphia Chromosome Positive Acute Lymphoblastic Leukemia in the Era of Tyrosine Kinase Inhibitor-Based Therapy

aSCT in CR1 was the only curative treatment option for Ph⁺ ALL in the pre-TKI era. Although the addition of TKI therapy has significantly improved the outcome of Ph⁺ ALL, many recent studies have also highlighted the continued role of aSCT for Ph⁺ ALL. In an update of the hyper-CVAD-imatinib protocol, the MD Anderson Cancer Center group reported that in a subgroup of patients younger than 40 years of age, the 3-year OS was 90% with an aSCT compared with 33% without aSCT ($p = .05$). In the Japanese study, aSCT was performed in the CR1 in 54 of the 74 CR1 patients younger than 55 years of age. Relapse occurred in 13% (7 out of 54) of the transplanted patients compared with 90% (18 out of 20) in those who were not transplanted. Similarly, OS at 3 years was 75% for the transplanted group versus 36% for the nontransplanted group.

Similar results have been reported in preliminary form by the MRC UKALLXII/ECOG E2993 trial group. In this study, 175 Ph⁺ ALL patients received imatinib plus chemotherapy (2003 onward). The authors reported that 44% of the patients were able to receive an aSCT per protocol, a number much higher than the 28% who were able to receive aSCT in the preimatinib era of this study (1993–2003). For the imatinib cohort, the 3-year OS for patients who received protocol aSCT was 59% versus 28% for those who did not receive aSCT. In a recent update of the GMALL study, 219 of 335 (66%) Ph⁺ ALL patients treated with an imatinib-based chemotherapy regimen underwent aSCT in CR1. For the transplanted patients, the median OS was 57% after 3 years and 52% after 7 years compared with the dismal outcome of the nontransplanted group (3-year OS of only 14%). Similarly, the GRAAPH2005 study from the GRAAL group showed that patients who received imatinib-based therapy and aSCT had a 4-year OS of 76%, whereas the OS was 33% for those that received imatinib maintenance alone. These studies provide a strong rationale for the continued recommendation for an aSCT in CR1 for Ph⁺ ALL patients.

While ASCTs (as described previously) have not demonstrated efficacy overall in ALL, a study from the CALGB (10001) suggests that this may be an effective approach for Ph⁺ ALL. A combination of imatinib and chemotherapy induction and postremission CNS intensification was followed by allogeneic or autologous transplant (if no sibling donor available) in newly diagnosed Ph⁺ ALL. Nineteen patients subsequently received autologous transplantation in CR1. The OS with a median follow-up of 6 years was not reached and the median DFS was 3.5 years compared with 4.1 years (not statistically different) in the 15 patients who received allogeneic SCT in CR1. The authors concluded that autologous transplantation represents a safe and effective alternative to allogeneic transplant in Ph⁺ ALL without a donor.

The role and duration of TKI therapy after transplant is currently an area of active investigation. Wassmann and colleagues (GMALL) treated 27 Ph⁺ ALL patients with imatinib upon detection of MRD after SCT. Approximately 50% of patients achieved a molecular remission after a median of 1.5 months and these patients had a significantly longer time to progression (28.6 months versus 3.6 months; $p < .001$) and OS (2-year OS, 80% versus 23%; $p < .001$) compared with those who had persistent *BCR-ABL1* transcript levels. The German group also reported results of a randomized study that compared prophylactic ($n = 26$) versus preemptive (after detection of *BCR-ABL1* transcripts, $n = 29$) imatinib after aSCT for Ph⁺ ALL. Imatinib was discontinued early in more than half the patients in both groups, mostly because of gastrointestinal toxicity. Prophylactic administration of imatinib significantly reduced the incidence of molecular relapse after the aSCT. However, the OS was similar in the two arms (5-year OS: 75% to 80%), suggesting that imatinib can be effective either prophylactically after aSCT or based on molecular relapse. At the present time, it appears that continuing TKI therapy after transplant is an appropriate strategy. Studies evaluating MRD may provide guidance with the question of duration of posttransplant TKI therapy. The CALGB 10701 study, which includes 1 year of maintenance dasatinib after transplant, has recently completed accrual and will provide further data to address this issue.

In summary, during the last decade the addition of TKIs to combination chemotherapy has resulted in significant improvement in DFS and OS for both younger and older adults with Ph⁺ ALL. High complete molecular remission rates can now be achieved and have been demonstrated to be associated with improved outcomes. While allogeneic SCT remains the current treatment of choice for eligible patients, the next generation of studies in Ph⁺ ALL may help to define the role of transplantation when complete molecular remissions are achieved with combination TKI and chemotherapy alone.

BURKITT LYMPHOMA/LEUKEMIA

BL is a mature B-cell lymphoma with an extremely short doubling time that often presents in extranodal sites or as acute leukemia.

Fig. 66.8 BURKITT LEUKEMIA/LYMPHOMA (A–C). Bone marrow biopsy and aspirate features of Burkitt leukemia/lymphoma are illustrated. The bone marrow (or lymph node) will show sheets of highly proliferating intermediate-sized neoplastic cells with a syncytial appearance. The cells are monotonous but have a stippled intermediate chromatin pattern with multiple small nucleoli. (C) On the aspirate, the Burkitt cells have an intermediate size, a denser chromatin than lymphoblasts, and deeply blue cytoplasm with prominent vacuoles.

Thus a brief description of the therapy is warranted in this chapter. Morphologically (Fig. 66.8), the malignant cells are intermediate in size, have round nuclei with small nucleoli, are intensely basophilic, and frequently have vacuolated cytoplasm. In a BM biopsy and in tissue sections, the tumor is classically described as having a “starry sky” appearance because of the presence of multiple tingible body macrophages with phagocytized cellular debris. Immunophenotypically, the tumor cells express moderate to strong levels of surface immunoglobulin M with light chain restriction, indicating origin of the tumor from a mature B cell. The tumor cells also universally express the B-cell antigens CD19 and CD20, and germinal center associated markers such as CD10 and BCL6. Unlike B-ALL, BL cells do not express CD34 or TdT. The genetic basis of the disease is the underlying MYC translocation at band 8q24 to either the Ig heavy chain region on chromosome 14 or less commonly at the lambda (22q11) or kappa (2p12) loci.

Prompt diagnosis and recognition of this entity is essential because this is now a highly curable leukemia (in the range of 65% to 80% in recent trials); however, failure to institute appropriate therapy at diagnosis for Burkitt lymphoma/leukemia results in emergence of early resistance and dismal outcomes. Traditional CHOP (cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], and prednisone) chemotherapy is inadequate and should not be used. Treatment should be initiated quickly and consists of aggressive combination chemotherapy with CNS prophylaxis. These patients are at HR for the development of tumor lysis syndrome; therefore aggressive hydration and administration of allopurinol and/or rasburicase is important. All current regimens rely on short intensive courses of chemotherapy that incorporate fractionated doses of alkylating agents, high doses of methotrexate and cytarabine, and intensive intrathecal prophylaxis. In the United States, commonly used regimens include CODOX-M/IVAC, CALGB 9251, and hyper-CVAD. With these regimens, approximately 80% achieve CR, and 2-year survival is around 60% to 70%. In the CALGB 9251 trial, 52% of the patients were alive and in continuous CR at a median follow-up of 5.1 years. Because Burkitt lymphoma/leukemia has a predisposition for CNS involvement, aggressive CNS-directed therapy is essential and typically consists of intrathecal administration of methotrexate, cytarabine, and hydrocortisone. Recurrence after the first 2 years rarely occurs; therefore maintenance therapy has not been shown to be beneficial and is not recommended.

Because of the strong expression of CD20 in mature B-cell ALL, several groups have incorporated rituximab into the frontline chemotherapy regimen with impressive further improvements in survival. The hyper-CVAD–rituximab regimen was reported in 31 patients with newly diagnosed Burkitt lymphoma/leukemia with a CR rate of 86% and a 3-year survival rate of 89%. Similarly, the addition of rituximab to the treatment in both the GMALL and CALGB

OS	69% (6 year)	67% (4 year)	78% (2 year)

ALL, Acute lymphoblastic leukemia; EFS, event-free survival; OS, overall survival.

regimens has proven feasible with OS of 91% (3 years) and 79% (2 years), respectively. Based on these exciting improvements in survival, the addition of anti-CD20 targeting to frontline therapies for BL is now considered the standard of care.

ADOLESCENTS AND YOUNG ADULTS WITH ACUTE LYMPHOBLASTIC LEUKEMIA: THE INTERSECTION BETWEEN PEDIATRIC AND ADULT CARE

Evaluation of the outcomes of young adult patients, here defined as patients between the ages of 15 and 39 years, presents specific challenges. Because of community referral patterns, these patients may be treated by either pediatric or adult oncologists. As such, the treating physician may view a patient in this age group either as an older child or as a younger adult. The oncologist will choose a regimen most appropriate for the population usually seen by that particular physician. A number of comparisons of the clinical outcome of adolescents enrolled on adult and pediatric clinical trials (Table 66.10) have resulted in interesting observations about what that appropriate treatment regimen should be and have guided the design of a number of prospective clinical trials designed specifically for AYAs with ALL.

Retrospective Comparison of Pediatric and Adult Cooperative Group Trials in Adolescents and Young Adults

The retrospective comparisons summarized in Table 66.10 were performed by large cooperative groups throughout the world and examined the outcome of the AYA patients aged 15–21 years treated on pediatric or adult cooperative group trials for newly diagnosed ALL that were conducted contemporaneously. The majority of these retrospective comparison studies demonstrated a significant survival advantage for AYA patients treated by the pediatric versus the adult cooperative group. The first of these trials to have been reported highlights many of the interesting questions posed by these comparisons and is reviewed briefly here. The CALGB and the Children's Cancer Group (CCG) examined the outcome of 321 AYA patients between 16 and 20 years of age treated on consecutive trials from 1988 to 2001. The two patient groups were well matched for biologic features, including immunophenotype and cytogenetics. Although the age range was the same in both groups examined, the median age of the patients in the CALGB studies was 19 years compared with 16 years for the CCG patients. CR rates were identical—90% for both CALGB and CCG AYAs. However, CCG AYAs had a 63% EFS at 7 years and 67% OS at 7 years in contrast to the CALGB AYAs, in which the 7-year EFS was only 34%. A difference in pattern of relapse was also noted. The incidence of CNS relapses was significantly higher in CALGB AYAs (11%) compared with the CCG AYAs (1.4%; $p < .001$).

Since the initial report of these findings in 2000, multiple national European cooperative groups have reported similar results with improvement in the outcome of AYAs treated on pediatric compared with adult protocols, and these are summarized in Table 66.10. Although the treatment approaches differ among countries, several treatment themes have emerged as being potentially important. Pediatric studies throughout the world use considerably more treatment with nonmyelosuppressive drugs, including glucocorticoids (both dexamethasone and prednisone), vincristine, and L-asparaginase. CNS prophylaxis is typically administered earlier, with a greater frequency, and for a more prolonged period during pediatric group trials. Finally, long-term maintenance therapy was also continued for a longer period in pediatric cooperative group trials. Based on additional retrospective data from Finland and the MD Anderson Cancer Center, it appears that treating patients in a uniform fashion by an experienced group of physicians and nurses is also a very important component in the successful treatment of young adults with ALL.

To begin to address the many unanswered questions that have been raised by the retrospective comparison trials and to determine whether AYA patients treated by adult hematologists and oncologists can achieve similarly improved outcomes to the pediatricians for this age group, prospective cooperative group trials are being conducted in North America and in Europe. Early results from several of these trials have recently been reported. The PETHEMA Protocol ALL-96 addressed the toxicity and results of a pediatric-based protocol in 35 adolescent (age: 15–18 years) and 46 young adults (age: 19–30 years) with SR ALL. In this trial, patients received a standard five-drug, 5-week induction course followed by two cycles of early consolidation, maintenance with monthly reinforcement cycles for 1 year after remission, and standard maintenance chemotherapy for up to 2 years after CR. The AYAs were well matched for pretreatment characteristics. The CR rate was 98%, and with a median follow-up of 4.2 years, the 6-year EFS and OS were 61% and 69%, respectively. The only significant predictor of poor EFS for the entire group was a slow response to initial induction therapy ($>10\%$ blasts remaining in BM aspirate done on day 14 of induction therapy). Thus the investigators concluded that a pediatric regimen was tolerable and efficacious in AYAs with ALL up to the age of 30 years.

Two pilot studies from French adult cooperative groups have also demonstrated the feasibility of using modified pediatric-inspired regimens in adults with ALL, but the age range of these studies

extends well into the middle years of adult life. In the French Acute Lymphoblastic Leukemia Pediatric group (FRALLE) study, 28 Ph⁺ adult ALL patients 16–57 years old were treated on the FRALLE 2000 protocol consisting of a prednisone prophase, four-drug induction including L-asparaginase, consolidation, delayed intensification, and maintenance chemotherapy. Four-year DFS was 90% versus 47% seen in matched historical control participants. In the GRAALL 2003 study, 225 Ph⁺ ALL patients 15–60 years old (median: 31 years) were treated between 2003 and 2005 with five-drug induction, dose-intense consolidation, delayed intensification, and 2-year maintenance therapy. Notably, aSCT for patients younger than 55 years was recommended in this trial and makes interpretation of this trial more problematic. The CR rate was 93.5%. Among the 139 CR patients, 71 actually underwent transplantation in CR1 and were censored at the time of transplant. At 42 months, EFS was 55% versus 41% when comparing patients from an earlier French trial, the LALA-94, and the OS was 61%, significantly better than the 41% OS observed in the LALA-94 trial ($p < .001$). The benefit of the GRAALL approach was not statistically significant in patients older than 45 years of age because of a significant increase in treatment-related mortality of 23% compared with 5% treatment-related mortality for patients younger than 45 years old. The investigators concluded that the use of a pediatric-inspired regimen in adults up to 45 years of age was tolerable and markedly improved outcome for “younger” adults with ALL. This regimen included older adults up to the age of 60 years and used only a modified pediatric regimen that did not use the dose intensity of corticosteroids, asparaginase, and vincristine that are routinely used in current pediatric regimens. Another difference from the pediatric regimens is that all patients in these trials still received prophylactic cranial irradiation. Also, the majority of CR1 patients actually underwent aSCT, which is not the approach used by pediatric groups. Thus any interpretation of the contribution of the “chemotherapy” intensification component of these trials to DFS is very difficult to assess.

The Dana-Farber Cancer Institute (DFCI) consortium has also extended its successful pediatric regimen to older patients 18–50 years old. The trial design here was a true pediatric approach with intensification of *Escherichia coli* L-asparaginase, glucocorticoids, and vincristine for patients up to 50 years old; aSCT was not routinely recommended. A total of 92 patients, with a median age of 28 years (range: 18–50 years) were evaluable. Seventy-nine patients (85%) achieved a CR after 1 month of intensive induction therapy. With a median follow-up time of 4.5 years, the 4-year DFS rate for all patients was 69% and the OS rate 67%. For the 74 patients with Ph⁺ ALL, DFS was 71%, and OS was 70%.

The largest prospective trial to evaluate the feasibility of using a pediatric regimen in AYA patients treated by adult medical hematologists and oncologists is ongoing in North America (CALGB-10403). The United States adult and pediatric cooperative groups are currently enrolling a total of 300 young adults aged between 16 and 39 years on a prospective phase II trial (CALGB-10403) that uses one treatment arm of a successful Children's Oncology Group (COG) protocol for adolescents (and HR children with ALL). Early results from this trial also suggest both the feasibility of use of an intensive pediatric regimen in young adults and significant improvement in EFS of 66% and OS of 79% compared with historical controls. Longer follow-up is required to substantiate these promising early results.

These prospective trials are demonstrating that it is possible to achieve significant improvements in outcome for AYAs with ALL, although many challenges remain to ensure access to care, to minimize treatment toxicity, and to develop and follow specific survivorship monitoring plans. As stated previously, the successful outcome of a patient with ALL is, largely, based on the ability of both the medical team and the patient to adhere to the rigorous and lengthy regimens that currently remain the gold standard of care. The next generation of studies, linked to important biologic, psychosocial, and pharmacologic correlates, will result in further insights into optimizing the comprehensive approach to treatment and follow-up for this significant group of patients with ALL, and may be the next step to

achieving the high cure rate and successful transition back to “normal” life now routinely achieved in children with ALL. In particular, due to significant pharmacogenomic variability and age-related changes in drug metabolism, further evaluation and potential dose modifications of some of the agents including glucocorticoids, vincristine, and asparaginase, crucial to the successful outcomes of children, will need to be addressed in future studies of AYA and older adults with ALL in order to optimize these regimens for these populations. Enrollment in clinical trials, which has led to the survival rates now approaching more than 90% in pediatric ALL, will be the key to making progress in survival rates for both younger and older adults with ALL.

Comparison of Pediatric-Inspired Regimens With Allogeneic Transplant for Adolescents and Young Adults

Given these very encouraging improvements in outcome for AYAs with ALL using intensified pediatric regimens, the role of aSCT in CR1 has been reexamined in a recently presented retrospective comparison study. The International Bone Marrow Transplant Registry (IBMTR) examined outcomes of patients 18–50 years old who were treated during 2002–2011 on the DFCI intensive pediatric regimen described above ($n = 108$) compared with registry patients who received aSCT in CR1 using HLA matched related or unrelated donors ($n = 422$). These investigators reported significantly better outcomes for patients receiving the intensive pediatric approach compared to transplant (HR: 3.12; $p < .0001$). Overall, treatment using a pediatric-inspired regimen for young adults with ALL appears to result in significantly improved survival compared to aSCT in CR1. Similarly, data from the GRAALL pediatric-inspired protocols GRAALL 2003 and 2005 showed that there was no difference in relapse, nonrelapse mortality, or relapse-free survival (RFS) overall in patients that went onto aSCT compared to those that did not undergo transplant. However, aSCT did result in a longer RFS in patients that were MRD positive after induction chemotherapy, suggesting there is a select HR group of patients that still benefit from transplant.

OLDER ADULTS WITH ACUTE LYMPHOBLASTIC LEUKEMIA

Older adults (generally defined as >60 years old) constitute a challenging subset of ALL patients with worse prognosis reported in many studies compared with their younger counterparts. Most studies demonstrate that adults older than 60 years old have survival rates below 15%. Various factors contribute to the poor outcome of these patients, both patient related (e.g., the presence of comorbidities, less likely to be eligible for aSCT, poor tolerance of intensive chemotherapies) and disease related (more likely to have unfavorable disease characteristics such as the presence of Philadelphia chromosome). It is important to note that many large clinical trials have excluded patients older than 60 years of age; therefore clinical outcome data for this group are sparse. Annino and colleagues reviewed the results of 679 older adult patients (variably defined as older than 50 to older than 65 years of age, depending on the study) from 19 studies and reported a CR rate of 59% (range: 31% to 85%) with an early mortality rate of 23% (range: 7.5% to 50%) and 2-year OS of 15% to 19%, all of which are inferior to younger ALL patients. With hyper-CVAD regimens, the CR rate and 3-year survival for patients 60 years of age or older ($n = 58$) were 88% and 29%, respectively. In a pooled analysis of six consecutive CALGB clinical trials, the CR rate and 3-year survival for patients 60 years of age or older ($n = 197$) were 61% and 15%, respectively.

Sancho and colleagues reported results of the Spanish PETHEMA-ALL 96 trial looking specifically at the outcomes of Ph^- ALL patients who were 55 years of age or older. They initially treated 10 patients with an induction regimen consisting of vincristine, daunorubicin, prednisone, asparaginase, and cyclophosphamide. However, 7 of the 10 patients died during induction. Asparaginase

and cyclophosphamide were then omitted from the induction cycle, and 23 additional patients were treated with a CR rate of 70%; the induction death rate was reduced to 22%. The 2-year DFS and OS for the entire series were 46% and 39%, respectively.

Because most patients in this age group may not be eligible for conventional myeloablative aSCT, consideration should be given for RIC-based aSCT. Initial results with the use of RIC conditioning have been favorable, and long-term data are awaited (see earlier section on [allogeneic stem cell transplant](#)).

Many novel agents are being evaluated for this group of patients given the poor prognosis with the currently available therapies. To date, with the exception of TKI-based therapy for Ph^+ ALL in older adults, none have resulted in improved outcomes. The GRAALL-SA1 randomized phase II trial compared the efficacy and toxicity of pegylated liposomal doxorubicin (Peg-Dox) versus continuous-infusion doxorubicin (CI-Dox) in patients 55 years of age and older with Ph^- ALL. Use of Peg-Dox led to significant lower toxicities; however, there was a trend toward a lower CR rate, more refractory disease, and higher relapse rate in the Peg-Dox arm compared with CI-Dox arm. Other newer agents approved for relapsed disease, including liposomal vincristine and the bispecific antibody blinatumomab, are being tested in frontline therapy for older adults with ALL; these trials are currently ongoing. Single-agent activity of these agents in the relapsed setting is described later in more detail in the novel therapies section. Consideration should be given to enrollment of older adults into these new frontline therapies given the lack of progress with dose intensification of traditional agents. Management of older adult patients with Ph^+ ALL is discussed in the Ph^+ ALL section; the incorporation of TKIs into frontline therapy has already made significant improvements in DFS for these high-risk patients.

RELAPSED ACUTE LYMPHOBLASTIC LEUKEMIA

As described earlier, with standard therapies for ALL, long-term DFS is only around 30% to 40%. Thus the majority of patients with ALL relapse despite the administration of postremission treatment. Postrelapse therapies will lead to a second CR (CR2) in 30% to 40% of patients with a 5-year OS of only around 10%. An aSCT is the only chance for long-term cure in these patients and must be considered for all patients.

In the largest report of relapsed adult ALL patients to date, Fielding and colleagues analyzed the outcomes of relapsed adult ALL patients who were treated in the MRC UKALLXII/ECOG E2993 trial. Of the 1508 evaluable patients, 1372 (91%) achieved CR1, of whom 609 (44% of the CR1 patients) relapsed at a median of 11 months. The 5-year OS was only 7% for the relapsed patients, which was significantly worse compared with 38% for the newly diagnosed ALL patients in this study. The median OS for the relapsed patients was 5.5 months. The sites of the relapses were BM alone (86%), CNS alone (4%), BM plus CNS (5%), and other extramedullary sites (4%). The majority of the relapses (81%) occurred within 2 years of diagnosis. In this series, none of the 55 patients who had CNS involvement at relapse were alive at 5 years. Receiving aSCT after relapse led to significant improved outcomes compared with chemotherapy alone (5-year OS, 23% for matched sibling SCT versus 4% for the chemotherapy-alone arm).

Tavernier and colleagues reported outcomes of 421 ALL patients who experienced first relapse after treatment on the French LALA-94 trial. A CR2 was achieved in 44% patients with a median DFS of 5.2 months and median OS of 6.3 months. Factors associated with favorable outcome after relapse included transplant performed in CR2, CR1 of longer than 1 year, and platelet count greater than 100,000/ μL at relapse. The outcomes after relapse were not influenced by risk stratification at diagnosis or the treatment received during first CR. An aSCT was performed in 24% ($n = 99$) of the relapsing patients (in CR2 [$n = 61$] or with active disease at the time of SCT [$n = 38$], directly as a salvage therapy after relapse [$n = 14$], or after failure of salvage regimen [$n = 24$]). Median OS from an aSCT was 6.7 months with 5-year OS of 25% with a significantly

higher OS at 3 years after aSCT in CR2 compared with those with active disease at the time of SCT.

Oriol and colleagues reported the outcomes of 263 ALL patients in first relapse treated in four consecutive PETHEMA trials. CR2 was achieved in 45% of patients, a rate similar to that in the French LALA trials. The median OS after relapse was 4.5 months, with a 5-year OS of 10%. Factors associated with a favorable outcome after relapse included age younger than 30 years and CR1 duration of longer than 2 years. The best subgroup of patients was younger than 30 years of age with CR1 longer than 2 years in which the 5-year DFS and OS were 53% and 38%, respectively.

Vincristine is an important component of ALL treatment. In preclinical models, encapsulation of vincristine into sphingomyelin liposomes or “sphingosomes” has been shown to lead to increased efficacy without increased neurotoxicity compared with conventional vincristine. Sphingosomal vincristine administered every 2 weeks in relapsed or refractory ALL reported an overall response rate of 14%. A weekly schedule resulted in a higher CR rate of 19% overall, and 29% in first salvage treatment. Based on an improved toxicity profile and comparable efficacy in relapsed/refractory (RR) ALL, particularly as a single agent, in 2012 the FDA approved vincristine sulfate liposome injection (VSLI) for the treatment of adult patients with Ph-negative ALL in second or greater relapse or whose disease has progressed following two or more antileukemia therapies. An ongoing international phase III trial is examining the benefit of liposomal vincristine as frontline therapy of older adults with ALL.

Blinatumomab is a novel bispecific T-cell-engaging antibody targeted against CD3 on T cells and CD19 on leukemia B cells. When blinatumomab concurrently binds CD3 and CD19, the T cells are activated and directed to CD19-expressing target B cells, resulting in a cytotoxic T-cell response. Among 189 patients with relapsed/refractory ALL treated with blinatumomab, 43% achieved CR or CR with incomplete recovery of counts (CRi), and 82% became MRD negative. Patients that achieved MRD negativity had higher RFS and OS, 6.9 and 11.5 months, respectively, compared to patients in CR with MRD, 2.3 and 6.7 months respectively. The FDA granted accelerated approval for the use of blinatumomab in relapsed/refractory ALL in 2014. A small trial of blinatumomab for relapsed Ph⁺ ALL has also been completed; however, at the present time, this agent is only approved for Ph⁻ B-cell ALL.

Nelarabine is a prodrug that is demethylated by adenosine deaminase to the deoxyguanosine analog (ara-G). T lymphoblasts are sensitive to the cytotoxic effects of nelarabine, and this drug has been studied in T-cell ALL in the relapsed or refractory setting. DeAngelo and colleagues treated 26 patients with T-cell ALL and 13 patients with T-cell lymphoblastic lymphoma with nelarabine. The median age was 34 years (range: 16–66 years). The CR rate was 31% with a 1-year OS of 28%. Neurotoxicity was seen in many patients. Nelarabine is currently approved in the United States for both pediatric and adult patients with T-cell ALL and T-cell lymphoblastic lymphoma who have failed at least two chemotherapeutic regimens. The COG has recently completed a study evaluating the addition of nelarabine to the frontline setting for T-ALL, but longer follow-up will be needed to evaluate its impact on progression-free survival.

Despite the approval of these new agents, patients with relapsed ALL continue to be a challenging subgroup of patients, and additional novel therapies (see later discussion) may improve outcomes by improving CR2 rates and increasing the percentage of patients who could be candidates for aSCT. Importantly, these agents are now entering trials in the frontline setting with the hope that they will decrease relapse rates, obviate the need for rescue therapy, and improve OS in ALL.

NOVEL THERAPIES

Chemotherapy

Many new agents are being investigated for patients with ALL, both in the relapsed and frontline setting. Clofarabine is a purine

nucleoside analog that is currently approved by the FDA for the treatment of pediatric patients with relapsed or refractory ALL who have failed two prior regimens. The response rate CR, CR with incomplete recovery of platelets (CRp), and partial response (PR) in pediatric ALL is approximately 30%. Response rates in the adult population appear to be considerably lower and may be associated with significant toxicity. Kantarjian and colleagues reported 17% response rate (CR, CRp, PR) with single-agent clofarabine in adults with relapsed or refractory ALL. Based on the modest single-agent activity, studies evaluating the role of the combination of clofarabine with cytarabine or cyclophosphamide are being conducted. The Southwest Oncology Group Study S0530 was a phase II trial of a combination of clofarabine and cytarabine for relapsed or refractory ALL patients ($n = 37$) and demonstrated a response rate of 17% (CR/CRp), which was not better than that reported as a single agent. The COG is now testing the addition of clofarabine to frontline therapy in an attempt to improve the outcomes for high-risk children and adolescents.

(Table 66.11) CD22 is a commonly expressed antigen on the precursor B-cell lymphoblast cell surface that is internalized upon ligand binding, which makes it an attractive target for monoclonal antibodies and antibody drug conjugates. Epratuzumab, a humanized monoclonal antibody against CD22, also has activity in a subset of patients with ALL. In a COG pilot study, epratuzumab in combination with standard reinduction chemotherapy was evaluated in 15 pediatric patients with relapsed ALL. There was rapid clearing of surface CD22 antigen, and 9 out of 15 patients achieved a CR. In adult patients epratuzumab has been combined with cytarabine and clofarabine in relapsed/refractory precursor B-ALL. Thirteen out of 29 patients responded and five patients had MRD assessments, of which one achieved a significant molecular remission. The rate of response with epratuzumab, clofarabine, and cytarabine appeared to be greater than historical control of clofarabine and cytarabine (SWOG S0530); however, long-term DFS and OS data are not yet available. Given its modest initial response rates, the field has moved onto the evaluation of anti-CD22 conjugates, described briefly here.

Inotuzumab ozogamicin, a CD22 monoclonal antibody attached to immunotoxin calicheamicin, has shown activity in non-Hodgkin lymphoma and is currently being evaluated in ALL patients. Inotuzumab has demonstrated response rates of up to 80% in relapsed/refractory ALL and 78% of responding patients became MRD negative. Veno-occlusive disease and transaminitis are toxicities suggesting off-target drug effects that will need to be evaluated further. Longer clinical follow-up data are expected from ongoing trials regarding DFS and OS. In particular, a randomized phase III trial comparing inotuzumab to salvage chemotherapy in patients with relapsed/refractory ALL to determine efficacy and OS will serve as a registration trial for this antibody conjugate. Frontline introduction of this agent is also being tested. Inotuzumab, in combination with low-dose chemotherapy (cyclophosphamide, vincristine, cytarabine, methotrexate, dexamethasone, rituximab) is being evaluated in newly diagnosed and relapsed older adult (>60 years of age) ALL patients. Preliminary feasibility and efficacy data from an ongoing trial at the MD Anderson Cancer Center were recently reported. In 26 treatment-naïve patients, 25 achieved a CR or CRp (overall response rate: 96%) and MRD negativity with 86% progression-free survival and 81% OS at 1 year.

Moxetumomab pasudotox is another antibody–drug conjugate that consists of an anti-CD22 monoclonal antibody fused to a truncated form of *Pseudomonas* exotoxin A. In a phase I dose-escalation study, 21 pediatric patients with relapsed or refractory ALL were enrolled. The drug was well tolerated. In this heavily pretreated patient population (median number of prior therapies: four), preliminary efficacy results are encouraging with hematologic improvement in 41% and CR in 24% of the patients. Moxetumomab is currently under investigation in children and young adults with relapsed/refractory CD22⁺ ALL, as well as adults with relapsed/refractory ALL.

Coltuximab ravtansine (CoR) or SAR3419 is an anti-CD19 monoclonal antibody linked to the tubulin inhibitor maytansinoid

DM4, which demonstrated efficacy in vitro and in vivo in ALL, as well as safety in a lymphoma phase I study. The results of a phase II trial of CoR in relapsed/refractory adult B-ALL are awaited.

Combotox is constructed from two antibody–drug conjugates, consisting of a monoclonal anti-CD19 antibody and an anti-CD22 antibody conjugated to the toxin deglycosylated ricin A chain in equal parts. In relapsed/refractory pediatric pre-B-ALL only 18% of patients achieved a CR; however, 35% had a greater than 95% decrease in their peripheral blood blast counts. In adults Combotox reduced the leukemic disease burden in all patients, but no CRs were observed. In an ALL xenograft model Combotox acted synergistically with cytarabine, leading to a phase I trial of Combotox and cytarabine in adults with relapsed/refractory ALL.

In addition to the relapsed/refractory disease setting, antibody-based therapies are also being investigated for MRD. Blinatumomab was initially evaluated in MRD positive B-ALL after induction or molecularly relapsed disease. Eighty percent of patients achieved a molecular remission, including 57% of patients who had never previously been MRD negative. Based on these promising results, a United States Intergroup Trial, ECOG 1910, is comparing blinatumomab plus chemotherapy to chemotherapy alone in adults with newly diagnosed B-ALL. Another study in older adult patients, SWOG 1318, will investigate blinatumomab and POMP (prednisone, vincristine, methotrexate, 6-mercaptopurine) chemotherapy in newly diagnosed Ph⁻ ALL and dasatinib, prednisone and blinatumomab for newly diagnosed Ph⁺ ALL.

Although less prevalent than CD19 or CD22 antigen expression, 70% of all (both precursor B-cell and precursor T-cell) ALL patients express CD52. Alemtuzumab, a humanized anti-CD52 monoclonal antibody, has been evaluated in ALL as an agent for eradication of MRD during postremission therapy. Alemtuzumab decreased MRD and improved DFS compared to chemotherapy alone in adult ALL. However, alemtuzumab failed to demonstrate significant activity in relapsed/refractory pediatric ALL. Additional studies have been conducted with alemtuzumab and other agents in order to further assess their role in frontline therapy of ALL (CALGB 10102) and have demonstrated feasibility; outcome data have not yet been formally reported.

Immunotherapy

Chimeric Antigen Receptor T Cells

Potentially one of the most exciting breakthroughs in ALL therapy is the development and early results from trials evaluating chimeric antigen receptor (CAR)-T cells (Table 66.11).

CAR-T cells are genetically engineered autologous T cells that express antigen receptors that result in recognition and killing of targeted malignant cells. In ALL, the CAR-T cells contain antibody-binding domains of single-chain variable fragments linked to T-cell-stimulating moieties, most commonly CD3 ζ with either CD28 or CD137 (41BB) costimulatory domains. The chimeric receptor CTL019 binds CD19 on malignant B cells and leads to tyrosine kinase-mediated activation of the T cell through the CD3 ζ -chain portion and costimulatory activity of CD137 or CD28. Investigators at the University of Pennsylvania treated 25 pediatric and five adult patients with relapsed/refractory ALL with anti-CD19-CD137/CD3 ζ CAR-T cells. CRs were achieved in 90% of patients. Two patients also achieved CNS remission without evidence of disease recurrence at 6 months. The probability of CAR-T cell persistence at 6 months was 68%. B-cell aplasia continued as long as CTL019 cells persisted; however, increased rates of infection were not reported. After a limited 6-month follow-up the EFS was 67% and OS 78%, suggesting promise compared to standard salvage chemotherapy.

Investigators at the Memorial Sloan Kettering Cancer Center (MSKCC) treated 24 relapsed/refractory adult B-ALL patients with CD19-specific CD28/CD3 ζ CAR-T cells. Prior to CAR-T cell treatment, of 22 evaluable patients, 10 were MRD positive and 12 had morphologic evidence of disease. Overall, 91% responded to CAR-T

cells, and 90% of these patients were MRD negative. Six patients remain in remission after 1 year. Three out of five patients that relapsed received repeat CAR-T cell infusion and two of these patients regained CR. Cell levels expanded and peaked at 1–2 weeks and were low or undetectable by 2–3 months.

In both studies all responding patients experienced cytokine-release syndrome (CRS). CRS timing correlated with peak T-cell expansion and severity correlated with disease burden prior to treatment and appears to be mediated by release of interleukin-6 (IL-6) and other inflammatory cytokines. MSKCC defined severe CRS (sCRS) requiring treatment for fevers for greater than or equal to 3 consecutive days and at least one clinical sign of toxicity such as hypotension requiring a vasopressor, or hypoxia, or neurologic symptoms (confusion, obtundation, and seizures). Neurologic toxicities were also common, ranging from delirium during CRS to encephalopathy independent of CRS; however, the pathophysiology of this is unclear. Recently, CAR-T investigators have successfully employed tocilizumab, an anti-IL-6 antibody to treat and reverse the symptoms associated with CRS. Several patients received T cells of donor origin after prior allogeneic stem cell transplant; interestingly, no graft-versus-host disease occurred following CAR-T cell infusions in either study.

Philadelphia Chromosome Positive Acute Lymphoblastic Leukemia

Bosutinib 500 mg daily has been found to be safe in relapsed/refractory Ph⁺ ALL, with diarrhea being the most common toxicity. However, further investigation is required to assess efficacy. Other agents, such as the dual BCR-ABL/LYN TKI INNO-406 and the aurora kinase inhibitor MK-0457, have also been evaluated in Ph⁺ ALL, but demonstrated limited efficacy. ABL001 is an allosteric BCR-ABL inhibitor that mimics the myristoylated N-terminus of the kinase domain by occupying its vacant binding site, thus restoring the negative regulation of the kinase activity. ABL001 is currently being investigated in a phase I study as a single agent and was also developed to be dosed with nilotinib.

Philadelphia Chromosome-Like Acute Lymphoblastic Leukemia

There has been an increasing understanding of the molecular biology of ALL, which may translate into newer therapeutic options. Mullighan and colleagues reported loss of the *IKZF1* gene on 7p12, which encodes the early lymphoid transcription factor Ikaros in 84% of BCR-ABL–positive ALL and in 28% of BCR-ABL–negative B-cell ALL. An *IKZF1* deletion was reported in 63% of 83 adult Ph⁺ ALL patients treated in various GIMEMA trials. The presence of the deletion of the *IKZF1* gene has been associated with poor prognosis, with worse DFS and increased relapse risk. Patients with *IKZF1* alteration have a gene expression profile similar to that of Ph⁺ ALL (Ph-like ALL described earlier), and one-third of such patients have rearrangements of the lymphoid cytokine receptor gene *CRLF2*, either alone or with mutations of the Janus kinase (JAK) genes *JAK1* and *JAK2*. This has been further identified in pediatric and young adult ALL patients. Among 1725 B-ALL cases analyzed, the prevalence of Ph-like ALL increased from 10% in children to 27% in young adults. Kinase activating mutations in *ABL1*, *ABL2*, *CRLF2*, *CSF1R*, *EPOR*, *JAK2*, and *PDGFRB* were found in 91% of Ph-like ALL cases observed. *CRLF2* mutations were present in up to 60% of young adults and 55% of patients with *CRLF2* mutations had concurrent JAK mutations, most commonly in *JAK2*. Twelve patients with *ABL*, *JAK2*, or *PDGFR* mutations were ultimately treated with dasatinib, imatinib, or ruxolitinib, and achieved rapid and sustained responses. This provides rationale to test ABL and JAK inhibitors as a targeted strategy for this group of patients.

Targeting Intracellular Signaling Pathways

The *NOTCH1* gene encodes a transmembrane receptor protein that drives stem cell commitment to T-cell differentiation. *NOTCH1*

TABLE
66.11

Novel Immunotherapies in Relapsed/Refractory Acute Lymphoblastic Leukemia

Trial	Cell Surface Antigen Target and Agent	Class	Disease Status	n	CR (%)	MRD Negativity ^a (%)	Survival Outcomes
CD19							
	Blinatumomab	Bispecific T-cell-engaging antibody					
Topp M ⁴⁰			MRD+ or relapsed	21		16 (80)	RFS: 61% at 33 months
Topp M ⁴¹			RR	189	81 (43)	60 (82)	Median RFS: 5.9 months Median OS: 6.1 months
CAR-T cells							
Maude S ⁴²		CAR-T cells	Pediatric/adult RR	25/5	27 (90)	22 (81)	EFS: 67% OS: 78% at 6 months

CD19 and CD22							
	Combotox	Combined antibody–drug conjugate					
Herrera L ⁴⁸			Pediatric RR ALL	17	3 (18)		
Schindler J ⁴⁹			Adult RR ALL	17	0 (0)		Xenograft models demonstrate survival benefit

^aMRD in ALL refers to the presence of leukemic cells below the threshold of detection by conventional morphologic methods. Patients who achieved a CR by morphologic assessment alone can potentially harbor a large number of leukemic cells in the bone marrow.

Current multicolor flow cytometry or PCR methods can detect leukemic cells at a sensitivity threshold of $<1 \times 10^{-4}$ ($<0.01\%$) bone marrow mononuclear cells.

ALL, Acute lymphoblastic leukemia; CAR-T cell, chimeric antigen receptor-T cell; CR, complete remission; DOR, duration of response; EFS, event-free survival; MRD, minimal residual disease; OS, overall survival; RFS, relapse-free survival; RR, relapsed/refractory ALL; SCT, stem cell transplantation.

activation occurs in more than 50% of patients with precursor T-cell ALL and has been used as a therapeutic target. γ -Secretase is required for *NOTCH1* proteolytic activation. The γ -secretase inhibitor, MK-052, caused high rates of gastrointestinal toxicity and failed to induce responses in relapsed/refractory T-ALL. In addition to Notch, γ -secretase affects other substrates, suggesting that the drug likely has off-target effects. Another γ -secretase inhibitor, PF-03084014, is currently under investigation in a phase I trial. The anti-NOTCH1 receptor monoclonal antibody demcizumab may avoid the toxicities of γ -secretase inhibitors and warrants investigation. In vitro data demonstrated that NOTCH1 is a key driver in the mTOR pathway and c-MYC serves an intermediary between NOTCH1 and mTOR, suggesting that mTOR inhibition alone or with NOTCH1 inhibition may also be highly relevant for T-ALL.

The PI3K/AKT/mTOR pathway is also thought to be active in Ph⁺ and Ph⁻ B-ALL. As a single agent, the rapalogue sirolimus only resulted in stable disease in relapsed/refractory pediatric ALL. Temsirolimus, everolimus, and sirolimus are each under investigation in combination with chemotherapy in relapsed/refractory ALL. BEZ-235 is a dual inhibitor of PI3K and mTORC1/mTORC2, which in vitro in T- and B-ALL, including Ph⁺ cells, caused cell cycle arrest and apoptosis, and acted synergistically with chemotherapy. In a phase I trial of BEZ-235 in relapsed/refractory acute leukemias, one out of 10 ALL patients achieved a CR and two additional patients had improvement in blood counts. Similar to

rapalogues, this agent may be more effective in combination with chemotherapy.

Epigenetic Modulation

MLL gene rearrangements at position 11q23 occur in approximately 10% of ALL, AML, or MLL, and are associated with an aggressive disease course. MLL gene mutations result in oncogenic fusion proteins that associate with disruption of telomeric silencing 1-like (DOT1L), leading to hypermethylation and activation of MLL target genes that drive leukemogenesis. The DOT1L inhibitor, EPZ5676, is currently being evaluated in a phase I trial in relapsed/refractory acute leukemias. In a preliminary report, four out of 28 patients responded to treatment.

Bone Marrow Microenvironment

AMD11070 is an orally available, small molecule inhibitor of CXC-chemokine receptor 4 and has been studied in ALL cell lines and mouse models as an agent to eradicate leukemic cells that are otherwise protected by stromal elements. Mice with murine Ph⁺ ALL survived significantly longer when treated with a combination of nilotinib and AMD11070. Similarly, a combination of vincristine and AMD11070 showed encouraging responses.

SURVIVORSHIP

Although fewer specific data are available on long-term complications of survivors of young adults with ALL, the long-term complications of successful treatment of children with ALL have been well described and include neurocognitive and neurologic dysfunction, endocrine and metabolic abnormalities (including obesity), bone toxicity (osteonecrosis), cardiac toxicity, and secondary malignancies. To guide the frequency and focus of medical visits and the ordering of appropriate surveillance tests, comprehensive guidelines have been published in many countries, including North America, where guidelines created by the COG, titled “Long-Term Follow-up Guidelines for Survivors of Childhood, Adolescent and Young Adult Cancers” are available at <http://www.survivorshipguidelines.org> and should be adopted by the adult oncology community.

FUTURE DIRECTIONS

ALL is a heterogeneous group of diseases with varied clinical outcomes, depending on molecular, cytogenetic, and clinical characterization. There have been significant advances in our understanding of the molecular pathogenesis of this disease, which should translate into effective targeted therapies and better patient outcomes. Given the rarity of this disease, it is strongly recommended that patients are referred to centers of expertise, and it is crucial that patients be enrolled in clinical trials designed to evaluate subset-specific therapies to improve survival.

CHRONIC MYELOID LEUKEMIA

Ravi Bhatia

Chronic myeloid leukemia (CML) is a hematopoietic malignancy originating from transformation of a primitive hematopoietic cell. Without treatment, CML progresses from an initial chronic phase (CP), characterized by marrow hyperplasia and increased numbers of circulating differentiated myeloid cells, to more advanced phases of disease (accelerated phase [AP] and blast crisis [BC]) marked by a block in differentiation, accumulation of blasts, and depletion of normal hematopoietic cells, especially white blood cells (WBCs) and platelets. CML was the first malignant disease found to be consistently associated with a specific cytogenetic abnormality, the Philadelphia chromosome (Ph), resulting in the formation of the *BCR-ABL* fusion oncogene. Study of the *BCR-ABL* gene has not only led to sensitive methods to detect residual disease and predict outcome, but has also yielded highly effective “targeted” therapies aimed at inhibiting abnormal tyrosine kinase activity resulting from the *BCR-ABL* fusion oncogene. In addition, CML was one of the first diseases demonstrated to be curable by hematopoietic cell transplantation (HCT). Thus, CML has become the model for “tailored” therapy, in which various treatments can be escalated on the basis of molecular response.

ETIOLOGY/EPIDEMIOLOGY/GENETICS

CML was recognized as a distinct entity, associated with massive splenomegaly and leukocytosis without other explanations, in the mid-1800s. The modern history of CML was initiated by Nowell and Hungerford in 1960. They used newly developed techniques to detect a small chromosome in metaphase preparations of marrow cells from CML patients. This abnormal chromosome was the first consistent chromosomal abnormality in human malignancies and was termed the *Philadelphia chromosome* after the city of its discovery. Rowley showed that the Philadelphia chromosome resulted from a translocation between chromosomes 9 and 22 [t(9;22)(q34;q11)] (Fig. 67.1). The genes involved in this translocation were cloned in the 1980s, and the t(9;22) translocation was shown to result from the fusion of the breakpoint cluster region (*BCR*) gene on chromosome 22 to the Abelson leukemia virus (*ABL*) gene on chromosome 9, with formation of the *BCR-ABL* fusion oncogene. This oncogene codes for a constitutively active cytoplasmic tyrosine kinase, which is the principal cause of the CP of CML. Until the 1970s, CML was regarded as an incurable and inevitably lethal disorder. It was then recognized that selected patients can be cured by allogeneic HCT. However, transplantation therapy for CML is limited by donor availability and the risk for life-threatening toxicity. More recently, imatinib mesylate and other tyrosine kinase inhibitors (TKIs), which specifically block the enzymatic action of the abnormal tyrosine kinase coded by the fusion oncogene, have resulted in a high rate of remission and improved survival in CML patients.

CML is the most common of the myeloproliferative diseases and represents 15% to 20% of all new leukemia cases. The annual incidence of CML is 1 to 1.5 cases per 100,000 population per year. The median age at diagnosis is 67 years and the incidence sharply rises with age. The disease occurs slightly more often in men than in women. CML may occur in children, but only approximately 10% of cases occur in individuals between 5 and 20 years of age, representing only 3% of all childhood leukemias. Concordance of disease is not observed between identical twins. Persons exposed to high-dose irradiation, including survivors of atomic bombing, have a

significantly increased risk for leukemia. High-dose irradiation of myeloid cell lines in vitro induces the expression of *BCR-ABL* transcripts indistinguishable from those that characterize CML. The *BCR-ABL* gene can be detected at low levels in a proportion of healthy individuals using a very sensitive polymerase chain reaction (PCR) assay. These findings suggest that the fusion gene develops relatively frequently in hematopoietic cells, but only infrequently leads to leukemia development. The mechanism by which the Ph chromosome is first formed and the time required for progression to overt disease are unknown.

PATHOPHYSIOLOGY

CML is generally believed to develop from transformation of a primitive hematopoietic stem cell (HSC) by the *BCR-ABL* fusion gene. The progeny of transformed HSCs have a proliferative advantage over normal hematopoietic cells, thus allowing the Ph-positive clone to gradually displace residual normal hematopoiesis. The translocation is found in cells of myeloid, erythroid, megakaryocytic, and B-lymphoid origin, consistent with a HSC origin of the disease. Hematopoietic expansion in patients with CP disease primarily involves an increase in myeloid cell mass, related to an expansion of mature cells, as well as increased numbers of precursor and progenitor cells. In CP, the leukemic cells are minimally invasive and are primarily located in hematopoietic tissues including the blood, bone marrow, spleen, and liver. The proliferative advantage of the malignant clone may be related to enhanced responsiveness to hematopoietic growth factors and/or reduced response to inhibitory factors. CML progenitors also demonstrate altered adhesion to marrow stromal cells and extracellular matrix. Altered microenvironmental interactions may contribute to another feature of CML, which is abnormal progenitor trafficking with increased numbers of circulating progenitors and extramedullary hematopoiesis. Several observations indicate that although the Ph-positive clone displaces normal hematopoiesis, it does not destroy residual normal stem cells. For example, Ph-negative progenitors can be seen after cultures of CML cells in vitro are selected on the basis of cell surface phenotype, and can be identified in the blood after high-dose chemotherapy. As described later in the Therapy section, treatment with agents such as interferon (IFN) or TKIs can result in restoration of Ph-negative hematopoiesis in CML patients.

The *BCR-ABL* gene originates from a chromosomal translocation that results in the fusion of the *ABL* gene on chromosome 9 and the *BCR* gene on chromosome 22. The translocation is related to a break in *ABL* upstream of exon a2 and in the major breakpoint cluster region of the *BCR* gene. This leads to juxtaposition of a 5' portion of *BCR* and a 3' portion of *ABL* on a shortened chromosome 22 (the derivative 22q-, or Ph). The resulting messenger RNA (mRNA) usually contains one of two *BCR-ABL* junctions, designated e13a2 (formerly b2a2) and e14a2 (or b3a2). Both *BCR-ABL* mRNA molecules are translated into a 210-kD fusion protein, referred to as p210*BCR-ABL*. Rarely, other variant breakpoints and fusions can give rise to full-length, functionally oncogenic *BCR-ABL* proteins, notably p190*BCR-ABL* (associated with an e1a2 mRNA junction) and p230*BCR-ABL* (associated with an e19a2 mRNA junction). Of patients with CML who have a normal-appearing karyotype, one-third have a cytogenetically occult *BCR-ABL* gene, usually located on

Fig. 67.1 PARTIAL KARYOTYPE SHOWING THE $t(9;22)(q34;q11.2)$. The Philadelphia chromosome is the derivative chromosome 22 (right arrow).

a normal-appearing chromosome 22 but occasionally on chromosome 9. In the remaining patients with Ph-negative, *BCR-ABL*-negative disease, the molecular basis of leukemia is not known.

Some studies have suggested that pathogenesis of CML may be a multistep process, with development of clonal hematopoiesis preceding the $t(9;22)$ translocation. However, there is substantial evidence to suggest that the generation of a classic *BCR-ABL* fusion gene in a HSC is sufficient to initiate CML. Expression of *BCR-ABL* has been shown to transform mouse fibroblast cell lines, growth factor-dependent hematopoietic cell lines, and primary murine bone marrow cells. Expression of *BCR-ABL* in human $CD34^+$ cells also causes increased proliferation, reduced apoptosis, and altered adhesion and migration, mimicking alterations seen in progenitor cells from CML patients. Transplantation of murine bone marrow cells made to ectopically express the *BCR-ABL* gene by retroviral transduction induces a myeloproliferative disorder (MPD) that closely resembles human CML with increased numbers of peripheral blood cells (with a predominance of granulocytes), splenomegaly, and extramedullary hematopoiesis, although the disease is much more fulminant than human CML. Initial development of transgenic and knock-in mouse models of CML was problematic. It appears to be crucial to express this oncogene in the proper cell type. Expression of *BCR-ABL* in B-cell lymphocytic and megakaryocytic precursors resulted in the development of B-acute lymphocytic leukemia and megakaryocytic myeloproliferative syndrome. Specific expression of the oncogene in HSCs through a stem cell leukemia enhancer to regulate expression induces development of a CML-like disease.

The *ABL* gene encodes a nonreceptor tyrosine kinase that is expressed in most tissues. Mice with homozygous disruption of the *ABL* gene demonstrate increased perinatal mortality, lymphopenia, and osteoporosis, and are smaller, with abnormal head and eye development. The *BCR* gene also encodes a signaling protein that contains multiple modular domains. Although *BCR*-deficient mice develop normally, their neutrophils produce excess levels of oxygen metabolites following activation. The normally regulated tyrosine kinase activity of the ABL protein is constitutively activated by the juxtaposition of N-terminal *BCR* sequences. BCR acts by promoting protein dimerization, leading to phosphorylation of tyrosine residues in the kinase-activation loops and leading to constitutive activation of kinase activity. The fusion of *BCR* sequences to *ABL* also adds new regulatory domains/motifs to ABL, such as the growth factor receptor-bound protein 2 (GRB2) SH2-binding site. The uncontrolled kinase activity of *BCR-ABL* and enhanced interaction with a variety of effector proteins lead to deregulation of cell signaling mechanisms that regulate proliferation. The ABL protein is located in both the nucleus and the cytoplasm, and shuttles between these two compartments, whereas the *BCR-ABL* protein is exclusively cytoplasmic and localizes to the cytoskeleton, where it appears to contribute to adhesion and migration abnormalities.

The structure of the *BCR-ABL* protein and the biochemical pathways affected have been extensively studied. However, most such interactions have been studied only in cell lines and conditions of forced overexpression. Their existence in primary leukemia cells and relevance to CML pathogenesis is not certain. The murine

transduction-transplantation CML model has been helpful in studying the role of *BCR-ABL* domains and signaling interaction in primary hematopoietic cells in vivo. The ABL tyrosine kinase is crucial for oncogenic transformation. Mice that express a form of *BCR-ABL* with a point mutation in the ATP-binding site of ABL that inhibits its kinase activity do not develop leukemia, suggesting that the ABL kinase activity is essential for *BCR-ABL* leukemogenesis in vivo. The success of kinase inhibitor therapy for CML provides further proof of the importance of kinase activity in maintenance of human disease. Other important domains in *BCR-ABL* also regulate the kinase activity of ABL or connect to other downstream signaling pathways. The N-terminal coiled-coil oligomerization domain of BCR is an important activator of ABL kinase activity, and also promotes the association of *BCR-ABL* with F-actin fibers. Phosphorylation of BCR at tyrosine 177 generates a GRB2-binding site, which is important for RAS activation. Mutation of the tyrosine-177 residue of *BCR-ABL* to phenylalanine (Y177F) largely abolishes its ability to bind GRB2, without affecting the kinase activity of ABL. The Y177F mutant has a greatly reduced ability to induce MPD in mice. A tyrosine phosphorylation site in the activation loop of the ABL kinase domain and the SH2 domain of ABL also contribute to RAS activation. Mutations in the SH2 domain of ABL and a Y1294F point mutation reduce the ability of *BCR-ABL* to induce a CML-like MPD in mice. The C-terminal region of ABL is required for the proper function of normal ABL. However, deletion of the ABL actin-binding domain was reported to not affect the ability of *BCR-ABL* to induce CML-like MPD in mice, suggesting that this domain may be dispensable for *BCR-ABL*-mediated leukemogenesis. Certain *BCR-ABL* domains may have complementary or overlapping functions. Many signaling proteins become phosphorylated in *BCR-ABL*-expressing cells and/or interact with *BCR-ABL* through various functional domains. These interactions in turn activate signaling through mechanisms including RAS, phosphatidylinositol 3-kinase, AKT, JNK, and SRC family kinases, protein phosphatase, signal transducers and activators of transcription, nuclear factor- κ B, and MYC. *BCR-ABL* also induces expression of cytokines such as interleukin-3, granulocyte colony-stimulating factor (G-CSF), and granulocyte-macrophage colony-stimulating factor.

Progression to AP and BC is associated with an increase in immature blast cells that may be located within hematopoietic tissues or may infiltrate a number of extramedullary sites, including lymph nodes, skin, soft tissue, and the CNS. A number of molecular mechanisms, rather than a single gene defect, are likely to underlie the arrest of maturation, enhanced proliferation and survival, and increased tissue invasiveness that characterize BC CML. Increased level of *BCR-ABL* expression is a common feature and appears to be a key factor in the development of features of BC, through effects on cell signaling and on transcription and translation of important regulatory genes. Additional cytogenetic and molecular changes are frequently seen during progression. It appears that genetic instability in CML may be induced by several factors, including increased oxidative stress, reduced DNA repair, or reduced DNA damage checkpoint signaling response. Genetic changes observed in leukemic cells from blast-phase CML patients include nonrandom cytogenetic changes such as $++8$, $++Ph$, $++19$, and $I(17)q$; point mutations in *TP53*, *RB*, and *CDKN2A* ($p16^{INK4A}$); and overexpression of *EVII* and *MYC*. Additional chromosome translocations are also observed, such as $t(3;21)(q26;q22)$, which generates *AML1-EVII*. Other CML-associated fusion genes include *AML1-ETO*, resulting from the $t(8;21)(q22;q22)$ translocation; *NUP98-HOXA9*, resulting from the $t(7;11)(p15;p15)$ translocation; and *CBFB-SMMHC*, which results from $inv(16)(p13;q22)$. These observations suggest that the block in myeloid differentiation in BC may involve cooperation between *BCR-ABL* and defects in hematopoietic transcriptional regulators. Gene expression analyses suggest that the progression of CML from CP to advanced phase is associated with gene expression changes occurring early in AP before the accumulation of increased numbers of leukemia blast cells. Especially noteworthy and potentially significant in the progression program are deregulation of the WNT/ β -catenin pathway, decreased expression of *JUNB* and *FOS*, and

Fig. 67.2 CHRONIC MYELOID LEUKEMIA, PERIPHERAL BLOOD TUBE, AND IMAGES OF BLOOD SMEAR AND BONE MARROW BIOPSY AND ASPIRATE IN CHRONIC PHASE. (A) The spun tube of peripheral blood (ethylenediaminetetraacetic acid collected) is from a patient with chronic-phase chronic myeloid leukemia who presented with a white blood cell count of about 600 K/ μ L. Note the markedly expanded “buffy coat” layer (*asterisk*) due to the severe leukocytosis. (B) Peripheral smear showing marked leukocytosis due to a granulocytic proliferation of all stages with particularly increased myelocytes and absolute basophilia. (C) Bone core biopsy illustrating markedly hypercellular marrow due to granulocytic proliferation and increased small hypoblasted megakaryocytes. (D) Bone marrow aspirate showing the same granulocytic proliferation and small, “dwarf” megakaryocytes. Mild fibrosis as seen on reticulin stain (E), and pseudo-Gaucher cells (F).

alternative kinase deregulation. Other studies suggest that the granulocyte/macrophage progenitor (GMP) pool is expanded in patients with blast-phase CML, and that these cells have increased levels of *BCR-ABL* expression and increased WNT signaling activity that may lead to increased self-renewal capacity, transforming GMP cells into leukemic stem cells.^{1,2}

CLINICAL FEATURES

History

Most CML patients (>90%) present in CP. CML is often diagnosed incidentally during routine examination or examination for another illness. Symptoms usually include fatigue, weight loss, bone pain, sweating, and abdominal discomfort and early satiety related to splenomegaly. Symptoms are generally gradual in onset over weeks to months. Uncommon presenting symptoms include those related to leukostasis, acute abdominal pain related to splenic infraction, priapism, and hypermetabolism, hyperuricemia, and gouty arthritis.

Physical Examination

Physical examination may detect pallor and splenomegaly. In the past, the incidence of splenomegaly was often greater than 90% at diagnosis, but this has been decreasing in frequency since the disease is being diagnosed earlier.

Laboratory Manifestations

Laboratory findings at presentation generally include leukocytosis, thrombocytosis, and anemia (Fig. 67.2). The total leukocyte count is always elevated at the time of diagnosis and is usually over 25×10^9 /L. The WBC count rises progressively if patients are left untreated. Striking cyclic variations in WBC counts have been described in rare patients. Differential counts reveal granulocytes at all stages of differentiation in peripheral blood cells. Circulating granulocytes are usually normal in appearance. The blast percentage is between 0.5% and 10%. Neutrophil alkaline phosphatase activity is low or absent in more than 90% of patients. However, activity can increase in response to infection, inflammation, and reduction of counts by treatment. Functional abnormalities of neutrophils are mild and are not associated with predisposition to infection. Although the proportion of eosinophils is usually not increased, the absolute eosinophil count is usually increased. The absolute basophil count is almost always increased in CML. The proportion of basophils is usually less than 15% in CP patients, although rarely this may be higher. In contrast to mastocytosis, hyperhistaminemia is uncommon. The absolute lymphocyte count is increased as a result of an increase in T but not B cells.

The platelet count is elevated in 50% of patients at the time of diagnosis. The platelet count may increase during the course of CP. Platelet dysfunction may occur, but disorders of thrombosis and hemorrhage are rare. Thrombocytopenia is rare at diagnosis and usually is a sign of progression toward AP. A deficiency in the second wave of aggregation to epinephrine is the most common abnormality

and is associated with deficiency of adenine nucleotides in the storage pool. The hematocrit is decreased in most patients at diagnosis. Red cells tend to show only mild alterations with increased variability of size and shape. Small numbers of nucleated red blood cells and mild reticulocytosis may be seen.

Chemical abnormalities seen in patients with untreated CML include hyperuricemia and hyperuricosuria. The formation of urate stones is common, and patients with underlying susceptibility may develop acute gouty arthritis or urate nephropathy. Patients have increased serum levels of vitamin B₁₂-binding capacity related to release of transcobalamin I and II from mature neutrophils. The serum B₁₂ level in CML is an average of 10-fold higher than normal. Serum lactate dehydrogenase is elevated in CML. Pseudohyperkalemia may be seen related to release of potassium from WBCs during clotting. Spurious hypoglycemia or hypoxemia may result from consumption by neutrophils after a sample is drawn.

Examination of the marrow usually reveals a very hypercellular marrow, with 75% to 90% marrow cellularity (see Fig. 67.2C and D). The granulocytic-to-erythroid ratio is increased to 10:1 to 30:1, with increased granulopoiesis and reduced erythropoiesis. Eosinophils and basophils may be increased. Blasts usually represent fewer than 5% of cells. The presence of more than 10% blasts indicates transformation to AP. Megakaryocytes are typically smaller than usual and may have hypolobated nuclei. Megakaryocyte numbers may be normal or slightly decreased, but 40% to 50% of patients show moderate-to-extensive proliferation of megakaryocytes. Collagen type III detected by silver staining is typically increased (see Fig. 67.2E). Approximately half of patients demonstrate increased reticulin fibrosis, which may be associated with increased megakaryocytes in marrow. Increased fibrosis may be associated with larger spleen size, anemia, and increased blasts in blood and marrow. Pseudo-Gaucher cells and sea-blue histiocytes, secondary to increased marrow cell turnover, may be seen in 30% of specimens (see H5eC69, Fig. 67.2F). The spleen shows enlargement related to infiltration of the cords of the red pulp with granulocytes at different stages of maturation. The liver may show infiltration with granulocytic cells in the portal areas and hepatic sinusoids.

Cytogenetic examination shows t(9;22)(q34;q11) and Ph chromosome in more than 90% of patients. Additional chromosomal abnormalities besides the Philadelphia chromosome are seen at diagnosis in 20% of patients including -Y and +8, and have not been shown to affect disease course. Variant Ph chromosomes are seen in 5% of patients, with complex rearrangement involving exchange of material with an additional chromosome besides chromosomes 9 and 22. In a small proportion of patients cryptic or complex translocations can be detected by fluorescence in situ hybridization (FISH) or PCR assays. The methodology used for identifying *BCR-ABL* transcripts has evolved over the years. Initially it was possible only to identify the presence or absence of *BCR-ABL* transcripts by either single-step amplification or a two-step “nested” amplification with internal primers to increase the sensitivity. Real-time quantitative PCR (RQ-PCR) provides an accurate measure of the total leukemia cell mass, and the degree to which *BCR-ABL* transcripts are reduced by therapy correlates with progression-free survival (PFS). A consensus meeting at the National Institutes of Health in October 2005 made suggestions for (A) harmonizing the different methodologies for measuring *BCR-ABL* transcripts in patients with CML undergoing treatment and using a conversion factor whereby individual laboratories can express *BCR-ABL* transcript levels on an internationally agreed scale; (B) using serial quantitative-PCR results rather than bone marrow cytogenetics or FISH for the *BCR-ABL* gene to monitor individual patients responding to treatment; and (C) detecting and reporting Ph-positive subpopulations bearing *BCR-ABL* kinase domain mutations. An international scale for comparison of *BCR-ABL* mRNA levels has been subsequently developed and implemented to facilitate common interpretation of data derived from individual laboratories and comparison of clinical studies, as well as to guide clinical decision. *BCR-ABL* values generated by different laboratories were aligned to the international scale such that major molecular response (MMR) was defined as *BCR-ABL*

values of 0.1% or less. Alignment was achieved using laboratory-specific conversion factors calculated by comparisons of results of assays performed with patient samples against a reference method. A validation procedure was completed, and showed that there was good agreement between the overall MMR rates between different validated assays.³

In any new patient whose blood count suggests the diagnosis of a chronic MPD, the detection of *BCR-ABL* transcripts in a blood specimen is probably the best way to confirm the diagnosis of CML. Current guidelines recommend that circulating *BCR-ABL* transcript numbers be measured and marrow cytogenetics be studied in every new patient with CML before initiation of treatment. Marrow cytogenetics is essential to identify any unusual translocations or additional cytogenetic abnormalities, and RQ-PCR for *BCR-ABL* at diagnosis will identify whether the commonly observed e13a2 (b2a2) or e14a2 (b3a2) transcripts are present or whether one of the less common fusion transcripts that are not amplified by the standard primer sets is present. This can prevent confusion if a patient on therapy has undetectable *BCR-ABL* transcripts because their transcripts were not amplified in the standard assay. If collection of marrow cells is not feasible, FISH performed on a blood specimen using dual probes for the *BCR* and *ABL* genes is an alternate method of confirming the diagnosis. FISH may also detect cytogenetically “silent” *BCR-ABL* rearrangements and deletions in the derivative 9q+, which have prognostic significance, and may therefore be performed in conjunction with marrow cytogenetics and RQ-PCR for *BCR-ABL* transcripts.

Natural History

The natural history of CML, determined more than 75 years ago, suggests a median survival from diagnosis of approximately 3 years. Without therapy, CML evolves from a CP to an AP, and eventually to BC. In approximately 25% of patients, there is no intervening AP between CP and BC (Table 67.1). Median survival times have been significantly prolonged with therapy (discussed later in the Therapy section). Following the introduction of imatinib treatment, a dramatic decrease in CML deaths was seen in age-adjusted death data from the US Surveillance Epidemiology and End Results (<http://seer.cancer.gov/statistics/>).⁴ Long-term follow-up of CML patients who achieved complete cytogenetic response (CCR) 2 years after starting imatinib treatment showed that CML-related deaths are uncommon and survival is not statistically significantly different from that of the general population.⁵

Accelerated Phase

In general, AP is characterized by symptoms of fever, night sweats, weight loss, and bone pain, difficulty in controlling counts using conventional therapy, increased numbers of blasts and early myeloid cells in marrow and peripheral blood, and evidence of karyotypic evolution (Fig. 67.3). The World Health Organization classification defines AP of CML as one or more of the following changes: (A) 10% to 19% myeloblasts in peripheral blood or bone marrow; (B) peripheral blood basophils higher than 20%; (C) persistent thrombocytopenia, less than $100 \times 10^9/L$; (D) persistent thrombocytosis, more than $1000 \times 10^9/L$ unrelated to therapy; (E) increasing WBC count and increasing spleen size unresponsive to therapy; and/or (F) evidence of clonal evolution. The most common cytogenetic changes associated with disease evolution are an additional Ph chromosome, trisomy 8, isochromosome 1(17q), and trisomy 19.

Blast Crisis

The blast phase of CML resembles acute leukemia. BC is defined as having more than 20% blasts in the bone marrow or peripheral blood, the presence of large aggregates and clusters of blasts in the

bone marrow biopsy, or the development of extramedullary blastic infiltrates. In approximately two-thirds of patients, the blasts have a myeloid or undifferentiated-like phenotype, whereas in the remaining third the blasts appear more lymphoid-like. Immunophenotypic analysis is recommended to characterize the nature of the blasts (Fig. 67.4). Extramedullary BC most commonly affects the skin, lymph nodes, spleen, bone, or CNS, but it may occur elsewhere and may be of myeloid or lymphoid lineage.

TABLE 67.1	WHO Criteria for Accelerated and Blast Phases of Chronic Myeloid Leukemia
Accelerated phase	Diagnosis can be made if one or more of the following is present: - Blasts 10% to 19% of peripheral blood white cells or bone marrow cells - Peripheral blood basophils at least 20% - Persistent thrombocytopenia ($<100 \times 10^9/L$) unrelated to therapy, or persistent thrombocytosis ($>1000 \times 10^9/L$) unresponsive to therapy - Increasing spleen size and increasing WBC count unresponsive to therapy - Cytogenetic evidence of clonal evolution (i.e., the appearance of an additional genetic abnormality that was not present in the initial specimen at the time of diagnosis of CP CML) - Megakaryocytic proliferation in sizable sheets and clusters, associated with marked reticulin or collagen fibrosis, and/or severe granulocytic dysplasia, should be considered as suggestive of AP CML. (These findings have not yet been analyzed in large clinical studies; thus, it is not clear whether they are independent criteria for AP. They often occur simultaneously with one or more of the other features listed.)
Blast crisis	Diagnosis can be made if one or more of following is present: - Blasts 20% or more of peripheral WBCs or bone marrow cells - Extramedullary blast proliferation - Large foci or clusters of blasts in bone marrow biopsy

AP, Accelerated phase; CML, chronic myeloid leukemia; CP, chronic phase; WBC, white blood cell.

PROGNOSIS

A number of prognostic scoring systems have been developed with the goal of predicting the length of CP in individual patients. The best-known and most widely used index was developed by Sokal and colleagues. An algorithm was identified using spleen size, percentage of circulating blasts, platelet count, and age as prognostic factors for CP patients. However, the Sokal scale was based on therapies available at that time (busulfan [BU], splenectomy), and newer systems for patients treated with IFN subsequently resulted in newer prognostic scoring systems. These scales, however, may have limited predictive value in the age of TKIs.

Approximately 20% of patients with CML have deletions of chromosomal material of varying size on the derivative 9q+. These deletions presumably occur at the same time as the formation of the Ph chromosome, and are thus not considered to be additional clonal changes as would be suggestive of AP disease. Patients with der 9q+ have a worse prognosis if they receive IFN therapy; it is unclear whether or not such deletions have a poor prognosis in patients receiving imatinib therapy.

Population-based studies investigating CML mortality in the imatinib era are now becoming available. They show that the pattern of mortality in CML patients related to high Sokal scores has become similar to those of intermediate scores induced by the use of imatinib in CP-CML patients.⁴

THERAPY

Definitions of Response to Treatment

Hematologic, cytogenetic, and molecular responses to treatment in CML have been defined (Table 67.2). A complete hematologic response (CHR) is defined as the achievement of normal WBC and platelet counts and normal differential, along with the disappearance of all symptoms and signs of CML. A partial hematologic response is defined as a decrease in the WBC count to less than 50% of the pretreatment level or the normalization of the WBC count accompanied by persistent splenomegaly or immature cells in the peripheral blood. A CCR is defined as the absence of Ph⁺ metaphases in marrow cells, along with partial cytogenetic response as 1% to 34% Ph⁺ metaphases. Major cytogenetic remission (MCR) combines the percentages of complete and partial response. There is now increasing reliance on *BCR-ABL* mRNA levels for assessment of response. According to the international scale for comparison of *BCR-ABL* mRNA levels, a MMR is defined as a value of 0.1% or less.³ Lack of detection of *BCR-ABL* mRNA is referred to as a complete molecular response (CMR). Since the ability to detect *BCR-ABL* mRNA depends on the sensitivity of the PCR assay, there is now consensus

Fig. 67.3 CHRONIC MYELOID LEUKEMIA, ACCELERATED PHASE. (A) Peripheral smear showing increased immaturity in a case in which blasts were more than 10% of circulating leukocytes. (B) Peripheral smear illustrating increased basophils in a case in which basophils were more than 20% of circulating leukocytes. (C) Bone core biopsy showing increased fibrosis and small dysplastic megakaryocyte. These findings are suggestive of accelerated phase.

Fig. 67.4 CHRONIC MYELOID LEUKEMIA, BLAST PHASE. (A) Bone marrow aspirate showing myeloid blast phase associated with $t(9;22)$ and $inv(16)$. Note abnormal eosinophil (center). (B) Bone marrow aspirate showing lymphoid blast phase in the background of residual chronic myeloid leukemia. (C) Bone core biopsy illustrating focal blast phase.

TABLE 67.2 Response Definition and Monitoring

Hematologic Response	Cytogenetic Response	Molecular Response
Complete: platelet count $<450 \times 10^9/L$; WBC count $<10 \times 10^9/L$; differential without immature granulocytes and with less than 5% basophils; nonpalpable spleen	Complete: Ph^+ 0 Major: Ph^+ 1–35% Minor: Ph^+ 36–65% Minimal: Ph^+ 66–95% None: Ph^+ $<95\%$	Complete: <i>BCR-ABL</i> transcripts nonquantifiable and nondetectable ^a Major: $\leq 0.10\%$

BCR-ABL to control gene ratio according to the proposed international scale for measuring molecular response, with a standardized “baseline”, as established in the IRIS trial, taken to represent 100% on the international scale, and a 3-log reduction from the standardized baseline (major molecular response) fixed at 0.10%.

^aQualified by the limit of sensitivity of the polymerase chain reaction assay employed. ABL, Abelson leukemia virus; BCR, breakpoint cluster region; Ph^+ , Philadelphia chromosome positive; WBC, white blood cell.

that CMR be defined based on assay sensitivity (e.g., $CMR^{4.0}$, where *BCR-ABL* mRNA levels are 0.01% or 4.0-log reduced).

Chemotherapy

BU chemotherapy for CML was introduced in the 1950s. BU was administered in doses of 4–6 mg/day and then held when the WBC count fell to $30 \times 10^9/L$. The drug effect could persist for weeks, and the counts could fall further after therapy was discontinued. BU therapy was associated with serious adverse effects, including prolonged aplasia, pulmonary fibrosis, and a syndrome simulating adrenal insufficiency.

Treatment with hydroxyurea (HU) was started as an alternative to BU. HU therapy is usually initiated at doses of 1–6 g/day in an attempt to lower counts. HU administered at doses of 1–2 g/day is then used to maintain blood counts in the normal range. HU is less toxic than BU. Its major adverse effect is reversible marrow suppression. In randomized trials, HU was shown to prolong survival of patients with CP CML when compared with BU therapy. Median survival of HU-treated patients was 5 years compared with 3.75-year median survival of BU-treated patients. Because neither drug results in significant selective suppression of the Ph^+ clone, the aim of therapy with these agents is to control disease and symptoms. HU is now commonly used to achieve control of counts simultaneous with, or prior to, initiation of treatment with imatinib or other disease-specific therapies.

Several other chemotherapeutic agents can be used to reduce the white cell counts in CML. Low-dose cytosine arabinoside can be used either as an intermittent bolus or as a daily infusion to control disease in cases where neither HU nor BU is proving useful. Cytosine arabinoside has also been used in combination with other agents, including IFN and imatinib in an attempt to enhance response.

Hyperuricemia and hyperuricosuria are frequently encountered problems in newly diagnosed and relapsed CML patients. Allopurinol given at a dose of 300 mg daily and adequate hydration should be started before initiating treatment. Allopurinol should be discontinued after the WBC count has been controlled.

Interferon

Pioneering observational studies initiated in the 1980s by investigators at the MD Anderson Cancer Center provided evidence for efficacy of IFN in CML and indicated a 70% to 80% probability of complete hematologic remission in selected CML patients. Initial research involved the use of human leukocyte IFN, but subsequent clinical studies used recombinant human IFN- α (rIFN- α). Recombinant IFN- γ (rIFN- γ) has been shown to be relatively ineffective for CML. The potential mechanisms by which IFN works in CML are not understood but may include inhibition of increased proliferation, correction of the adhesion defect of the malignant progenitor in CML, or stimulating an immune response to CML. Rates for complete and partial cytogenetic remissions range from 0% to 38%. Evidence exists for a dose–response relationship, with IFN doses of 4–5 million units/ m^2 /day more likely to achieve remission (and toxicity) than lower doses. The pegylated form of IFN, designed to have a longer half-life in the blood, may be associated with increased efficacy. Durable remissions are more common in young patients, those treated soon after diagnosis, patients with less advanced stage disease, and those with a favorable prognostic outlook. Hematologic remissions usually occur within 1 to 3 months after starting IFN. The median time to CCR is 9 to 18 months but may occur after 4 years of therapy. Durable cytogenetic responses, some lasting as long as 10 years, are more common in patients who achieve a CCR compared with partial cytogenetic remission.

Virtually all patients receiving IFN experience constitutional adverse effects, and discontinuation of treatment as a result of toxicity is necessary for 4% to 18% of patients compared with 1% of those receiving HU. Acute adverse effects are generally mild to moderate and include influenza-like symptoms such as fever, chills, and malaise. A constellation of other more severe acute reactions and chronic complications can occur. Overall, the mechanisms underlying the toxic effects are not well understood, but adverse effects are usually dose and duration dependent.

Randomized studies show an improvement in survival rates in patients receiving IFN compared with patients receiving BU or HU. An Italian multicenter study randomly assigned 218 patients to receive IFN and 104 patients to receive HU or BU (the control group). Cytogenetic remissions were significantly more common in the IFN group. After a median follow-up of 68 months, the observed 6-year survival rate was 50% for IFN-treated patients and 29% for controls, with median survivals of 72 and 52 months, respectively. The time for progression from CP to accelerated or blast phase was lengthened from 45 months to more than 72 months. In a German multicenter study, 622 patients were randomized to receive IFN, BU, or HU. The 5-year survival rate in the IFN group (59%) exceeded that of the BU group (32%) but was not significantly higher than that of the HU group (44%). Much of the discrepancy between the Italian and German findings can be explained by differences in case mix and treatment regimens. Two other randomized trials also showed benefit for IFN treatment compared with chemotherapy. The UK Medical Research Council randomly assigned 293 patients to receive IFN and 294 patients to receive HU or BU. The 5-year survival rate was 52% for the IFN group and 34% for the control group. A Japanese randomized control trial compared IFN (80 patients) with BU (79 patients). Hematologic and cytogenetic remission rates did not differ significantly. After a median follow-up of 50 months, the predicted 5-year survival rate was 54% for patients receiving IFN and 32% for those receiving BU.

The added value of combining IFN with cytosine arabinoside was shown in a French multicenter trial, wherein 360 patients were randomly assigned to receive IFN combined with cytosine arabinoside (20 mg/m²/day for 10 days) and 361 patients to receive only IFN. After 3 years, the survival rate was 86% with IFN and cytosine arabinoside and 79% with IFN alone. The rate of hematologic response was higher in the IFN–cytosine arabinoside group than in the IFN group. Major cytogenetic responses were observed 12 months after randomization in 41% of patients treated with IFN–cytosine arabinoside and in 24% of patients treated with IFN only.

Thus, accumulated evidence from randomized trials suggests that IFN improves survival in CP patients with favorable features compared with BU and HU. Metaanalysis suggests that the pooled 5-year survival rate is 57% (50–59%) for IFN and 42% (29–44%) for chemotherapy, which results from a delay in the onset of BC. The controlled trials suggest that IFN increases life expectancy by a median of approximately 20 months compared with BU and HU. There is no direct evidence that IFN has a greater impact on survival than does HU for patients who are in the later stages of CP (e.g., more than 1 year after diagnosis) or for those who are more ill (e.g., more than 10% to 30% blasts in peripheral blood). Adding cytosine arabinoside to IFN appears to add further survival benefit but also increases toxicity. Although IFN clearly is beneficial in patients with CML patients, benefit is limited by low levels of cytogenetic response and considerable toxicity. As discussed later, the use of IFN in the modern treatment of CML patients has been replaced by use of imatinib and other TKIs.

Tyrosine Kinase Inhibitor Treatment

Because the tyrosine kinase activity of BCR-ABL plays a critical role in cellular transformation, it is an attractive target for inhibition. The introduction of TKIs into clinical practice has dramatically changed CML treatment. TKI therapy, now the mainstay of treatment, is remarkably effective for CP CML, inducing remissions in most patients and leading to excellent survival. TKI resistance can occur, especially in AP and BC CML, usually as a result of tyrosine kinase domain point mutations. Resistance to imatinib can often be treated by “second-generation” TKIs dasatinib or nilotinib, and there is evidence that these drugs may be even more effective than imatinib for front-line treatment of CML. Molecular endpoints that correlate with long-term outcomes have been developed and have been incorporated into guidelines to monitor response to TKIs treatment.

Imatinib Mesylate

Imatinib mesylate is a small, 2-phenylaminopyrimidine molecule that inhibits the kinase activity of all proteins that contain ABL, ABL-related gene (ARG) protein, or platelet-derived growth factor receptor, as well as the KIT receptor, at micromole concentrations.⁶ Imatinib is a competitive inhibitor that acts at the ATP-binding site in the kinase domain to inhibit the normal binding of ATP and blocks the ability of BCR-ABL to phosphorylate tyrosine residues on its substrates (Fig. 67.5).

Initial phase I and phase II trials established that imatinib was well tolerated and induced hematologic as well as cytogenetic response in the majority of patients with CP CML in whom other treatments had failed.⁷ In a phase II study, 532 CP patients who were refractory to or intolerant of IFN- α were treated with imatinib at a dose of 400 mg daily. A CHR was achieved in 95% of patients, MCR in 60% of patients, and CCR in 41% of patients. With a median follow-up of 18 months, the estimated PFS was 89%. Only 2% of patients discontinued therapy because of adverse events.

Subsequently the International Randomized Interferon and STI571 (IRIS) study compared imatinib at 400 mg daily with IFN- α plus cytosine arabinoside in 1106 newly diagnosed patients in first CP. This study was closed with the conclusion that imatinib is the initial nontransplant treatment of choice for patients with newly diagnosed CP CML. This conclusion was based primarily on a higher rate of disease progression in the patient group receiving IFN plus cytosine arabinoside. In the initial report from this study, after a median follow-up of 19 months, the estimated rate of an MCR at 18 months was 87.1% (95% confidence interval [CI]: 84.1–90.0) in the imatinib group and 34.7% (95% CI: 29.3–40.0) in the IFN plus cytosine arabinoside group ($p < .001$).⁸ The estimated rates of CCR were 76.2% (95% CI: 72.5–79.9) and 14.5% (95% CI: 10.5–18.5), respectively ($p < .001$). At 18 months, the estimated rate of freedom from progression to AP or BC CML was 96.7% in the imatinib group and 91.5% in the IFN group ($p < .001$). Imatinib was better tolerated than combination therapy. In a subsequent 60-month follow-up report for this study, the estimated cumulative incidence rate of CHR, MCR, and CCR for patients on first-line imatinib was 98%, 92%, and 87% at 60 months (Fig. 67.6). Only 7% of patients progressed to advanced phase, and the estimated overall survival (OS) was 89%. Crossover between arms was permitted for treatment failure, and 382 (69%) of 553 patients originally allocated to the IFN/cytarabine arm crossed over to the imatinib arm at a median of 60 months from start of treatment. The main reason for crossover from IFN to imatinib was intolerance of treatment, but reasons also included disease progression and failure to achieve hematologic or cytogenetic response. During the 6th year of study treatment, there were no further reports of disease progression and the toxicity profile remained unchanged. Of all patients randomized to receive imatinib and still on study treatment, 63% showed CCR at last assessment. The estimated event-free survival (EFS) at 6 years was 83%, and the estimated OS was 88%.⁹

A dose of 400 mg of imatinib daily is currently the standard dose for initiating therapy in newly diagnosed CP patients. Nonrandomized studies suggested that patients receiving initial therapy with 800 mg imatinib daily will achieve CCR more rapidly than patients receiving standard 400-mg daily doses. The Tyrosine Kinase Inhibitor Optimization and Selectivity study compared imatinib 800 mg/day ($n = 319$) to 400 mg/day ($n = 157$). Higher dose imatinib provided faster response CCR rates at 6 months (57% vs. 45%, respectively), but there was no significant difference between the arms at 12 months (70% vs. 66%, respectively) or 24 months (76% in both groups). Similarly, no difference in EFS, PFS, or OS was seen. However, a subset of patients who can tolerate higher doses of imatinib, without interruptions for side effects, can have a better response.¹⁰

Cumulative response estimates do not take into account patients who have left the study for a variety of reasons. It is also clear that the results of imatinib therapy in the community setting are less favorable. Thus, only 55% of patients treated with first-line imatinib

Fig. 67.5 CHRONIC MYELOID LEUKEMIA, BEFORE AND 3 MONTHS AFTER IMATINIB THERAPY. Chronic-phase chronic myeloid leukemia, as seen in the peripheral blood (A), aspirate (B), and biopsy (C), and after 3 months of imatinib therapy (D–F). Note normalization of white cell count (D), megakaryocyte size (E), and marrow cellularity (F).

in the IRIS study were still receiving imatinib at follow-up of 8 years, while the remainder had discontinued therapy as a result of inadequate therapeutic effect or toxicity. A report from the Hammersmith Hospital, which defined imatinib failure more broadly than the IRIS study as discontinuation of drug for any reason, including toxicity as well as a lack of major cytogenetic response, calculated 5 years EFS at only 63%.¹¹

Comparison of health-related quality of life (QOL) of imatinib-treated patients and the general population indicated marked impairments of QOL in younger patients, especially between 18 and 39 years of age, related to physical and emotional problems. Women had worse QOL than men. The most frequently reported symptom was fatigue. Patients older than 60 years had a QOL similar to that of the general population.¹²

Prognostic Indicators

Pretreatment risk factors can predict the likelihood of achieving and maintaining response to imatinib. At 60 months, the estimated risk for disease progression was significantly higher for patients with a higher pretreatment Sokal score (estimated rates for high-risk, intermediate-risk, and low-risk groups of 17%, 8%, and 3%, respectively; $p < .002$).

The achievement of certain milestones of response can also predict prognosis. For example, patients who do not experience a CHR response by 3 months of treatment, any cytogenetic response by 6 months, or a major cytogenetic response by 12 months do poorly in comparison with patients achieving these milestones. Reduction of *BCR-ABL* levels observed with cytogenetic and quantitative PCR monitoring is also predictive of prognosis (Fig. 67.7). A landmark analysis indicated that at 60 months, 97% of the patients (95% CI: 94–99) who had achieved CCR at 12 months after the initiation of imatinib treatment ($n = 350$) had not progressed to AP or BC

(see Fig. 67.7). For patients who did not have a MCR within 12 months ($n = 73$), the estimate was 81% (95% CI: 70–92; $p < .001$). Of interest, the Sokal score was not predictive of risk for disease progression in patients who had a CCR (95%, 95%, and 99% in the high-risk, intermediate-risk, and low-risk groups, respectively; $p = .20$). The prognostic significance of molecular responses at 6, 12, and 18 months in predicting EFS and time to progression to AP/BC at 7 years was evaluated in the IRIS cohort. Patients with *BCR-ABL* mRNA levels $>10\%$ at 6 months and $>1\%$ at 12 months using the international scale had inferior EFS and higher rates of progression compared with all other molecular response groups. Conversely, patients who achieved MMR (*BCR-ABL* [IS] $<0.1\%$) by 18 months enjoyed durable responses, with no progression, 95% EFS, and only 3% probability of loss of complete cytogenetic remission (CCyR) at 7 years.¹³ In an analysis from the Hammersmith group, patients with *BCR-ABL* mRNA levels $>9.84\%$ at 3 months had significantly lower 8-year probabilities of OS (56.9% vs. 93.3%; $p < .001$), PFS, cumulative incidence of CCyR, and CMR than those with higher levels. Similarly, *BCR-ABL* mRNA levels $>1.67\%$ at 6 months and $>0.53\%$ at 12 months also identified patients at increased risk for progression.¹⁴ These results indicate a strong association between the degree of reduction of *BCR-ABL* transcript numbers and long-term clinical outcome, and have led to the adoption of time-dependent molecular response measurements in determining optimal response to therapy. The European Leukemia Net criteria consider an optimal response for survival, as well as deeper responses allowing treatment-free remission, to include *BCR-ABL* transcript levels $<10\%$ at 3 months, $<1\%$ at 6 months, $<0.1\%$ at 1 year, and $<0.01\%$ subsequently. Molecular monitoring should include mutational analysis in case of failure. Recent retrospective analyses have shown that the dynamics of the early molecular response may be a more important prognostic indicator than the molecular response at 3 months, but requires monthly monitoring following initiation of treatment.

Fig. 67.6 RESPONSE OF NEWLY DIAGNOSED CHRONIC MYELOID LEUKEMIA PATIENTS TO IMATINIB MESYLATE BASED ON 5 YEARS' FOLLOW-UP ON THE INTERNATIONAL RANDOMIZED INTERFERON AND STI571 (IRIS) STUDY. (A) Kaplan–Meier estimates of the cumulative best response to initial imatinib therapy. (B) Kaplan–Meier estimates of the rates of event-free survival and progression to the accelerated phase or blast crisis of chronic myeloid leukemia for patients receiving imatinib. (Data from Druker BJ, Guilhot F, O'Brien SG, et al: Five-year follow-up of patients receiving imatinib for chronic myeloid leukemia. *N Engl J Med* 355:2408, 2006.)

Lack of adherence to medication is a major underlying reason for failure of treatment. It has been reported, on multivariate analysis, that in CML patients treated with imatinib for some years, the adherence rate and failure to achieve a MMR were the only independent predictors for loss of CCR and discontinuation of imatinib, and poor adherence may be the predominant reason for inability to obtain adequate molecular responses.^{15,16}

Results of Treatment in Accelerated Phase and Blast Crisis

A phase II study in AP patients enrolled 235 patients. Some hematologic response was seen in 82% of patients, with 34% of patients

Fig. 67.7 EVENT-FREE SURVIVAL OF NEWLY DIAGNOSED CHRONIC MYELOID LEUKEMIA PATIENTS TREATED WITH IMATINIB MESYLATE AFTER 7 YEARS' FOLLOW-UP ON THE INTERNATIONAL RANDOMIZED INTERFERON AND STI571 (IRIS) STUDY BASED ON MOLECULAR RESPONSE AT 6- (A), 12- (B), AND 18-MONTH (C) LANDMARKS. (Data from Hughes TP, Hochhaus A, Branford S, et al: Long-term prognostic significance of early molecular response to imatinib in newly diagnosed chronic myeloid leukemia: An analysis from the International Randomized Study of Interferon and STI571 (IRIS). *Blood* 116:3758, 2010.)

achieving a CHR. A major cytogenetic response occurred in 24% of patients, with 17% complete responses (CRs). Estimated 12-month PFS and OS rates were 59% and 74%, respectively.

A phase II study of 260 patients in myeloid BC who were treated with imatinib showed an overall response rate of 52%, with sustained hematologic responses lasting at least 4 weeks in 31% of patients. Eight percent of patients achieved a complete remission with peripheral blood recovery. Another 4% of patients cleared their marrows to less than 5% blasts but did not meet the criteria for CR because of persistent cytopenias. Eighteen percent of patients either "returned" to CP or had partial responses. Major cytogenetic responses were seen in 16% of patients, with 7% having CCRs. The median survival was 7 months. These results compare favorably with historical controls treated with chemotherapy for myeloid BC in which the median survival is approximately 3 months. In patients with Ph-positive ALL, 29 out of 48 (60%) responded to a single agent, imatinib. However, the duration of response was relatively short, with a median estimated time to disease progression of only 2 months.

Toxicity

Myelosuppression is particularly common in CML patients treated with imatinib and is more common in patients with advanced disease. In the phase III randomized trial of newly diagnosed patients in the CP, grade 3 neutropenia (absolute neutrophil count [ANC] $<1000/\text{mm}^3$) was experienced by 11% of patients, grade 4 neutropenia (ANC $<500/\text{mm}^3$) occurred in 2% of patients, grade 3 thrombocytopenia (platelets $<50,000/\text{mm}^3$) occurred in 6.9% of patients, and grade 4 thrombocytopenia (platelets $<10,000/\text{mm}^3$) occurred in less than 1% of patients. Myelosuppression can occur at any time during imatinib therapy, but it usually begins within the first 2 to 4 weeks of starting therapy for BC, with a slightly later onset in patients in AP or CP. Although grade 3 and 4 neutropenia is frequent, particularly in advanced phases, infectious complications are relatively rare, possibly related to the lack of mucous membrane damage in patients on imatinib. CNS and gastrointestinal hemorrhages may occur, most frequently in patients in BC with platelet counts less than 20,000 and with uncontrolled leukemia. The primary goal in treating otherwise healthy patients in CP is to avoid the risk for potentially dangerous neutropenia and platelet transfusion dependence. For patients with BC or high-risk AP disease ($>15\%$ blasts), a suggested approach is to balance risks and benefits, and support patients with a platelet count under $10,000/\text{mm}^3$ or under $50,000/\text{mm}^3$ with clinically evident bleeding with platelet transfusions. In the event of clinically significant bleeding, imatinib should be held immediately until the bleeding is controlled. In patients whose ANC is less than $500/\text{mm}^3$, imatinib should be continued if the marrow is hypercellular or if there are $>30\%$ blasts. In cases where the marrow is hypocellular and the ANC is $<500/\text{mm}^3$ for 2 to 4 weeks, imatinib may be held, the dose may be reduced, or myeloid growth factors can be used. Concurrent administration of growth factors and imatinib is well tolerated, and patients have not experienced a greater rate of relapse.¹⁷

The most common nonhematologic adverse events related to imatinib were nausea, muscle cramps, fluid retention, diarrhea, musculoskeletal pain, fatigue, and skin rashes. Only a minority of patients experienced grade 3 or 4 toxicity, and there was a low rate of discontinuance of therapy because of toxicity of 5%, 3%, and 2% in the phase II studies for BC, AP, and CP, respectively. The higher rate of severe toxicity in patients with advanced-phase disease may relate to the higher doses administered or to the poorer underlying health of patients. Most adverse effects can be managed successfully with supportive measures. Some toxicities (e.g., mild skin rashes, mild elevations of transaminases, bone pain, and arthralgias) may improve spontaneously despite continued therapy at the same dosage.

Imatinib Resistance

Both de novo and acquired resistance have been observed in imatinib-treated CML patients. The most commonly described mechanisms associated with resistance are point mutations in the *BCR-ABL* gene that prevent imatinib from inhibiting kinase activity and *BCR-ABL* gene amplification. *BCR-ABL*-independent mechanisms may also play a role in imatinib resistance in some patients. Activation of the SRC family kinase, LYN, has been demonstrated in cells from patients with acquired imatinib resistance. The Sawyers group, in an original study of nine patients who relapsed on imatinib treatment, detected *BCR-ABL* gene amplification in three patients and kinase domain mutations in six. Relapse was associated with reactivation of *BCR-ABL* kinase activity. Subsequent studies have shown that there are >90 different amino acid substitutions detected in imatinib-resistant patients (see Fig. 67.1), occurring with varying frequency.¹⁸ The different mutations conferred varying degrees of imatinib resistance. In patients with stable CP disease, detection of mutations correlated with subsequent disease progression. Mutations have been found in some patients before the start of treatment, supporting a model in which preexisting *BCR-ABL* mutations that confer imatinib resistance acquire a selective clonal growth advantage during imatinib treatment.

Intensive efforts have been made to characterize the biologic and clinical significance of *BCR-ABL* kinase mutations and to develop kinase inhibitors with efficacy against the maximum number of mutants. The structure of the ABL kinase domain in complex with imatinib has been solved. This information sheds light on the mechanisms by which kinase domain mutations confer drug resistance. Mutations may affect residues that directly contact imatinib, such as a mutation resulting in substitution of isoleucine for threonine in the T315 position (T315I). Mutations in the P-loop of the ABL kinase prevent conformational changes required for imatinib binding. Imatinib captures and stabilizes the ABL kinase in its inactive conformation, but is sterically excluded from the active conformation. The M351T mutation and mutations in the activation loop result in the kinase remaining in the active conformation rather than the inactive conformation required for imatinib binding. Clinical experience with the second-generation TKIs dasatinib and nilotinib demonstrates that a much narrower spectrum of mutations retain insensitivity to these agents. These mutations are nonoverlapping, with the exception of the T315I mutation.

Knowledge of *BCR-ABL* mutation status is being integrated into therapeutic decision-making algorithms for patients. The European Leukemia Net guidelines for the use of mutation testing in management of CML patients recommends mutation testing in CP CML patients receiving first-line imatinib treatment only in case of failure or suboptimal response. Mutation analysis is recommended in imatinib-resistant patients receiving an alternative TKI in case of hematologic or cytogenetic failure.¹⁸

Second-Generation Tyrosine Kinase Inhibitors

Because the active conformations of ABL and SRC bear a high degree of structural similarity, compounds with SRC kinase inhibitory activity have been evaluated against native and mutant *BCR-ABL*. BMS-354825 (dasatinib, Sprycel) is a dual SRC-ABL kinase inhibitor that exhibits approximately 300-fold higher potency against native *BCR-ABL*. Dasatinib can effectively inhibit most clinically detected *BCR-ABL* kinase domain mutants at low nanomolar concentrations, with the notable exception of T315I. Another compound, AMN107 (nilotinib) was generated by rational modification of imatinib to enhance *BCR-ABL* kinase binding activity. Nilotinib binds ABL but with significantly increased avidity and can overcome resistance of most kinase domain mutants, with the exception of T315I. It is evident, however, that both agents have significant activity in imatinib-resistant CML. Of note, responses occurred in patients with and without *BCR-ABL* kinase domain mutations at trial entry, with the exception of patients with the T315I mutation. Responses in CP and, to a lesser extent, in AP have been stable. In contrast, many patients with myeloid and all patients with lymphoid BC or Ph-positive ALL have relapsed. These data are similar to the results of the initial studies with imatinib and indicate that once the disease has progressed beyond the CP, TKI-based monotherapy is not sufficient to induce lasting responses. Both dasatinib and nilotinib are approved for the treatment of patients with CML that is resistant to imatinib and those who are intolerant to the drug. Both agents are quite effective in resistant disease, yielding CCR in approximately 50% of CP cases (for cases who discontinue imatinib because of drug intolerance, the CCR rates are $>70\%$).

Because of this strong clinical activity, both drugs have been tried as first-line therapy in newly diagnosed CP CML. Two single-center trials of dasatinib and nilotinib have been performed at the MD Anderson Cancer Center. At 18 to 24 months, both agents showed a similarly small but consistent benefit in CCR over historical controls treated on imatinib trials. An Italian phase II study of nilotinib in newly diagnosed CP cases showed a similarly high rate of CCR of $>90\%$ after 12 months of therapy. Dasatinib and nilotinib were compared with imatinib for front-line treatment of CP CML. The Dasatinib Versus Imatinib Study in Treatment-Naïve CML (DASISION) study tested 100 mg dasatinib daily versus 400 mg imatinib daily.¹⁹ The Evaluating Nilotinib Efficacy and Safety in Clinical Trials

Newly Diagnosed Patients (ENESTnd) study compared two nilotinib doses (400 mg twice daily and 300 mg twice daily) with imatinib 400 mg daily.²⁰ Both studies found the experimental arms (dasatinib and nilotinib) to be superior to imatinib in achieving the primary endpoints (dasatinib: CCR by 12 months; nilotinib: MMR at 12 months). Patients treated with nilotinib had a significantly reduced risk for progression. Based on these results, both nilotinib and dasatinib were approved for front-line therapy of newly diagnosed CP CML patients in the United States (US) in 2010.

Bosutinib, another dual Src/Abl kinase inhibitor, has also shown potent activity against CML and was approved for the treatment of CP, AP, and BC CML by the US Food and Drug Administration (FDA) in 2012. Bosutinib overcomes the majority of imatinib-resistant *BCR-ABL* mutations except the T315I and V299L mutations. Bosutinib shows activity against certain mutations conferring resistance to dasatinib (e.g., F317L) and nilotinib (e.g., F359V). The recommended dose is 500 mg orally, taken once daily with food. The toxicity profile of Bosutinib differs from other approved TKIs in CML, possibly due to the minimal activity against platelet-derived growth factor receptor and KIT. The most common nonhematological adverse events are gastrointestinal, including diarrhea, nausea, vomiting and abdominal pain, predominantly occurring within the first 4 weeks of treatment and generally resolving spontaneously, and ALT elevations. Bosutinib provides an important additional treatment of CML patients previously treated with one or more TKIs, for whom imatinib, nilotinib, and dasatinib are not appropriate options.

The choice of TKI in newly diagnosed patients remains open to debate. Dasatinib and nilotinib are associated with faster and deeper reduction in leukemia burden. On the other hand, no differences in OS have been observed yet, although follow-up is required and long-term data from randomized clinical studies are needed to confirm the initial findings. Imatinib is less expensive, and there is longer experience with its use. A direct comparison between nilotinib and dasatinib has not been performed. Since their overall efficacy appears to be similar, the selection may be based primarily on side effect profile and convenience. Dasatinib treatment is associated with higher rates of myelosuppression and hemorrhage, and with pericardial and pleural effusion. In contrast, nilotinib can induce an increase in pancreatic enzymes, although radiographic/clinical pancreatitis is rarely noted. Hyperglycemia and hyperbilirubinemia are observed in some nilotinib-treated patients. More recent data suggest a risk for severe peripheral arterial occlusive disease and other cardiovascular events, including cerebral ischemia and myocardial infarction, in patients receiving nilotinib. Skin rash is also a prominent side effect of nilotinib therapy, but this is usually moderate and/or resolves spontaneously. Severe, uncontrolled diabetes and past pancreatitis may be considered as risk factors for nilotinib use, whereas patients with a history of hypertension, asthma, pneumonia, gastrointestinal bleeding, chronic obstructive pulmonary disease, congestive heart failure, vascular disease, autoimmune disorders, or concomitant aspirin use may be at increased risk for pleural and pericardial effusions, bleeding, and infection with dasatinib. For the choice of the second- or third-line TKI, mutational analyses, the occurrence of adverse events related to treatment, and coexisting patient pathologies are important considerations.

Drugs Targeting the T315I Mutation

The fact that the T315I mutant is not responsive to either dasatinib or nilotinib and that this mutant has been detected in some patients with acquired resistance to dasatinib and nilotinib underscores the need for drugs with T315I inhibitory activity.²¹ Ponatinib is a multitargeted kinase inhibitor active against all *BCR-ABL* mutants, including T315I. In a phase I study, more than 50% of patients in CP, mostly patients in whom two or more TKIs had failed, attained CCR.²¹ The CCR rate was 92% in patients with the T315I mutation. Responses were less frequent and stable in patients with advanced disease. This was confirmed in a phase II study where 51% of patients resistant to or intolerant of second-generation TKIs and 70% of

patients with the T315I *BCR-ABL* mutation experienced a major cytogenetic response. However, 1 year after its accelerated approval by the US FDA, a high number of vascular occlusive events, both arterial and venous thromboembolic events, began to be reported, leading to the US FDA placing a partial clinical hold on the drug. The hold was lifted following dose-reduction recommendations, but use is currently restricted to patients with the T315I mutation or for whom no alternative TKI is available.

Omacetaxine mepesuccinate is a semisynthetic formulation of homoharringtonine, an alkaloid extracted from various *Cephalotaxus* species.²² It has a distinct mechanism of action related to inhibition of protein synthesis—interfering with initial protein elongation—leading to decreased levels of proteins important for leukemia cell survival, including *BCR-ABL* MYC and MCL1. Omacetaxine is approved for the treatment of adult patients with CP or AP CML with resistance or intolerance to two or more TKIs. Of 111 CP or AP CML patients who received two or more prior TKIs, major cytogenetic response was achieved in 18% of patients with CP, with median response duration of 12.5 months and major hematologic response in 14% of patients with AP, with a median response duration of 4.7 months. Omacetaxine is supplied as a single-use vial for parenteral administration. Common adverse reactions included thrombocytopenia, anemia, neutropenia, diarrhea, nausea, fatigue, asthenia, injection site reaction, pyrexia, and infection.

Residual Disease in Patients Treated With Tyrosine Kinase Inhibitors

Currently, reverse-transcriptase PCR (RT-PCR) is the most sensitive method for detecting low numbers of *BCR-ABL* transcripts in a patient after apparently successful HCT. Most patients who have been treated with imatinib and have responded well continue to demonstrate evidence of residual disease using sensitive PCR assays. Recent updates of clinical trials of imatinib in CP CML patients indicate that an increasing proportion of patients appear to enter molecular remission over time, including some patients achieving a PCR-undetectable status. However, even patients with negative PCR (so-called CMR) may still have significant numbers of residual malignant cells. Several groups have identified *BCR-ABL*-expressing leukemia stem cells in patients with sustained undetectable molecular residual remission. Patients with undetectable minimal residual disease (MRD) after imatinib therapy continued to have *BCR-ABL* rearrangement detectable at the genomic level, indicating persistence of residual leukemic cells not detected by RT-PCR. It is important to note that residual leukemic cells with leukemia-initiating capacity have been shown to persist in CML patients in sustained molecular remission on imatinib.²³ Together, these data suggest that imatinib alone may not be capable of eradicating the leukemic cell clone, and at present, patients are recommended to continue medication indefinitely, outside of investigational studies as described later.

Discontinuation of Tyrosine Kinase Inhibitor Treatment

Discontinuation of imatinib has emerged as an investigational approach for patients with CP CML with undetectable MRD. A pilot study of imatinib discontinuation in patients in CMR for 2 years indicated that half of the patients experienced molecular relapse within 6 months of treatment discontinuation, but that the remaining patients did not develop molecular relapses with an extended follow-up of 4 years. These results were confirmed in the multicenter STIM study, in which 40 out of 69 patients (61%) lost CMR within the first 6 months, and the probability of persistent CMR at 12 months was 41%.²⁴ Comparable results were reported in the Australian TWISTER study, which used very similar entry criteria. At 24 months, the actuarial estimate of stable treatment-free remission was 47.1%. Most relapses occurred within 6 months of stopping imatinib, and no relapses beyond 27 months were seen. The multicenter

According to STIM (A-STIM) study evaluated whether the loss of MMR, defined as $<0.1\%$ BCR-ABL (IS), was a safe and clinically relevant measure for defining molecular relapse after imatinib discontinuation. Eighty patients with CP-CML in prolonged CMR were studied. Cumulative MMR loss was 36% at 24 months, whereas probability of losing CMR was higher. Fluctuation of BCR-ABL transcript levels below the MMR threshold was observed in 31% of patients. Treatment-free remission was estimated as 61% at 36 months. These results suggest that loss of MMR is a practical and safe criterion for restarting therapy after treatment discontinuation in CML patients with prolonged CMR.

Management of Pregnancy in CML Patients

Imatinib therapy has been associated with a constellation of rare congenital malformations and spontaneous abortions. All couples should be counselled on the risks associated with pregnancy whilst receiving TKI therapy. At the time of diagnosis, fertility preservation should be discussed with both male and female patients of childbearing potential. Patients should be counselled regarding fertility options such as semen cryopreservation, oocyte retrieval and storage, and embryo cryopreservation because of potential deleterious effects of TKIs on gonadal function and fertility. Pregnancy in CML presents specific management challenges, and requires a multidisciplinary approach with close collaboration with the obstetricians. Management of patients who become pregnant whilst receiving TKI therapy requires balancing risks to the fetus of continuing therapy versus risks to the patient from treatment interruption and loss of disease control. Patients presenting with CP CML during pregnancy could safely continue their pregnancy to term and be successfully managed with leukapheresis during the first and subsequent trimesters, and introduction of IFN in the second trimester onwards if needed. Patients presenting in advanced phase disease should consider elective termination of pregnancy in order to commence induction chemotherapy and/or a TKI.²⁵

Allogeneic Hematopoietic Cell Transplantation

Allogeneic HCT is a well-established treatment for CML, associated with the possibility of long-term disease-free survival, but has largely been replaced as an initial curative strategy as a result of the success of TKI treatment of CML.

The Seattle team reported initial results of HLA-matched sibling donor hematopoietic cell transplants performed as therapy for 10 CML patients in 1982, and subsequently published a larger study on 167 patients transplanted from matched siblings through 1983. Long-term follow-up demonstrates that approximately 40% of patients transplanted in CP nearly 20 years ago are surviving. HCT became the first curative treatment in CML. Data from 4267 recipients of matched sibling transplants reported to the Center for International Blood and Marrow Transplant Research (CIBMTR) between 1994 and 1999 show a probability of survival of $69\% \pm 2\%$ for 2876 patients transplanted within the first year from diagnosis, and $57\% \pm 3\%$ for 1391 patients transplanted more than 1 year from diagnosis. Contemporary results from selected single institutions continue to demonstrate excellent outcomes with HCT, in part because of advances in preparative regimens, supportive care, and HLA typing for unrelated donors (Fig. 67.8). For example, the Seattle group, using a preparative regimen of targeted BU plus cyclophosphamide (CY) in 131 consecutive CP CML patients, reported survival at 3 years posttransplant of 86%, with 87% of surviving patients molecularly negative for BCR-ABL.

The outcome of allogeneic HCT in CML is influenced by many factors, including the phase of disease, type of donor used (related or unrelated), the source of the stem cell product (marrow or peripheral blood), and the age of the patient. Outcomes are superior for HCT in CP compared with advanced phases of disease. In a Seattle analysis of 58 patients with AP CML who received transplants from

Fig. 67.8 Probability of survival following (A) related donor transplantation and (B) unrelated donor transplantation for chronic myeloid leukemia, chronic phase, accelerated phase, and blast crisis performed after 1992, at the Fred Hutchinson Cancer Research Center, Seattle.

HLA-identical siblings, the 4-year probabilities of survival and EFS were 49% and 43%, respectively, and the probability of relapse was 12%. The outcome of transplantation for patients in BC is poor, with a high rate of disease recurrence and transplant-related deaths with EFSs of 43%, 18%, and 11% at 100 days, 1 year, and 3 years, respectively. Before the development of imatinib, only a small proportion of patients with blast-phase CML (generally, patients with lymphoid BC) could achieve a hematologic remission with chemotherapy. Response rates of patients with CML in blast phase to imatinib are considerably higher than those seen with conventional chemotherapy. These responses tend to be short, particularly in the setting of lymphoid BC. The German CML Study Group reported 3-year respective OS rates in selected high-risk CP, imatinib-failure CP, and AP/BP patients after allogeneic HCT of 88%, 94%, and 59%, supporting its use as a second-line treatment following TKI failure.

Preparative regimens have improved incrementally. The majority of patients treated in the early 1980s received a preparative regimen of 120 mg/kg CY, followed by total-body irradiation (TBI). Tutschka and colleagues later described the use of 16 mg/kg BU administered over 4 days combined with 60 mg/kg CY on each of 2 successive days, in myeloid malignancies. In 1988 a randomized trial of BU/CY versus CY/12 Gy TBI in myeloid malignancies showed no differences between the CY/TBI and BU/CY treatment groups in survival at 3

years (80%), relapse (13%), or EFS (68% for CY/TBI and 71% for BU/CY). Updated results showed OS of 78% at 10 years with BU/CY versus 64% with CY/TBI. The absorption and metabolism of BU varies considerably from patient to patient, and BU assays were incorporated into transplant trials. Patients with a steady-state BU concentration less than the median value (<917 ng/mL) of the cohort had a significantly higher risk for disease recurrence and worse OS than those with levels greater than 917 ng/mL. A subsequent report of 131 consecutive CML CP patients who received transplants from HLA-identical relatives showed a 3-year survival of 86%, a relapse rate of only 8%, and a nonrelapse mortality rate of 14%. Surprisingly, there were no significant differences in outcome related to patient age up to 65 years of age.

Only approximately one-third of patients have HLA-matched family members to serve as donors. Although early results with matched unrelated donor transplantation in CML showed results somewhat poorer than those seen with matched siblings, advances in donor selection, graft-versus-host disease (GVHD) prophylaxis, and supportive care have resulted in continued improvements in outcome. Thus, in many institutions results following unrelated transplants are almost equivalent to those seen with matched siblings (with a caveat that unrelated donor transplants have a lower age patient exclusion), and registry data of multiple centers report 65% survival at 5 years among younger patients transplanted within a year of diagnosis.

Marrow was used as the stem cell source in all initial transplant studies. Two large randomized trials involving a variety of hematologic malignancies have shown that use of filgrastim (G-CSF)-mobilized peripheral blood hematopoietic cells leads to more rapid myeloid and platelet recovery when compared with marrow, with no significant difference in acute or chronic GVHD and an OS advantage. Although there was a trend toward improved survival in CML patients with the use of peripheral blood, it should be noted that these studies were not prospectively designed to address the role of peripheral blood versus marrow for individual disease states. Furthermore, the results of a randomized study of CP CML showed no statistically significant differences in outcome between the marrow and peripheral blood groups, although relapse rates were lower in the peripheral blood group and chronic GVHD occurrence was higher compared with patients transplanted with marrow.

Several studies have shown that an increased interval from diagnosis to transplant is associated with a worse transplant outcome for patients treated in CP. No single cause of failure is markedly

increased with delay; rather there is a modest effect of delay on relapse rate and nonrelapse mortality. A CIBMTR report suggested that exposure to low-dose BU led to a worse outcome with subsequent transplantation. Reports have suggested that exposure to IFN might worsen the outcome of unrelated donor transplant, but data on the effect of IFN on matched sibling transplantation were less clear. In a recent German report, the 5-year survival rate from transplant was 46% for the 50 patients who received IFN within the last 90 days before transplant and 71% for the 36 patients who did not. These observations suggest that IFN should be avoided, if possible, in the months immediately preceding allogeneic HCT.

The form of GVHD prophylaxis used in treatment regimens also influences the outcome of transplantation for CML, especially in CP. Although successful in reducing the incidence of GVHD, T-cell depletion in CML was associated with high rates of graft failure and relapse, leading to poorer disease-free and OS. These findings illustrated the critical role of the graft-versus-leukemia (GVL) effect in eradicating CML following allogeneic transplantation. Because of these observations, T-cell depletion was largely abandoned as a method to control GVHD in CML transplants. However, there has been renewed interest in the possibility of preventing GVHD without loss of a GVL effect by combining T-cell depletion with an intensified conditioning regimen and delayed reinfusion of viable donor lymphocytes.

Several studies have investigated the effect of prior imatinib and transplant outcomes. Early reports warned of an increase in regimen-related toxicity and mortality, especially from hepatic causes. Larger studies have failed to show a deleterious effect of pretransplant imatinib (Fig. 67.9). A study of only CML patients showed no difference in regimen-related mortality, survival, or relapse between 140 patients who received imatinib versus 200 historical controls. Curiously, in a few studies, the incidence of chronic GVHD has been significantly lower in patients receiving imatinib before transplant. However, an analysis from the CIBMTR of CML patients undergoing allogeneic transplantation showed that the cumulative incidence rates of acute and chronic GVHD and treatment-related mortality were not affected by pre-HCT IM exposure. On multivariate analysis conventional prognostic indicators remained the strongest determinants of transplant outcomes.²⁶ The biology underlying this effect is unknown. Allogeneic transplantation appears to be an effective treatment for T315I-mutated leukemias, providing acceptable survival rates with long-term control of the malignancy without detectable residual disease in some cases.²⁷

Fig. 67.9 EFFECT OF PRIOR TREATMENT WITH IMATINIB ON OVERALL SURVIVAL AFTER TRANSPLANTATION. AP, Accelerated phase; BC, blast crisis; CP, chronic phase; CP2, a return to chronic phase after treatment for accelerated phase or blast crisis disease. (Data from Oehler VG, Gooley T, Snyder DS, et al: The effects of imatinib mesylate treatment before allogeneic transplantation for chronic myeloid leukemia. *Blood* 109:1782, 2007.)

Graft Versus Leukemia Effect in Chronic Myeloid Leukemia

Although evidence for a GVL effect can be found in many settings, nowhere is it as strong as in the setting of allogeneic HCT therapy for CML. Evidence in support of such an effect includes the following: the higher rates of relapse following syngeneic and T-cell-depleted transplants compared with unmodified allogeneic transplants; the close association between the development of acute and chronic GVHD and freedom from relapse following non-T-cell-depleted transplants; and the high response rate to donor lymphocyte infusions (DLIs) to treat posttransplant relapse (range: 50–100%), which is higher than in any other malignancy. The markedly increased relapse rates seen with T-cell depletion indicate a role for T cells in GVL. T-cell targets might include minor histocompatibility antigens shared by most cells in the body, thus accounting for the association of GVL with GVHD. Alternatively, there may be polymorphic minor histocompatibility antigens, with expression limited to hematopoietic tissue. A third possible category of targets for the GVL effect in CML is the overexpression of protein targets in CML cells. Understanding the cells and their targets responsible for the potent GVL effect seen in CML will be critical to the development of more effective, less toxic transplant-based therapies in the future.

Reduced-Intensity Conditioning

Reduced-intensity conditioning (RIC) or nonablative transplant approaches have been introduced with the aim of avoiding the toxicities of high-dose preparative regimens while retaining GVL effects. These approaches are of particular relevance for patients with CML because their median age at diagnosis is 67 years. Using a preparative regimen consisting only of 200-cGy TBI, and GVHD prophylaxis using cyclosporine and mycophenolate mofetil, McSweeney and colleagues reported CMRs in five out of nine patients transplanted for CML in CP ($n = 6$) or AP ($n = 3$). The other four patients rejected their grafts. By adding 30 mg/m² fludarabine pretransplant, graft rejection has been eliminated as a problem following matched sibling transplantation. Or and colleagues recently reported similar encouraging results using a preparative regimen of fludarabine, low-dose BU, and antithymocyte globulin. The MD Anderson Cancer Center group reported outcomes of 64 CML patients with advanced-phase disease (80% beyond first CP), not eligible for myeloablative preparative regimens because of older age or comorbid conditions, who received transplants with fludarabine-based reduced intensity conditioning regimens (matched related, $n = 30$; one antigen-mismatched related, $n = 4$; matched unrelated, $n = 30$).²⁸ At 5 years, the OS and PFS were 33% and 20%, and treatment-related mortality was 48%. In multivariate analysis, only disease stage at time of HSCT was significantly predictive for survival. These results indicate that reduced-intensity transplantation may offer a safe and effective way to treat CML in the CP, but alternative treatment strategies need to be explored in patients with advanced disease.

Residual Disease Posttransplantation

The detection of *BCR-ABL* transcripts posttransplant is a strong predictor of relapse following transplantation. In a study of 346 patients after transplantation, 40% of patients were positive for *BCR-ABL* residual disease at 3 months posttransplant, but this finding was not predictive of outcome, suggesting that eradication of the CML clone posttransplant takes an extended period of time. In contrast, at 6 or 12 months posttransplant, 27% of patients were *BCR-ABL* positive and at this time the assay was a powerful predictor of outcome, as only 3% of PCR-negative patients eventually relapsed compared with 42% of PCR-positive patients. The predictive power of PCR detection of *BCR-ABL* among longer term survivors is somewhat weaker. At 18 months posttransplant, 1% of 289

BCR-ABL-negative patients subsequently relapsed compared with 14% of 90 *BCR-ABL*-positive patients. The advent of reliable quantitative PCR testing further refined risk prediction of *BCR-ABL* detection. Olavarria and colleagues studied 138 transplant patients at 3 to 5 months posttransplant and were able to define patients as having a low risk for relapse (16%), an intermediate risk (43%), or a high risk (86%) based on *BCR-ABL* quantification. Further studies have confirmed the importance of quantitative *BCR-ABL* monitoring of minimal residual disease after transplantation for CML, which offers an obvious opportunity for early intervention for patients with residual or recurring disease.

Treatment of Posttransplant Relapse

The pace of disease progression after posttransplant relapse is variable; some patients remain low-level PCR positive for *BCR-ABL* for years without relapsing, and some relapse with low levels of Ph⁺ metaphases and remain stable for many years. An appreciation of the likely tempo of progression is thus important when considering treatment intervention options.

An increasing number of potential interventions are available for relapsing disease. IFN can produce both clinical and cytogenetic remissions in patients who have relapsed after transplantation. Results with IFN appear better if treatment is initiated at the time of cytogenetic relapse instead of waiting until hematologic relapse. A large number of studies now demonstrate cytogenetic CR rates of 50% to 100% in patients treated with DLI for clinically relapsed CP CML. Response rates tend to be higher for patients treated earlier at the time of cytogenetic relapse and lower for patients in AP. The two major complications of DLI are transient marrow failure and the development of GVHD. Marrow failure only occurs in patients treated in hematologic relapse. Treatment earlier in the course of relapse can avoid this complication. The overall incidence of GVHD following DLI is approximately 50% in most series. It has since been reported that large numbers of T cells are tolerated with less GVHD if administered in a fractionated fashion rather than as a single bulk dose. A recent report from the European Group for Blood and Marrow Transplantation provides further support for starting at lower doses of lymphocytes and escalating dosage as required.

Imatinib mesylate has been shown to be active as posttransplant therapy. In a report of 128 patients who were treated with imatinib for posttransplant relapse, an overall response rate of 79% was seen, with CHR seen in 100% of patients in CP, 83% in AP, and 43% in BC. CCR was seen in 29% of patients. Recurrence of GVHD was seen in 18%, and granulocytopenia requiring dose adjustments of imatinib developed in 43% of patients. Imatinib appears to be well tolerated if given early after transplantation to prevent relapse in high-risk Ph⁺ cases. Twenty two patients with Ph⁺ ALL or advanced-phase CML received imatinib at a median of 28 days postengraftment. Of these patients, 17 out of 19 adults and all 3 children tolerated imatinib at the targeted dose (400 mg/day for adults, 260 mg/m²/day for children), and 19 completed the planned course of 1 year of imatinib therapy. At a median follow-up of approximately 1½ years, 12 out of 15 of the Ph⁺ ALL and 5 out of 7 of the CML patients were in molecular remission. The use of TKI early posttransplant appears to be safe and effective in reducing relapse in CP CML, but less effective in advanced CML. Administration of TKIs with DLIs appears to be safe and does not increase the risk of GVHD. Two retrospective analyses suggested that posttransplant TKI therapy was associated with a lower incidence of extensive chronic GVHD. However, prospective studies are needed to determine the benefit of posttransplant TKIs, as well as to optimize TKI dose and duration.

Indications for Allogeneic Transplant in the TKI Era

In the period before the advent of TKIs, allogeneic transplant was the front-line treatment of choice for CML, especially for younger patients. With the firm establishment of imatinib and other TKIs as

front-line therapy for CML with excellent outcomes on long-term follow-up, the number of patients undergoing allogeneic transplantation has declined dramatically. Currently, allogeneic transplantation is a preferred treatment for patients in whom a second-generation TKI has failed, patients with TKI-resistant mutations such as T315I, and patients in AP or blast phase CML. The MD Anderson Cancer Center group reported outcomes of imatinib-resistant CML patients (CP, $n = 34$; AP, $n = 9$; and BC, $n = 4$) who underwent allogeneic transplantation. Nineteen patients (40%) had *BCR-ABL* mutations, 15 of whom had advanced disease. Thirty-two patients (68%) had a MMR after transplantation, with a 2-year EFS of 36% and 58% for the mutant and nonmutant groups, and a 2-year OS of 44% and 76%, respectively. These results confirm the effectiveness of transplantation as salvage treatment for TKI-resistant patients.²⁹ Since patients with mutations are more likely to develop advanced disease and have worse outcomes after transplantation, this procedure should be considered early for patients with poor response to a second-generation TKI. Major or CCR to TKI therapy was associated with better posttransplant outcome, supporting the use of TKIs to reduce disease burden before allogeneic HCT for AP and BC CML.

Autologous Transplantation

The rationale for autologous transplantation in CML was provided by experimental and clinical evidence for persistence of polyclonal Ph^- progenitors capable of reconstituting hematopoiesis in CML patients. This is most dramatically demonstrated by the high rate of cytogenetic and molecular response in CML patients treated with TKIs. Furthermore, it was shown that transplantation of autologous cells may allow restoration of Ph hematopoiesis. Initial studies carried out using unmanipulated autologous marrow or blood cells indicated that autologous transplantation could reestablish CP in patients with advanced disease and induce cytogenetic responses in a small proportion of CML CP patients. Subsequent studies indicated that depletion of Ph^+ progenitors by ex vivo graft manipulation was associated with cytogenetic remission posttransplant. Another approach to depleting malignant cells from the graft was to treat patients before harvesting marrow or peripheral blood for transplantation, also called *in vivo purging*. However, remissions following autologous transplantation were usually of short duration. In addition, the procedure was often associated with significant toxicity and delayed recovery. Although the compiled results of 200 autologous transplants at eight different centers in Europe and North America indicated a possibility of improved survival, it is not possible to make any definite conclusions in the absence of controlled clinical trials. A meta-analysis of six trials in which patients were randomly allocated to receive autologous HCT or an IFN-based regimen did not show an advantage for HCT.

Autologous HCT fell out of favor in view of the excellent results of TKI treatment in CML patients. Collection of peripheral blood stem cells from patients responsive to TKIs may form the framework of any future attempts to perform autologous transplantation in CML, and is well tolerated and results in more consistent achievement of Ph^- collections. However, additional strategies are needed to further deplete leukemia cells and to improve therapy for residual disease posttransplant. At this point, autologous HCT for CML should be limited to investigational trials for patients who lack allogeneic donors and for those in whom TKIs have failed.

TREATMENT OF CML PATIENTS WITH ADVANCED DISEASE

The incidence of BC has been significantly reduced following the advent of TKI treatment compared with the pre-TKI era. The German CML study IV, a five-arm study of imatinib-based treatments, reported an 8-year cumulative BC incidence of 5.6% compared with 12% to 62% in studies preceding the TKI era. The highest incidence of BC occurs in the first year after diagnosis. Treatment of CML patients with advanced disease depends on previous therapy,

Management of the Newly Diagnosed Chronic Myeloid Leukemia Patient

What should be the initial management for CML patients? After years of clinical research, we know (A) imatinib is remarkably effective for patients treated in CP, because more than 85% of patients obtain a CCR and approximately 70% of cases remain in CCR at 5 years of follow-up; (B) second-generation TKIs, dasatinib and nilotinib, used as first-line treatment for CP CML, may be even more effective, resulting in faster and more profound reduction in *BCR-ABL* levels; (C) allogeneic transplantation is generally associated with 10-year survival rates of 70% or better for younger patients in early CP; and (D) outcome for patients receiving TKI treatment can be effectively monitored by sensitive RT-PCR assays.

Imatinib has become the initial treatment of choice for patients with CML. For patients diagnosed during CP, imatinib is a reasonable first choice of therapy. However, in view of the association between cytogenetic and molecular responses on imatinib and survival, it is reasonable to suggest that the faster and deeper reduction in disease burden using the second-generation agents may reduce the risk for progression when compared with imatinib. The tolerability of the newer agents appears to be comparable with imatinib, although long-term effects of treatment are a potential concern. It is notable that differences in overall survival have not been observed as yet. In addition, low-risk CP patients demonstrate excellent survival with imatinib, and imatinib is considerably less expensive than the newer agents and a generic form will soon be available, reducing costs further. Careful monitoring of imatinib response could potentially identify the subset of patients who will benefit from second-generation TKI treatment. An alternative strategy to universal first-line use of second-generation TKIs was tested in the Australian Therapeutic Intensification in De Novo Leukemia II study, which used imatinib to treat CML first-line, with selective nilotinib switching based on failure to achieve targeted reduction in *BCR-ABL* levels at designated time points. This approach was associated with excellent molecular response and survival, supporting the feasibility of this approach. At present, the choice of first-line TKI is dependent on individual preference based on risk group, toxicity profile, dosing schedule, and economic factors.

For patients with CP disease, tyrosine kinase treatment can be initiated with simultaneous workup of family donors and unrelated donors. Criteria for failure or suboptimal response have been developed. Certainly, the failure of imatinib treatment to achieve a CHR at 3 months of treatment, lack of any cytogenetic response by 6 months, or lack of a major cytogenetic response by 12 months is an indication to switch therapy. By a conservative approach, patients should achieve a CCR by 18 months of therapy. Similarly, *BCR-ABL* mRNA levels greater than 10% at 6 months and greater than 1% at 12 months (using the international scale) are indicators to switch treatment. Patients who relapse after a CCR, especially those with *ABL* point mutations, should consider alternative therapy, including transplant. For patients diagnosed in accelerated phase or in blast crisis, initial treatment with dasatinib results in better responses than those seen with imatinib, but in general these responses tend to be short-lived; thus advanced-phase patients should consider transplantation as soon as possible.

the type of BC (myeloid or lymphoid), and whether or not HCT is possible. Allogeneic HCT remains the only curative option for patients with available matched donors who are able to tolerate the procedure. The best results are achieved if the patient returns to CP, especially with significant cytogenetic or molecular improvement prior to transplant. All TKIs except nilotinib are approved for the treatment of BC. Hematologic and cytogenetic responses with single-agent TKIs are achieved in about 50% and 12%, respectively, the 1-year overall response ranges from 25% to 49%, and median survival from 6 to 11.8 months. The combination of dasatinib and the hyperCVAD regimen has shown efficacy in relapsed Ph^+ ALL or lymphoid BC of CML (CML-LB). The overall response rate was 91%, with 71% of patients achieving CR, and 21% CR with incomplete platelet recovery. Grades 3 and 4 toxicities included hemorrhage, pleural and pericardial effusions, and infections. The 3-year OS of patients with CML-LB was 70%, with 68% remaining in CR at 3 years. Therefore long-term leukemia-free survival is possible in CML-LB patients even without allogeneic HCT.

THE POLYCYTHEMIAS

Marina Kremyanskaya, Vesna Najfeld, John Mascarenhas, and
Ronald Hoffman

Under normal conditions, the red blood cell (RBC) mass in humans is tightly controlled and remains relatively constant in a given individual. The numbers of senescent RBCs lost daily are replaced by newly formed ones by a carefully controlled network of growth factors and progenitor cells. Erythropoiesis can be augmented by a variety of stimuli that increase the delivery of oxygen to tissues. This delicate balance can be disturbed by various pathologic conditions and can result in either reduced numbers of RBCs (anemia) or excessive numbers of RBCs (polycythemia). Hematocrit values over 49% in males and 48% in females are abnormal and require further evaluation to determine if the patient has an absolute increase in their RBC mass and if investigation of its cause should be pursued. The RBC mass is increased if it is greater than 125% above that expected for sex and body mass. The measurement of the RBC mass is a diagnostic study that is now available at a dwindling number of tertiary care centers, making other diagnostic studies pivotal in evaluating patients with elevated hematocrit levels. Polycythemic states can be caused by a variety of disorders that can be attributed to several pathophysiologic mechanisms. Determination of the etiology of an individual's polycythemia is a critical step in defining the patient's appropriate prognosis and treatment plan. Primary polycythemias are the result of innate abnormalities involving hematopoietic progenitors and stem cells that lead to constitutive overproduction of RBCs, which are accompanied by low erythropoietin (EPO) levels. By contrast, secondary polycythemias are the consequence of a number of conditions that lead to increased EPO production, which acts on normal progenitors to overproduce RBCs. In a small number of patients, the cause of erythrocytosis cannot be determined; these patients are classified as having idiopathic erythrocytosis.

ERYTHROPOIESIS

RBC production can be influenced by numerous factors, including nutrients, growth factors, numbers and function of bone marrow (BM) progenitor and precursor cells, and cellular receptors and transcription factors. EPO is considered to be the physiologic regulator of the terminal phases of erythropoiesis. Alterations in its production are followed by adjustments in the rate of formation of RBCs. In humans, EPO production is controlled by the relative supply of oxygen to the kidneys, the major site of EPO production. In states of severe hypoxia, EPO production can be increased up to 1000-fold. In a healthy person after phlebotomy, EPO excretion increases, and an inverse logarithmic relationship between hematocrit and EPO excretion rates exists. Patients with secondary erythrocytosis caused by chronic hypoxia have either normal or increased basal EPO values, but they also have increased values after reduction of the hematocrit to normal levels by phlebotomy. By contrast, EPO excretion is invariably subnormal in patients with polycythemia vera (PV), which demonstrates that this disorder is not a result of excessive EPO production.

ERYTHROPOIETIN, OXYGEN SENSING, AND HYPOXIA-INDUCIBLE FACTOR

Under normal conditions, EPO production is mediated by a reduced oxygen content, termed *hypoxemia*, which leads to decreased oxygen

delivery to tissues. Regulation of oxygen homeostasis is critical to survival. In humans, oxygen sensing occurs at many levels, leading to both acute and chronic adaptation. The acute reduction of the availability of oxygen leads to the initiation of a cascade of adaptive events that sets in place compensatory events to correct the lack of oxygen supply. Low oxygen levels, or hypoxia (60 mmHg), in humans cause oxygen-sensing chemosensory cells to undergo rapid membrane depolarization within seconds, leading to the production of action potentials, influx of calcium ions, and release of the neurotransmitters that result in stimulation of the brain stem that controls the respiratory and cardiovascular systems. These chemosensory cells are found within the glomus cells of the carotid body located at the bifurcation of the internal and external carotid arteries. The released neurotransmitters activate the nerve endings of the carotid body sensory nerve to convey to the CNS signals that command ventilation to fight hypoxia, resulting in an increase of the lung ventilation rate and restoration of normal oxygen tension to vital organs. In addition, there are changes in blood pressure and heart rate to maximize oxygen delivery. The carotid body is the organ with the greatest blood flow within the body. Activation of the carotid body results in the sensation of breathlessness experienced by individuals at high altitudes. During chronic hypoxia when the carotid body is permanently active, there is marked enlargement of the carotid body because of an increase in capillaries and a marked reduction in the mean distance from the capillaries to the edge of the chemoreceptor cells.

In response to chronic hypoxia, multiple compensatory mechanisms come into play over several days within the kidneys, the major site of EPO production. Hypoxic stimulation results in production of hypoxia-inducible factor-1 (HIF-1), the major factor responsible for transcriptional activation of the *EPO* gene.¹ The HIF transcriptional system is a master regulator of the hypoxic response controlling a large number of genes in multiple cell types. HIF-1 is a heterodimeric protein consisting of HIF-1 α and HIF-1 β , which is required for normal development of the heart, blood vessels, and blood cells. The levels of HIF-1 α increase exponentially as the oxygen concentration declines. As the key mediator of cellular oxygen maintenance, HIF-1 facilitates body oxygen delivery and responses to oxygen deprivation by regulating the expression of gene products that are involved in cellular energy metabolism and glucose transport, angiogenesis, erythropoiesis and iron metabolism, pH regulation, apoptosis, cell proliferation, and cell–cell and cell–matrix interactions. Classic HIF target genes include phosphoglycerate kinase, glucose transporter-1, vascular endothelial growth factor (VEGF), and EPO. The HIF proteins are members of the Per–ARNT–Sim family of heterodimeric basic helix–loop–helix transcription factors (Fig. 68.1).

In contrast to the constitutively expressed, HIF-1 β subunits, HIF-1 α is an oxygen-labile protein that becomes stabilized in response to hypoxia. HIF-1 α mRNA and protein levels are induced by hypoxia, and HIF-1 α protein levels decay rapidly with return to normoxia. The posttranslational regulation of HIF-1 α protein accounts for the majority of the regulation of this gene. Normoxia-induced, ubiquitin-mediated degradation of the HIF-1 α protein is the major regulator of HIF-1 α levels, thereby reducing the stimulus for additional EPO production. The targeting and subsequent polyubiquitination of HIF-1 α require the von Hippel-Lindau (VHL) protein, oxygen, and three different iron-requiring proline hydroxylase (PHD) enzymes (see Fig. 68.1). The PHD proteins exist in three

Fig. 68.1 SCHEMATIC REPRESENTATION OF THE RELATIONSHIP BETWEEN HYPOXIA SENSING AND ERYTHROPOIETIN PRODUCTION. *GLUT*, Glucose transporter 1; *HIF*, hypoxia-inducible factor; *PHD*, proline hydroxylase; *VEGF*, vascular endothelial growth factor.

isoforms, PHD1, PHD2, and PHD3. HIF-1 α is hydroxylated by all three isoforms but primarily by PHD2. The prolyl hydroxylation of HIF-1 α is necessary for the binding of HIF-1 α to VHL, which is the substrate-recognition subunit of an E3 ubiquitin-protein ligase. Different parts of the HIF-1 α chains have different functions. The N-terminus part of HIF-1 α is involved in DNA binding and dimerization, and the C-terminus portion has regulatory functions. One domain at the C-terminus influences transcriptional activity without affecting HIF-1 α protein levels, and the other region, termed the oxygen-dependent degradation domain (ODD), affects protein abundance. The ODD is divided into an N-terminus and a C-terminus subdomain. The VHL protein physically interacts with the ODD of HIF-1 α , targeting it for ubiquitination and destruction by the proteasome. Iron-chelating drugs can also block the interaction of HIF-1 α with the VHL protein, suggesting a role for iron in the degradation of HIF-1 α .

Under normoxic conditions, hydroxylation of HIF-1 α is essential for HIF proteolytic degradation by promoting interaction with the VHL tumor-suppressor protein through hydrogen bonding to the hydroxy proline-binding pocket in the VHL- β domain. As oxygen levels decrease, hydroxylation of HIF decreases, and HIF-1 α then no longer binds VHL. As a result, it becomes stabilized, dimerizes with HIF-1 β , and activates transcription of target genes. The activity of PHDs depends on the availability of molecular oxygen, which qualifies these enzymes as oxygen sensors. In addition, these dioxygenases require 2-oxoglutarate as a cosubstrate and vitamin C to keep their central nonheme iron in the ferrous state. Although PHD-2 appears to be the hydroxylase that is essential for HIF-1 α degradation under normoxic conditions, PHD-3 is important for hydroxylation of HIF-1 α during reoxygenation. Different effects of individual PHDs on HIF-1 α and HIF-2 α hydroxylation indicate that the stability of individual HIF-1 α subunits and their target gene expression might be affected by tissue- and cell-type differences in PHD expression and activity levels. The activity of PHDs can be modulated by mitochondrial reactive oxygen species, implicating mitochondria in oxygen sensing. Another protein termed HIF-2 α has been identified that

under hypoxic conditions dimerizes with HIF-1 β and activates the transcription of a set of target genes that overlap with the target genes regulated by HIF-1 α /HIF-1 β heterodimers. HIF-1 α is expressed by all nucleated cells, but HIF-2 α is expressed by specific cell types, including vascular endothelial cells, renal interstitial cells, hepatocytes, cardiomyocytes, and astrocytes. HIF-2 α appears to play a critical role in regulating EPO production in adult mammals, and HIF-1 α is also important during yolk sac erythropoiesis. HIF-1 also controls the absorption and delivery of iron to the BM through its repression of hepcidin and activation of genes encoding transferrin and the transferrin receptor.

VHL syndrome is a hereditary cancer syndrome that is associated with exaggerated responses to hypoxia caused by posttranslational abnormalities in HIF. VHL syndrome is characterized by a propensity for developing clear-cell renal carcinomas, retinal hemangioblastomas, cerebellar and spinal hemangiomas, pancreatic and renal cysts, islet cell tumors of the pancreas, and pheochromocytomas.² The tumors result from somatic mutations that cause a loss of heterozygosity (LOH) of the *VHL* gene. VHL disease affects approximately 1 in 35,000 individuals and is transmitted in an autosomal dominant manner. Individuals with VHL disease carry one wild-type (WT) *VHL* allele and one inactivated *VHL* allele. This inactivation can occur by somatic mutation or hypermethylation. Tumor or cyst development is linked to somatic inactivation or loss of the remaining WT *VHL* allele. Approximately 20–37% of VHL patients have large or partial germ-line deletions, 23–27% have nonsense or frame-shift mutations, and 30–35% have missense mutations. More than 150 different *VHL* mutations linked to VHL disease have been reported. The tumors linked to *VHL* inactivation are often highly vascular and can produce angiogenic factors such as VEGF. In addition, renal cell carcinoma, cerebellar hemangioblastomas, and pheochromocytomas have been associated with paraneoplastic erythrocytosis caused by overproduction of EPO. Overproduction of HIF-inducible mRNAs is the hallmark of VHL protein defective cells. Genotype–phenotype correlates in VHL disease suggest that VHL has functions independent of HIF regulation that might play a role in tumor formation.

VHL protein has other binding partners, including atypical protein kinase C and a family of deubiquitinating enzymes called *VHL-interacting deubiquitinating enzymes 1 and 2*. In addition, VHL has been involved in numerous cellular processes, including regulation of extracellular matrix, cytoskeleton stability, cell cycle control, and differentiation. VHL disease is not associated with erythrocytosis.

THE ERYTHROPOIETIN RECEPTOR

Interaction of EPO with the EPO receptor (EPOR) present on the erythroid progenitor and precursor cells leads to its homodimerization, resulting in (1) stimulation of cell division, (2) differentiation by induction of erythroid-specific gene expression, and (3) prevention of erythroid progenitor and precursor cell apoptosis. EPOR is a member of the type I cytokine receptor superfamily. Signal transduction through the receptor is initiated by ligand binding, which induces dimerization of EPOR monomers. The predominant signaling cascade activated by EPOR and other cytokine receptors is the Janus-activated kinase (JAK)/signal transducer and activator of transcription (STAT) pathway. JAK tyrosine kinases are constitutively associated with the membrane proximal regions of cytokine receptor cytoplasmic domains and are activated by receptor dimerization. The EPOR associates predominantly with JAK2. JAK2 binds to EPOR in the endoplasmic reticulum and acts as a chaperone protein transporting the EPOR to the plasma membrane. Immediately after EPO binding, JAK2 phosphorylates itself and the EPOR on multiple tyrosine residues in its cytoplasmic domain, thus creating a platform for the recruitment and activation of multiple key signaling regulators. One of such proteins is STAT5. JAK2–STAT5 signaling plays an essential role in EPO/EPOR-mediated regulation of erythropoiesis. Consistent with their essential roles in erythropoiesis, EPO-, EPOR- and JAK2-deficient mice die embryonically from severe anemia.

The C-terminal cytoplasmic portion of the EPOR also possesses a negative regulatory domain. Hematopoietic cell phosphatase (HCP; also known as *SHP-1* or *PTP N6*) interacts with this portion of the EPOR and downregulates signal transduction by promoting dephosphorylation (Fig. 68.2). Inactivation of the HCP-binding site leads to prolonged phosphorylation of JAK2–STAT5. Another negative regulator of erythropoiesis, suppressor of cytokine signaling-3 (SOCS-3), binds to the cytoplasmic portion of the EPOR and

suppresses EPO-dependent JAK2–STAT5 signaling. Thus, deletion of the distal C-terminal cytoplasmic portion of the EPOR abolishes negative regulatory elements and results in increased proliferation of erythroid progenitor cells. Mutations in the *EPOR* gene have been observed in some patients with primary familial and congenital polycythemia (PFCP) and are occasionally found in erythroleukemia (see Fig. 68.2). Such secondary growth factors as insulin-like growth factor-1 (IGF-1) and the components of the renin–angiotensin system (RAS) may also influence the production of RBCs.

THE RENIN–ANGIOTENSIN SYSTEM AND HEMATOPOIESIS

The RAS regulates fluid and electrolyte homeostasis and blood pressure, and has been hypothesized to also play a role in the regulation of erythropoiesis. The primary function of angiotensin during development is the regulation of tissue growth and differentiation. Angiotensin II (AngII) is a ligand for two distinct receptors, type 1 and type 2 (AT1 and AT2). AT1 appears to play a major role in the regulation of cell proliferation.³

The RAS was first postulated to influence erythropoiesis in the 1980s after the use of angiotensin-converting enzyme (ACE) inhibitors to treat hypertension was shown to result in anemia. In animals, increased blood levels of renin (a major regulator of AngII synthesis) were found to result in elevated serum EPO levels and erythrocytosis. In humans, the infusion of AngII in healthy volunteers increased serum EPO levels by 35% or higher via activation of the AngII type I receptor, and ACE inhibitors significantly decrease plasma EPO levels by as much as 20–30%. The pathway underlying AngII-driven EPO secretion is unknown. However, some investigators have suggested that AngII modulates renal EPO production through changes in renal perfusion and sodium reabsorption. This hypothesis is based on the presumption that reduced oxygen pressure in the kidneys triggers HIF-1 α to induce release of EPO. AngII also directly stimulates proliferation of hematopoietic progenitors in vitro, and inhibition of this effect with ACE inhibitors induces apoptosis of erythroid progenitors in renal transplantation patients. ACE-1 knockout mice develop a normocytic anemia that can be fully reversed by infusion of AngII. ACE-related anemia is most pronounced in patients with renal insufficiency or end-stage renal disease and in patients who have

Fig. 68.2 SCHEMATIC REPRESENTATION OF THE ERYTHROPOIETIN RECEPTOR AND THE DEFECT IN THE RECEPTOR UNDERLYING PRIMARY FAMILIAL AND CONGENITAL POLYCYTHEMIA. HCP, Hematopoietic cell phosphatase; JAK, Janus kinase; STAT, signal transducer and activator of transcription.

received a renal allograft. The pathogenesis of this anemia is not clear, but reduced levels of circulating EPO are not solely responsible, suggesting that there might be other contributing factors. The AT1 receptor is present on erythroid progenitors, and its ligand, AngII, augments EPO stimulation of erythropoiesis. The involvement of JAK2 kinase in AngII signaling suggests that this signal transduction pathway mediated by EPO and AngII might overlap. Postrenal transplant erythrocytosis likely can be accounted for by activation of the RAS.

DEFINITION AND CLASSIFICATION OF POLYCYTHEMIA

The term *polycythemia* is a literal translation from Greek, meaning “too many cells in the blood,” and refers to an increase in the RBC mass; it is frequently used interchangeably with the term *erythrocytosis*. Polycythemia may be due to a myriad of causes (Table 68.1). The polycythemias can be classified as relative and absolute. Relative polycythemia is a disorder in which the patient characteristically has a modest elevation of the hematocrit level without an elevated RBC mass but rather because of contraction of the plasma volume. The absolute polycythemias are accompanied by an actual increase in the circulating RBC mass. Polycythemias can also be classified according to the responsiveness of their erythroid progenitor cells to growth factors or the circulating levels of such growth factors. Primary polycythemias are characterized by increased sensitivity of the erythroid progenitors to regulatory growth factors as a result of acquired

somatic or inherited germ-line mutations expressed by hematopoietic progenitor cells (HPCs). In contrast, secondary polycythemias are characterized by an increase in regulatory growth factors, primarily EPO, and normal responsiveness of their erythroid progenitors to these growth factors. These conditions can usually be distinguished by in vitro assays of erythroid progenitor cells, quantitation of serum EPO levels, and detection of somatic *JAK2* mutations. In a small number of patients, the cause of erythrocytosis cannot be determined; these patients are classified as having idiopathic erythrocytosis.

RELATIVE POLYCYTHEMIA

Individuals with a modestly increased venous hematocrit level that is not accompanied by an increased RBC mass are frequently thought to be polycythemic by imprecise yet widely accepted medical practice. Frequently, these individuals are thought to be polycythemic owing to the lack of appreciation by a clinician of what constitutes the upper limit of normal values for a hematocrit (49% in males and 48% in females). Such individuals frequently prove not to have an absolute polycythemia as defined by an actual increase in the measured RBC mass. *Relative* or *spurious polycythemia* is a term used to describe an elevation of the hematocrit level either caused by an acute transient state of hemoconcentration associated with intravascular fluid depletion or a chronic sustained relative polycythemia caused by contraction of the plasma volume (see Table 68.1).

Transient polycythemias may be a result of acute depletion of the plasma volume from a variety of disorders, including protracted vomiting or diarrhea, plasma loss from external burns, sudden cold exposure or protracted exercise, insensible fluid loss from fever, sepsis, diabetic ketoacidosis, or acute ethanol intoxication. These elevations of hematocrit can be easily corrected by appropriate replacement of intravascular fluids.

Gaisböck syndrome, first described in 1905, is a condition observed mainly in obese, hypertensive, middle-aged, male smokers. Alcohol, diuretics, obesity, hypoxia, psychologic stress, and excess catecholamine secretion have been identified as possible causes of relative polycythemia. Such individuals can have a chronic modest-to-moderate elevation of the hematocrit level associated with a normal RBC mass and low plasma volume, which has been attributed to reduced venous compliance, or they can have a high normal RBC mass with either a normal or slightly decreased plasma volume. The primary significance of the identification of a patient with relative polycythemia is the recognition of the increased risk of developing thrombotic vascular events likely caused by excessive smoking, hypertension, and obesity associated with this disease. Treatment is generally directed at correction of the patient's underlying cardiovascular risk factors.

It is also important to emphasize that overfilling of blood collection vacuum tubes can result in pseudopolycythemia, pseudothrombocytopenia, and pseudoleukopenia as a result of inadequate sample mixing. Careful attention to such a seemingly trivial detail can help avoid expensive, unnecessary diagnostic workups.

ABSOLUTE POLYCYTHEMIAS

Primary Familial and Congenital Polycythemia

This is an autosomal dominant disorder. Although PFCP is uncommon, it is more prevalent than polycythemia caused by high-oxygen-affinity hemoglobin mutants or a 2,3-bisphosphoglycerate deficiency. Unlike patients with PV, patients with PFCP lack splenomegaly and do not progress to acute leukemia. It is not unusual for these patients to present with headaches, dizziness, epistaxis, and exertional dyspnea that resolve with normalization of the hematocrit level.⁴ An increased incidence of cardiovascular events and premature morbidity and mortality has been reported in some affected members, but many appear to have a benign clinical course. Although clinical symptoms are relieved by phlebotomy, the increased risk of cardiovascular

TABLE 68.1 Differential Diagnosis of the Polycythemias

Relative or Spurious Polycythemia

1. Decreased plasma volume—reduced fluid intake, marked loss of body fluids (diaphoresis, vomiting, diarrhea, “third spacing”)
2. Gaisböck syndrome
3. Overfilling of blood in collection vacuum tubes

Absolute Polycythemia

1. Secondary polycythemia

A. Acquired

Hypoxia

- Pulmonary disease
- Cyanotic congenital heart disease
- Hypoventilation syndromes: sleep apnea, Pickwickian syndrome
- High altitude
- Smokers' polycythemia, hookah polycythemia, carbon monoxide intoxication caused by industrial exposure

Postrenal transplantation erythrocytosis

Aberrant erythropoietin production

- Tumors: renal cell carcinoma, Wilms tumor, hepatic carcinoma, uterine leiomyomata, virilizing ovarian tumors, vascular cerebellar tumors
- Miscellaneous renal and hepatic disorders: solitary renal cysts, polycystic kidney disease, renal artery stenosis, hydronephrosis, viral hepatitis

Endocrine disorders: Cushing syndrome, primary aldosteronism

Androgen use

Erythropoietin use

B. Congenital polycythemias

- Abnormal high-affinity hemoglobin variants
- Bisphosphoglycerate deficiency
- Congenital methemoglobinemia
- Chuvash polycythemia (von Hippel-Lindau mutations)
- Prolyl hydroxylase mutations
- Hypoxia-inducible factor gene mutations

2. Primary polycythemias

- Primary congenital and familial polycythemia
- Polycythemia vera

morbidity is not corrected by maintaining a normal hematocrit. Characteristic laboratory findings are (1) an increased hematocrit and RBC mass without an increased leukocyte or platelet count, (2) an absence of an activating mutation of *JAK2*, (3) a normal hemoglobin-oxygen dissociation curve, (4) low serum EPO levels, and (5) in vitro hypersensitivity of erythroid progenitors to EPO. Even though PFPCP is present at birth, many affected patients are incidentally diagnosed later in life after the performance of routine blood counts or when evaluated in the context of multiple family members having polycythemia. It is of interest that one individual so affected was an accomplished cross-country skier who had won medals at the Olympic Games. Numerous mutations of the EPOR associated with PFPCP have been described, leading to a loss in the negative regulatory domain of the EPOR.

The physiologic basis for EPO-mediated activation of erythropoiesis is as follows: EPO activates its receptor by conformational changes of its dimers, leading to initiation of an erythroid-specific cascade of events. The first signal is initiated by the binding of a tyrosine kinase to the EPOR and its phosphorylation and activation of a transcription factor, STAT5, which regulates erythroid-specific genes. This “on” signal is negated by dephosphorylation of the EPOR by HCP, that is, the “off” signal. Truncation of the EPOR leads to a loss in the negative regulatory domain of the EPOR, a binding site for HCP, leading to a gain-of-function mutation of the EPOR (see Fig. 68.2). In addition, the negative regulation of erythropoiesis by SOCS-3, cytokine-inducible SH2 domain containing protein (CIS), and Src homology region 2 domain-containing phosphatase-1 (SHP-1) is presumed to contribute to the underlying cause of PFPCP.

Alternative explanations for the increased sensitivity of erythroid progenitors to EPO of patients with PFPCP have been proposed. EPOR downregulation provides another mechanism by which EPO desensitization can occur. EPOR downregulation is a complex process that involves EPOR-induced internalization or ubiquitination and degradation by proteasomes. EPO-induced receptor internalization is an efficient means of rapidly reducing EPO responsiveness. This process is mediated by binding of the EPOR to the p85 subunit of phosphatidylinositol 3-kinase (PI3K) but does not involve its kinase activity as the PI3K inhibitor wortmannin does not impair EPOR internalization. All of the truncated mutants associated with PFPCP are associated with failure to internalize the EPOR, contributing to prolonged signaling through the EPOR. The EPOR degradation process removes all of the phosphorylated tyrosine residues in the intracellular domain of the receptor, thereby preventing further signal transduction. The remaining part of the EPO-EPOR complex is then internalized and degraded by lysosomes. The E3 ligase B-transducin repeat containing protein-1 (B-Trcp-1) is responsible for EPOR ubiquitination and degradation. Mutations in *B-Trcp-1* abolish EPOR ubiquitination and degradation, making cells expressing the EPORs hypersensitive to EPO. Each of the *PFPCP* mutations involving the EPOR results in loss of the binding site for B-Trcp-1. These findings suggest that the EPO hypersensitivity in PFPCP might not only be attributable to a failure to recruit negative regulators such as phosphatases to inactivate JAK2, but that these mutant receptors are defective in EPO-induced receptor downregulation.

The effect of a truncated EPOR is not always predictable. Some patients who inherit an EPOR mutation are not polycythemic. This observation suggests that undefined environmental or genetic factors may mask the development of polycythemia. Also, the heterogeneity of the polycythemic phenotype observed in a PFPCP animal model appears to be strain dependent. This indicates that gene modifiers or epigenetic factors may mask the development of the full PFPCP phenotype. Recently, four different rearrangements of the EPOR have been observed in Philadelphia chromosome-like (Ph-like) acute lymphoblastic leukemia (ALL) B cells. Normal B cells do not express the EPOR, but the EPOR has been described in ETV6-RUNX1-positive ALL blast cells. All of these rearrangements are different from those observed in PFPCP but result in truncation of the cytoplasmic tail of the EPOR at residues similar to those mutated in PFPCP, with preservation of the proximal tyrosine essential for receptor activation and loss of distal regulatory residues. This leads

to dysregulated EPOR expression, hypersensitivity to EPO stimulation, and heightened JAK-STAT activation. Expression of truncated EPOR in murine B-cell progenitors leads to the development of ALL in vivo (see Chapters 64 and 66). Several observations suggest that the EPOR mutations in human leukemic cells in Ph-like ALL are driver mutations that are acquired during early stages of leukemogenesis and are logical targets for therapeutic targeting with JAK2 inhibitors.

Mutations of genes encoding proteins other than the EPOR account for most cases of PFPCP. Mutations of the EPOR have been found in only 10–20% of subjects with PFPCP. Additional disease-causing genes and their mutations have yet to be identified. In patients with erythrocytosis who are *JAK2V617F* negative and do not have a *JAK2* exon 12 mutation, and who have life-long erythrocytosis associated with a low serum EPO level, sequencing of the EPOR should be pursued.

SECONDARY POLYCYTHEMIAS

Secondary polycythemias can be either congenital or acquired (see Table 68.1). Conditions leading to hypoxia, such as high altitude, cyanotic heart disease, or chronic lung disease, may result in physiologic polycythemia mediated by increased levels of EPO. There are marked variations in EPO levels and subsequent erythroid response in the face of chronic hypoxia, suggesting that some of these factors may be genetically determined. The same degree of renal tissue hypoxia may induce substantially different levels of EPO production in response to high altitude. It is likely that these individual variations are a function of genetic differences in hypoxia sensing and the hypoxia response pathways. For purposes of simplicity and clinical diagnostic usefulness, the secondary polycythemic disorders are divided into those that are acquired and those that are congenital. It should be kept in mind that this division, although useful for differential diagnosis, is artificial. Patients with inherited germ-line mutations, for instance, can develop an EPO-secreting pheochromocytoma or renal cell cancer, and a patient with PV can smoke and have chronic obstructive pulmonary disease (COPD). In other instances, polycythemia caused by a germ-line mutation can be masked by an acquired environmental factor or another gene-modifying mutation.

Acquired Secondary Polycythemias

Polycythemias of Cyanotic Heart Disease and Pulmonary Disease

Patients with cyanotic heart disease and pulmonary disease frequently have arterial hypoxemia, leading to increased production of EPO and polycythemia. Excessive EPO production occurs when the PaO_2 is sustained below 67 mmHg as a result of severely impaired pulmonary mechanics. Because patients with severe pulmonary disease and secondary erythrocytosis frequently have elevated plasma volumes, the degree of elevation of the hematocrit level may be modest. Hematocrit levels as high as 65% or rarely 75% have, however, been reported. Moderate elevations of hematocrit have been estimated to occur in 20% of patients with COPD. Polycythemia in this setting can contribute to pulmonary hypertension, pulmonary endothelial cell dysfunction, reduced cerebral blood flow, hyperuricemia, gout, and an increased risk of venous thromboembolic disease.

Why some patients with pulmonary disease and congenital heart disease develop polycythemia but others do not is not clear. Increased oxygen-carrying capacity may improve oxygen delivery; however, it is not obvious at what hematocrit level the resultant elevation in blood viscosity impairs blood flow to the tissues, leading to a reduction in oxygen uptake. In addition, oxygen uptake to the tissues is markedly influenced by whole blood volume. Thus, whereas the optimal hematocrit level for oxygen delivery is about 45% in normovolemic subjects, it rises to over 60% in hypervolemic states, likely as a result of engorgement of the vascular bed and a decrease in peripheral resistance. Furthermore, chronic exposure to hypoxia leads

to respiratory alkalosis that in turn promotes the synthesis of 2,3-bisphosphoglycerate (2,3-BPG), facilitating increased oxygen delivery to tissues.

The practical relevance of an elevated hematocrit level in this clinical situation is whether and at what level it is harmful or beneficial. An extremely elevated hematocrit level may be detrimental to optimal oxygen delivery. Extreme but not moderate polycythemia caused by chronic hypoxia may affect systemic vascular function by altering blood viscosity, vessel wall shear stress, reduced endothelial cell-derived nitric oxide release, and increasing the secretion of endothelin. Although it is widely accepted that polycythemic pediatric patients with cyanotic heart disease are at an increased risk for developing cerebrovascular accidents, the literature provides conflicting data as relates to the prevalence of such events among adults. A 10–13.6% prevalence of stroke and transient ischemic attacks (TIAs) has been reported in a cohort of adult patients with cyanotic heart disease, but others have claimed that such events are rare.

Iron deficiency occurs in more than 30% because of the total depletion of iron stores to support erythropoiesis. Microcytic RBCs are, however, rarely found, and despite the iron deficiency, these patients frequently have normal mean corpuscular volumes and high mean corpuscular hemoglobin concentrations, which might maximize the amount of hemoglobin within an individual RBC, thereby maximizing oxygen delivery. In the past, compensatory erythrocytosis was thought to lead to an increased plasma viscosity, leading to a compromised microcirculation, resulting in such symptoms as headache, sluggish mentation, dizziness, blurry vision, muscle weakness, or paresthesias. In reality, such symptoms are rare in patients with chronic compensated secondary erythrocytosis, and the secondary erythrocytosis is viewed as a physiologically desirable response to chronic hypoxia. The symptoms delineated above are likely attributable to decreased tissue oxygen delivery rather than hyperviscosity.

The treatment of hyperviscosity secondary to erythrocytosis in cyanotic heart disease with prophylactic phlebotomy is rarely used. In fact, phlebotomy has been reported to have harmful rather than beneficial effects in adults with cyanotic congenital heart disease. Because almost one-third of these patients are iron deficient even though their RBC indices do not reflect this, routine assessment of the patient's iron status is suggested with gradual supplementation with sufficient iron to attain appropriate compensatory levels of erythropoiesis but avoiding excessive sudden increases in the degree of erythrocytosis. The present evidence indicates that prophylactic phlebotomy promotes the development of iron deficiency, decreases exercise tolerance, and increases the number of cerebrovascular events. Currently, experts in this field recommend that phlebotomy should be restricted to individuals with symptoms with extreme erythrocytosis (hematocrit >65%) and preoperatively to improve hemostasis. Clinical data to justify these recommendations are lacking. Phlebotomy should be followed by the infusion of an equal volume of fluids to maintain intravascular volume and blood flow, as well as to provide a dilutional effect to reduce the hematocrit level. Hydroxyurea therapy has been used occasionally to reduce erythropoiesis in this situation to reduce the need for phlebotomy, but little evidence exists for this approach. The superiority of hydroxyurea therapy versus phlebotomy therapy has not been documented. Hydroxyurea might act not only by suppressing RBC production but also by promoting macrocytic RBC formation, thereby increasing RBC deformability and decreasing RBC adhesiveness.

Chronic oxygen therapy in patients with severe COPD has resulted in relief of hypoxia and a modest reduction in hematocrit levels. Pharmacologic interventions, including theophylline, inhaled nitric oxide, sildenafil, or antagonism of the renin-angiotensin pathway with losartan, may also reduce the degree of pulmonary hypertension or secondary erythrocytosis.

Obstructive Sleep Apnea–Induced Polycythemia

Obstructive sleep apnea syndrome is characterized by repetitive episodes of partial or complete obstruction of airflow during sleep.

Common symptoms include loud snoring and breathing pauses observed by a bed partner, feelings of nonrefreshing sleep, and excess daytime sleeping. Although the evidence is largely anecdotal, secondary polycythemia is a widely recognized complication of long-standing sleep apnea, being found in 5–10% of those with nocturnal apnea and hypopnea. Similarly, 25% of those with unexplained polycythemia are subsequently found to have sleep apnea. The mechanism by which sleep apnea causes polycythemia is unclear. Differences in EPO levels between normoxic and hypoxemic patients referred for suspected sleep apnea have not been documented. Obstructive sleep apnea is also associated with an increased risk of developing cardiovascular diseases, including systemic hypertension, pulmonary hypertension, cardiac arrhythmias, atherosclerosis, ischemic heart disease, and stroke. Intermittent hypoxia is thought to be a major cause of cardiovascular complications. These patients undergo repeated episodes of hypoxia and normoxia. The hypoxia leads to ischemia, and the reoxygenation causes a sudden increase of oxygen. This reoxygenation phase results in the production of reactive oxygen species and the promotion of oxidative stress, leading to an inflammatory response and the development of vascular complications.

Conversely, PV may induce central sleep apnea by decreasing cerebral blood flow to diencephalic respiratory centers, and patients so affected can have complete resolution of their sleep disorder with normalization of their blood counts.

Pickwickian Syndrome and Polycythemia

Pickwickian syndrome or obesity-hypoventilation syndrome, seen in morbidly obese individuals, is characterized by chronic hypoxemia and hypercapnia caused by alveolar hypoventilation, with a resultant increase in EPO production, polycythemia, and cor pulmonale. The three principal causes are the high cost of the work of respiration in morbidly obese individuals, dysfunction of the respiratory centers, and repeated episodes of nocturnal obstructive apnea. Effective treatments include surgically induced weight loss, nasal continuous positive airway pressure ventilation, and the respiratory stimulant medroxyprogesterone acetate.

Polycythemia Caused by High Altitude

Polycythemia caused by the hypoxic conditions encountered by high-altitude dwellers would appear at first glance to represent a universal adaptive process to altitude. High altitude results in hyperventilation, alkalosis, and shifting of the O_2 dissociation curve to the left, leading to the impaired release of O_2 from hemoglobin and ultimately tissue hypoxia. This tissue hypoxia results in markedly increased EPO production, leading to increased plasma iron turnover, reticulocytosis, and a rising hematocrit level. Residents of the Andes Mountains who live 4200 m above sea level frequently have 30% higher hematocrit levels than individuals living at sea level.

People native to high altitudes (highlanders) live in a hypobaric hypoxic environment characterized by a low ambient partial pressure of oxygen. In response to this environment, they develop alveolar hypoxia, hypoxemia, and polycythemia. Healthy highlanders develop pulmonary hypertension, right ventricular hypertrophy, and an increased amount of smooth muscle cells in the distal pulmonary arterial branches, which leads to increased pulmonary vascular resistance and pulmonary artery pressure compared with individuals living at sea level. The importance of these structural changes in the pulmonary vasculature in highlanders is confirmed by the slow decline of pulmonary artery pressure, which is normalized after living for 2 years at sea level. Despite these adaptive changes, healthy highlanders are able to perform physical activities similar to or often even more strenuous than those living at sea level. In fact, there are differences in ventilation rates between athletes performing at sea level and those at high altitudes. Ventilation rates of athletes increase normally during exercise at sea level, but relative hypoventilation occurs in highlanders. This relative hypoventilation is characteristic

of Andean natives and has been ascribed to desensitization of the carotid bodies to the hypoxic stimulus. The erythrocytosis observed in individuals who reside at high altitudes for relatively short periods of time (days) can also be attributed in part to excessive water loss and contraction of the plasma volume. Total acclimatization of an individual who moves from sea level to a high altitude may actually require years. Individuals who reside at sea level and are acutely exposed to high altitudes are at increased risks of developing deep venous thrombosis, pulmonary infarction, retinal hemorrhage, and ischemic digits because of increased blood viscosity. High-altitude climbers frequently combat these problems by intravenous administration of isotonic saline, with considerable success.

The chronic responses of various ethnic and racial groups to high altitudes are quite variable. Andean natives, known as the Quechua and Ayamara Indians, experience a gradual increase in their hemoglobin levels with age. In addition, hemoglobin values are almost 10% higher in those living at 5500 m above sea level than in those living at 4355 m above sea level. Curiously, their Tibetan and Ethiopian counterparts living at similar altitudes do not respond to the resultant chronic hypoxia by increasing their hematocrits. It has been suggested that high levels of nitrous oxide in the exhaled breath of Tibetans may improve oxygen delivery by inducing vasodilatation and increasing blood flow to tissues, thus making the compensatory increased RBC volume unnecessary. Interestingly, Tibetans and Ethiopians have lived much longer as mountain dwellers than the Quechua or Ayamara Indians, suggesting that extreme elevation of the RBC mass is a maladaptation that Tibetans and Ethiopians have avoided by adopting more physiologic compensatory mechanisms. Many residents of the Tibetan plateau reside at elevations exceeding 4000 m and experience oxygen concentrations that are about 40% lower than experienced at sea level. Human adaptation to a high-altitude environment has been believed to be the result of advantageous genetic mutations and selective pressure.⁵ These genetic adaptations are shared by common ancestors within East Asian but not Central and South Asian populations and confer characteristics including adaptation to hypoxia, the absence of CMS, and high offspring survival rates. Polymorphisms in the *EPAS1* gene that encodes HIF-2 α , and the *EGLN1* gene, which encodes PHD2, have been positively selected and have been shown to be associated with the key adaptive features in Tibetans. The putative advantageous haplotypes of *EGLN1* and *EPAS1* have revealed negative correlations with hemoglobin levels in Tibetans compared with lowlander Han Chinese. Tibetans do not exhibit increased hemoglobin levels at high altitude. A high-frequency missense mutation in the *EGLN1* gene, which encodes PHD2, contributes to this adaptive response. A variant in *EGLN1*, c.[12C>G; 380G>C], has been shown to contribute functionally to the Tibetan high-altitude phenotype. PHD2 triggers the degradation of hypoxia-inducible factors (HIFs). The PHD2 p.[Asp4Glu; Cys127Ser] variant exhibits a lower K_m value for oxygen, suggesting that it promotes increased HIF degradation under hypoxic conditions. Whereas hypoxia stimulates the proliferation of WT erythroid progenitors, the proliferation of progenitors with the c.[12C>G; 380G>C] mutation in *EGLN1* is significantly impaired under hypoxic culture conditions. The c.[12C>G; 380G>C] mutation abrogates hypoxia-induced and HIF-mediated augmentation of erythropoiesis, which provides a molecular mechanism for the observed protection of Tibetans from polycythemia at high altitude.

This individual variability of elevation of serum EPO levels in high-altitude dwellers and the resultant increase in RBC mass appears widespread. For example, acclimatization to moderately high altitudes when combined with low-altitude training (so-called *living high, training low*) improves sea-level performance in endurance athletes, in part because of the erythropoietic effects of altitude exposure. This substantial individual variability in response to all forms of altitude training correlates with improved athletic performance and with elevation of EPO levels. A large component of this individual variability appears to be related to differences in the peak and rate of decay of the increase in EPO in response to altitude exposure. These observations suggest that genetically determined variables account for individual responses to hypoxia.

Chronic mountain sickness (CMS) is a pathological loss of adaptation to altitude. CMS is a clinical syndrome that occurs in native or lifelong residents living above 2500 m. Anecdotal reports of families or people being particularly susceptible to CMS are frequently cited as evidence that certain individuals have an innate susceptibility to develop CMS. It is characterized by excessive erythrocytosis (females, Hb >19 g/dL; males, Hb >21 g/dL); severe hypoxemia; and in some cases, moderate or severe pulmonary hypertension that may lead to the development of cor pulmonale and congestive heart failure. The clinical picture of CMS gradually disappears after descending to lower altitudes and reappears after returning to high altitudes. The prevalence of CMS is higher in men than women and increases with altitude, aging, associated lung disease, history of smoking, and air pollution. CMS is a public health problem in mountainous regions of the world living above 2500 m. In China alone, 80 million people live above that altitude, but in South America, 35 million people live above 2500 m. The CMS phenotype has been associated with a single-nucleotide polymorphism (SNP) in the Sentrin-specific Protease 1 (*SENPI*) gene.⁶ The *SENPI* gene encodes for a protease that regulates the function of hypoxia-relevant transcription factors such as HIF and GATA, and thus might have an erythropoietic regulatory role in CMS through modulation of the expression of EPO or EPOR. Fibroblasts obtained from CMS patients express less SNEP1 protein than their healthy counterparts under hypoxic conditions. *SENPI* has been shown to regulate EPO production by regulating the stability of HIF1 α during hypoxia, and indeed *SENPI*^{-/-} mice die of anemia during early life. *SENPI* also mediates a positive-feedback loop under hypoxic conditions that is responsible for VEGF production and angiogenesis. The major mechanism underlying the development of CMS is relative alveolar hypoventilation. Healthy highlanders characteristically hyperventilate. A gradual decline in the rate of alveolar ventilation in these individuals leads to progressive loss of adaptation to chronic hypoxia and the development of CMS. The main components of this syndrome include (1) alveolar hypoventilation leading to relative hypercapnia and increasing hypoxemia; (2) excessive polycythemia leading to increased blood viscosity and expansion of the total lung blood volume; (3) pulmonary hypertension and right ventricular hypertrophy that may evolve to hypoxic cor pulmonale and heart failure; and (4) neuropsychiatric symptoms, including sleep disorders, headache, dizziness, and mental fatigue. Physical examination reveals cyanosis of the nail beds, ears, and lips in contrast to the ruddy color that is characteristic of a healthy highlander. In some cases, the face is almost black, and the mucosa and conjunctiva are dark red. The fingers are frequently clubbed, and auscultation of the heart reveals an increased pulmonary second sound. The patients are frequently hypertensive and have evidence of heart failure. Chest radiographic and electrocardiographic findings are characteristic of right atrial and right ventricular hypertrophy. Criteria for the diagnosis of CMS have been published and are useful in identifying CMS patients as well as monitoring their response to treatment.

The definitive treatment for CMS is descent to lower altitudes or sea level. The degree of polycythemia decreases after a few weeks or months, and eventually the hematocrit level returns to sea-level values. Pulmonary hypertension and right ventricular hypertrophy gradually resolve and disappear after 1–2 years of living at sea level. Phlebotomy or isovolemic hemodilution can reduce the excessive erythrocytosis and hyperviscosity, improve oxygenation and leads to relief from symptoms. Due to its transient effects, phlebotomy is not a long-term treatment for CMS. A variety of drugs has also been evaluated for the treatment of patients with CMS. Ten weeks of the respiratory stimulant medroxyprogesterone acetate at doses of 60 mg/day led to a reduction of the hematocrit level from 60% to 52% and an increase in arterial oxygen saturation from 84% to 90% in 17 highlanders with CMS. Medroxyprogesterone use, however, was associated with a loss of libido in men and therefore is infrequently used in this population. Therapy with almitrine, a respiratory stimulant, or enalapril, an ACE inhibitor (10 mg/day for 30 days), has resulted in even more modest reductions of hematocrit levels. Therapy with acetazolamide is the most useful treatment for CMS.

Acetazolamide therapy has been evaluated in two double-blind, placebo-controlled, randomized clinical trials of patients with CMS. Acetazolamide is an inhibitor of carbonic anhydrase and stimulates ventilation by promoting the development of metabolic acidosis. Furthermore, acetazolamide reduces renal EPO production. Patients with CMS were randomized to receive placebo or acetazolamide therapy at a dose of 250 or 500 mg/day for 21 days. Drug therapy at both doses of acetazolamide resulted in reduction of hematocrit levels by 7% ($p < .001$) and serum EPO levels by 50–67% ($p < .1$), with an increase in nocturnal oxygen saturation levels of 5% ($p < .01$). Presently, 250 mg of acetazolamide daily appears to be an inexpensive, nontoxic, and effective therapy for CMS.

Smokers' Polycythemia or Carbon Monoxide-Induced Polycythemia

Smoking is the most common cause of secondary polycythemia. Those affected have a carboxyhemoglobin-induced increase in RBC mass or decrease in plasma volume, either of which is reversible with smoking cessation. Excessive carbon monoxide exposure can also be attributed to exposure to industrial emissions and automobile exhaust. Carbon monoxide binds to hemoglobin with a more than 200-times greater affinity than oxygen, resulting in not only occupation of one of the heme groups of hemoglobin but also an increase in the O_2 affinity by the remaining heme group. Individuals smoking even one pack of cigarettes a day frequently have elevated hematocrit levels. These patients characteristically have normal blood gases and elevation of carboxyhemoglobin levels, resulting in a reduction in P_{50O_2} . The elevation of the hematocrit level is reversed with interruption of the smoking behavior. Increased hematocrit levels have been observed in 3–5% of heavy smokers. Although these patients are not immune to thrombotic complications, the number of thromboembolic events is lower than in patients with PV. Polycythemia has also been reported to be associated with hookah use. A hookah is an oriental pipe containing tobacco often mixed with molasses and fruit flavors connected by a long flexible tube that draws the smoke to the bowl of water. Hookah use exposes the user to generous amounts of carbon monoxide, resulting in erythrocytosis.

Postrenal Transplantation Erythrocytosis

Postrenal transplantation erythrocytosis (PTE) is defined as a persistently elevated hematocrit level greater than 51% after renal transplantation without an elevation of the WBC count or platelet count. PTE is a potentially dangerous condition found in approximately 10–15% of renal allograft recipients. PTE usually develops within 8–24 months after a successful renal transplantation and resolves spontaneously within 2 years in about 25% of patients despite persistently good renal allograft function. PTE is more common in males and may recur in the same patient after a second successful renal transplantation. Factors that increase the likelihood of its development are a lack of EPO therapy before transplantation, a history of smoking, diabetes mellitus, transplant-related renal artery stenosis, retention of the native kidney, low serum ferritin levels, and normal or high pretransplantation EPO levels. PTE is also more frequent in patients who do not experience rejection. There is some evidence that the use of cyclosporine as an immunosuppressive agent is associated with increased risk of PTE. At higher hematocrit levels (usually >60%), thrombotic events may complicate the clinical course of patients with PTE.

Approximately 60% of patients with PTE experience malaise, headache, plethora, lethargy, and dizziness. In addition, from 10% to 20% develop thromboembolic complications involving either arteries or veins. Retention of the native kidney is essential for the development of PTE in most cases. Although the transplanted kidney produces EPO under normal regulatory mechanisms, the native kidney overproduces EPO despite the development of erythrocytosis.

Frequently, the PTE resolves with removal of the native kidney. Plasma EPO levels can be normal or high in patients with PTE.

The molecular basis of PTE remains unclear; AngII is believed, however, to play an important role in its pathogenesis by sustaining the secretion of EPO. Growing evidence indicates that increased AT1R expression makes erythroid progenitor cells hypersensitive to AngII. Furthermore, AngII can modulate release of erythropoietic stimulatory factors, including EPO and IGF-1. Androgens are thought to play a role in the development of the syndrome. Androgens can directly affect erythroid progenitor cells or stimulate EPO production or actually the RAS. Treatment of patients with PTE includes intermittent phlebotomy or administration of drugs. The ACE inhibitor enalapril suppresses the renin–angiotensin pathway and virtually eliminates the need for therapeutic phlebotomy in these patients. Maximal reduction of hemoglobin levels is evident 6 months after starting therapy with either ACE inhibitor or angiotensin receptor blockers. Some patients are exquisitely sensitive to these medications and may become severely anemic. The AT1R antagonist losartan has been shown to be as effective in treating PTE as are ACE inhibitors. Therapy is usually begun at hematocrit levels above 55% with the hope of maintaining hematocrit levels below 50% to reduce the risk of thrombosis. Furthermore, the ACE inhibitor fosinopril in an open-label crossover trial with theophylline was shown to produce a dramatic reduction in hematocrits in patients with PTE (51.3–43.7%; $p < .005$). Low doses of ramipril, another ACE inhibitor, normalized the hematocrit level in 26 out of 27 patients with PTE after a mean of 127 days of therapy.

Polycythemia Accompanying Kidney and Liver Diseases and Neoplastic Disorders

Polycythemia has been reported in association with kidney diseases such as renal cell carcinoma, renal artery stenosis, hydronephrosis, Wilms tumor, and polycystic kidney disease, paragangliomas, and pituitary adenomas. Renal tumors account for approximately one-third of cases of tumor-associated polycythemia. The tumor tissue has been demonstrated to produce excessive amounts of EPO, and the erythrocytosis resolves with surgical resections of the tumor. The mechanisms underlying the activation of the *EPO* gene have been related to somatic mutations of the *VHL* gene in clear-cell renal carcinomas. Clear-cell carcinoma is associated with erythrocytosis and high serum EPO levels caused by increased expression of EPO mRNA, HIF-1 α , and HIF-2 α . These abnormalities were related to a point mutation in the *VHL* gene that impaired the bindings of HIF-1 α to VHL, leading to its accumulation and increased production of EPO. Polycythemia is also a well-described paraneoplastic manifestation of hepatocellular carcinoma in 2.5–10% of patients and is again caused by the production of EPO by the tumor. Polycythemia in hepatoma patients is strongly related to tumor burden and elevated α -fetoprotein levels. Polycythemia has also been associated with cerebellar hemangioblastomas and very large uterine fibromas. In tumor-associated erythrocytosis, EPO production has been shown to be autonomous of hypoxic stimuli. Paragangliomas are tumors arising from extraadrenal paraganglionic neural crest cells. Most paragangliomas arise retroperitoneally or within the peritoneal cavity and are associated with high EPO levels and erythrocytosis. After tumor resection, reduction of the EPO levels and erythrocytosis occurs. Germ-line mutations involving two Krebs cycle enzymes, fumarate hydratase and succinate dehydrogenase, have been implicated in the hereditary paraganglioma–pheochromocytoma syndrome. In tumors deficient in these enzymes fumarate and succinate accumulate, which inhibits PHD, leading to accumulation of HIF-1 α and eventually resulting in erythrocytosis. In another patient with a paraganglioma who did not have the inherited syndrome but had extreme erythrocytosis, a germ-line mutation in *PHD2* was demonstrated. In this patient's tumor, tumor analysis showed LOH with the mutant allele predominating, which was associated with a loss of function. The degradation of both HIF-1 α and HIF-2 α was decreased. These data indicate that PHD2 can act as a tumor suppressor gene. The tumor

suppressor activity of PHD2 has also been reported in sporadic endometrial, breast, and pancreatic cancers, with inactivating mutations ultimately leading to the increased production of growth factors that contribute to tumor growth. Two plasma cell dyscrasias, POEMS (Polyneuropathy, Organomegaly, Endocrinopathy, Monoclonal protein, Skin changes) syndrome and TEMPI (Telangiectasias, Erythrocytosis with elevated erythropoietin levels, Monoclonal gammopathy of unknown significance [MGUS], Perinephric fluid collections, and Intrapulmonary shunting syndrome) have been recently been reported to be associated with erythrocytosis. Treatment is directed at the underlying disease. In TEMPI syndrome, the most effective treatment has been bortezomib, which suggests that TEMPI syndrome is a consequence of the abnormal plasma cell clone.

Polycythemia in Endocrine Disorders

Polycythemia is also associated with Cushing syndrome, acromegaly, and primary aldosteronism. Secondary polycythemia can also be seen in 24% of older hypogonadal men receiving long-term androgen-replacement therapy and a significant number of competitive athletes taking anabolic steroids. For instance, in a small study of professional bodybuilders, 67% of those examined had hematocrit levels above 50%. The effectiveness of drug screening in athletic competitions is demonstrated by the very low rate of positive test results for androgens (<2% of 170,000 tests) on random testing at the Olympic Games and other international events. Despite previous assertions regarding increased EPO excretion after androgen therapy, none of the athletes examined had elevated levels of EPO. Recombinant human EPO has also been abused by athletes competing in endurance sports and can be detected by analyzing the individual's hematocrit level, reticulocyte count, percentage of macrocytic RBCs, serum EPO level, serum transferrin receptor level, and electrophoretic mobility of the EPO molecule (recombinant EPO is less negatively charged than endogenous EPO).

Congenital Secondary Polycythemias

High-Oxygen-Affinity Hemoglobins and Bisphosphoglycerate Deficiency

More than 100 mutations of hemoglobin lead to increased oxygen affinity and thus decreased oxygen delivery and compensatory polycythemia (see Chapter 43). These mutations involve either the α - or β -chain globin chains.⁷ Such polycythemias are usually well tolerated in young patients but may lead to thrombotic complications in older patients. High-oxygen-affinity hemoglobin variants are transmitted as autosomal dominants. Phlebotomy therapy of such patients has been reported to not be of any beneficial value and has been shown to decrease exercise tolerance. The best test to detect high-oxygen-affinity hemoglobin relies on the determination of hemoglobin dissociation kinetics and P_{50} (partial pressure of O_2 at which hemoglobin is 50% oxygenated). If cooximetry is not available, the P_{50} can be mathematically estimated from a venous blood gas measurement by using a computer algorithm, which is available online.

Whereas a $P_{50}O_2$ below 17 mmHg is indicative of a mutant hemoglobin with high oxygen affinity, a level above 35 mmHg is strongly suggestive of a mutant hemoglobin with a low oxygen affinity. Hemoglobin electrophoresis is not a reliable screen to rule out such a hemoglobin mutation because only about half of these mutants are electrophoretically distinguishable. Hemoglobin electrophoresis will reveal the presence of an abnormal hemoglobin only if the mutation leads to a change in electrical charge. If such a charge differential is not present, high-performance liquid chromatography or mass spectrometry followed by polymerase chain reaction (PCR)-directed sequencing will be required to establish the diagnosis.

A rare cause of congenital polycythemia is 2,3-bisphosphoglycerate (2,3-BPG; previously known as 2,3-DPG) deficiency (see Chapter 44). 2,3-BPG is synthesized in RBCs and binds to hemoglobin, thereby reducing its affinity for oxygen. An absence of 2,3-BPG

therefore leads to increased affinity of hemoglobin for oxygen, resulting in a lifelong hypoxic stimulus and erythrocytosis.

Congenital methemoglobinemias, whether caused by cytochrome b5 reductase mutations or globin mutations, may be associated with mild polycythemia (see Chapter 43). When hemoglobin is oxidized to methemoglobin, all of the four subunits of the tetramer may be affected, eliminating the oxygen transport capacity of hemoglobin.

Hypoxia-Inducible Factor Pathway Mutations Leading to Erythrocytosis

Alterations of a number of proteins in the HIF pathway have been shown to lead to increased EPO production and erythrocytosis (see Fig. 68.1). Chuvash polycythemia (CP) is an autosomal recessive disorder associated with germ-line mutations of *VHL* and erythrocytosis. CP was first described in the mid-1970s and is endemic in the Chuvash population of the Russian republic. The serum EPO concentration in affected individuals is elevated compared with healthy first-degree family members, although some patients may have normal serum EPO levels. They also have elevated levels of VEGF and plasminogen activator inhibitor-1. The erythroid progenitors of patients with CP are also hypersensitive to EPO; thus, CP has characteristics of both primary and secondary polycythemias. A homozygous missense mutation in the *VHL* gene, *VHL*598C→T mutation, has been identified in CP patients. The disorder is characterized by high hemoglobin levels (usually >20 g/L), increased plasma EPO levels, varicose veins, vertebral hemangiomas, low blood pressure, and an elevated concentration of VEGF. The defective *VHL* gene product is not capable of promoting the ubiquitin-mediated degradation of HIF-1 α and HIF-2 α , thereby leading to increased levels of both of these proteins and increased elaboration of EPO. The CP-*VHL* mutants have been shown to affect EPO signaling in erythroid progenitor cells of patients with CP. JAK2 phosphorylation of STAT5 triggers not only erythroid progenitor development but also a negative feedback mechanism by transactivating the expression of SOCS family members, which bind and inhibit activated JAKs by promoting their ubiquitination and proteasomal degradation. The CP mutation causes conformational changes, leading to a tight CP-*VHL*-SOCS-1 association, thereby slowing phosphorylated JAK2 degradation. These events lead to hyperactivation of the JAK2-STAT pathway in erythroid progenitor cells, causing their hypersensitivity to EPO, which likely contributes to the excessive erythrocytosis characteristic of CP. Inheritance occurs as an autosomal recessive, and the frequency of the allele has been estimated to be at 0.057 in the Chuvash population. Several other similar types of mutations in *VHL* have been described that have been observed in a variety of other ethnic groups. A number of heterozygotes with erythrocytosis have been reported, which can likely be accounted for by an as yet undiscovered additional defect. CP is associated with a high mortality rate from thrombotic and hemorrhagic vascular complications. Most patients complain of chronic headache, fatigue, and/or lower extremity pain, and are noted to have lower blood pressures. Cerebrovascular events are especially common causes of death. The median age of death from cerebrovascular events is 42 years. Estimated survival to age 65 years is 29% for individuals with CP and 64% for age-matched community members. There is a perfect genotype-phenotypic correlation, with all patients with CP being homozygotes for the mutation. Interestingly, heterozygous carriers do not develop erythrocytosis but do have lower blood pressures and do not seem to be at increased risk for tumors, which contrasts with patients with *VHL* syndrome. Patients with CP also have larger livers, spleens, and kidneys than control patients, which has been attributed to enhanced cellular proliferation caused by HIF-2 α suppression of p21Cip1.

Germ-line mutations of *VHL* alleles have been reported in several patients with apparent congenital polycythemia that had no evidence of developing a tumor; some of these subjects had germ-line mutations of both *VHL* alleles. Other subjects with congenital polycythemia of various ethnicities, including Pakistanis, Punjabis, African-Americans, and whites, harboring homozygosity for the CP

VHL mutation or double heterozygosity for CP and other *VHL* mutations, have been found. The *VHL*598C→T mutation has been shown to originate in a single haplotype in the Chuvash patients, as well as in whites, Asian Indians, and one African-American individual. Homozygosity of this mutation appears to be the most common genetic defect leading to congenital polycythemia. The mutation originated from a single founder 12,000–51,000 years ago. This suggests that such wide dissemination from the original founder may be associated with some survival advantage for heterozygotes carrying this mutation. Such an advantage might be related to a subtle improvement of iron metabolism, erythropoiesis, embryonic development, energy metabolism, or some other yet unknown effect.

VHL mutations are likely the most common cause of congenital polycythemia, greatly exceeding the number of patients with hemoglobin chain mutations. In point of fact, in one study of more than 200 unrelated subjects with apparently congenital polycythemia, none had a 2,3-BPG deficiency, two had a globin mutation (Hgb Vanderbilt, and Hemoglobin San Diego), and 12 had *EPOR* mutations to account for their polycythemia. By contrast, when 50 patients were examined for the *VHL* mutation, 22 had *VHL* mutations, most of them being the CP *VHL* mutation, occurring either homozygously or in combination with another *VHL* mutation. The failure of patients with CP to develop VHL syndrome tumors is consistent with the concept that dysregulation of HIF-1 α and VEGF are not sufficient to cause tumors. A cluster of patients with clinical features identical to patients with CP has been documented on the island of Ischia in the Bay of Naples, Italy. All of these patients also had the *VHL*598C→T mutation. Twelve of the 14 patients were homozygotes, and two were heterozygotes. The homozygotes had symptoms identical to patients in Chuvashia with this mutation. Unlike heterozygotes in Chuvashia, the heterozygotes from Ischia developed erythrocytosis associated with high EPO levels, which raises the possibility that genetic alterations of additional components of the oxygen-sensing pathway other than *VHL* may contribute to the development of erythrocytosis in the Italian patients. The disorder in Ischia has a gene frequency even higher than that in Chuvashia, with 14% of the population estimated to be heterozygotes, which has led to the suggestion that heterozygotes have a survival advantage, perhaps caused by heterozygosity conferring protection from developing anemia.

The Chuvash mutation has also been shown to have a profound effect on the cardiopulmonary system. Patients with CP have significant abnormalities of cardiopulmonary physiology, including elevated basal ventilation rates and increased pulmonary vascular tone, with extremely high ventilatory rates and heightened pulmonary vasoconstriction and heart rates in response to acute hypoxia. These observations indicate that the *VHL*–HIF pathway might also play a central role in calibrating the pulmonary system to hypoxic challenges. Such undesirable exaggerated hypoxic responses and the resulting elevated pulmonary vascular hypertension may contribute to the morbidity and mortality associated with CP. Increased expression of endothelin-1 has been documented in patients with CP. Endothelin-1 has been associated with the development of hypoxia-related pulmonary hypertension. Endothelin-1 receptor inhibitors might therefore be useful in reversing the associated pulmonary hypertension in these patients. Treatment strategies for patients with CP have included phlebotomy, aspirin, and occasionally chemotherapy. Most patients are treated empirically with phlebotomy therapy, but at present it remains unknown if this approach reduces the incidence of thrombotic incidences or improves the quality of life.

Additional genetic abnormalities of oxygen sensing have been reported that lead to familial polycythemia. A heterozygous C-to-G change at base 950 of the coding sequence of *PHD2* (*P317R* mutation) was first detected in all three affected family members with this syndrome. Hydroxylation of HIF-1 by *PHD2* facilitates its interaction with *VHL*, thereby favoring its ubiquitination and degradation by the proteasome.⁸ The failure of *PHD2* *P317R* to bind HIF-1 and HIF-2 α and promote HIF hydroxylase activity ultimately leads to increased HIF-1 and EPO levels, resulting in the development of erythrocytosis. The *PHD2* *P317R* mutation is inherited as an autosomal dominant trait in contrast to the CP defect, which is an

autosomal recessive disorder. Polycythemic patients with *PHD2* *P317R* do not have any evidence of tumors characteristic of the *VHL* syndrome. Additional mutations in *PHD2* have been reported that lead to erythrocytosis. All of these mutations are germ-line and heterozygous, encoding predicted mutant full-length *PHD2* proteins. A series of HIF-2 α gain-of-function mutations have also been reported to lead to familial erythrocytosis. These mutations lead to weakened bonds between *PHD2* and HIF-1 α , resulting in less hydroxylation of HIF-1 α and subsequent recognition of HIF-1 α by *VHL*. Many of these patients present in their twenties, although patients have also been diagnosed in their fifties with erythrocytosis associated with high EPO levels. All patients have heterozygous mutations, suggesting that one allele is sufficient to cause erythrocytosis. It is not unusual for patients to have a clinical history of thrombotic disorders, but there does not appear to be an increased incidence of cancer.

Neonatal Polycythemia

Because of the high oxygen affinity of fetal hemoglobin, many neonates have markedly elevated hematocrit levels. Babies with hematocrit levels over 65% have more neurologic and functional impairments, and are more likely to be born to diabetic mothers. Although phlebotomy has been recommended, there is little evidence that it has been beneficial for these babies.

Drug-Induced Erythrocytosis

The administration of EPO, corticosteroids, or androgens to an excessive degree has each been associated with reversible erythrocytosis. Androgens have been shown to simulate EPO production and to directly affect erythroid progenitor cells. Approximately 5% of patients receiving long-term testosterone therapy for testosterone-deficiency syndrome develop erythrocytosis. Androgens activate HIF-1 and HIF-1-regulated gene expression, leading to increased expression of VEGF and presumably EPO. Rarely, erythrocytosis can be the presenting manifestation of Cushing syndrome. Blood doping refers to the use of EPO to increase the RBC mass and enhance oxygen delivery with the hope of increasing endurance performance in athletes. A monitoring of an athlete's hematologic profile longitudinally provides some insight into the likelihood of blood doping playing a role in the development of erythrocytosis.

The development of paradoxical polycythemia in three patients with *VHL* syndrome and CNS or retinal hemangioblastomas treated with a VEGF receptor inhibitor has been reported. The cause of these phenomena remains unknown. In addition, reversible paradoxical erythrocytosis has been reported with the use of VEGF tyrosine kinase inhibitors, including sunitinib, sorafenib, axitinib, pazopanin, and the anti-VEGF monoclonal antibody bevacizumab, primarily in patients with renal cell carcinomas. These patients become symptomatic due to fatigue, pruritis, myalgias, headaches, and malignant hypertension. The cause of the erythrocytosis associated with these drugs has been attributed to either elevation of EPO levels or sensitization of erythroid cells to EPO. The erythrocytosis in this situation can be controlled with phlebotomy therapy with relief of symptoms.

POLYCYTHEMIA VERA

PV is a clonal, chronic, progressive myeloproliferative neoplasm (MPN) often of insidious onset characterized by an absolute increase in RBC mass and often by leukocytosis, thrombocytosis, and splenomegaly. PV leads to excessive proliferation of erythroid, myeloid, and megakaryocytic elements within the BM. Vaquez first described this clinical entity in 1892, noting the characteristic physical findings. At the turn of this century, Cabot and Osler independently associated the name PV with this clinical disorder.

PV differs from many other hematologic malignancies in that prolonged survival is enjoyed by most patients if the excessive production of RBCs and platelets can be controlled. This prolonged survival, however, can be punctuated by the development of other syndromes,

Fig. 68.3 EVOLUTION OF POLYCYTHEMIA VERA. MF, Myelofibrosis; PV, polycythemia vera.

such as myelofibrosis (MF), termed *post-PV MF*, and acute leukemia (Fig. 68.3). Frequently, patients present asymptotically to a physician only to find that they have splenomegaly, isolated erythrocytosis, or thrombocytosis. Left untreated, these patients will become symptomatic owing to the excessive production of RBCs, platelets, or both, leading to arterial or venous thromboses, aquagenic pruritus, and symptoms caused by increasing splenomegaly. After a number of years, the erythrocytotic phase of the disease frequently becomes inactive, and the patient may no longer have the sequelae of excessive RBC production. Subsequently, these patients can develop post-PV MF, which is frequently indistinguishable from another MPN, primary MF (PMF). Finally, a significant proportion of these patients will go on to develop acute myeloid leukemia (AML). Only a limited number of patients undergo this orderly transition; many patients transition from the polycythemic phase directly into an acute leukemia or a myelodysplastic disorder.⁹

The transition from one phase of this MPN to another is not necessarily unidirectional. About 10–15% of patients with *JAK2V617F*-positive essential thrombocythemia eventually develop erythrocytosis and are reclassified as having PV. A number of cases of presumed PMF either spontaneously or after chemotherapy have been described where the patient develops erythrocytosis and a syndrome that is virtually indistinguishable from *de novo* PV. The constantly changing clinical picture of this malignant hematologic disorder requires careful observation and treatment to deal with the numerous problems that can be encountered.

Epidemiology

PV is the most common primary polycythemia. Incidence rates (IRs) have been reported to be around 2.8 per 100,000 persons per year. It is important to emphasize that no or very few population-based estimates of the prevalence of this disorder are presently available. Actual determination of its prevalence has been a difficult process because of the need in the past to pursue an extensive diagnostic

evaluation to differentiate this disorder from other causes of spurious or absolute erythrocytosis. The diagnosis of PV has been simplified by the identification of PV-associated mutations (*JAK2V617F* and *JAK2* exon 12 mutations), permitting for the first time molecular epidemiologic studies. The prevalence of the *JAK2V617F* mutation in a normal population in Denmark was recently determined to be 0.2%, with 63% of these individuals not having a previously detected hematological malignancy. The presence of the mutation was associated with increasing age, male sex, and a lower cumulative survival. Recently available 2001–2012 data from the Surveillance, Epidemiology and End Results (SEER) Program from the US National Cancer Institute provided new insight into the IR of the MPNs. This study utilized the WHO Diagnostic Criteria and for the last 5 years of the study *JAK2V617F* testing was included. The age adjusted IR of PV and essential thrombocythemia (ET) were 10.9 and 9.4 per 1 million per year, respectively. The IR for PMF was 3.1. In order to grasp the magnitude of the IR of these various MPNs, the IR of CML was 3.3, demonstrating that the IR of these Ph⁻ MPNs were sevenfold higher than CML. Both PV and PMF were more frequent in males while the IR for ET was greater in females. Several groups have reported that 50% of patients with a splanchnic vein thrombosis without an overt MPN are *JAK2V617F* positive and that more than 50% of these individuals subsequently develop an MPN. However, the incidence of the mutation with unprovoked thromboembolism in the more usual sites (deep venous thrombosis involving the leg veins or pulmonary embolism) ranges between 0.2 and 1.0%. Such data have led to the conclusion that systematic screening for *JAK2V617F* in such a patient population is not warranted.

The prevalence of PV has been reported by several investigators to be higher among American Jews and lower among African-Americans and Hispanics. The reported lower incidence in African-Americans might reflect a referral bias characteristic of centers with research interest in MPN because the authors, when practicing in several large urban areas, have observed a considerable number of African-Americans with MPNs, including PV. The incidence of the disorder is greater among Ashkenazi Jews, who originate from eastern and central Europe, than among Arabs and Sephardic Jews. Interestingly, extremely low occurrence rates have been reported from Japan. These findings suggest that important genetic factors might be involved in the biogenesis of this disorder. The importance of genetic factors in the origin of this disease is further emphasized by reports of multiple cases of *JAK2V617F* or *JAK2* exon 12 mutation-positive and -negative MPN, including PV, within multiple generations of a number of families. These forms of familial PV must be distinguished from PFCP, CP, and polycythemia associated with mutations in the HIF pathway. The reports of families in which multiple members have PV first raised the possibility that a genetic predisposition to acquire such mutations exists in these families that is inherited in an autosomal dominant pattern with decreased penetrance. Clinical analyses of affected family members confirmed that they have clonal hematopoiesis and that their clinical manifestations are identical to patients with sporadic PV. In a large population study from Sweden, the relatives of MPN patients were shown to have a significantly increased risk of developing a Ph⁻ MPN and possibly chronic myeloid leukemia.¹⁰ It was estimated that first-degree relatives of MPN patients have a five- to sevenfold greater risk of developing an MPN, again supporting the hypothesis that common strong susceptibility genes predispose one to develop PV, essential thrombocytosis (ET), PMF, and possibly CML.

One notable exception to the low prevalence of PV in Japan has been the higher incidence observed among populations exposed to atomic bomb explosions. The possibility that radiation exposure is an etiologic factor in the generation of PV was also raised by the observation in the United States of four cases of PV 10–20 years after the Smokey nuclear weapons test in which 3000 military observers were exposed. An epidemiologic investigation that focused on occupational exposure among petroleum refinery and chemical plant workers has revealed an increased incidence of PV relative to the general population. In this study, the increased incidence of PV was linked to similar increases in the frequency of multiple myeloma and

non-Hodgkin lymphoma, suggesting involvement of a putative environmental toxin that may have broad hematopoietic toxicity. The possibility of environmental factors contributing to the development of PV was recently raised by the identification of a cluster of patients with *JAK2V617F*-positive PV in an area of Eastern Pennsylvania that contained numerous sources of hazardous materials including, waste coal power plants and United States Environmental Protection Agency Superfund sites. What possible environmental factors might contribute to this fourfold increase in the number of PV cases is currently the subject of intense investigation.

In several large studies, 5% of patients with PV were younger than 40 years of age, 1% were younger than 25 years at diagnosis, and 0.1% were younger than 20 years. Small numbers of patients with PV have been reported who presented during childhood. Interestingly, females comprise the majority of PV patients diagnosed before the age of 40 years, suggesting a unique risk factor for developing the disease at early age.¹¹ These young female patients tend to present with unique complications such as abdominal venous thrombosis and their risk of transformation to MF or AML is similar to older patients.

The *JAK2V617F* mutation has a prevalence of 0.1–0.2% in the general population. These individuals usually have an allele burden of less than 10%. Some these patients have an undiagnosed MPN or represent an early molecular stage of a MPN, which will evolve over time. Those normal individuals with an allele burden of <2% likely have a latent form of an MPN.

Pathobiology

Considerable speculation has centered on the pathobiology of the erythrocytosis that characterizes PV. The expanded RBC mass in PV patients is due to a two- to threefold increase in the production of RBCs by a hyperplastic BM and is not attributable to prolongation of the RBC lifespan. Granulocyte and platelet production are also increased in this disorder. This overly exuberant production of all cellular elements of the blood suggests that the basic defect resides at the level of the pluripotent hematopoietic stem cell (HSC).

Serum EPO levels have been shown to be subnormal in patients with PV, elevated in many but not all cases of secondary erythrocytosis, and normal in patients with relative polycythemia, indicating that PV cannot be an abnormality of EPO production.

In 1951, Dameshek postulated that chronic myeloid leukemia, PV, essential thrombocythemia, and PMF were related disorders, which he called *myeloproliferative disorders*, but are now termed *MPNs* because of the evidence that these disorders are hematologic malignancies.

Since the mid-1970s, data have accumulated that conclusively demonstrate PV to be the result of a neoplastic proliferation of hematopoietic cells. The cellular origin of the disorder was first established by the analysis of glucose-6-phosphate dehydrogenase (G6PD) isoenzymes in African–American women who were heterozygous for this X-linked gene. This approach was based on the random irreversible inactivation of one X chromosome in each female somatic cell during embryogenesis. Inactivation of the same X chromosome occurs in the progeny of these cells. A normal African–American female heterozygous for G6PD will therefore have approximately equal populations of BM cells with a different G6PD isoenzyme. The G6PD isoenzymes can be readily distinguished by electrophoretic methods.

This approach was exploited in a seminal study by Adamson and coworkers in an effort to determine the cellular origin of PV. They presumed that cells comprising a tumor that arises from a single cell in a G6PD heterozygote would express a single isoenzyme type, but a neoplasm originating from multiple cells would express both isoenzyme types. These investigators found that circulating RBCs, granulocytes, and platelets obtained from African–American female patients who were G6PD heterozygotes express the same isoenzyme, but skin and cultured BM fibroblasts obtained from these same patients demonstrate both isoenzymes. They concluded that PV represented a clonal proliferation of neoplastic HSCs and was not

multicellular in origin or the consequence of excessive proliferation of normal HSCs.

The clonality of blood cell production in PV has subsequently been confirmed using restriction fragment length polymorphisms of the active X chromosome. A monoclonal pattern of X chromosome inactivation has been defined in RBCs, granulocytes, monocytes, and platelets in female patients with PV.

On the basis of the knowledge that RBC production in PV is not associated with excessive EPO production, numerous investigators hypothesized that the erythroid progenitor cell in this disorder was no longer subject to physiologic regulators. PV BM can form substantial numbers of erythroid colonies in vitro in the absence of exogenous EPO, but normal human BM is incapable of forming such colonies without the addition of EPO. These erythroid colonies were termed *endogenous colonies*. When erythroid PV and normal BM were subsequently assayed in the presence of EPO, PV BM was characterized by a higher cloning efficiency. Additional observations suggested that the altered response to cytokines was not restricted to EPO but included a variety of other cytokines and that this cytokine hypersensitivity was characteristic of progenitor cells committed to a variety of other lineages.

In addition, BM cells cloned from African–American female G6PD heterozygotes with PV in the presence and absence of exogenous EPO revealed that the erythroid colonies that formed in the absence of exogenous EPO contained the same G6PD isoenzyme type as that expressed by peripheral blood elements. Thus, the so-called *endogenous erythroid colonies* arose from the abnormal clone that was responsible for supplying RBCs, granulocytes, and platelets to the peripheral blood. When exogenous EPO was added, increasing numbers of colonies were formed containing cellular elements expressing the other G6PD isoenzymes; presumably, these colonies originated from cells not involved in the malignant process. Similarly, small numbers of granulocyte–macrophage colonies not originating from the PV clone were also observed in these assays. These data collectively indicate the existence of malignant and nonmalignant populations of HPCs in PV BM. The relative frequency of the neoplastic clone in relation to normal progenitor cells was further examined by Adamson and coworkers, who, by monitoring the proportion of neoplastic erythroid clones and their numeric relationship to normal clones over a period of several years, showed disease progression to be associated with a significant decline in the frequency of normal progenitor cells and increasing proportion of the neoplastic clone. Erythroid progenitor cells from PV patients are, in fact, abnormally sensitive to the actions of this EPO. This increased responsiveness allows these cells to form colonies in the presence of small amounts of EPO. Most PV patients possess two distinct populations of erythroid progenitor cells: a normally EPO-responsive population and a population of cells similar in proliferative and maturational behavior in vitro but requiring little or no EPO. These investigators suggested that the proliferation of the normal progenitor cells in vivo was at a disadvantage. A number of investigators have demonstrated that the increased responsiveness of these BM progenitor populations extends to their responses to other cytokines, including SCF, IL-3, GM-CSF, and IGF-1.

Identification of *JAK2V617F* Mutation in PV

For more than two decades a number of research groups searched for the genetic defect underlying PV. Most groups predicted that this defect involved the signaling pathways downstream of the EPOR. These pathways include the tyrosine kinase JAK2 and the transcriptional signal transducers and activators of transcription, STAT3 and STAT5. The initial discovery of a mutation was predicated on a somewhat simplistic yet revealing set of experiments performed by Vainchenker and colleagues in France.¹² They observed that the inhibition of JAK2 by a small molecule (AG490) or by small interfering RNA (siRNA) reduced EPO-independent colony formation by PV BM mononuclear cells. This observation prompted them to directly sequence JAK2 in the hematopoietic cells of PV patients and

Fig. 68.4 *JAK2V617F* SIGNALING IN MYELOPROLIFERATIVE DISORDERS. (A) Structure of *JAK2V617F*: the mutation is located in pseudokinase JAK JH2 and disrupts the autoinhibition of this regulatory domain. Consequently, the tyrosine kinase corresponding to the JH1 domain is constitutively activated. (B) In the presence of a homodimeric cytokine receptor (e.g., erythropoietin receptor), the two *JAK2V617F* proteins bound to the intracellular domain of the receptor transphosphorylate its tyrosine residues. In turn, STAT5, PI3K, and RAS signaling pathways are activated, leading to the downstream modulation of transcription and protein levels for cell cycle, proliferation, and apoptosis-related factors. *Bcl-X_L*, B-cell lymphoma-extra large; *ERK*, extracellular signal-related kinase; *GATA*, GATA-binding factor; *GRB*, growth factor receptor-bound protein; *JAK*, Janus kinase; *JH2*, JAK homology domain 2; *MEK1*, dual specificity mitogen-activated protein kinase kinase 1; *NF*, nuclear factor; *P*, Phosphate; *PI3K*, phosphatidylinositol 3-kinase; *PIP2* and *PIP3*, phosphatidylinositol bi- and triphosphate; *RAS*, renin-angiotensin system; *SH2*, src homology 2; *SOCS*, suppressor of cytokine signaling; *STAT*, signal transducer and activator of transcription. (From Delhommeau F, Pisani DF, James C, et al: *Oncogenic mechanisms in myeloproliferative disorders*. Cell Mol Life Sci 6363:2939, 2006.)

to discover a single recurrent point mutation. A guanine-to-thymine mutation was observed that resulted in a substitution of valine to phenylalanine at codon 617 within the pseudokinase domain (JH2) of *JAK2* (*JAK2V617F*; Fig. 68.4). These findings were quickly confirmed by several different groups. Kralovics et al¹³ had previously identified a region of LOH on chromosome 9p in PV and identified a 6.2-Mbp region common to all PV patients screened. Because this region contained *JAK2*, with its known role in erythropoiesis, it was screened for mutations and the same *JAK2V617F* mutation identified. Three other groups targeted *JAK2* as part of a global sequencing screen of tyrosine kinases and phosphatases in MPNs. *JAK2V617F* is an acquired somatic mutation present exclusively in hematopoietic cells. All patients with PV have a population of erythroid progenitor cells that are homozygous for the mutation. Using quantitative PCR, patients can be divided into those with a low allele burden of *JAK2V617F* in granulocytes (<50%) and patients with a

higher burden of *JAK2V617F* (>50%). A subset of patients with PV are homozygous for *JAK2V617F*, which is the result of mitotic recombination and duplication of the mutant allele (Fig. 68.5). The occurrence of mitotic recombination has been observed during the clinical course of individual patients, leading to *JAK2V617F* heterozygous patients becoming homozygous over time. The concept of the conversion of *JAK2V617F* low burden to high burden is further supported by the observation that the median duration of disease at the time of evaluation was 48 months in high-burden PV patients compared with 23 months in low-burden PV. These observations are consistent with a multistep pathogenesis of PV. The first step consists of the acquisition of *JAK2V617F*, which results in a low allele burden of *JAK2V617F*, followed by a second step, homologous recombination, that leads to *JAK2V617F* homozygous progenitor cells and eventually granulocytes with a high burden of *JAK2V617F*. It remains unknown at present if a lesion occurring before acquisition

Fig. 68.5 POSSIBLE ROLE OF *JAK2V617F* IN THE BIOLOGY OF MYELOPROLIFERATIVE DISORDERS. The chromosome 9 with the wild-type *JAK2* sequence (G) is depicted in *white*, and the chromosome 9 with the G–T transversion (T) is shown in *red*. Circles symbolize the nuclei of the cells. Deletion of the telomeric part of wild-type chromosome 9p as a potential mechanism for 9pLOH is shown on the *left*. Alternatively, mitotic recombination could also result in 9pLOH, shown on the *right*. The events during mitosis and the resulting cell progeny after mitotic recombination of chromosome 9p are also shown. (Adapted from Kralovics R, Passamonti F, Buser AS, et al: A gain-of-function mutation of *JAK2* in myeloproliferative disorders. *N Engl J Med* 352:1779, 2005.)

of the *JAK2V617F* mutation predisposes an individual to acquire *JAK2V617F*.

The mutational frequency of *JAK2V617F* in PV is greater than 95% of cases. Approximately 50–60% of patients with ET and PMF are also *JAK2V617F* positive. ET is distinguished from PV by being associated with a low allele burden. In the overwhelming majority of cases, PV is characterized by a population of *JAK2V617F* homozygous colonies with some heterozygous and WT colonies. By contrast, in ET, there are few homozygous colonies, with the majority being heterozygous or WT. The majority of ET and PMF patients who are negative for *JAK2V617F* have clonal hematopoiesis, which indicates that these *JAK2V617F* diseases likely are the consequences of other genetic events including mutations in the thrombopoietin receptor, MPL, or calreticulin, which are discussed in [Chapters 69](#) and [70](#). The *JAK2V617F* allele has also been observed in a limited number of patients with chronic myelomonocytic leukemia, myelodysplastic syndromes (MDS), refractory anemia with ringed sideroblasts and thrombocytosis, and AML, although most *JAK2V617F* mutations in AML occur in patients with a preceding diagnosis of PV, ET, or PMF. *JAK2V617F* is an acquired somatic mutation, does not appear in nonhematopoietic cells, and has not been detected in patients with secondary erythrocytosis. Moreover, *JAK2V617F* has not been observed in lymphoid malignancies, although other mutations in *JAK2* have been identified in 10% of patients with pediatric high-risk ALL.

Other *JAK2* Mutations in Polycythemia Vera

Other mutations of *JAK2* associated with erythrocytosis, however, can also constitutively activate *JAK2* kinase activity. Several gain-of-function mutations affecting *JAK2* exon 12 within an area immediately adjacent to the pseudokinase domain of *JAK2V617F*-negative patients have been identified in 2.5–3.4% of PV patients and

approximately 30% of *JAK2V617F*-negative PV cases. To date, >40 different such mutations have been identified. Two-thirds of patients with a *JAK2* exon 12 mutation presented with an isolated erythrocytosis and distinctive BM morphology, and had reduced serum EPO levels, but the remainder of patients have erythrocytosis plus leukocytosis, thrombocytosis, or both. These exon 12 mutations perturb the autoinhibitory domain of *JAK2*. *JAK2* exon 12 mutations have not been reported in patients with ET or PMF, but have been occasionally observed in patients with refractory anemia and ringed sideroblasts associated with thrombocytosis. Erythroid colonies cloned from their blood samples in the absence of exogenous EPO were most frequently heterozygous for the mutation, with homozygous colonies only rarely occurring, but colonies homozygous for the mutation occur in most PV patients with *JAK2V617F*, suggesting that a *JAK2* exon 12 mutation results in a stronger activation of the *JAK2*-mediated intracellular signaling pathways. Patients with exon 12 mutations can develop thrombotic episodes and can evolve into PV-related MF or acute leukemia. In several series, approximately 2.7% of patients with a clinical syndrome that resembles PV have been observed who have a WT *JAK2*. The existence of such patients may be the result of several factors, including limited sensitivity of the assay used for genotyping; prior treatment with interferon (IFN), which might eliminate the *JAK2* mutations; or lack of efforts to exclude inherited genetic disorders associated with erythrocytosis that have been described in this chapter. Alternatively, additional acquired genetic lesions that have yet to be described may be responsible for the disease phenotype.

JAK2V617F Is Likely Not the Disease-Initiating Event in Polycythemia Vera

Despite data generated using a variety of mouse models suggesting that *JAK2V617F* might be sufficient for the development of PV,

increasing evidence shows that PV is not solely initiated by *JAK2V617F*. The fact that *JAK2V617F* has been identified in patients with three phenotypically related but clinically distinct MPNs suggests that additional genetic or epigenetic events likely contribute to the phenotypic divergence of these disorders. These differing disease phenotypes have been hypothesized to be caused by striking differences in the degree to which the mutation activates the JAK-STAT pathway. Mutant *JAK2* activates multiple cytokine receptor-associated pathways, including STAT1 and STAT5, which can have competing consequences. STAT1 appears to be activated in association with *JAK2V617F* ET but not PV. Inhibition of STAT1 in ET progenitor cells enhances erythropoiesis, indicating that in ET, the phospho-STAT1 response to *JAK2V617F* constrains erythropoiesis and promotes megakaryocytic differentiation, but in PV, the reduced pSTAT1 response removes the break on erythropoiesis, allowing enhanced erythropoiesis to occur.

The role of *JAK2V617F* in the underlying pathogenesis of PV has been extensively explored using either restricted fragment length polymorphism analysis or the presence of marker cytogenetic abnormalities in patients with MPNs. The percentage of granulocytes and platelets that are *JAK2V617F* positive is often lower than the percentage of granulocytes belonging to the malignant clone. In addition, these marker cytogenetic abnormalities may occur before or after the acquisition of *JAK2V617F*. Furthermore *JAK2V617F*-negative erythroid colonies have been cloned in vitro in the absence of the addition of EPO, a hallmark of PV, indicating the presence of an undefined molecular lesion that precedes the *JAK2V617* mutation.

Several investigators have reported families in which multiple members have MPNs, including PV, ET, PMF, and CML, and have analyzed the *JAK2V617F* and *CALR* status of family members. The families with multiple members with MPNs have been analyzed for mutational status. In affected patients the *JAK2V617F* mutation was the most commonly acquired followed by *CALR* exon 9 mutations, with no *MPL W515L/K* mutations being detected. Interestingly, in some families, both *JAK2V617F*-positive and -negative members with MPN were observed. A small number of relatives who were *JAK2V617F* negative and did not have a diagnosis of PV, ET, or PMF had hematopoietic cells that formed endogenous erythroid colonies in vitro. Disease evolution can be highly variable within families presenting with the same type of MPN. These results suggest that as yet unidentified genetic event, either germ-line or somatic, might contribute to the pathogenesis of PV, ET, and PMF, regardless of *JAK2* mutational status, and that there may be “initiating events” that precede the acquisition of *JAK2V617F* in these disorders. Acquired mutations of the ten–eleven translocation 2 gene (*TET2*), which are discussed in greater detail in Chapter 70, were studied in these families to determine if it was a gene that played a role in PV before acquisition of *JAK2V617F*. These acquired *TET2* mutations occurred in approximately 12% of patients with sporadic MPNs. The frequency and types of *TET2* mutations in patients with familial MPNs were similar to that observed in sporadic MPNs. As a whole, 20% of the family members with *JAK2V617F* MPNs have *TET2* mutations, and 17% of *JAK2V617F*-negative members had a MPN with a *TET2* mutation. In addition, the *TET2* mutation may occur either before or after the acquisition of *JAK2V617F*. When *JAK2V617F* coexisted with *TET2*, the *TET2* allele burden varied from 20% to 60%. Different *TET2* mutations were observed in affected members of the same family and were shown to be acquired, indicating that *TET2* mutations were not a major predisposing factor to either sporadic or familial MPNs. Familial clustering of MPNs supports the evidence that the pathologic phenotype is driven by yet to be defined susceptibility genes.

Evidence has accumulated from epidemiological and familial studies that indicate that common low-penetrance factors present in the general population contribute to the risk of developing an MPN and possibly to the phenotype of the particular MPN. The germ-line constitutive *JAK2* haplotype, called GGCC or 46/1, has been shown to be a susceptibility factor for the development of *JAK2V617F*-positive PV.¹⁴ The *JAK2* 46/1 haplotype is also weakly associated with exon 12 *JAK2* PV, *MPL W515* MPNs, as well as MPNs that lack

MPL mutations. How this *JAK2* SNP promotes the development of *JAK2V617F* MPNs remains the subject of great speculation, but two hypotheses have been proposed: (1) hypermutability of the chromosome region facilitates the acquisition of somatic mutation; or (2) the *JAK2* SNP confers a selective proliferative advantage, the so-called *fertile ground hypothesis*. Recently, germ-line polymorphisms in the *TERT* gene have also been reported to predispose to *JAK2V617F*-positive and -negative sporadic and familial MPNs. The predisposition was far stronger in familial than sporadic MPNs, suggesting that low-penetrance variants might be responsible for the familial clustering of MPNs. Two additional SNPs involving *TERT* and *HBS1L/ MYB* were shown to have a stronger association with MPN populations with *CALR* or *MPL* mutations that lacked *JAK2V617F*.¹⁵ Reduced expression of *MYB* has been linked to ET-like disease in several animal models. In *JAK2V617F/JAK2V617F*-positive individuals, the reduced *MYB* associated with the *MYB* SNP favored the development of an ET phenotype. In addition, polymorphisms of the glucocorticoid receptor have been associated with PV and PMF but not ET.

In the MPNs, acquisition of mutations in either *TET2* or *JAK2* may occur first, but those patients that acquire *JAK2V617F* first are more likely to develop PV. The concept that the MPN phenotype is the consequence of the order of mutational acquisition was first proposed by Ortmann and coworkers.¹⁶ *JAK2* and *TET2* mutations each occurred first in 50% of patients. *JAK2V617F* homozygosity was not required for acquisition of a *TET2* mutation to occur. *JAK2* first patients were more likely to present with PV, were younger, more sensitive to ruxolitinib treatment, and were more likely to suffer from a thrombotic event than those individuals who acquired a *TET2* mutation initially. These data indicate that the order of acquisition of mutations might influence the clinical phenotype of the resultant MPN. *TET2* mutations have been shown to result in expansion of the malignant clone in elderly persons with normal blood counts, and in murine studies, a double-mutant *TET2-JAK2* clone was out competed by its *TET2* single-mutant ancestor. In mice, expression of *JAK2 V617F* but not *TET2* resulted in increased erythropoiesis. A *TET2*-inactivating mutation but not *JAK2V617F* leads to hematopoietic stem cell expansion. The report by Ortmann and coworkers suggests that in patients who acquire *TET2* first, *TET2* single-mutant hematopoietic stem and progenitor cells expand but do not give rise to excess differentiated megakaryocytic and erythroid cells until a *JAK2* mutation is acquired. By contrast, in patients who acquire *JAK2* first, *JAK2* single-mutant hematopoietic stem and progenitor cells generate increased numbers of megakaryocytic and erythroid cells, and stem cell numbers only expand after acquisition of a *TET2* mutation. This model is consistent with the earlier clinical presentation of patients who first acquire a *JAK2* mutation since they more rapidly generate excess megakaryocytic and erythroid cells. The initial *TET2* mutation may modify the epigenetic program of HSCs and progenitor cells, and thus alter the consequences of the second mutation. A prior mutation of *TET2* alters the transcriptional consequences of *JAK2 V617F* in a cell-intrinsic manner and prevents *JAK2 V617F* from upregulating stem and progenitor cell proliferation.

The *JAK2V617F* Mutation Is Present in Hematopoietic Stem Cells in Polycythemia Vera

Previous studies had demonstrated that the majority of patients with PV had clonal involvement of multiple lineages, including myeloid, erythroid, and lymphoid cells. These results suggested that PV originates in hematopoietic progenitors with the ability to differentiate into multiple lineages. In addition, LOH at 9p24, known to correspond to homozygous *JAK2V617F* mutations, can be identified in both myeloid and lymphoid cells in some patients with PV, further suggesting that the underlying mutations occur in progenitor cells with the ability to differentiate into multiple hematopoietic lineages.

The *JAK2V617F* mutation has been detected in hematopoietic colony-forming cells and more mature progeny, such as neutrophils

and platelets. Populations of cells enriched for HSCs, common myeloid progenitors (CMPs), granulocyte–macrophage progenitors (GMPs), and megakaryocytic–erythroid progenitors (MEPs) from patients with PV have been analyzed for the presence of the *JAK2V617F* mutation. *JAK2V617F* was detected in HSCs, CMPs, GMPs, and MEPs from patients with PV, supporting that PV is a disorder that arises in HSCs and involves the myeloid, erythroid, and megakaryocytic lineages. These data indicate that *JAK2V617F* in PV originates in lymphomyeloid progenitor cells.¹⁷ Analyses of hematopoietic cells from PV patients has suggested that *JAK2V617F* amplifies the terminal stages of hematopoiesis but not the more primitive hematopoietic stem/progenitor cells. In mouse models, however, *JAK2V617F* has been shown to lead to the amplification of both stem and progenitor cells, providing them with a competitive advantage compared with their normal counterpart through increased cell cycling and a reduced rate of apoptosis resulting in the emergence of the MPN phenotype. *JAK2V617F* may give only a subtle advantage, which will require several years for mutated stem and progenitor cells to predominate in humans over their normal counterparts. In man, other mutations such as *ASXL1*, *DNMT3a*, and *TET2* may further alter the biology of the *JAK2V617F*-mutated clone in a manner that affects phenotype as well as disease evolution.

Structural and Functional Aspects of *JAK2V617F*-Mediated Transformation

The *JAK2V617F* mutation occurs within the JH2 domain of JAK2, which has significant homology to the kinase domain of JAK2 (JH1) but lacks catalytic activity (see Fig. 68.4). The JH2 domain exerts an inhibitory effect on JAK2 kinase activity, and the *V617F* mutation is predicted to disrupt this inhibition. In vitro kinase assays with *JAK2V617F* and WT *JAK2* have revealed that *JAK2V617F* has greatly increased kinase activity, as assessed by autophosphorylation and by substrate phosphorylation. Ectopic expression of *JAK2V617F* in either epithelial or hemopoietic cell lines results in autophosphorylation of mutant *JAK2*, but not the WT *JAK2*, and activation of downstream signaling events. BAF3 or FDCP cell lines expressing the EPOR and engineered to stably express *JAK2V617F* are largely independent of the addition of exogenous growth factors and are hypersensitive to EPO. Coexpression of *JAK2V617F* and a homodimeric type 1 cytokine receptor (EPOR, TPOR, or G-CSFR) facilitates the transformation of cells to growth factor independence, suggesting that the mutant *JAK2* requires a receptor scaffold to be active. This contrasts with the effects of the *TEL-JAK2* fusion gene, which can readily transform cells on its own, presumably because of the strong homodimerization effects of the *TEL* moiety. Ectopic expression of *JAK2V617F* can also sensitize cells to the effects of IGF1, a characteristic feature of PV progenitors.

Expression of *JAK2V617F* in hematopoietic cells activates intracellular signaling pathways downstream of the EPOR, including STAT5, STAT3, the MAP kinase pathway, and the PI3K–Akt pathway. STAT5 is normally phosphorylated by the cytokine receptor–JAK2 complex, and phosphorylated STAT5 then translocates to the nucleus and activates the transcription of target genes. The target genes of STAT5 include Bcl- X_L , an important antiapoptotic protein known to be expressed in increased levels in PV proerythroblasts. The possibility that STAT5-mediated activation of Bcl- X_L is important in the pathogenesis of PV was suggested by observations that expression of either constitutively active STAT-5 or Bcl- X_L resulted in spontaneous erythroid colony formation. Furthermore, the degree of apoptosis can also be altered by p53 levels. *JAK2V617F* appears to functionally inactivate p53 by upregulating MDM2, an E3 ubiquitin ligase, thereby decreasing the degree of apoptosis. In addition, cells expressing *JAK2V617F* display constitutive activation of the MAP kinase pathway (as assessed by phosphorylation of ERK), and of the PI3K pathway (as assessed by phosphorylation of AKT). Furthermore, JAK2 has been shown to play a role in cellular MPL trafficking. Decreased expression of MPL on the cell surface of platelets and Mks is an established feature of PV and MF. Lower expression of MPL

on the cell surface of platelets and Mks in MPNs has been reported to be due to both a reduction in the recycling and maturation of the receptor as well as an increase in MPL proteasomal degradation mediated by *JAK2V617F* protein. Furthermore, *JAK2V617F* and activated STAT5 have been shown to increase the expression of 6-phosphofructokinase/fructose-2,6-bisphosphatase 3 (PFKFB3), which controls glycolytic flux through 6-phosphofructo-1-kinase. PFKFB3 is required for *JAK2V617F*-dependent lactate production, oxidative metabolic activity, and glucose activity, thereby promoting cell proliferation. It is important to note that many other oncogenic tyrosine kinases activate the same signal transduction pathways, and the role and requirement for each of these signaling pathways in the transformation of hematopoietic cells by *JAK2V617F* remain unknown. Although once thought to reside strictly in the cytoplasm of cells, a growing body of evidence indicates that both JAK1 and JAK2 are present in the nucleus of certain cells under conditions associated with high rates of cell proliferation. Nuclear JAKs have been reported to affect gene expression by activating other transcription factors besides STATs and influencing epigenetic events by phosphorylating H3 and activating global gene expression. *JAK2V617F* may alter chromatin structure by selectively phosphorylating the arginine methyltransferase PRMT5, impairing PRMT5 methyltransferase activity by negatively affecting its association with methylome protein 50. Reduced PRMT5 activity increases HPC proliferation and promotes erythroid differentiation.

Many PV patients have a low burden of *JAK2V617F*, as assessed by DNA sequencing, suggesting that there is either a subpopulation of cells that are homozygous for *JAK2V617F* mixed with WT cells or a clonal population of cells with one WT copy of *JAK2* and one mutant copy of *JAK2*. In PV, data from clonality or quantitative *JAK2V617F* assessment and from colony assays suggest that most PV patients have a subpopulation of cells homozygous for *JAK2V617F*, but in ET, clonal progenitor cells are heterozygous for *JAK2V617F*. It is therefore important to determine whether the WT allele can interfere with the ability of *JAK2V617F* to constitutively signal in the heterozygous state and whether there is an effect of gene dosage on the activation of signal transduction pathways. Transient coexpression of WT JAK2 does not interfere with the ability of *JAK2V617F* to autophosphorylate even when WT JAK2 is expressed at higher levels than the mutant kinase. This suggests that *JAK2V617F* kinase activity is unaffected by coexpression of WT JAK2. In contrast, when *JAK2V617F* and WT *JAK2* were coexpressed in Ba/F3 cells, cytokine-independent growth was attenuated, suggesting in this cellular context that WT JAK2 is able to interfere with *JAK2V617F*-mediated transformation. SOCS proteins bind to the JH1 catalytic loop and target JAK2 for degradation.¹⁸ SOCS-1 and SOCS-3 bind to the catalytic groove belonging to JAK2 and inhibit its catalytic activity. SOCS-3 binds to EPOR and JAK2 to inhibit EPOR signaling. SOCS proteins inhibit JAK2 by functioning as E3 ubiquitin ligases. Although SOCS-1, SOCS-2, and SOCS-3 inhibit phosphorylation of WT JAK2, they are incapable of blocking phosphorylation of *JAK2V617F*. On the basis of their findings, SOCS-3 appears to be unable to inactivate *JAK2V617F*, and SOCS-3 itself is not degraded but accumulates and actually promotes the further phosphorylation of *JAK2V617F*. Such dysregulation likely enhances *JAK2V617F*-induced cell proliferation and prolongs signaling. These data have been suggested as an explanation for why *JAK2V617F* hematopoiesis predominates in PV heterozygotes. Low levels of *JAK2V617F* signaling in *JAK2V617F* heterozygotes likely induce SOCS-3, which would downregulate JAK2 WT signaling and enhance signaling by *JAK2V617F*, permitting the malignant clone to predominate.

Additional Mutations Associated With Polycythemia Vera

After the application of whole-genome assays (comparative genomic hybridization and SNPs) as well as whole-genome sequencing, an increasing number of mutations have been observed in patients with Philadelphia chromosome-negative MPNs. These mutations are not

unique to any of the MPNs and are associated with AML and MDS.¹⁹ Four of these genes—*EZH2*, *ASXL*, *DNMT3a*, and *TET2*—participate in the epigenetic control of transcription and are discussed in greater detail in Chapter 70. *EZH2* mutations occur in 3% of PV patients, 7–16% of PV patients have *TET2* mutations, and 5–7% have mutations of *DNMT3a*; *ASXL* mutations are rare in PV (<7%). Each of these mutations may precede *JAK2V617F*, but the converse may also occur. Each of these mutations are far less frequent in PV and ET than PMF, supporting that these events may combine to generate a more accelerated phase of the classic MPN that phenotypically presents as MF. In addition to epigenetic regulators, mutations in genes that encode proteins that participate in the process of splicing immature mRNA have also been described in MPNs, specifically SF3B1, SRSF2, and U2AF1. *SF3B1* mutations are mostly found in PMF where they cluster within exons 12–16. Alterations in SRSF2 are mostly found in PMF and MPN evolved to AML. *U2AF1* mutations are detected in up to 15% of PMF cases, but are not present in ET or PV patients. *IDH1/2*, *IKZF* deletions, *NRAS/KRAS*, *p53* mutations, and *RUNX1* mutations rarely occur in PV but are all associated with transformation of an underlying MPN such as PV to acute leukemia.¹⁸

The Hypercoagulable State That Characterizes Polycythemia Vera

Thrombosis is a major cause of morbidity and mortality in PV patients. These thrombotic events are most frequently microcirculatory and arterial, but venous thromboses are also of important clinical significance. The increased risk for thrombosis can be attributed to abnormalities in the vessel wall, blood cell components, and the dynamics of blood flow. A number of risk factors for thrombosis have been investigated, but most of them are not firmly established.

In the European Collaboration on Low-Dose Aspirin in Polycythemia Vera (ECLAP) study, the incidence of cardiovascular complications was higher in patients older than 65 years (5.0% of patients per year; hazard ratio [HR]: 2.0; 95% confidence interval [CI]: 1.22–3.29; $p < .006$) or with a history of thrombosis (4.93% of patients per year; HR: 1.96; 95% CI: 1.29–2.97; $p = .0017$). Patients both with a history of thrombosis and older than 65 years had the highest risk of developing additional cardiovascular events (10.9% of patients per year; HR: 4.35; 95% CI: 2.95–6.41; $p < .0001$).²⁰ These data confirm previous findings that increasing age and history of thrombosis are the two most important prognostic factors for the development of vascular complications.

This information does not negate the increased incidence of thrombotic incidents also observed in younger patients with this disorder. In a series of 58 PV patients younger than 40 years of age, a disturbingly high incidence of life-threatening thrombotic events was observed. In fact, seven of the 10 patients in this series who died during the period of observation died from thrombotic events—four from Budd-Chiari syndrome (BCS), one from a pulmonary embolism, and two from cerebral thrombosis. Therefore, although a significant factor, preexisting atherosclerotic disease is not the sole etiologic factor in the genesis of thrombosis in PV. Analysis of the ECLAP study identified smoking in addition to older age as an important risk factor for major thrombosis. A retrospective study of 450 patients with PV demonstrated that hypertension and tobacco use were associated with arterial thrombosis ($p < .02$) and diabetes mellitus was associated with venous thrombosis ($p = .002$).

The principal hemorrheologic abnormality in PV is an elevated whole blood viscosity. The blood viscosity in PV is higher than that of normal control participants at all shear rates. In a retrospective analysis of PV patients with histories of vascular thrombosis, a strong correlation in univariate analysis between hematocrit level and the development of thrombotic episodes, including many cerebrovascular occlusions, was demonstrated. Cerebral blood flow is reduced in patients with PV in whom the hematocrit level is 53–62%. These abnormalities were observed even in patients with hematocrits at the lower levels of normal, that is, 46–52%. Reductions in cerebral blood

flow are correctable with phlebotomy. Reduction of the hematocrit by relatively small amounts frequently led to substantial improvements in whole blood viscosity and cerebral blood flow. Some PV patients apparently still maintain a higher than normal whole blood viscosity despite the normalization of the hematocrit, suggesting that an increase in hematocrit may not be the only factor responsible for increased blood viscosity. There appear to be important gender differences as related to the location of thromboses in PV patients. Women appear to have a higher incidence of thromboses within the abdominal cavity involving the portal, mesenteric, or hepatic vessels but a comparable rate of other vascular complications. Several groups have reported that patients with splanchnic vein thromboses frequently have endothelial cells that are affected by *JAK2V617F*, suggesting that in such individuals, their MPN might originate not at the level of the HSC but rather at the level of a hemangioblast, from which myeloid and endothelial cells originate. Such *JAK2V617F*-positive endothelial cells have been shown to exhibit a high efficiency of adhering to normal mononuclear cells, thereby likely leading to an increased risk of thrombosis.

A number of possible explanations have been suggested for the observed relationship between hematocrit level and the development of thrombotic events in PV patients. Platelet adhesion and thrombus formation on the vascular subendothelium are determined in part by the rate at which platelets are transported to the vascular surface. In a polycythemic condition in which increased numbers of RBCs are present, a greater number of intercellular collisions between RBCs and platelets occurs. These collisions could lead to increased platelet movement in a direction perpendicular to blood flow. This facilitation of platelet transport to the vessel wall may be an important factor in the development of thrombosis. An alternative explanation for the association between hematocrit level and the risk of thrombosis is based on the knowledge that blood viscosity is particularly sensitive to hematocrit levels. Increased hematocrits lead to increased blood viscosity, in turn leading to increased peripheral vascular resistance and an actual reduction in blood flow to a variety of organs, predisposing them to the development of thrombosis. The issue of hematocrits and thrombosis in PV has been prospectively investigated in an analysis of 1638 patients enrolled in the ECLAP study. In this prospective study, despite recommendations of maintaining hematocrit levels lower than 45%, only 50% of patients achieved this target during the follow-up, and 10% had hematocrit levels above 50%. These different hematocrit values were not associated with different thrombotic outcomes as assessed using univariate and multivariable analysis. However, in a recent prospective randomized clinical trial of 365 patients with PV, it was shown that patients with hematocrit maintained at less than 45% had a lower incidence of cardiovascular events compared with patients whose hematocrits were maintained at 45–50% (4.4% vs. 10.9%; $p = .02$). The group with lower hematocrit also had lower death rates from cardiovascular events or major thrombosis.²¹ This study confirmed the need for strict hematocrit control in PV patients.

Additional factors have been implicated in the development of thrombosis in PV patients. Almost all patients with PV are iron deficient. Decreased RBC deformability has been said to accompany iron deficiency, leading to increased blood viscosity and a decreased ability of RBCs to pass through small-bore polycarbonate filters. This increased membrane stiffness, however, might be counterbalanced by the effect of a reduced RBC size on the adherence of blood platelets to arteriolar subendothelium. RBC size is a major determinant of platelet adherence, with larger RBCs leading to increased platelet adherence and smaller RBCs to decreased platelet adherence. Whether the increased membrane stiffness associated with iron deficiency is counterbalanced by the decreased platelet adherence associated with smaller RBCs is yet to be determined.

Inflammation may be another predictor of thrombosis in patients with PV. In a retrospective study patients with increased inflammation as evidenced by an increased C-reactive protein (CRP) had significantly greater risk for thrombosis based on a multivariate analysis that adjusted for age, sex, ET, or PV diagnosis, cardiovascular risk factors, and *JAK2V617F* mutation status.

Thrombocytosis and qualitative platelet abnormalities occur frequently and are likely to be important contributory factors to the development of thrombosis. Some investigators have implicated uncontrolled thrombocytosis as a cause of thrombosis in these patients, but this relationship has not been confirmed by others. Increased plasma and urinary thromboxane production has been linked to increased platelet activation in these patients. A low-dose aspirin regimen selective for inhibition of platelet cyclooxygenase has been found to suppress increased thromboxane production in vivo and to clinically benefit patients with PV. Furthermore, elevated levels of serum VEGF and plasma TPO have been observed in patients with PV. These growth factors have been shown to lead to platelet activation.

Despite conflicting data, no clear clinical relationship between platelet number or function and the incidence of hemorrhage or thrombosis in PV patients has been delineated. An argument in favor of a role of elevated platelet numbers in the genesis of thrombosis in PV and ET is the observation in patients with ET that a reduction of excessive platelet numbers with the use of hydroxyurea is associated with a reduction in the risk of developing thrombotic events. However, this should not be taken as evidence that the reduction in developing additional vascular events was caused by platelet count normalization alone; very likely, it may be related to the suppression by hydroxyurea of each of three myeloid lineages. In line with this interpretation are the results of a randomized study performed by the Medical Research Council in the United Kingdom (PT-01) in which patients with ET were randomized to receive either hydroxyurea or anagrelide therapy. This study showed that hydroxyurea therapy rather than anagrelide, a selective platelet number-reducing drug, was associated with a reduction in the number of arterial thrombotic events, especially in *JAK2V617F* patients. In this study the rate of thrombosis in PV patients during follow-up did not vary according to different platelet numbers. Select patients with PV have, however, been afforded prompt resolution of vascular complications such as erythromelalgia or TIAs after institution of platelet antiaggregating agents or cytoreduction. It is important to emphasize that erythromelalgia does not resolve in PV patients with phlebotomy alone or with anticoagulation, but requires the use of platelet antiaggregating agents or reduction of platelet numbers. What distinguishes the clinical courses of these patients from those of others is unknown. These reports, coupled with the knowledge of abnormal thromboxane metabolism of platelets in PV, provide substance to the belief that platelets contribute to the generation of the thrombotic and hemorrhagic tendencies observed in PV. Although a number of clinical assessments of platelet function have been used to identify patients who are potentially at a high risk of developing a life-threatening hemorrhagic or thrombotic event, the results of these studies to date have been very disappointing. It appears that the etiology of thrombosis and hemorrhage in PV is multifactorial, and that the available tools are inadequate to identify patients at highest risk.

An elevation of WBC number occurs in 50–60% of PV patients, which may also have a detrimental effect on the rheology of the microcirculation in PV. An analysis of the ECLAP database showed that a baseline WBC count above $15,000 \times 10^6 \text{ L}^{-1}$ was associated with the development of major arterial events, mainly myocardial infarction. A retrospective study of 459 patients with PV showed a significant association between baseline leukocyte count $>15 \times 10^9/\text{L}$ and venous thrombotic events during a median follow up of 64 months. Similar results were shown in two additional studies in patients with ET. Activated leukocytes may release proteases and oxygen radicals that alter endothelial cells and platelets so as to favor the development of a prothrombotic state. A series of markers of leukocyte activation, including expression of membrane CD11b and leukocyte alkaline phosphatase antigen, cellular elastase content, plasma elastase levels, and myeloperoxidase levels, are elevated in patients with PV. Limited and conflicting data are available as to whether or not there is a correlation between the presence of platelet–leukocyte interactions and thrombotic events. Increased expression of leukocyte adhesion molecules increases the adhesion of leukocytes to platelets and the endothelium. These cell-to-cell interactions

stimulate the activation of endothelial cells and platelets, and induce the release from activated leukocytes reactive oxygen species as well as proteases that are capable of impairing a number of hemostatic processes. Platelet–leukocyte aggregates are increased in number in PV and are associated with an increased propensity to thrombose. In addition, the prothrombotic state in PV has been attributed to an acquired resistance to the naturally occurring anticoagulant, protein C, which is associated with reduced levels of protein S. The loss of protein S in PV patients is especially profound in those with a high *JAK2V617F* allele burden, but its cause remains unknown, although some have speculated that it is the consequence of the degradation of protein S by the increased levels of neutrophil elastase.

JAK2V617F allele burden has also been implicated as a potential risk factor for thrombosis. In a prospective study of 173 patients with PV that were followed for a median of 24 months, patients with a *JAK2V617F* allele burden of $>75\%$ had a sevenfold increased risk of thrombosis compared with patients with an allele burden of $<25\%$. However, another prospective study comparing patients with an allele burden of $<50\%$ versus $>50\%$ did not confirm the association between *JAK2V617F* allele burden and thrombotic risk. In a retrospective study of 186 patients with MPN, individuals harboring the *JAK2V617F* mutation were at highest risk for VTE. *JAK2* allele burdens higher than 20% identified patients with a sevenfold increased risk of VTE but not arterial thrombosis. More studies are needed to clearly establish higher *JAK2V617F* allele burden as a risk factor for thrombosis.

Clearly, the thrombotic tendencies in PV are multifactorial and in the future it is likely that the thrombotic risk will be assessed on an individual basis, taking into account many of the factors mentioned previously.

Polycythemia Vera and the Risk of Hemorrhage

Patients with PV are also at an increased risk of developing life-threatening hemorrhagic complications. Abnormalities in platelet function and number have been implicated as the cause of this hemorrhagic tendency. Qualitative platelet abnormalities frequently found in these patients include platelet hypofunction, as demonstrated by defective in vitro platelet aggregation, acquired storage pool disease, and platelet membrane defects, and increased platelet reactivity, as demonstrated by enhanced platelet aggregation, increased plasma β -thromboglobulin levels, and shortened platelet survival. With platelet counts greater than $1000 \times 10^9 \text{ L}^{-1}$, the development of acquired von Willebrand syndrome has been reported and is associated with life-threatening hemorrhagic episodes.

Post-Polycythemia Vera Myelofibrosis and Acute Myeloid Leukemia

A major cause of morbidity and mortality in PV results from the transition from the polycythemic phase of the disease to post-PV MF and to acute leukemia. Post-PV MF is characterized by cytopenias, MF, and extramedullary hematopoiesis. In a variety of MPNs, the fibroblastic component of the BM has been shown not to be directly involved in the malignant process but to be a reactive event to the neoplastic clone. Several investigators have suggested that the release of growth factors, particularly VEGF, fibroblast growth factor, transforming growth factor- β , lipocalin, and tumor necrosis factor- α from myeloid cells are responsible for the marrow fibroblastic proliferation, increased marrow microvessel density, osteosclerosis, as well as the systemic symptoms observed in patients with PV-related MF. Whether the use of any particular therapeutic agents for treatment of PV accelerates the development of PV related MF remains hotly debated, although it is well established that the use of alkylating agents such as piprobroman or chlorambucil increases the risk of developing acute leukemia. It remains a source of debate if treatment with hydroxyurea increases the risk of developing MF or AML. The bulk of evidence does not support a clear leukemogenic role for this drug that is the

standard of care for high-risk PV patients. Nevertheless, as a cautionary principle, it is wise to consider carefully the use of this agent in very young patients, in those carrying cytogenetic abnormalities, and in patients previously exposed to alkylating agents. In a report in which patients were treated exclusively with hydroxyurea with an average follow-up of 16.3 years, the cumulative incidence of AML/MDS was 7.3%, 10.7%, and 16.6% at 10, 15, and 20 years, respectively, and was significantly lower than in patients treated with the alkylating agent piprobroman.²² However, patients treated with hydroxyurea had a greater chance of developing MF (at 20 years, 31.6% vs. 21.3%). Whether hydroxyurea really is leukemogenic is difficult to say from this study. The possibility exists that these rates of evolution reported with hydroxyurea use merely reflect the natural history of the disease.

Genetic studies of paired samples before and after leukemic transformation have suggested there are at least two distinct routes for leukemic transformation that are operational. Some patients who present with a *JAK2V617F/MPL* mutation-positive MPN progress to *JAK2V617F/MPL* mutation-positive AML that is associated with the acquisition of additional genetic alterations. A second, more complex, route to AML from MPN has been described in which a *JAK2V617F/MPL* mutation-positive MPN is followed by *JAK2V617F/MPL* mutation-negative AML. Clonality studies using X-chromosome inactivation in informative females demonstrated that *JAK2V617F/MPL* mutation-positive MPN and *JAK2V617F/MPL* mutation-negative AML are clonally related, consistent with transformation of an antecedent, pre-*JAK2V617F/MPL* mutation mutant clone that can progress to AML. Patients with *JAK2V617F*-positive MPN who developed *JAK2V617F*-negative leukemias had a shorter time between the diagnosis of the original MPN and the leukemic transformation (3 + 2 vs. 10 + 7 years, respectively) than patients with *JAK2V617F*-positive leukemias. SNP array analysis has shown that genomic alterations occur at an increased frequency during the period of blastic transformation and that no single gene or molecular pathway is sufficient to cause transformation. A surprising correlation has been observed between the phenotype of the preceding MPN and the *JAK2* mutational status of the leukemic blasts after transformation. In contrast to *JAK2* WT AML in this setting, evolution to *JAK2V617F*-positive leukemia is invariably preceded by a myelofibrotic transformation of ET/PV or *JAK2V617F*-positive PMF. Because of these observations, myelofibrotic transformation of ET or PV is thought by many to represent an accelerated phase of the initial MPN preceded by genetic changes that result in evolution to MF and eventually leukemia. *JAK2* WT leukemia, by contrast, usually arises in patients with chronic-phase PV or ET that do not undergo evolution to MF. Some have suggested that these leukemias are therapy related. The reversion from *JAK2V617F* to WT *JAK2* in these leukemias has been shown not to be caused by homologous recombination. Two models have been proposed to account for the clonal relationship between *JAK2* WT AML and its preceding MPN: (1) both the chronic MPN and the AML arise from a shared pre-*JAK2V617F* founder clone; and (2) the chronic MPN and the AML arise from two independent stem cells. It remains possible that each model is viable and operates in different individual patients. Mutations in *CALR*, *JAK2*, *TP53*, *IDH2*, and *ASXL1* are frequent events in AML, which evolves from a prior MPN, while mutations in *NPM1*, cohesin complex members, *FLT3*, and *CEBPA*, which are common events in de novo AML, are rarely, if ever, observed in post-MPN AML. These data provide genetic evidence that post-MPN AML is a distinct disease from classical AML with a unique mutational profile and molecular pathogenesis and that lack of response to AML chemotherapy regimens reflects the divergent biology of post-MPN AML. Important differences in the mutational spectrum of *JAK2V617F* and *JAK2*-WT in post-MPN AML have been observed. *TP53* mutations are frequent, cooccurring events in patients with *JAK2V617F* mutations but not in patients with *CALR* mutations. In patients with cooccurring *JAK2V617F* and *TP53* mutations, the *JAK2/TP53* mutant clone dominates, consistent with potent cooperativity in vivo and with a dominant role in inducing transformation from the chronic *JAK2V617F*-positive MPN to AML. By contrast, mutations

in members of the RAS pathway, *SRSF2*, and in *ASXL1* were more common in *JAK2* WT post-MPN AML, and these mutations often were present as subclonal disease alleles at the time of transformation, suggesting they are not rate limiting in the transformation from MPN to AML.

CLINICAL MANIFESTATIONS

The principal clinical manifestations of PV can largely be attributed to the excessive production of cells belonging to each of the myeloid lineages affected by the malignant process, including RBCs, platelets, and WBCs. With the implementation of laboratory tests during annual physical examinations, increasing numbers of people are being diagnosed with PV before the symptoms related to this neoplastic process become apparent. Symptomatic patients with PV may present to a physician with a myriad of nonspecific complaints, including headaches, weakness, pruritus, dizziness, excessive sweating, visual disturbances, paresthesias, joint symptoms, abdominal distress, a thrombotic or hemorrhagic episode, and weight loss. Thrombosis is a frequent presenting event. Two-thirds of such thrombotic events occur either at presentation or before diagnosis and the remainder most often during the first 10 years of follow-up. At diagnosis, one-third of patients have already lost 10% of their body weight, presumably secondary to the hypermetabolism associated with this disorder, and complaints of fatigue are common. Arthropathies are frequently observed and are largely caused by the clinical manifestations of gout. The hyperproliferative BM state characteristic of PV and the increased nucleoprotein degradation are contributory factors in the development of hyperuricemia.

The principal findings on physical examination of a patient with PV include ruddy cyanosis, conjunctival plethora, hepatomegaly, splenomegaly, and hypertension.

Untreated patients are at particularly high risk for thrombotic and hemorrhagic events. In several large series of patients with PV, thrombosis was the cause of death in 30–40% of patients. Arterial thrombotic events account for two-thirds of such events, with venous thrombotic events representing the remainder. Ischemic stroke, myocardial infarction, and TIAs are the most common arterial thrombotic events. Patients may also present with deep venous thrombosis in the lower extremities, pulmonary embolism, or peripheral vascular occlusions. The cumulative rate of thrombosis ranges from 2.5% to 5% per patient per year. The prevalence of thrombosis at diagnosis ranges from 34% to 39%. It is not unusual for patients with PV to develop thromboses at unusual anatomic sites; in particular, thromboses are relatively frequent in the splanchnic veins, including the splenic, hepatic, portal, and mesenteric vessels or cerebral sinus veins, thrombosis of the vena cava, and intraventricular thrombosis. A particularly serious thrombotic event associated with PV is BCS, which results from hepatic venous or inferior vena caval thrombosis and obstruction. These events lead to hepatic venous outflow obstruction, increased hepatic sinusoidal pressure, and portal hypertension. Portal venous perfusion of the liver is frequently reduced, leading to portal venous thrombosis and hypoxic damage of liver parenchymal cells. This cascade of events results in centrilobular hepatic necrosis, centrilobular fibrosis, and nodular regenerative fibrosis, which culminates in the development of cirrhosis of the liver. The cause of BCS can be identified in 75% of cases, including hereditary and acquired prothrombotic disorders, trauma, and infection. PV account for 10–40% of all cases of BCS. Paroxysmal nocturnal hemoglobinuria is also a frequent cause of BCS. Because BM cells from 87% of patients with idiopathic BCS form erythroid colonies in the absence of EPO, such patients were in the past believed to have a forme fruste of an MPN. The identification of these latent MPNs, without elevated blood counts, has been facilitated by screening for *JAK2V617F*. These patients tend to be younger and female, and to have normal blood counts caused by hemodilution and hypersplenism, which mask an elevated RBC mass. Many of these patients (37%) also have another predisposing factor for thrombosis such as exposure to oral contraceptives, antiphospholipid antibodies,

factor V Leiden, or protein C deficiency. The *JAK2V617F* mutation has been reported in 32.7% patients of 831 patients with an idiopathic splanchnic vein thrombosis. The mutation was present in 49% of patients at diagnosis of the idiopathic form of splanchnic vein thrombosis, of which 60% were diagnosed as having a coexisting MPN; more than 52% of the remaining patients went on to develop an MPN after a median of 49 months. *JAK2V617F* was detected in 45% of patients with BCS, and at least in one series, neither exon 12 *JAK2* mutations nor *MPL* mutations were observed. Furthermore, additional patients (6.9%) who have idiopathic splanchnic vein thrombosis have a BM histopathologic picture diagnostic of an MPN but are *JAK2V617F* negative. The diagnostic value of low serum EPO level in BCS has been questioned because elevated levels have been attributed in *JAK2V617F*-positive patients with necrotic liver tissue.

There are fulminant, acute, subacute, and chronic forms of BCS. These clinical manifestations depend on the extent and rapidity of hepatic vein occlusion and the development of venous collaterals to decompress the venous sinusoids. One should always consider a diagnosis of BCS in any patient with an MPN with ascites, upper abdominal pain, and liver function abnormalities. This syndrome is characterized by hepatosplenomegaly, ascites, edema of the peripheral extremities, and distention of superficial abdominal veins caused by resultant portal hypertension. Routine biochemical determinations of hepatocellular function and injury are frequently of little diagnostic value in patients with suspected BCS. Doppler ultrasonography is the best tool for screening patients for BCS. This test has a sensitivity and specificity of 85%. Characteristic findings include an absence of flow in the hepatic veins or nonvisualization of the hepatic vein. Contrast-enhanced computed tomography scanning and magnetic resonance imaging (MRI) are useful in better defining the hepatic venous anatomy. Hepatic venous and inferior vena caval catheterization is a key diagnostic procedure indicating the sites of venous obstruction. The diagnosis can be definitively made by a spider web pattern on hepatic venography. Transjugular liver biopsy specimens usually reveal intense congestion and cellular atrophy.

It has been emphasized that patients with PV can present with portal or hepatic vein thrombosis with normal hemoglobin or hematocrit values. Such patients may have leukocytosis, thrombocytosis, or splenomegaly. Screening for the *JAK2* mutation should be systematically carried out in such situations and may substitute for BM examinations in individuals who are *JAK2V617F* positive. In patients with an idiopathic form of splanchnic vein thrombosis but who are *JAK2V617F* negative, a BM aspirate and biopsy are recommended to exclude the possibility of a *JAK2V617F*-negative MPN. Gastrointestinal bleeding or an increase in plasma volume that is a consequence of splenomegaly often accounts for the normal blood counts in such patients with BCS. The factors operational in the PV patient that lead to the development of hepatic vein thrombosis are believed to be multiple. Whereas splenomegaly causes increased portal blood flow, extramedullary hematopoiesis within the hepatic sinusoids frequently obstructs hepatic blood flow, and *JAK2V617F*-positive endothelial cells might affect adhesion to monocytes, leading to aggregation of blood elements. These processes are surely important contributory factors in addition to the other previously discussed risk factors that lead to the development of thrombosis in this patient population.

Neurologic abnormalities occur in almost 60–80% of untreated or poorly controlled PV patients and include TIAs, cerebral infarction, cerebral hemorrhage, fluctuating dementia, confusional states, and choreic syndromes. PV associated chorea has been reported as a presenting complaint, primarily in older females, which typically involves the orolingual or appendicular musculature and often resolves with phlebotomy or cytoreductive therapy. In addition, complaints of dizziness, paresthesias, visual disturbances, tinnitus, and headaches have been attributed to the increased blood viscosity and reduced cerebral blood flow caused by erythrocytosis. The transient neurologic symptoms can also be the consequence of small infarcts in the region of the basal ganglia, which can be detected by computed tomography. These small infarcts are known as *lacunae* and result from the occlusion of small penetrating arteries, which are

particularly susceptible to thrombosis. Cerebrovascular thrombosis occurs more often in PV patients than in the general population. Symptoms caused by intermittent carotid or vertebral basilar artery insufficiency (or both) occur so frequently in PV that it is suggested that every patient with focal cerebrovascular insufficiency should at least have a complete blood count test to exclude the diagnosis of an underlying MPN.

Thrombosis of the dural sinus or cerebral veins (CVT) is an uncommon form of stroke, usually affecting young individuals. CVT represents about 0.5–1% of all strokes. While 3.8% of CVT patients are diagnosed with MPNs, 0.4% of MPN patients have a CVT during their clinical course. Headache, generally indicative of an increase in intracranial pressure, is the most common symptom in CVT. Clinical manifestations of CVT may also depend on the location of the thrombosis. The superior sagittal sinus is most commonly involved, which may lead to headache, increased intracranial pressure, and papilledema. A motor deficit, sometimes with seizures, can also occur. Scalp edema and dilated scalp veins may be seen on examination. For lateral sinus thromboses, symptoms related to an underlying condition (middle-ear infection) may be noted, including constitutional symptoms, fever, and ear discharge. Pain in the ear or mastoid region and headache are typical. Hemianopia, contralateral weakness, and aphasia may sometimes be seen owing to cortical involvement. Approximately 16% of patients with CVT have thrombosis of the deep cerebral venous system (internal cerebral vein, vein of Galen, and straight sinus), which can lead to thalamic or basal ganglial infarction. Cavernous sinus thrombosis is usually associated with a primary infectious etiology involving a focus in the face, throat, mouth, ear, or sinuses. Aseptic cavernous sinus thrombosis is an extremely rare phenomenon that has been reported in patients with PV. These patients present with monocular blindness and the characteristic features of ipsilateral cavernous sinus thrombosis, and only retrospectively is the diagnosis of PV made. Therefore, patients found to have this symptom complex who have no known infectious predisposing causes should be carefully evaluated to rule out this diagnosis. The most sensitive diagnostic technique is MRI in combination with magnetic resonance venography.

Thrombosis of large-caliber arteries is a relatively rare event in PV patients, but there have been case reports of thromboses within the chambers of the heart, leading to refractory congestive heart failure and acute aortic occlusion. Such catastrophic thrombotic events in the heart or large vessels would suggest that cardiac catheterization be performed with some caution.

PV frequently manifests with symptoms caused by peripheral vascular disease. In these cases, patients may first be seen by surgeons or dermatologists. Intense redness or cyanosis of the digits with or without burning, classic erythromelalgia, digital ischemia with palpable pulses, or thrombophlebitis without another known cause may be the presenting symptoms.

Erythromelalgia is characterized by burning pain in the digits, an objective sensation of increased temperature, and relief by cooling. PV is the most common cause of erythromelalgia and is one of the few disorders in which digital ischemia with or without ulceration may exist in the presence of palpable pulses. Other disorders that can lead to this abnormality include embolism, trauma, cutaneous infarction, neuritis, infection, and various types of arteritis. Painful and ulcerating toes and fingers have frequently been observed to be presenting symptoms in patients with PV. The likelihood that arterial insufficiency is the cause of such ulceration is quite small in patients who have a palpable dorsalis pedis and posterior tibialis pulses; in this situation, the possibility of an underlying hematologic disorder such as PV should be entertained. Foot pain at rest is a distressing but not widely recognized symptom of PV. In patients with this complaint, peripheral pulses are of normal character, and cutaneous circulation appears to be adequate. The pain is most severe at night, is dull in nature, and occurs primarily in the feet or legs. These symptoms have been shown to be the results of platelet activation and aggregation *in vivo*, which preferentially occur in arterioles. If untreated, erythromelalgia can progress to ischemic acrocyanosis or gangrene. Phlebotomy alone in PV does not improve erythromelalgia. These

symptoms can be abolished by reducing the platelet counts to normal levels and can be rapidly reversed after the institution of antiplatelet aggregation therapy but not coumadin. Therefore, the cause of erythromelalgia appears to be closely linked to abnormal arachidonic acid metabolism that occurs within platelets in this disorder.

Retrospective reviews have revealed a higher than expected number of patients with PV and pulmonary hypertension. Proposed etiologies include direct obstruction of pulmonary arteries by circulating megakaryocytes, extramedullary hematopoiesis in the pulmonary parenchyma, smooth muscle hyperplasia induced by release of PDGF from activated platelets, chronic disseminated intravascular coagulation, and unrecognized recurrent pulmonary emboli. The diagnosis of pulmonary hypertension is made, on average, 9.5 years after the diagnosis of the underlying MPN and is associated with a poor prognosis, with death usually occurring as a result of congestive heart failure or pneumonia. Although anecdotal reports have claimed improvements in patients' pulmonary artery pressure with control of the underlying disease, others have not found any change in serial measurements of 11 patients' pulmonary arterial pressures despite good disease control. Recently, ruxolitinib therapy has been reported to result in improved outcomes, pulmonary and echocardiographic findings, as well as correction of cytokine dysregulation in MPN patients with pulmonary hypertension.

As many as 30–40% of patients with PV experience some sort of hemorrhagic event, which can be relatively trivial, such as epistaxis or gingival hemorrhage, or can be life-threatening, such as gastrointestinal hemorrhage or hematomas involving vital organs. The gastrointestinal tract is a frequent site of hemorrhagic complications because patients with PV are predisposed to portal vein thrombosis and resultant variceal bleeding and peptic ulcer disease. Gastrointestinal erosions and ulcers, and *Helicobacter pylori* infection are all significantly more common in PV patients than in control patients with dyspepsia. This may be partly attributable to altered mucosal blood flow as a result of increased plasma viscosity or increased histamine release caused by peripheral blood basophilia. Cerebral hemorrhage is a common cause of morbidity and mortality. Bleeding events frequently occur with the use of aspirin or other nonsteroidal antiinflammatory agents; an association between the hemorrhage and the use of high doses of these platelet-paralyzing drugs has been made in almost one-third of such instances. Low-dose aspirin therapy has, however, been reported not to lead to an increased incidence of life-threatening hemorrhagic events. Spontaneous bleeding in patients with PV is relatively rare, although spontaneous retropharyngeal hematomas leading to acute upper airway obstruction or hematomas in the groin or retroperitoneum have been reported.

Patients with PV who undergo surgical procedures are at a very high risk of developing postoperative complications. In one series of 62 major operations on 54 patients with PV, postoperative complications occurred in 49% of patients; 52% of complications were from hemorrhage, 18% from thrombosis, and 14% from hemorrhage and thrombosis. The postoperative mortality rate in this patient population was 18%. In another series of 15 patients, five had serious complications secondary to thrombosis and hemorrhage. A study by an Italian group retrospectively evaluated 311 surgical interventions in 105 patients with PV and 150 with ET: 24 arterial or venous thromboses (7.7%), 23 major hemorrhages (7.3%), and five surgery-related deaths (1.6%) were observed within 3 months of the procedure. PV patients with uncontrolled erythrocytosis before surgery have been shown to have the highest complication rate. Patients with inadequately controlled disease had a 79% incidence of complications, but in those with adequate hematologic control before surgery, the rate of perioperative and postoperative complications was reduced to 28%. In addition, the duration of disease control was an important factor in decreasing surgical risk; a prolonged period of effective disease control before surgery reduced the complication rate to 5%. Complication rates after surgery can therefore be dramatically reduced by appropriate therapeutic interventions with normalization of blood counts. The chief deterrent to such an approach has been the failure by physicians to recognize the risk associated with PV in the surgical setting.

Another situation that puts patients with PV and ET at high risk for thrombosis is pregnancy. Maternal and fetal complications have been reported. Specifically, the rate of fetal loss is higher than that of the general population.

Generalized pruritus occurs in approximately 40% of cases of PV. Water contact, such as during showers or bathing, induces attacks of intolerable pruritus. There appears to be no clear relationship between the degree of the pruritus and severity of the disease, and 20% of patients continue to experience itching despite reduction of their hematocrits to normal levels. Aquagenic pruritus is significantly more common among *JAK2V617F* homozygous patients than heterozygotes. The degree of pruritus is so severe in some patients that they are unable to tolerate bathing at all and find it necessary to substitute gentle skin swabbing or to simply not bathe. The etiology of the pruritus in PV remains uncertain. Several groups have attempted to implicate elevated blood and urine histamine levels in its pathobiology. A strong correlation between skin mast cell numbers and the severity of itching has been demonstrated, and mast cells in PV have been shown to be *JAK2V617F* positive. However, the failure of the pruritus to respond to antihistamine therapy in many patients suggests that abnormally high histamine levels probably do not constitute the sole factor in its development.

Iron deficiency has also been implicated as a factor contributing to pruritus in PV patients who are almost invariably iron deficient. Iron-substitution therapy has resulted in symptomatic improvement, but this approach is less than optimal because it frequently results in uncontrollable erythrocytosis. Ruxolitinib therapy has been reported to be effective in alleviating the patient's aquagenic pruritus in 80% of patients.

The development of post-PV MF was increased with prolonged duration of disease and is directly related to the duration of long-term follow-up, but the influence of the modality used to treat the initial PV phase of the disease on the rate of transformation to this more accelerated form of the disease remains uncertain. Post-PV MF should be considered the natural evolution of PV. Criteria for the diagnosis of post-PV MF have been established (Table 68.2) and can be used as a guide for documenting this transition in disease phenotype, which in reality represents a point in the continuum of PV. For patients with disease duration greater than 10 years, the hazard ratio was 15.24 (95% CI: 4.22–55.06; $p < .0001$). The median interval between the diagnosis of PV and the development of post-PV MF is 13 years. Post-PV MF is characterized by (1) increasing splenomegaly;

TABLE 68.2

International Working Group for Myelofibrosis Research and Recommended Treatment Criteria for Post-Polycythemia Vera Myelofibrosis

Required Criteria

1. Documentation of a previous diagnosis of polycythemia vera as defined by the WHO criteria
2. Bone marrow fibrosis grade 2–3 (on 0–3 scale) or grade 3–4 (on 0–4 scale)

Additional Criteria (Two Are Required)

1. Anemia or sustained loss of requirement of either phlebotomy (in the absence of cytoreductive therapy) or cytoreductive treatment for erythrocytosis
2. A leukoerythroblastic peripheral blood picture
3. Increasing splenomegaly defined as either an increase in palpable splenomegaly of ≥ 5 cm (distance of the tip of the spleen from the left costal margin) or the appearance of a newly palpable splenomegaly
4. Development of $\geq$ one of three constitutional symptoms: $>10\%$ weight loss in 6 months, night sweats, unexplained fever ($>37.5^\circ\text{C}$)

WHO, World Health Organization.

Adapted from Proposed criteria for the diagnosis of post-polycythemia vera and post-essential thrombocythemia myelofibrosis: A consensus statement from the international working group for myelofibrosis research and treatment. *Leukemia* 22:437, 2008.

(2) teardrop RBC morphology; (3) extensive BM fibrosis; (4) a leukoerythroblastic blood picture, systemic symptoms including fatigue, weight loss, night sweats, bone pain, and fevers; and (5) anemia and or thrombocytopenia. The patients may be entirely asymptomatic but often complain of fatigue, dizziness, weight loss, and anorexia. Splenomegaly can lead to abdominal pain caused by repeated splenic infarcts and to early satiety caused by mechanical obstruction of the upper gastrointestinal tract. Patients with post-PV MF are virtually all *JAK2V617F* positive and characteristically have high *JAK2V617F* allele burdens.

The anemia that characterizes post-PV MF is primarily a result of splenic pooling, ineffective erythropoiesis, hemolysis, and extramedullary production of RBCs with a shortened RBC survival. Patients positive for *JAK2V617F* are less likely to require blood transfusions but have a poorer survival. Occasionally, the anemia is exacerbated by folate or iron deficiency. Before assuming that a patient has entered post-PV MF, it is prudent to assess BM iron stores. Replacement therapy with iron may lead to the resurgence of erythropoiesis and prevent the faulty categorization of disease progression.

Bleeding abnormalities caused by thrombocytopenia or qualitative platelet abnormalities are especially common during this phase of the disease. Frequent instances of epistaxis or ecchymoses occur, and gastrointestinal hemorrhage caused by esophageal varices arising from portal hypertension is a recurrent problem. The majority of hemorrhagic events are minor in nature. Frequently, patients have generalized wasting characterized by progressive asthenia and weight loss. Severe hyperuricemia, leading to secondary gout or uric acid nephropathy, may also complicate the clinical course.

The median survival for patients with post-PV MF is 5.7 years. Patients with post-PV MF are at a high risk for the development of acute leukemia. Of patients who develop post-PV MF, approximately 18% will undergo leukemic transformation after 3 years and likely a greater number with longer follow-up.

The leukemic transformation of PV has been extensively described. The possibility, that a relationship exists between the therapeutic modality used during the erythrocytotic phase and the frequency of development of acute leukemia, has been a point of heated discussion. Some of the controversy surrounding this question was formerly caused by a lack of understanding of the basic origins of PV. Clinical hematologists in the 1950s and 1960s frequently thought of PV as a benign hematologic abnormality and believed that therapeutic interventions either with alkylating agents or radiotherapy were solely responsible for the development of acute leukemia. That concept has proved erroneous, and PV, similar to the other MPNs, has been shown to be a clonal malignant hematologic disorder. The evolution to acute leukemia can therefore be thought of as a natural consequence of this malignant disorder, which can be accentuated by the therapeutic interventions already discussed. In fact, 25% of patients who develop acute leukemia have never been exposed to any form of cytotoxic therapy.

Further insight into the relationship between acute leukemia and PV has been best provided by the results of the PV Study Group (PVSG), which described a randomized trial comparing the use of phlebotomy, chlorambucil, and ^{32}P for the treatment of this disorder. The incidence of acute leukemia was approximately 1.5% in patients treated with phlebotomy alone, 17.5% in patients treated with chlorambucil, and 10.9% in patients treated with ^{32}P after over 15 years of follow-up. The incidence of acute leukemia in the patients treated with phlebotomy alone is therefore much higher than that expected in a normal age-matched control group, again indicating that leukemia is a natural evolutionary event in the clinical course of an individual with PV. The incidence of acute leukemia can be increased, however, by the institution of therapy with either alkylating agents or ^{32}P . The time course for the development of acute leukemia appears to be dependent on the treatment used to control the polycythemia. The development of acute leukemia in patients treated with phlebotomy in the PVSG trial was limited to the first 5 years of treatment, suggesting that the development of acute leukemia is not solely attributable to the prolongation of survival. In contrast, analysis of the hazard function was virtually flat for

patients treated with chlorambucil from years 2 to 7 after randomization; however, the risk for acute leukemia became alarmingly high after 10 years of study, suggesting that the risk of acute leukemia increases with time even after the drug has been stopped. One half of the cases of acute leukemia in the chlorambucil arm occurred during the first 5 years, with the remainder equally split between the second and third 5-year periods. In contrast, 60% of the cases of acute leukemia in the group treated with radioactive phosphorus occurred 6–10 years after randomization. Of particular concern is the high incidence of leukemia recently reported in patients who were initially treated with radioactive phosphorus or busulphan and then switched to maintenance therapy with hydroxyurea, previously believed to be a nonleukemogenic agent. These findings suggest that a combination of an alkylating agent, busulphan, piprobroman, or melphalan, and another chemotherapeutic agent (hydroxyurea) may particularly increase the risk of leukemia. Approximately 30–50% of patients with PV who develop acute leukemia have previously entered the post-PV MF phase. In contrast, approximately 50% of patients progress directly from the erythrocytotic phase to acute leukemia. The phenotype of the leukemia cells that characterize the leukemic phase is overwhelmingly myeloid, although rare cases of lymphoblastic and biphenotypic leukemias have been reported. Patients with *JAK2V617F*-positive MPN are also at a higher risk of developing both additional hematologic malignancies and solid tumors. The SNPs for TERT, which is a susceptibility factor for familial and sporadic MPNS, have also been shown to be associated with a variety of solid tumors. The presence of this SNP predisposes to the development of MPNS and the cooccurrence of solid tumors, especially in patients receiving cytoreductive therapy. Some investigators have suggested that prolonged cytoreductive therapy be avoided in patients with the TERT polymorphism. In addition, low-grade lymphoproliferative disorders such as chronic lymphocytic leukemia and MGUS have been shown to coexist in patients with a variety of MPNs, including PV, and not to have an adverse effect on prognosis.

In some instances, a preleukemic phase characterized by refractory anemia with excess blasts has been described. In fact, half of such cases of acute leukemia in one series were preceded by a myelodysplastic disorder.

LABORATORY MANIFESTATIONS

Laboratory evaluation of patients with erythrocytosis involves the careful use of a broad range of diagnostic studies. These studies must be used in a rational manner or the evaluation can become extremely costly. Because PV is a panmyelosis, the overwhelming number of patients has elevated hematocrits, WBC counts, and platelet counts. The diagnosis of PV has been greatly simplified by the discovery of the *JAK2V617F* mutation, which is present in more than 90% of PV patients. Hematocrit values greater than 49% in males and greater than 48% in females are abnormal and require further evaluation. Documentation of the absolute increase in RBC mass is rarely required and is a test that is available at smaller and smaller numbers of institutions. A hematocrit value greater than 60% in men or greater than 55% in women is almost always associated with an absolute erythrocytosis. Occasionally, an elevated RBC mass can actually be present in the face of a normal hematocrit value. In cases of splenomegaly caused by portal hypertension, an expanded plasma volume may mask an elevated RBC mass. In addition, iron deficiency can also lead to a normalization of the hematocrit in PV, making the diagnosis difficult. PV is associated with a 20–30% frequency of peptic ulcers and gastritis, which can be associated with blood loss. In this situation, thrombocytosis may be exacerbated as a consequence of the iron deficiency. Iron supplementation is not necessary to make a diagnosis of an MPN because of the availability of molecular diagnostic studies. Administration of iron to such patients must be performed carefully to avoid a rapid increase in RBC mass, which can be associated with a high risk of thrombosis.

Leukocytosis is present in approximately two-thirds of cases and seems to be proportional to the burden of *JAK2V617F*. Thrombocytosis is observed in 50% of cases. Abnormalities of RBC, WBC, and platelet morphology are frequently observed. The morphologic RBC changes observed during the erythrocytotic phases are characteristic of iron deficiency and include microcytosis, hypochromia, and frequently polychromatophilia. Some anisocytosis and poikilocytosis can be seen as well. Fetal hemoglobin levels and the number of RBCs containing fetal hemoglobin, known as *F cells*, may be increased. The WBCs are characterized by normal morphology, although the numbers of basophils, eosinophils, and immature myeloid forms can be increased. Platelet morphology is also quite striking in PV. Frequently, megathrombocytes (platelets the sizes of RBCs) are seen on the peripheral blood smear. Patients frequently have platelet counts of less than $1 \times 10^6 \text{ mm}^{-3}$, but it is not unusual to observe a patient with a platelet count higher than this value. PV-related MF is characterized by a leukoerythroblastic blood picture, with the appearance in the peripheral blood of dacryocytes or teardrop RBCs, myelocytes, metamyelocytes, and (rarely) blasts and promyelocytes in addition to nucleated RBCs in the peripheral blood.

Platelet aggregation studies do not correlate frequently with the risk of bleeding episodes. The most common abnormalities are decreased primary and secondary aggregation to either or both epinephrine and adenosine diphosphate, and decreased response to collagen with generally a normal response to arachidonic acid. An abnormal platelet storage pool disease is a characteristic feature and is caused by abnormal platelet activation. Prothrombin times (PT) and partial thromboplastin times (aPTT), as well as fibrinogen levels, are usually normal. Profound abnormalities of the PT and aPTT, however, are frequently reported. This is largely a laboratory artifact caused by the extreme erythrocytosis, which results in a relatively smaller volume of plasma being present in the whole blood sample. Coagulation assays are performed on blood anticoagulated with sodium citrate, and the citrate concentration in the anticoagulant is calibrated to chelate the plasma calcium and inhibit coagulation reactions. All coagulation assays include the addition of calcium chloride to neutralize the excess citrate and provide free calcium to mediate coagulation reactions. In patients with extreme erythrocytosis, the ratio of citrate in the collection tube to the volume of plasma is too high; therefore, excess citrate is present, and the standard amount of calcium chloride added during the performance of the PT and aPTT is insufficient to neutralize the excessive citrate, and the coagulation assays are frequently and factually prolonged. To avoid this problem, the clinician should calculate the relative amount of plasma compared with the normal amount and remove the corresponding volume of sodium citrate from the blood collection tube. Normal values can then be confidently anticipated in patients with erythrocytosis. A shortened fibrinogen half-life has been detected in some patients with PV and a significantly increased fractional catabolic rate of the plasma fibrinogen pool per day. In addition, elevated platelet β -thromboglobulin and plasma β -thromboglobulin levels are observed. The constellation of findings is indicative of increased platelet turnover. Prothrombin fragments F1 and 2, thrombin-antithrombin complex, and D-dimer levels are frequently elevated in PV patients. These are enzyme-inhibitor complexes or byproducts of active thrombosis that serve as a biochemical signature of the hypercoagulable state that characterizes PV.

Acquired von Willebrand syndrome occurs frequently in patients with PV and ET with over $1 \times 10^6/\text{L}$ platelet numbers. This syndrome is characterized by a normal or prolonged bleeding time, normal factor VIII level, and normal von Willebrand factor (vWF) antigen level, but abnormal vWF ristocetin cofactor actively associated with a decrease or absence of large vWF multimers. This acquired defect resembles type II vWF disease. Because the molecular size of vWF is a major determinant of its adhesive function and the larger multimers are most active in achieving hemostasis, the deficiency of large vWF multimers is associated with a bleeding tendency. The decrease in the frequency of large vWF multimers occurs in patients with platelet counts over $1000 \times 10^9 \text{ L}^{-1}$. This abnormality has been reported not only with patients with severe thrombocytosis caused by MPN, but

also in patients with reactive thrombocytosis. An inverse correlation between the proportion of large vWF multimers and platelet numbers has been observed. In addition, normalization of the platelet count is accompanied by restoration of a normal vWF multimer pattern. These findings suggest that thrombocytosis of any etiology may favor the adsorption of larger forms of vWF multimers onto platelet membranes, resulting in their removal from the circulation and subsequent degradation by platelet-associated proteases. Although patients with MPN frequently have bleeding tendencies, this is not the case in secondary thrombocytosis, possibly because of the limited periods of extreme thrombocytosis observed in such patients. Patients with PV with clinical courses punctuated by hemorrhagic events, extreme thrombocytosis, and acquired von Willebrand syndrome should not receive aspirin therapy if they are having a thrombotic episode but should be phlebotomized, and platelet-reduction therapy should be initiated. Patients with PV and acquired von Willebrand syndrome have recurrent bleeding from mucous membranes and the digestive tract, and easy bruisability. These symptoms frequently resolve with normalization of the platelet count.

Deficiencies of one or more natural anticoagulants as well as the antiphospholipid antibody syndrome have been observed in patients with PV and thrombosis. These studies indicate that either familial or acquired antithrombin III deficiency, protein C or S deficiency, factor V Leiden mutation, or the prothrombin G gene mutation may contribute to the hypercoagulable state observed in PV. Of note, although hyperhomocysteinemia caused by deficiency of cobalamin or folate can be found in 32–56% of PV patients, there is no agreement as to its role in the genesis of thrombotic episodes. Such inherited disorders associated with the erythrocytosis of PV provide a scenario that frequently favors thrombosis in affected individuals. In attempting to determine if a patient with PV and an active thrombosis has such an inherited predisposition, it is important to be aware that proteins C and S as well as antithrombin III levels can be low in patients with an ongoing acute thrombosis or liver cirrhosis. Normal prothrombin and factor VII levels in such patients eliminate liver cirrhosis as a cause of the reduction of these circulating anticoagulants. Individuals with inherited prethrombotic conditions frequently have levels of specific proteins below 10–20% of normal during periods of active thrombosis.

The leukocyte alkaline phosphatase activity level is elevated in 70% of patients. Moreover, recent data indicate an increase of neutrophil elastase levels in granulocytes and in plasma that correlates with *JAK2* mutational status. Whereas serum vitamin B₁₂ concentrations have been found to be elevated in 40% of patients, serum vitamin B₁₂-binding proteins are elevated in 70% of patients. Hyperuricemia occurs in an overwhelming number of patients, and elevated histamine levels are also frequently observed. BM aspirates and biopsies obtained at the time of diagnosis of patients with PV are hypercellular and display characteristic erythroid, granulocytic, and megakaryocytic hyperplasia. The cellular elements (Fig. 68.6) are frequently morphologically normal. Iron stores are almost uniformly absent in pretreatment biopsy specimens. Significant increases in BM reticulin may be present in biopsies obtained early in the course but also may develop during the erythrocytotic phase and may be present for long periods before the onset of the post-PV MF. It is important to emphasize that individuals may have considerable BM fibrosis, which occurs as a consequence of the underlying MPN. The presence of minimal BM fibrosis should not be considered a harbinger of the development of post-PV MF. In patients with post-PV MF, a moderate-to-marked increase in reticulin fiber is observed, either simultaneously with or within 1 year of this clinical transformation.

Several investigators have attempted to use BM biopsy morphology as a differential diagnostic tool to differentiate between PV and secondary forms of erythrocytosis. The marked hypercellularity, erythroid and megakaryocytic hyperplasia with pleiomorphic enlarged megakaryocytes that are the hallmarks of MPNs are useful parameters for identifying such individuals (see Fig. 68.6). It is imperative to use the BM biopsy rather than the aspirate specimens for this purpose. It has been suggested that those PV patients with minor BM fibrosis

Fig. 68.6 PHOTOMICROGRAPH OF BONE MARROW BIOPSY OBTAINED FROM A PATIENT WITH POLYCYTHEMIA VERA IN MYELOFIBROTIC PHASE DEMONSTRATING HYPERCELLULARITY AND INCREASED NUMBER OF MEGAKARYOCYTES ($\times 160$).

are at an increased risk to develop a thrombotic episode or to evolve into post-PV MF but not acute leukemia during the course of their disease.

The pathologic appearance of the spleen in PV depends on the stage of the disease at which the organ is examined. Splens from patients in the erythrocytotic phase of the disease are characterized by striking congestion with mature erythrocytes. Small numbers of hematopoietic precursor cells are frequently present. By contrast, splens examined during the PV-related MF phase are characterized by prominent numbers of foci of extramedullary hematopoiesis, with representation of all BM precursor elements.

Allele-specific PCR methods can be used to detect the *JAK2V617F* or a *JAK2* exon 12 mutation in approximately 95% of patients with PV. The very high frequency of *JAK2V617F* in PV has dramatically improved our ability to diagnose this disease. Patients with isolated erythrocytosis associated with normal neutrophil and platelet counts but low serum EPO levels and the formation of erythroid colonies by peripheral blood mononuclear cells in the absence of EPO *in vitro* are the characteristic phenotype of patients with the exon 12 mutation. BM biopsies from these patients were slightly hypercellular with isolated erythroid hyperplasia. Megakaryocytes were morphologically normal and not clustered. The exon 12 mutations were frequently present at low levels in granulocyte DNA but were readily identifiable in endogenous erythroid colonies generated *in vitro*. Because granulocyte involvement with *JAK2* exon 12 mutations is low, it is important to sequence DNA from BM cells or from endogenous erythroid colonies generated *in vitro* to make this diagnosis. At diagnosis, serum EPO levels in PV are either reduced or at the lower limits of normal. Even after normalization of the hematocrit, the serum EPO level in PV remains low in two thirds of patients.

Arterial blood gas measurements are frequently performed to rule out hypoxia as a cause of erythrocytosis. In PV with extreme thrombocytosis, such routine measurements can prove to be misleading. Spurious hypoxemia can frequently be attributed to either significant leukocytosis or thrombocytosis caused by *in vitro* consumption of oxygen, the so-called *platelet and leukocyte larceny*. In this situation, pulse oximetry can be a useful tool for establishing the patient's true oxygenation status.

CYTOGENETIC ABNORMALITIES

The occurrence of nonrandom cytogenetic abnormalities in PV is anticipated because this is a feature of most hematologic malignancies. Such abnormalities have been observed without a single characteristic abnormality defined; the most frequent abnormalities are the gain of chromosome 9 as well as 9p, deletion of the long arm of chromosome 20, gain of the long arms of chromosome 1, trisomy 8, and deletion of chromosome 13 (Fig. 68.7). Balanced translocations are rarely observed in PV. At diagnosis, approximately 28% of patients have a recurrent clonal chromosome marker.

Fig. 68.7 Most frequent chromosomal abnormalities associated with polycythemia vera at diagnosis include (*top row*) a gain of derivative(9)t(1;9), resulting in three copies of the long arms of chromosome 1 and three copies of the long arms of chromosome 9, including Janus kinase 2; gain of chromosome 8 and simultaneous gain of both chromosomes 8 and 9 (*bottom row*); gain of chromosome 9 alone; interstitial deletion of chromosome 13; and interstitial deletion of chromosome 20.

Interphase fluorescence *in situ* hybridization (FISH) testing with 12 probes for loci most frequently associated with PV and other Ph⁻ MPNs occasionally identifies cryptic +9p, del(20q) or del(13q) abnormalities and thus may increase the frequency of detecting a chromosomal rearrangement at diagnosis to 29–30%.²³ However, interphase FISH (I-FISH) does not appear to significantly increase the detection rate in untreated patients. Among 452 patients with PV cytogenetically studied at the authors' institution between 1984 and April 2011, 28% had cytogenetic abnormalities at diagnosis. I-FISH studies alone (without cytogenetic examination) using an MPN panel of 12 probes revealed that 29% of patients had genomic changes (Fig. 68.8). The frequency of detection of cytogenetic abnormalities in PV increases over time, with 35–55% of patients having clonal cytogenetic abnormalities after extended follow-up and more than 80% of those patients in whom acute leukemia eventually develops. Progression from a normal to an abnormal karyotype is an important adverse prognostic parameter.

Trisomy of the long arms of chromosome 1 is a recurrent abnormality present in about 4–6% of patients with PV with an abnormal karyotype. This abnormality has also been described in PMF and other myeloid malignancies. Specifically, 70% of patients with post-PV MF develop trisomy 1q as a result of unbalanced translocations. Trisomy 1q rarely occurs alone and is most frequently found translocated to another chromosome, creating an unbalanced +1q translocation. The recipient chromosome most frequently involved is chromosome 6 followed by chromosome 9. Jumping translocations are rare cytogenetic phenomenon whereby a part of one chromosome is translocated to several recipient chromosomes, creating multiple related clones within a single patient. Jumping 1q in MPN occurs in 4.2% of cytogenetically abnormal MPN; 86% of such patients

Fig. 68.8 Myeloproliferative neoplasm fluorescence in situ hybridization (FISH) panel includes 12 loci on eight different chromosomes for detection of the most frequent chromosomal rearrangements when cytogenetics are either not available or in conjunction with conventional cytogenetics for detection of cryptic abnormalities. Discrepancy in frequency of abnormality detected by interphase FISH and conventional cytogenetics are present and often suggest a proliferative advantage of the abnormal clone.

progress to AML after an average of 8 months, suggesting that 1q jumping translocations are associated with both disease progression and poor prognosis.

Gain of chromosome 8 is a recurrent abnormality not only in Ph⁺ MPN, but it is also one of the three most frequent abnormalities in MDS and is present in 10% of patients with malignant hematopoietic disorders of both myeloid and lymphoid lineages. The prognostic significance in PV is unknown. Some patients with PV with trisomy 8 do not acquire other abnormalities after 20 years. The simultaneous presence of both +8 and +9 is PV specific, and is observed in 3–4% of PV cases; it is rarely seen in other hematologic malignancies. In PV, trisomy 8 has been demonstrated in myeloid

Fig. 68.9 NUMEROUS CHROMOSOMAL ABNORMALITIES RESULTING IN TRISOMY, TETRASOMY, OR AMPLIFICATION OF THE SHORT ARMS OF CHROMOSOME 9. *JAK2*, Janus kinase 2.

cells but not in lymphoid cells. The genetic consequences of trisomy 8 are unclear, although recent studies have suggested a role for microRNAs that are localized on chromosome 8. MicroRNAs are small noncoding RNAs (≈19–25 nucleotides in length) that act as regulators of gene expression by inducing translational inhibition and cleavage of target mRNAs.

Trisomy 9 and gain of the short arms of chromosome 9 is most frequently and almost exclusively observed in PV. There are three types of 9p abnormalities in PV: (1) about 30% of patients have uniparental disomy of the 9p region; (2) numerical gain, such as different chromosomal rearrangements that contribute to trisomy, tetrasomy, or amplification of 9p; and (3) unbalanced translocations, of which the most frequent, +der(9)t(1;9), results in a trisomy of both 9p and 1q, and appears to be a relatively specific abnormality in PV patients (Fig. 68.9). This rearrangement provides an extra copy of mutated *JAK2*. Trisomy 9p and three copies of mutated *JAK2* are rare recurrent abnormalities resulting from unbalanced chromosome 9 translocations such as der(18)t(9;18)(p13;p11)/der(9;18)(p10;q10). I-FISH has been used to detect cryptic chromosome 9 rearrangements. FISH has uncovered chromosome 9 rearrangements in 53% of patients with abnormal FISH patterns, indicating that a gain of 9p is the most frequent genomic alteration in PV. The association between the trisomy of 9p and PV was one of the keys to the identification of the *JAK2V617F* mutation. Cytogenetic studies of 9p and LOH indicate that the LOH is attributable to mitotic recombination. The prognostic significance of +9/+9p is still unknown.

Interstitial deletions of the long arms of chromosome 13 are not specific for PV and are more frequently observed in PMF than in PV. About 1–13% of cytogenetically abnormal patients with PV have del(13q). Among patients with del(13q), about 91% have breakpoints in 13q12–14 to q21–22 regions. Fine FISH mapping has defined the commonly deleted region to 13q13.3–q14.3 encompassing Rb1 and two microsatellite loci, D13S319 and D13S25. Cryptic del(13q) occurs and is easily identified with the FISH method. Deletions are heterogeneous and may involve one, two, or all three loci, including Rb1.

Del(20)(q11q13), an interstitial deletion of the long arm of chromosome 20, is the second most common cytogenetic abnormality in PV (Fig. 68.10). Del(20)(q11q13) is not diagnostic of PV because it also occurs in PMF and ET, as well as in MDS and AML. Heterogeneity of the breakpoints is suggested by the observation that two minimally deleted regions (MDRs) characterize different disorders. A 2.7-Mb region spanning D20S10-8 (proximal) and D20S481 (distal) is identified in Ph⁺ MPN, and a 2.6-Mb region spanning R52161 (proximal) and Wi-12515 (distal) is found in other malignancies. Two commonly deleted regions (CDR), CDR1 spanning 2.4 Mb between bands 20q11.23 and 20q12, and CDR2 encompassing 1.8 Mb within 20q13.12, have been identified. The commonly retained region (CRR)1 spans 1.9 Mb within 20q11.21 and CRR2 encompasses 2.5 Mb within 20q13.33. High-resolution genotyping has not revealed any somatic copy-neutral LOH within these regions. Investigations to date of candidate genes within the deleted segments have failed to identify any mutations within deleted segments. In contrast, haploinsufficiency of the *L3MBTL1* gene, the

Fig. 68.10 A karyotype from a dividing megakaryocyte showing (arrows) two copies of deleted 20q in a cell with 92 chromosomes.

human homolog of the *Drosophila* L(3)MBT polycomb group tumor suppressor gene located on the 20q12 within a region commonly deleted in several myeloid malignancies, may play a role in erythropoiesis in PV. Downregulation of *L3MBTL1* expression in primary hematopoietic stem progenitor cells (HSPCs) causes enhanced commitment to and acceleration of erythroid differentiation. Moreover, overexpression of *L3MBTL1* in primary hematopoietic CD34⁺ cells as well as in 20q cell lines limits erythroid differentiation. Therefore, haploinsufficiency of *L3MBTL1* may contribute to erythroid differentiation in PV. It has also been demonstrated that *L3MBTL1* is important for the normal progression of cells through mitosis because both overexpression and loss of activity can affect cell division. There is evidence that 20q deletions may impair the release of granulocytes into the peripheral blood. Some patients with PV and 20q deletion in BM cells have cytogenetically normal peripheral blood granulocytes, which has been attributed to del(20q) cells being preferentially retained or destroyed in the BM. The significance of this abnormality remains unknown because it may be dormant for many years before cells with del(20q) gain proliferative advantage. It is important to emphasize, however, that patients with del(20q) have been observed without further karyotypic instability for more than 10 years.

Other rare recurrent chromosomal abnormalities may occur at the onset of the disease or are associated with disease progression. Both interstitial deletions of the long arms of chromosomes 5 and 7 have been reported at diagnosis and are associated with disease progression. Loss of P53 as a result of del(17p) or other chromosomal rearrangements is a rare finding in PV and appears to be related to disease progression. Del(17p) is not PV specific because it is found in many other myeloid malignancies.

Chromosome abnormalities including +8, +9, and del(20)(q11q13) are related to the biogenesis of the disease rather than occurring as a consequence of the chemotherapy. However, in some patients an abnormal clone (abnormalities of chromosome 5, 7, or 17) appears to develop as a consequence of exposure to chemotherapeutic agents. Some investigators have suggested that patients with cytogenetic abnormalities at diagnosis have a statistically significant poorer survival rate than those in whom a normal karyotype is observed. This influence of cytogenetic abnormalities on prognosis has, however, not been verified.

DIFFERENTIAL DIAGNOSIS

In most patients, establishing the cause leading to erythrocytosis is not difficult. Initially, it is critical to be certain that one is dealing with a patient with absolute erythrocytosis. A hematocrit level greater than 60% on several occasions in men or greater than 55% in women, however, is certainly associated with an elevated RBC mass. Testing for *JAK2V617F* and *JAK2* exon 12 mutations can be extremely useful in diagnosing PV and is now a standard practice to make a diagnosis in any patient who is suspected of having PV. The presence of splenomegaly is an important finding on clinical examination, and adjunctive laboratory findings include normal arterial oxygen saturation, elevated leukocyte alkaline phosphatase activity, and *JAK2V617F* assays. Splenic sizing by ultrasonography can be useful in documenting splenic enlargement when the spleen is not palpable by physical examination.

It is initially important to differentiate PV from the large number of other causes of secondary erythrocytosis. Characteristically, the patient with PV will present with erythrocytosis, leukocytosis, thrombocytosis, and splenomegaly, and is positive for *JAK2V617F*. The BM biopsy shows hypercellularity with trilineage hyperplasia. In individuals who lack a mutated *JAK2*, it is important to determine the SaO₂ using an arterial blood gas, the carboxyhemoglobin level, and the P₅₀O₂ in patients with other family members with erythrocytosis to exclude obvious causes of secondary erythrocytosis. Because smokers' polycythemia is the most frequent cause of erythrocytosis, it is wise to measure carboxyhemoglobin levels early on in the investigation. In addition, a PaO₂ greater than 67 mmHg or an O₂ saturation greater than 95%, as quantitated on an arterial blood gas, is helpful in ruling out hypoxic conditions that lead to erythrocytosis. In patients with intermittent hypoxia, such as sleep apnea syndrome or alveolar hypoventilation caused by obesity, such blood gas determinations can be normal. A low P₅₀O₂ is indicative of a hemoglobin mutant with high O₂ affinity, leading to tissue hypoxia and erythrocytosis. Patients with PV characteristically exhibit serum EPO levels below the 95% CIs for the range observed in normal control participants. It is not unusual to have a normal EPO level in some patients with hypoxic causes of secondary erythrocytosis, unless the hypoxia exists over an extended period of time. A normal EPO level cannot be used to exclude a hypoxic cause of erythrocytosis. EPO

TABLE 68.3 World Health Organization Criteria for Polycythemia Vera²⁴**2016 WHO Diagnostic Criteria for PV**

Major criteria:

1. Hemoglobin >16.5 g/dL in men, 16 g/dL in women, or hematocrit >49% (men), >48% women or increased RCM^a
2. BM biopsy showing hypercellularity for age with trilineage growth (panmyelosis) including prominent erythroid, granulocytic, and megakaryocytic proliferation with pleomorphic, mature megakaryocytes
3. Presence of *JAK2V617F* or *JAK2* exon 12 mutation

Minor criteria:

1. Serum EPO level less than the reference range for normal

Diagnosis requires meeting either all three major criteria or the first two major criteria and the minor criterion

^aMore than 25% above mean normal predicted value.

BM, Bone marrow; EPO, erythropoietin; PV, polycythemia vera; RCM, red cell mass; WHO, World Health Organization.

Data from Arber DA, Orazi A, Hasserjian R, et al: The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia. *Blood* 127:2391, 2016.

measurements do, however, remain an important diagnostic tool. Elevation of EPO levels in the face of erythrocytosis is indicative of a hypoxic cause of secondary erythrocytosis, but extremely low levels of EPO (<4 mIU/mL) are virtually diagnostic of PV.

Incorporating a mutational screen into the algorithm for investigating a case of suspected polycythemia will help to streamline the diagnosis of PV, although the presence of a *JAK2* mutation alone does not distinguish PV from PMF or ET. Clinical criteria for the diagnosis of PV have been defined by the World Health Organization (WHO), which serves as a uniform platform with which to diagnose PV. It is important, however, for the clinician to realize that some patients undoubtedly have an MPN disorder resembling PV but do not fulfill all the diagnostic criteria of the PVSG or the WHO. The criteria for the diagnosis of PV, including the use of the *JAK2V617* assay and histopathologic parameters, have been provided by the WHO (Table 68.3).²⁴ These criteria are the consensus of many experts working in this field.

There will always be unusual cases with clinical characteristics that cannot be pigeonholed into a particular diagnostic category. If these patients have serious symptoms, the individual physician must make treatment decisions on the basis of the risk–benefit ratio for that patient.

A particularly difficult dilemma occurs when evaluating patients with isolated pure erythrocytosis. These patients have elevated RBC masses, normal WBC counts, normal platelet counts, no evidence of splenomegaly, and no evidence of any recognizable cause of secondary erythrocytosis. Clearly, some of these patients have *JAK2V617F*-positive PV or mutations of exon 12 *JAK2*, leading to isolated erythrocytosis. The PFCs are caused by truncation of the EPOR, characterized by increased sensitivity of erythroid progenitor cells to EPO, and can be easily distinguished from PV. These patients frequently present in childhood, and this disorder is characterized by isolated erythrocytosis that is associated with an increased risk of thrombotic events. There is a strong family history of polycythemia. The BM progenitor cells are hypersensitive to EPO, yet no colonies form in the absence of EPO. The patient with profound erythrocytosis who is negative for *JAK2V617F* as well as exon 12 *JAK2* mutations and does not have erythrocytosis caused by smoking, cyanotic heart disease, an EPO-secreting tumor, sleep apnea, or resides at a high altitude remains a diagnostic dilemma. All patients should have a good family and drug history, an arterial oxygen saturation study and a carboxyhemoglobin measurement, and measurement or calculation of p50, and quantitation of 2,3BPG and serum EPO levels. If these studies are unrewarding, these patients should then be investigated for mutations in the hypoxia-responsive element of the human *EPO* gene, HIF-2 α and HIF-1 α , VHL, PHD1,2,3, STAT5, LNK,

and TET2. Some of these tests can be performed by commercial laboratories, but often one will have to contact an academic reference laboratory to complete such an extensive investigative effort (www.mayomedicallaboratories.com/articles/features/erythrocytosis/testing).

PV must also be differentiated from the other MPNs, such as CML, ET, and PMF. Such classification has major prognostic implications and influences important therapeutic decisions, including the use of tyrosine kinase inhibitors. With the distinctive cytogenetic abnormalities and molecular genetic abnormalities that are unique to CML (Philadelphia chromosome, *BCR-ABL* gene fusion), these two disorders should not be difficult to differentiate. Occasional patients with an MPN have been shown to have both *JAK2V617F* as well as *BCR-ABL*; whether this unusual occurrence that takes place in two different clones and thereby represents two independent MPNs or a single clone and is caused by the predisposition of such patients to acquire mutations in their hematopoietic cells is a subject of speculation.

Patients with PMF can present with abnormalities that are virtually indistinguishable from those of patients with PV-related MF. Almost 50% of PMF are *JAK2V617F* positive, but more than 90% of patients with post-PV MF are *JAK2V617F* positive. The survival of patients with the latter disorder is much shorter than that of patients with the former condition. Unusual patients with PMF may actually develop PV after iron supplementation or the institution of chemotherapy. ET with a borderline elevated hematocrit and PV with marked thrombocytosis can easily be confused. When the RBC mass is used as a definitive diagnostic test, a distinction between ET and the erythrocytotic phase of PV is usually readily apparent. This measurement is not widely available and can also be normal or actually low in patients with PV who are iron deficient because of bleeding or excessive phlebotomy. Campbell and coworkers have used sensitive PCR-based methods to assess the *JAK2* mutational states in 806 patients with ET. The mutation was present in more than 50% of patients with ET. *JAK2V617F*-positive ET patients were characterized by multiple features that resembled those of patients with PV, including higher hemoglobin levels, higher WBC counts, more prominent BM erythroid and granulocytic hyperplasia, a higher incidence of venous but not arterial thrombosis, low serum EPO levels, and lower serum ferritin levels. Surprisingly, *JAK2V617F*-negative patients who likely had calreticulin mutations had higher platelet counts. Furthermore, *JAK2V617F*-positive ET patients had a higher probability of developing PV with long follow-up. Acquisition of homozygosity for the *JAK2V617* caused by homologous recombination is likely the critical event in the development of PV in *JAK2V617F* ET patients. Homozygosity for *JAK2V617F* occurs in at least 30% of patients with PV but is extremely rare in ET.

PROGNOSIS

The prognosis of a patient with PV depends on the nature and severity of the complications that occur during the clinical course of that particular patient's disorder. In addition, an individual patient's prognosis depends on the duration of the erythrocytotic phase or the time to transition to post-PV MF or acute leukemia. Survival is also influenced by whether appropriate treatment is instituted during the erythrocytotic phase of the illness. Patients who have uncontrolled erythrocytosis are at an extremely high risk for the development of thromboses. The median survival time from the onset of symptoms has been reported in a study that is over four decades old to be as short as 1.5 years in untreated patients, but this number seems excessive because of the relatively large number of patients who are diagnosed during routine examinations and are asymptomatic for prolonged periods of time. Determination of the optimal management of patients with PV has been a difficult task because the disease, when treated, is associated with a survival period of approximately 17 years. Studies of new potential therapeutic interventions therefore require prospective studies with prolonged follow-up times before

TABLE 68.4 Risk Stratification in Polycythemia Vera Based on Thrombotic Risk

Risk Category	Age >60 Years or History of Thrombosis	Cardiovascular Risk Factors ^a
Low	No	No
Intermediate	No	Yes
High	Yes	

^aHypertension, hypercholesterolemia, diabetes, and smoking (see text). Extreme thrombocytosis (platelet count $>1500 \times 10^9 \text{ L}^{-1}$) is a risk factor for bleeding. Its role as a risk factor for thrombosis is uncertain. An increasing leukocyte count has been identified as a novel risk factor for thrombosis, but confirmation is required.

Data from Finazzi G, Barbui T: How I treat patients with polycythemia vera. *Blood* 109:5104, 2007.

meaningful results can be generated determining their ability to improve upon overall survival.

Increasing age and history of vascular events have consistently proven to be independent predictors of developing additional thromboses in patients with PV. In the ECLAP trial, the incidence of cardiovascular complications was higher in patients older than 69 years of age, patients with a history of thrombosis, and patients with WBC counts higher than $15,000 \times 10^9 \text{ L}^{-1}$. Conventional cardiovascular risk factors, including hypertension, hyperlipidemia, diabetes, and smoking, are assumed to be associated with the same relative risk of developing thrombosis in PV patients as that observed in the general population. Although practicing hematologists are frequently concerned about elevated platelet counts in PV patients, several reports have failed to show any association between platelet count and thrombotic events, suggesting that therapies in PV targeting reduction of platelet numbers are ill conceived.

These data have led to stratification of therapy in patients with PV based on clearly identifiable risk factors (Table 68.4) of developing additional thrombotic events. The development of acute leukemia was a relatively rare event in PV, occurring in 22 out of 1638 patients in the ECLAP observational study after a median of 8.4 years from the time of diagnosis. Older age as well as treatment with alkylating agents was associated with a four- to eightfold increased risk of developing AML or MDS compared with patients treated with phlebotomy alone, hydroxyurea, or IFN. The effect of *JAK2V617F* allele frequency on the prognosis of PV patients has been examined. More than 95% of patients with PV are *JAK2V617F* positive, and their mutational load can be determined by allele-specific PCR. Approximately 30% of PV patients have a high *JAK2V617F* burden ($>50\%$), and the remainder have a lower burden ($<50\%$), with the small numbers being WT. Some investigators, but not all, have reported that high burdens of *JAK2V617F* in PV patients are associated with larger splenic volumes, more frequent aquagenic pruritus, a higher incidence of thrombotic events, and a higher rate of evolution into MF and acute leukemia.

High leukocyte counts ($>15,000 \times 10^9/\text{L}$) at the time of diagnosis have been identified as another independent predictor of developing a major thrombosis in PV patients. In addition, others have suggested that this parameter is predictive of evolution to MF and AML and an overall inferior survival time.

In a study of more than 1500 patients with PV, risk factors for survival included advanced age, leukocytosis, venous thrombosis, and abnormal karyotype. Median survival was 23 years in the absence of advanced age and leukocytosis, and 9 years with the presence of both of these risk factors. In another study of 327 patients with PV from France and Sweden, multivariable analysis identified age >70 years, leukocyte count $>13 \times 10^9/\text{L}$, and thrombosis at diagnosis as risk factors for survival. Patients with two or more of these risk factors had a 10-year relative survival of 26%, as opposed to patients with zero or one risk factors, who had a 10-year survival of 84% and 59%, respectively.

The choice of therapeutic agents used to treat the erythrocytotic phase of disease clearly influences patient outcomes. The use of

alkylating agents is associated with an established risk for leukemic transformation or evolution to MDS. Clearly, this risk is also associated with increased duration of the disease. The effect of hydroxyurea on leukemic transformation rates is limited, if any. In addition, the influence of long-term IFN therapy on disease outcomes is not at present clearly defined.

THERAPY

The cumulative duration of survival for PV patients treated with modern strategies is between 15 and 17 years. Despite the implementation of standard therapeutic strategies, the mortality rate of PV patients is increased by 1.84 compared with age- and sex-matched populations. The primary goals of treatment are to reduce the risk for thrombosis, ameliorate the PV symptom burden, and prevent evolution to MF and/or AML. Unfortunately, current therapies are not effective for this latter purpose, and controlling blood counts may have less of an effect than anticipated. The European Leukemia Net (ELN) expert panel defined a complete response as a hematocrit less than 45% without phlebotomy, platelet count less than $400 \times 10^9/\text{L}$, leukocyte count less than $10 \times 10^9/\text{L}$, normal spleen size, and no disease-related symptoms.²⁵ However, in a study of 261 patients with PV who were given hydroxyurea (HU) and followed up for a median of 4.4 years, no association was observed between achieving an ELN or a hematocrit response and better survival or fewer vascular complications. No particular platelet or leukocyte count could be shown to be protective against thrombosis. The ELN response criteria were updated in 2013, but they have not been validated to predict survival or progression to MF or AML. Therapy is also stratified based on the presumed risk of an individual patient to develop additional thrombotic episodes, with low-risk patients being treated with phlebotomy therapy alone plus a therapy directed toward paralysis of platelet function and high-risk patients receiving not only phlebotomy plus antiplatelet therapy but also some form of myelosuppressive therapy (hydroxyurea, IFN, busulfan, melphalan, ruxolitinib). At present, the therapeutic goals are to reduce the risk of thrombosis by normalizing the hematocrit levels to 45% (some experts advocate reducing the hematocrit to 42% in females) based on a randomized prospective study that demonstrated a decreased risk of cardiovascular morbidity and mortality with a goal hematocrit of less than 45% compared to 45–50%.²¹ Previous studies have indicated a lack of a relationship between thrombocytosis at diagnosis or during the period of follow-up with thrombotic complications. Whether therapy should be directed at normalization of platelets remains uncertain at present and should not be pursued unless within the context of a clinical trial. Extreme thrombocytosis ($>1 \times 10^9/\text{L}$), if associated with spontaneous hemorrhage, is an indication for normalization of platelet numbers. Phlebotomy therapy alone is the standard of care for low-risk PV patients (see box on General Principles of Therapy).

A series of studies, although completed more than 30 years ago, by the Polycythemia Vera Study Group answered several very important questions regarding the efficacy and associated complications of particular therapeutic modalities. These investigations have aided in the identification of optimal therapy for individual patients, which must be selected on the basis of age and comorbid disease status to minimize treatment-related complications.

The first PVSG randomized trial (01 trial) evaluated three treatment strategies: (1) phlebotomy alone to maintain the hematocrit level at less than 45%; (2) intravenous ^{32}P at 2.3 mCi/m^2 repeated every 12 weeks, if needed (maximum, 5 mCi per dose) supplemented by phlebotomy to maintain the hematocrit level at less than 45%; and (3) myelosuppression with chlorambucil 10 mg/day orally for 6 weeks and then daily on alternate months with necessary dose reductions and supplemental phlebotomy. More than 400 patients were randomly assigned to this protocol. The median survival duration from entry into the study until death was 9.1 years for patients treated with chlorambucil, 10.9 years for those treated with ^{32}P , and 12.6 years for the phlebotomy group. Long-term survival was inferior for patients treated with chlorambucil compared with those treated with

General Principles of Therapy

1. The etiology of erythrocytosis must be correctly categorized to be certain the patient has polycythemia vera (PV). This will avoid inappropriate exposure of patients with nonmalignant disorders to the adverse effects of myelosuppressive agents. To this end, a major contribution is played by incorporating molecular marker testing (*JAK2V617F* and exon 12 *JAK2* mutational determinations) in the diagnostic workup, and in this way, early phases of PV can be recognized as well. In individuals with erythrocytosis without a *JAK2* mutation, search for causes of secondary causes of erythrocytosis as well as inherited disorders that lead to erythrocytosis, which includes mutations in *EPOR*, *VHL*, *PHD2*, *HIF-1* and *HIF-2*.
2. Therapy should be individualized.
3. Initially, the hematocrit should be reduced to 45% as soon as possible. The speed of phlebotomy will depend on patients' general medical conditions (250–500 mL every other day). Elderly patients with compromised cardiovascular or pulmonary systems should be more carefully phlebotomized (twice a week), or smaller volumes of blood should be removed.
4. Hematocrit levels should be maintained at 45%.
5. The use of chemotherapeutic agents should be avoided in low-risk PV patients, and treatment with hydroxyurea or interferon (IFN) or ruxolitinib should be reserved for high-risk patients. Be on the lookout for toxicities from each of these agents.
6. Hyperuricemia is treated with allopurinol (100–300 mg/day).
7. Pruritus may be improved with PV-directed therapy (phlebotomy/hydroxyurea or IFN). Empiric therapy with antihistamines can be useful in selected patients. Selective serotonin uptake inhibitors (paroxetine 20 mg/day or fluoxetine 10 mg/day) or phototherapy can also be of use. Dramatic relief, however, can be achieved in almost all cases with the institution of ruxolitinib. Due to cost, ruxolitinib therapy should be reserved for individuals with pruritus not relieved by less costly strategies.
8. Elective surgery or dental procedures should be delayed until hematocrit levels have been normalized for more than 2 months. Aspirin should be withdrawn at least 1 week before surgery. If emergency surgery is contemplated, phlebotomy and cytapheresis should be pursued.
9. Women and men who are contemplating having children should be treated by phlebotomy plus low-dose aspirin therapy (81 mg/day) or with IFN- α to avoid teratogenic effects of chemotherapy. Such avoidance will also prevent deleterious effects on fertility. During pregnancy, therapy is frequently not necessary; if it is, phlebotomy plus low-dose aspirin should be exclusively used. If phlebotomy control is inadequate, treatment with IFN- α should be pursued.

³²P or phlebotomy. An early finding was the appearance during the first 5 years of a significant excess of deaths from acute leukemia in the chlorambucil arm, which reached 17% after 15 years of follow-up. As a result, the chlorambucil arm was discontinued, and patients were assigned randomly to one of the other two arms. Even though no statistical difference in overall survival between ³²P and phlebotomy alone was apparent through the first 10 years, the morbidity and mortality associated with each type of therapy were attributable to distinctly different causes. Thrombosis as a cause of death was much more frequent in the phlebotomy-only group during the first 5–7 years of follow-up. Analyses of factors associated with thrombosis revealed that the performance of phlebotomy, the rate of phlebotomy, advancing age, and history of previous thrombosis were statistically significant factors predictive of this outcome. Historical studies have raised concerns about therapy with phlebotomy alone. The need for more than four therapeutic phlebotomies a year in the phlebotomy-alone arm was associated with an increased thrombotic risk. This led to the belief that frequent phlebotomy requirements were detrimental and necessitated cytoreductive therapy. However, overall survival and risk of evolution to MF and AML were lower in the phlebotomy alone arm. Certain concerns about phlebotomy may be unfounded. Iron deficiency is a consequence of repeated therapeutic phlebotomy; but in fact, it should be viewed as a therapeutic goal to further limit

erythropoiesis. Although iron deficiency can be associated with a number of clinical signs and symptoms, including glossitis, dysphagia, cheilosis, koilonychia, fatigue, global weakness, cognitive deficits, neuromuscular disturbances, and pica syndrome, these rarely prompt treatment discontinuation. In contrast, the use of ³²P led to a lower rate of thrombosis during the first 5 years, but the incidences of leukemias, lymphomas, and nonhematologic malignancies increased during the next 5 years to nearly 10%. After a 15-year period of observation, the incidences of leukemia and lymphoma in the chlorambucil group had risen to 17%. A statistically significant increase in skin and gastrointestinal cancers occurred in the ³²P- and chlorambucil-treated cohorts compared with the group treated with phlebotomy alone (see box on [Algorithm for Management of Patients With Polycythemia Vera](#)). Based on these studies, therapy with chlorambucil and ³²P are no longer recommended.

Impetus for the use of nonchemotherapeutic agents for the treatment of PV was provided by an extensive natural history study of 1213 patients reported by the Gruppo Italiano Studio Policitemia. They showed that the age- and gender-standardized mortality rate of patients with PV was 1.7-times greater than the mortality rate of control participants in the general Italian population. In addition, four times as many patients who had previously received ³²P, alkylating agents, or hydroxyurea died of cancer compared with patients treated with phlebotomy alone. When this group combined the total number of deaths and the number of nonfatal myocardial infarctions and strokes, they found an unsatisfactory risk-to-benefit profile in patients treated with chemotherapeutic agents and suggested that antithrombotic strategies, such as low-dose aspirin, be carefully evaluated for use in the care of patients with PV.

PV platelets are known to have a generalized abnormality of arachidonate metabolism that is characterized by enhanced synthesis of thromboxane A₂, which likely reflects stimuli to platelet activation. The exact mechanism responsible for enhanced platelet synthesis of thromboxane A₂ in PV remains unknown and requires further investigation. A low-dose aspirin regimen (50 mg/day for 7–14 days) has been shown to suppress more than 80% of the excretion of the metabolites of thromboxane A₂. A pilot study was performed in which the toxicity of low-dose aspirin therapy in PV patients was evaluated. A very low-dose aspirin regimen (40 mg/day) was chosen to prevent thrombosis yet minimize the risk of bleeding. After follow-up of the low-dose aspirin treatment group and control group, low-dose therapy was shown not to be associated with an increased incidence of bleeding complications. Aspirin therapy was well tolerated and was associated with complete inhibition of platelet cyclooxygenase activity. A large, randomized, placebo-controlled clinical trial testing the risk-to-benefit ratio of low-dose aspirin therapy in preventing thrombotic episodes in PV has been completed. Treatment with low-dose aspirin (100 mg/day) compared with placebo reduced the risk of the combined end points of nonfatal myocardial infarction, nonfatal stroke, pulmonary embolism, major venous thrombosis, or death from cardiovascular causes. Overall mortality and cardiovascular mortality, however, was not reduced significantly by aspirin therapy. Importantly, the incidence of major bleeding episodes was not significantly increased in the aspirin group. It is important to emphasize that patients require aggressive phlebotomy therapy to the appropriate target hematocrit levels as well as the appropriate use of myelosuppressive agents as primary therapy, with the addition of aspirin serving as an adjunct to this strategy. The conclusions of this study have been questioned by several investigators. In addition, a retrospective analysis performed by independent investigators of the 630 patients treated by the ECLAP group has concluded that low-dose aspirin therapy in PV patients was associated with a statistically nonsignificant reduction in the risk of fatal thrombotic episodes without an increased risk of bleeding.²⁶ This meta-analysis is surely not a ringing endorsement of the widespread use of aspirin therapy, which is a strategy that has been indiscriminately used worldwide to treat such patients. Because it is unlikely that the value of aspirin therapy will be examined in a properly powered randomized trial, it is suggested that since aspirin therapy is a relatively innocuous therapy it should be used in high-risk patients judiciously.

Algorithm for Management of Patients With Polycythemia Vera

Low-Risk Young Patients (Age <60 Years) and No History of Thrombosis, Platelet Count $<1.5 \times 10^6 \text{ mm}^{-3}$

Phlebotomy + low-dose aspirin (81 mg/day) to maintain hematocrit lower than 45%. Aspirin should not be used in patients with histories of a hemorrhagic episode or with extreme thrombocytosis ($>1.5 \times 10^6 \text{ mm}^{-3}$) or acquired von Willebrand syndrome.

↓
Thrombosis or hemorrhage
Systemic symptoms
Severe pruritus refractory to histamine antagonists
Painful splenomegaly

↓
Hydroxyurea 15–20 mg/kg (unless age <40 years, pregnant, intolerant to hydroxyurea; consider pegylated interferon [IFN])

↓
Pegylated IFN 45–180 $\mu\text{g}/\text{week}$ or IFN- α (3×10^6 units three times a week; alter dose depending on response and toxicity) or ruxolitinib 10 mg twice daily and titrate dose depending on the response. →

In a patient with a prior thrombosis or a history of bleeding due to acquired von Willebrand's syndrome, normalization of platelet numbers is necessary. If platelet control is inadequate or the patient cannot tolerate interferon, one option is the use of anagrelide. In this case, supplemental phlebotomy is required to maintain hematocrit lower than 45%, and the use of hydroxyurea should be considered, especially if the patient continues to have thrombotic episodes.

↓
If the patient has increasing splenomegaly, systemic symptoms, or repeated thromboses despite adequate dose of hydroxyurea (2–3 g/day) or if unable to tolerate hydroxyurea, start ruxolitinib 10 mg twice daily and titrate up or down based on hematologic parameters

For patients unable to tolerate ruxolitinib or resistant to it, start low doses of busulphan or melphalan, which should be administered until the blood counts are normalized. Therapy should be then discontinued since patients frequently enjoy drug-free prolonged remissions lasting months. Therapy should only be reinstituted at the time the blood counts begin to be elevated again. Such therapy with alkylating agents should be rarely used in young patients. It should be mentioned that the sequential use of hydroxyurea and alkylating agents may be associated with an increased risk of leukemia. Supplemental phlebotomy may be required.

Painful splenomegaly

↓
Patients should be treated with ruxolitinib
If unable to tolerate or insufficient response
Splenectomy + continued systemic therapy

↓
High-risk patients (age >60 years), previous thrombosis, platelet count $>1.5 \times 10^6 \text{ mm}^{-3}$
Phlebotomy to hematocrit of 45%

Aspirin (81 mg/day) to be given only in patients with platelet counts $<1.5 \times 10^6 \text{ mm}^{-3}$

Myelosuppressive therapy with hydroxyurea 30 mg/kg orally for 1 week
Then 15–20 mg/kg

↓
If patient continues to have thrombotic episodes and has extreme thrombocytosis or cannot tolerate hydroxyurea

Consider pegylated IFN 45–180 $\mu\text{g}/\text{week}$, anagrelide, or ruxolitinib 10 mg twice daily, or add intermittent busulphan or melphalan (in older patients).

If on busulphan or melphalan, stop when blood counts are normalized or platelet count is lower than $300,000 \text{ mm}^{-3}$.

Occasional supplemental phlebotomy if hematocrit is >45%; when patient relapses (patient is symptomatic) initiate busulphan therapy again at same dose.

Patient Age >70 Years

Phlebotomy + low-dose aspirin + hydroxyurea

↓
No response or poor compliance
Ruxolitinib, melphalan, or busulfan.

However, it should be avoided in patients with extremely high platelet counts who are at risk for hemorrhage.

After the disappointing results experienced with the alkylating agent chlorambucil, the PVSG began a nonrandomized phase II investigation of hydroxyurea, an S-phase-specific ribonucleotide reductase inhibitor. The hope was that this agent would be nonleukemogenic. Of 53 patients with PV treated with hydroxyurea who had never received other forms of myelosuppression, after follow-up for a median period of 8.6 years and a maximum follow-up of 795 weeks, 5.4% developed acute leukemia compared with 1.5% of patients treated with phlebotomy alone on the original PVSG randomized study.

In a comparable trial from Israel, 71 patients were treated with hydroxyurea for a mean duration of 7.3 years. Remarkably, the incidence of thrombosis was only 6%, indicating the potential of hydroxyurea to lower the incidence of thrombosis in patients with PV, confirming an observation previously made by another group. The incidence of leukemia in the Israeli trial was 5.6%. In another retrospective series, the incidence of acute leukemia and myelodysplasia in patients with PV treated with hydroxyurea alone was 6.9%. In patients treated first with busulphan and then hydroxyurea, the rate of acute leukemia and myelodysplasia was 13.8%. Twenty-two patients developed AML and MDS in the ECLAP study that enrolled 1638 patients. AML and MDS were diagnosed after a median of 8.4 years from the diagnosis of PV; the variable associated with progression was older age, but overall disease duration (>10 years) failed to reach statistical significance. Exposure to P^{32} , busulphan, and piprobroman but not hydroxyurea alone had an independent role in producing an excess risk for progression to AML and MDS compared with treatment with phlebotomy or IFN. The potential leukemia-promoting potential of hydroxyurea has been readdressed in two additional studies. Kiladjian and coworkers²⁶ reported the results of a randomized trial of hydroxyurea versus piprobroman that was initiated in 1980; the overall survival was 20.3 years in the hydroxyurea-treated group compared with 15.4 years for the patients treated with piprobroman. The incidence of AML and MDS in the piprobroman group was dramatically higher, which is not unexpected because piprobroman is an alkylating agent. This trial was designed with a cross-over option, but 93 patients only received piprobroman. The incidence of AML and MDS in the patient group that only received hydroxyurea was 7.3%, 10.7%, and 16.6% at 10, 15, and 20 years, respectively. Since there was not a control arm treated with phlebotomy alone, one cannot determine if this rate of evolution to AML/MDS represents the natural history of PV or a possible limited leukemogenic effect of hydroxyurea. Interestingly, no difference in the incidence of vascular events was seen between the two arms. This same question was again addressed in a nested case-control study performed in Sweden.²⁷ The most important observation was that 25% of patients with various MPNs (68% had PV) who evolved to AML and MDS had not been exposed to any chemotherapeutic agent, indicating that the risk of leukemic evolution was higher than had been previously appreciated. The use of radioactive phosphorous and alkylating agents, but not hydroxyurea, was associated with a higher rate of AML and MDS. These reports indicate that nontreatment-related factors play a major role in the development of AML and MDS, and the contribution of hydroxyurea based on the best available evidence is at best minimal. These data and the ease of administration make hydroxyurea a very useful chemotherapeutic agent in older, high-risk patients with disease that cannot be controlled with phlebotomy alone. Excessive myelosuppression, macrocytosis, hypersegmentation of polymorphonuclear leukocytes, cutaneous actinic keratosis, squamous cell carcinoma of the skin, hyperpigmentation of the skin and nail beds, stomatitis, painful leg ulcers, creatinine elevations, and jaundice have been attributed to the use of hydroxyurea. Aphthous and leg ulcers occur in 9% of patients, usually after approximately 10 months of therapy (see Fig. 68.11).²⁸ Rarely, cycling of platelet and leukocyte counts but not RBCs occurs while patients are being treated with hydroxyurea. In this situation, the authors have maintained patients on a fixed dose of hydroxyurea rather than chasing cycling platelet counts. In addition, the use of

Fig. 68.11 EXAMPLE OF A HYDROXYUREA-INDUCED LEG ULCER. (From Soutou B, Aractingi S: *Myeloproliferative disorder therapy: Assessment and management of adverse events: A dermatologist's perspective*. Hematol Oncol 27:11, 2009.)

hydroxyurea requires patient compliance and careful monitoring of blood counts to avoid the sequelae of excessive myelosuppression.

Some clinical investigators have suggested that a program of phlebotomy alone with low-dose aspirin is the most appropriate for younger patients who have not experienced a cerebrovascular or cardiovascular event.

Anagrelide, a selective inhibitor of platelet production, has been used to treat uncontrolled thrombocytosis not responsive to hydroxyurea in PV patients with thrombotic or hemorrhagic complications. This agent appears to be nonleukemogenic and acts by impairing megakaryocyte maturation. Its use leads to a selective reduction in platelet numbers, and it has been effective in patients refractory to hydroxyurea and IFN. This drug does not effectively control the erythrocytosis and leukocytosis or systemic symptoms associated with PV, and therefore is best used as a supplement to phlebotomy therapy. The time to complete response generally ranges between 17 and 25 days. The dose of anagrelide required to control thrombocytosis remains constant over time in most patients. When anagrelide is discontinued, platelet counts returned to pretreatment levels within 5–7 days. The simultaneous administration of anagrelide and low-dose aspirin has been reported to lead to a significant increase in bleeding manifestations. Clinicians presume that the effects of anagrelide observed in ET patients will be relevant to patients with PV. This assumption has not been tested in a randomized clinical trial. Anagrelide therapy should be reserved for patients with recent thromboses (e.g., stroke, migraines, erythromelalgia) and with thrombocytosis that cannot be controlled with IFN, hydroxyurea, or ruxolitinib therapy alone. It can also be used in combination with hydroxyurea to minimize adverse events that accompany the use of each drug alone. Anagrelide should not be used in pregnant patients because it can easily cross the placenta, leading to adverse effects on the platelet count of the fetus.

Approximately 15–20% of patients treated with anagrelide discontinue the medication because of nonmyelosuppressive side effects. The spectrum of adverse effects involved neurologic (headaches and dizziness), cardiac (vasodilatation, fluid retention, congestive heart failure, palpitations, and tachycardia), and gastrointestinal (nausea) toxicities. These toxicities reflect the novel mechanism of action of anagrelide as a cyclic nucleotide phosphodiesterase inhibitor. Anagrelide should be used with caution in patients with known or suspected cardiac disease because of its ability to promote fluid retention. Because many patients with PV are elderly, careful attention to fluid status should be maintained to avoid slipping into congestive heart failure after the initiation of anagrelide.

IFN- α therapy has been explored for several decades for the treatment of PV patients, but its positive effects have been more greatly appreciated during the past 7–12 years.²⁹ Its effects on myeloid malignancies are likely the consequence of its broad range of biologic

activities, including direct effects on malignant cells, enhancement of antitumor immune responses, induction of proapoptotic genes, inhibition of angiogenesis, and promotion of the cycling of dormant malignant stem cells. Because of the recent development of “targeted” therapies, the use of IFN has been dramatically reduced over the past decade. The increasing awareness of the numerous mutations beyond those involving *JAK2* suggest, however, that such an approach using target-specific agents is not universally effective. This awareness provided the rationale for the use of an agent such as IFN- α that might be especially useful for the treatment of a disease in which multiple genetic, epigenetic, and environmental factors contribute to its origin and progression. IFN- α promotes apoptosis of a variety of tumor cell types. The induction of apoptosis by IFN- α involves the activation of a number of IFN-stimulated genes that mediate this response. Gene expression studies have identified more than 15 IFN-stimulated genes with proapoptotic functions. Although these IFN-stimulated genes alone are probably not sufficient to induce apoptosis, their cumulative effects likely result in apoptosis. Type 1 IFNs suppress the ability of normal human HPCs to proliferate in vitro in the presence of cytokine combinations. IFN- α acts directly against HPCs; this inhibitory activity has been documented using CD34⁺ cell populations. PV CD34⁺ cells are more sensitive to the inhibitory effects of IFN- α than normal HPCs.

The ability of type 1 IFNs to inhibit HPC proliferation and maturation has been documented to occur independently of the STAT pathway. Type 1 IFNs activate the p38 MAP kinase, a proline-directed serine/threonine kinase that is required for IFN-stimulated gene transcription through IFN-sensitive response elements (IRSE). The pharmacologic blockade of p38 in IFN-treated PV HPCs reverses the inhibitory effects of IFN- α . Activation of p38 MAP kinase results in mitochondrial translocation of the proapoptotic protein Bax, leading to the induction of apoptosis.

IFN has also been shown to be able to affect HSC behavior. High levels of IFN- α induce murine HSCs to exit from a normally quiescent state and to transiently proliferate. Several studies using either primary PV CD34⁺ cells or murine models of *JAK2V617*-positive PV have provided evidence that IFN- α is able to selectively deplete malignant PV stem cells. In the United States, the pioneering study by Silver in 1988 documented the clinical effectiveness of IFN- α in controlling erythrocytosis as well as pruritus and other constitutional symptoms in PV patients, and Austrian and French groups reported during the same period evidence that IFN- α was also effective in reducing thrombocytosis in ET patients. A number of clinical trials have been performed subsequently using several different commercial preparations of IFN. In almost all PV and ET trials, IFN- α therapy rapidly normalized platelet numbers and corrected the degree of leukocytosis and erythrocytosis, allowing reduction in the requirement for phlebotomies within a few months. In both diseases, an objective hematologic response was observed in about 80% of patients, including complete freedom from phlebotomies in PV in 60% of patients. In addition, IFN- α was also able to reduce PV-associated pruritus in a significant number of patients and appears to be an effective drug for this purpose. However, toxicity associated with IFN- α therapy was not trivial, leading to the discontinuation of treatment in almost 25% of patients. A pegylated form of IFN has been used with increasing frequency to treat patients with a variety of MPNs with great success. This form of IFN can be administered once weekly, and its use is associated with a more favorable toxicity profile. Several phase II studies using peg-IFN α -2a in PV and ET showed similarly impressive hematologic response rates compared with standard IFN- α , but with less associated toxicity (<10% of patients discontinued therapy during the first year of therapy). In addition, these studies showed for the first time evidence of significant molecular responses, as documented by a clear reduction in the *JAK2V617F* allele burden after IFN- α treatment. Overall, the two clinical trials with peg-IFN α -2a showed a meaningful and progressive reduction in the *JAK2V617F* allele burden in about 70% of PV and 40% of ET patients. Importantly, the *JAK2V617F* mutation became undetectable (with 1% sensitivity PCR assays) in 24% of PV patients in the French PVN-1 study after about 3 years' median follow-up,

and in 14% and 6% of PV and ET patients, respectively, in the United States study after about 2 years' median follow-up. Combining both studies, 12 out of 64 (19%) PV patients achieved a molecular complete response (MCR). Of note, many of these MCRs occurred after the 12th month of treatment, but hematologic responses occurred within a few weeks. Prolonged exposure (>12 months) to peg-IFN α -2a seems to be an important factor in achieving MCR. The reduction in the *JAK2V617F* allele burden was not influenced by the cumulative dose of peg-IFN α -2a in the PVN-1 study, but toxicity was clearly dose dependent in the United States study. Taken together, these results indicate that peg-IFN α -2a therapy is best initiated at very low doses that are gradually increased until hematologic response is achieved; this strategy avoids cessation of therapy and allows sufficient exposure to the drug to allow for the achievement of a molecular response. These results are in agreement with studies from Denmark, showing major molecular responses in PV after long-term treatment with IFN α -2b that could persist after IFN- α was discontinued. Finally, several who achieved MCR in the PVN-1 study have maintained this response after peg-IFN α -2a was discontinued (≤ 30 months after discontinuation), with none experiencing hematologic relapse. Such long-term clinical and molecular responses after the discontinuation of treatment have previously been reported after IFN- α therapy in MPN patients, an effect that has not been reported with other currently available therapies. It is important to emphasize that the elimination of *JAK2V617F* in this setting is not necessarily indicative of cure of the MPN, and that clinical implications of these molecular responses remain uncertain and require validation. It has been shown that molecular relapse can rapidly occur after IFN- α discontinuation in some cases. In one patient with a bclonal *JAK2V617F/TET2*-mutated PV, peg-IFN α -2a treatment did not affect the *TET2*-mutated cells, but the *JAK2V617F* clone was eradicated. Nevertheless, prolonged periods of time (≤ 40 months, personal unpublished data) during which the patient remained in complete hematologic remission without any cytoreductive therapy after peg-IFN α -2a withdrawal was observed in several patients of the PVN-1 study even though low levels of the *JAK2V617F* allele ($\approx 5\%$) were still detected. Such results suggests that despite the disease not being eradicated, long-term exposure to peg-IFN α -2a was sufficient to modify the clinical expression of the MPN for a sustained period of time.

In addition to clinical, hematologic, and MCRs achieved in a significant proportion of PV and ET patients, IFN- α therapy has also been shown recently to reverse BM histopathologic abnormalities in selected cases of both PV and PMF. Thus, IFN- α seems to be a drug able to deplete PV stem cells, and induce complete resolution of all clinical, biologic, and morphologic abnormalities in selected MPN patients, raising the hope that a curative outcome might be possible in a limited subset of such patients. These observations lead one to question the validity of the current therapeutic strategies for PV and ET patients in which myelosuppressive therapy is exclusively used in subpopulations of patients at high risk for developing additional thrombotic events.

IFN is not a leukemogenic drug but it is also not an innocuous agent, necessitating careful follow-up of patients receiving such treatment. Initially, many patients experience flu-like symptoms, which are controllable with acetaminophen or aspirin. Such symptoms usually resolve spontaneously after several months of therapy. More serious side effects, including excessive suppression of blood counts, irritability, high fevers, severe asthenia, reversible lower extremity bilateral neuritis, retinopathy, hypothyroidism, depression, sarcoidosis, and left-sided heart failure have been reported and may require cessation of IFN- α therapy. Exacerbation of depression and other psychiatric manifestations are serious potential side effects of IFN, and it should probably not be used in patients with history of clinically significant psychiatric conditions. Patients and family members should be counseled to watch for subtle evidence of depression, mood swings, and personality changes and to immediately report their concerns to the treating physician. The use of IFN should also be avoided in patients with any history of autoimmune diseases and new development of autoimmune disorders should be high on the

differential diagnosis of patients being treated with any formulation of IFN. The role of pegylated IFN therapy versus hydroxyurea therapy or pegylated IFN versus ruxolitinib will be defined only after the performance of a randomized phase III trial in newly diagnosed high-risk ET and PV patients. Two randomized multicenter trials comparing IFN and hydroxyurea are currently ongoing and will hopefully establish differences in terms of efficacy and tolerability of the two medications.

The use of small-molecule inhibitors of JAK1/2 ruxolitinib was first approved in the United States in 2011 for the treatment of advanced forms of MF, and most recently in 2015 was approved for the treatment of patients with PV that are intolerant or resistant to HU. In a phase III study (RESPONSE trial), hydroxyurea resistant or intolerant patients were randomized to receive either ruxolitinib or standard care.³⁰ To be eligible for the study entry patients had to have splenomegaly with a spleen volume of at least 450 cm³ and ongoing phlebotomy requirements, and be resistant to or intolerant of hydroxyurea according to the standardized criteria. Standard care was selected by the investigator and included hydroxyurea. Patients receiving standard therapy were able to cross over to ruxolitinib if they failed to achieve the primary end point by 32 weeks. The primary end point was achievement of hematocrit control and reduction in spleen size (at least 35% by MRI). This was achieved in 21% of patients in the ruxolitinib arm versus 1% of patients in the standard therapy arm. Hematocrit control was achieved in 60% of patients receiving ruxolitinib and 20% of patients receiving standard therapy, and 38% of patients in the ruxolitinib arm met the reduction in spleen end point versus 1% of patients in the standard therapy arm. By week 80, almost 60% of patients treated with ruxolitinib had normalization of their platelet counts. Patients on ruxolitinib enjoyed improvement in such PV-related symptoms as pruritus, headaches, fatigue, and night sweats. The mean change in *JAK2V617F* allele burden from baseline to week 32 was 12.2% in the ruxolitinib group and 1.2% in the standard therapy group. Based on an analysis after 80 weeks of follow-up, there was a suggestion that those patients receiving ruxolitinib had a reduced incidence of serious thrombotic events but that ruxolitinib therapy did not affect progression to MF and AML; these conclusions are not well substantiated since the study was not powered to examine these events. It also did not provide information on correction of the BM histopathological findings and chromosomal abnormalities in patients treated with ruxolitinib. In general, ruxolitinib was well tolerated with 85% of patients remaining on ruxolitinib at 81 weeks. The most common nonhematological adverse event was diarrhea, while the hematological toxicity included anemia, lymphopenia, and thrombocytopenia. In addition the rates of nonmelanoma skin cancer were higher in the ruxolitinib arm compared with those patients receiving standard therapy. An increase in infectious complications was observed on ruxolitinib treatment, specifically herpes zoster infection. This has also been observed in MF patients treated with ruxolitinib. Cases of tuberculosis activation, toxoplasmosis, and other atypical infections have been reported in ruxolitinib-treated patients. The increased number of infections has been attributed to the inhibition of both T- and NK-cell function by ruxolitinib.

Pruritus in PV patients occurs on exposure to sudden body cooling, especially after a warm bath, and is experienced by as many as 40–60% of patients treated with phlebotomy. Aquagenic pruritus in MPN patients and in patients without an associated malignancy has been associated with lactose intolerance. In some instances, multiple family members are affected, suggesting that genetic factors might predispose individuals to this symptom. In some studies, basophils and mast cells have been shown to be involved with *JAK2V617F* in patients with aquagenic pruritus and PV, likely leading to the elaboration of mediators that lead to itching. The frequency of pruritus appears to be somewhat lower in patients treated with myelosuppressive agents. This observation is related to the probable relationship between pruritus and degranulation of tissue mast cells and circulating basophils. Aged transgenic mice expressing *JAK2V617F* suffer from pruritus and the massive accumulation of mast cells in the skin. Cultured mast cells from these mice

exhibited enhanced proliferative signals, relative resistance to cell death upon growth factor deprivation, and a growth advantage over control cells under suboptimal growth conditions. A JAK inhibitor was shown to reduce mast cell numbers and alleviate pruritis in *JAK2V617F* transgenic mice. Some uncontrolled studies have attributed pruritus to hyperhistaminemia or severe iron deficiency, with relief associated with the use of histamine antagonists or ferrous sulfate. Iron replacement is frequently not possible because it can lead to dangerous elevations of the RBC mass. In a number of instances, however, iron replacement has been possible with disease control with IFN- α . The association between pruritus and tissue infiltration by mast cells would appear to explain the response of occasional patients to photochemotherapy with psoralens and ultraviolet irradiation. In addition, 80% of patients with pruritus have been reported to respond to the selective serotonin uptake inhibitors paroxetine or fluoxetine. Other effective options include anticonvulsant drugs such as pregabalin. Ruxolitinib and other JAK inhibitors both in PV and PMF have a remarkable effect on reducing the severity of intractable pruritus that not infrequently affects PV patients. These drugs appear to be much more effective in treating this particular symptom of PV compared with both hydroxyurea and IFN, but in occasional patients this effect, unfortunately, is not sustained.

BCS is a catastrophic illness that can lead to significant morbidity and mortality in patients with PV. Patients with MPN are at a high risk of developing this syndrome. Independently, the use of oral contraceptive pills and congenital and acquired thrombophilic factors are involved in its development. A number of cases of hepatic vein thrombosis have been reported in nonpolycythemic women taking oral contraceptives. Although no data are available, one must be concerned about the use of oral contraceptives in women with PV.

The optimal approach to the problem of BCS is obviously preventive and involves maintenance of normal blood values in the patient with PV. When BCS develops, the prognosis without treatment is dismal. The goals of therapy are to prevent further propagation of thrombus, relieve the intense hepatic congestion, and manage the severe ascites that often plague these patients. If untreated, these patients often have a slowly progressive course, with deterioration and death occurring within 3.5 years. Spontaneous resolution of the hepatic vein occlusion rarely occurs. There are no prospective randomized trials of anticoagulation in BCS, but retrospective studies suggest a survival benefit. Anticoagulation should be continued indefinitely unless there is a contraindication. Typically, low-molecular-weight heparin (LMWH) is used as the initial treatment with subsequent switch to warfarin. New oral anticoagulants that act by direct thrombin or factor Xa inhibition are being increasingly used for various prophylactic and therapeutic indications, but their use for these patients should be avoided until more reversal agents become available and the experience of using them becomes more widespread. The use of thrombolytic therapy directly in the thrombosed vein is infrequent due to the lack of data and potentially high risk of bleeding. Angioplasty with or without the use of stents attempts to restore hepatic blood flow and is often used if anticoagulation is not successful, and should be considered if liver function is deteriorating despite therapeutic anticoagulation. The overall success rate is about 95%, with a low periprocedural complications rate. The clinical deterioration of patients with BCS results from damage to the hepatocytes from necrosis associated with marked elevation in sinusoidal pressure coupled with ischemia from reduced hepatic arteriole perfusion. The only rational therapeutic intervention, therefore, involves some sort of portal vein decompression to achieve an effective reduction of sinusoidal pressure. Portosystemic shunting such as transjugular intrahepatic portosystemic shunt (TIPS) has been used extensively to treat refractory portal hypertension. Recent data show good long-term outcomes when using TIPS, and it is now considered standard management if anticoagulation or angioplasty are not successful, or if patients have high-risk disease. It has been shown that about a third of patients with BCS require TIPS placement. One-year survival in a recent large UK single-center study was 97% and 5-year survival 72%. Procedure-related complications are frequent but mortality rates are low.

Liver transplantation is a potential option for treatment of PV BCS patients with continued hepatic decompensation. The indications for liver transplantation are cirrhosis, fulminant hepatic failure, and failure of a portosystemic shunt. The overall actuarial survival at 1 year was 76% and was 68% at 10 years. Because PV is a slowly progressive disease, transplantation should not be withheld from these patients. Pretransplant predictors of mortality based on a multivariable analysis were impaired renal function and a history of a shunt. The hematologic consequences of polycythemia must be aggressively treated in the posttransplantation setting; hepatic vein occlusion may reoccur in the transplanted liver.

Therapy of CVT and sinuses includes anticoagulation with heparin to arrest the thrombotic process and to prevent pulmonary embolism. LMWH should be started as soon as the diagnosis is confirmed even in the presence of hemorrhagic infarcts. After the acute phase, life-long oral anticoagulant therapy is recommended. There is currently no available evidence from randomized clinical trials regarding the efficacy or safety of thrombolytic therapy.

The performance of any surgical procedures on patients with PV is, as previously discussed, accompanied by excessively high morbidity and mortality. Elective surgery should not be contemplated unless the patient's hematologic values have been normalized for several months. The longer the hematologic control has been in effect, the lower the incidence of postoperative complications. If emergency surgery is required, the patient should be phlebotomized rapidly until a normal hematocrit is reached, and platelets should be available in case excessive perioperative or postoperative bleeding occurs. After emergency or elective surgery, the patient should be mobilized as soon as possible, and strong consideration should be given to anticoagulation with LMWH unless the patient has some contraindication. Dental extractions can also result in excessive hemorrhage and should not be performed unless the patient is under strict hematologic control.

Perhaps the most difficult and frustrating period encountered during the clinical course of a patient with PV is the development of post-PV MF. The origins, manifestations, and management options are discussed in detail in [Chapter 70](#).

Limited information is available concerning the treatment of patients who develop acute leukemia after PV. The overwhelming majority of such cases involve myeloid leukemias. The leukemia is frequently preceded by post-PV MF but not always. Patients with post-PV MF and acute leukemia frequently have greater than 20% blasts in the peripheral blood but far fewer blast cells in the BM, which has led to a hypothesis that the leukemia originates from an extramedullary site, particularly the spleen. These cases tend to have a more indolent course, but patients with a greater degree of BM infiltration have a more highly proliferative form of leukemia that is associated with an even more aggressive course. The optimal treatment of such patients is unknown. In elderly adults with significant comorbidities, the choice not to institute chemotherapy is a reasonable option. These patients are frequently elderly, and poor results with standard regimens have been reported. Patients rarely achieve a complete remission but rather return to a clinical condition that resembles their original MPN for limited periods of time. In a retrospective analysis on 23 patients with leukemic transformation of PV, the median patient age was 68 years, and leukemia developed a median of 12.8 years from the diagnosis of PV. Twelve of the 14 patients in whom cytogenetic analyses were performed had complex cytogenetic abnormalities associated with high-risk leukemias. Fifteen patients were treated with palliative measures and had a median survival of 2.5 months. Of the eight patients treated with standard induction therapy, one obtained a complete remission, and seven died without obtaining a response. The median survival time of these chemotherapy-treated patients was 5.6 months. The median survival time of the entire cohort of 23 patients was 2.9 months. This poor outcome is likely the result of clinical and biologic features of the acute leukemia, advanced patient age, unfavorable cytogenetics, and patient comorbidities associated with advanced age. Selected patients are likely to tolerate and have a favorable outcome with allogeneic stem cell transplantation and reduced-intensity conditioning. In fact,

the only long-term survival with post-PV leukemia has been observed in patients receiving allogeneic stem cell transplantation. Whether the patients should receive some form of induction chemotherapy before receiving conditioning therapy for preparation of the transplant or proceed directly to transplant is a decision that varies from patient to patient and from center to center. Most patients with PV-related acute leukemia should be considered candidates for experimental therapeutic strategies. Recently, promising results with the use of DNA hypomethylating agents such as decitabine or azacitidine alone or in combination with ruxolitinib have been reported, with 50–60% of patients achieving clinically significant responses persisting for 6–24 months in the majority of cases. These chemotherapeutic regimens can frequently be administered as an outpatient but require treatment for at least six monthly cycles before clinical responses can be evaluated. Although many of these patients do not achieve true complete remissions, their prolonged survival and quality of life, at least based upon single-institutional studies, appears to be superior to that achieved with standard induction chemotherapy. The use of hypomethylating agents, JAK2 inhibitors, or both is now being explored as bridging therapies before patients receive allogeneic transplants.

PV occurs frequently during childbearing years. A discussion of contraception options is imperative because the use of oral contraceptive pills may be associated with an increased risk of deep venous thrombosis as well as splanchnic vein thrombosis. It seems prudent to entertain alternative forms of contraception with such individuals. Discontinuation of hydroxyurea in both men and women desiring to have a child is recommended. Hydroxyurea is capable of inducing azoospermia in men, frequently limiting their ability to father a child. Pregnancy is itself a prothrombotic condition. PV in a pregnant individual has been reported to lead to an increased incidence of fetal wastage, with 30% of pregnancies in PV patients terminating in spontaneous abortions. In addition, preeclampsia occurs more frequently in these women. A team approach requiring close communication between an obstetrician skilled in providing care for high-risk pregnancies and the responsible hematologist provides the optimal integration of care to the mother and the child. Pregnancy in PV patients is frequently associated with a gradual normalization of blood values, and it is not unusual for a woman who has required extensive therapy for control of her disease to no longer require phlebotomies during pregnancy. Delivery appears not to be complicated by excessive hemorrhage, but the postpartum period carries an increased risk of venous thrombosis. Although some degree of hematocrit level normalization can be explained by expansion of the plasma volume or by nutritional deficiencies that occur during pregnancy, it is unlikely that these factors can be solely responsible. It seems more reasonable to assume that the high estrogen levels characteristic of pregnancy suppress erythropoiesis. After completion of the pregnancies, the patients' hematologic values slowly drift back to their previously elevated values in parallel with the return to normal estrogen levels. Because pregnancy is usually associated with spontaneous control of the polycythemic state, no specific therapy is required except for careful observation. If needed, therapy should be limited to phlebotomy and low-dose aspirin therapy because of the mutagenic effects of chemotherapeutic agents. Aggressive treatment of hypertension is imperative, as well as attention to the risk of developing preeclampsia and toxemia, which should be treated in a standard fashion. In individuals with a history of repeated spontaneous abortions associated with placental infarction, consideration should be given to low-dose aspirin with LMWH therapy, making sure that these agents are discontinued at the time of delivery to avoid the risk of excessive hemorrhage. If this approach is not successful, IFN therapy is suggested because it is not known to be leukemogenic or teratogenic and does not cross the placenta. In the puerperium, thromboprophylaxis with 6 weeks of LMWH therapy is recommended. Aggressive intervention with hematocrit levels maintained below 45% and aspirin therapy with LMWH is associated with a positive outcome for the pregnancy. Breastfeeding is recommended if the mother is receiving therapy with heparin or Coumadin as long as the baby receives adequate supplementation with vitamin

K. Rapid mobilization of the mother after delivery is of great importance.

Because PV is ultimately a stem cell disorder, it should be possible to achieve a cure with stem cell transplantation. Thus far, the majority of patients undergoing allogeneic stem cell transplantation have been relatively young and have been transplanted after evolution to MF, MDS, or acute leukemia. Transplantation during the polycythemia phase of the disease is rarely appropriate.

FUTURE DIRECTIONS

The discovery of *JAK2V617F* mutations has led to a more comprehensive understanding of the pathophysiology of the MPNs, including PV. There is no question that the diagnostic tests for *JAK2V617F* and exon 12 mutations of *JAK2*, as well as mutations in *VHL*, *HIF-1*, *HIF-2*, the *EPOR*, and *PHD* have revolutionized the diagnostic approach to patients with erythrocytosis. PV is a stem cell disease that will ultimately require curative therapies at a minimum to deplete or eliminate malignant stem cells if curative small-molecule therapies are to become a reality. Before the *JAK2V617F* allele burden is used as a biomarker for outcomes of novel therapeutic approaches to treat patients with PV, studies are needed to determine the extent of reduction of allele burden that would be predictive of altering the natural history of PV and eliminating complications from thrombotic episodes or evolution to MF or acute leukemia. The use of drugs affecting only JAK2 are unlikely to be curative because multiple genetic and epigenetic events likely contribute to the origins and progression of PV. Randomized clinical trials of combinations of drugs, rather than single drugs, and comparing these outcomes with the standard of care are more likely to lead to significant advances in improving the natural history of PV patients.

ESSENTIAL THROMBOCYTHEMIA

John Mascarenhas, Camelia Iancu-Rubin, Marina Kremyanskaya, Vesna Najfeld, and Ronald Hoffman

Essential thrombocythemia (ET) is a chronic myeloproliferative neoplasm (MPN) characterized by platelet counts in excess of $450 \times 10^9/L$, profound bone marrow (BM) megakaryocyte hyperplasia, leukocytosis, splenomegaly, a clinical course punctuated by hemorrhagic and/or thrombotic episodes, and possible evolution to myelofibrosis (MF) and acute leukemia. ET is a clinically heterogeneous disorder, with more than half of patients meeting the criteria for diagnosis being asymptomatic at presentation. ET was first described in 1934 by Epstein and Goedel, who described a patient with an elevated platelet count who had repeated hemorrhagic episodes.

EPIDEMIOLOGY

The true incidence of ET is unknown because extensive epidemiologic studies are not available. The incidence of ET has been estimated to be approximately 1.5–2.4 patients per 100,000 populations annually. A Swedish study indicated that first-degree relatives of patients with an MPN, including ET, had a five- to sevenfold increased risk of developing an MPN, supporting the concept that there is a strong genetic predilection. ET occurs in individuals with a median age of 67–73 years. To gain additional insight into the patterns of occurrence of MPNs by age, sex, race/ethnicity, and susceptible populations, and provide a population-based assessment of patient survival, Srour and coworkers¹² used data from the Surveillance, Epidemiology and End Results (SEER) Program from the National Cancer Institute in the United States to better assess the incidence of MPNs in the United States from 2001 to 2012. Importantly, during part of this period of time the use of mutational analyses in making the diagnosis of MPNs became widespread. There were 31,904 MPN cases diagnosed among residents of 18 SEER registries evaluated. The age-adjusted incidence rates (IRs) were as follows: polycythemia vera (PV) 10.9 per 1 million patient years, ET (9.6), chronic myeloid leukemia (CML; 3.3), and primary myelofibrosis (PMF; 3.1). ET was the only MPN with a significantly lower IR among males than females; the average age at diagnosis was 68 years. The female predominance was most pronounced in individuals less than 60 years of age. Surprisingly, the IR of ET was 18% higher among blacks than non-Hispanic whites; ET was associated with a female predominance among non-Hispanic whites, white Hispanics, blacks and Asian-Pacific islanders, suggesting shared gender-specific risk factor(s) across these racial/ethnic groups.

The incidence patterns observed by Srour and coworkers¹² support inherent differences in susceptibility to developing an MPN. This study is of importance, since it represents the first step in appreciating the potential of molecular diagnostics on improving our understanding of the epidemiology of the MPNs. Future studies will need to include not only *JAK2V617F* analyses, but also documentation of mutations in calreticulin (*CALR*) and the thrombopoietin receptor (*MPL*). These data suggest that ET is a relatively common hematological malignancy that has an especially significant impact on women.

Recently, several groups have identified shared susceptibility genes that predispose individuals to develop one of the MPNs. The Janus kinase 2 (*JAK2*) mutations (*V617F* and exon 14 mutations) are not acquired randomly, but arise preferentially on a specific *JAK2*

haplotype (46/1). The *JAK2* 46/1 haplotype has been shown not only to predispose to *JAK2V617F*-positive ET, but also to ET harboring *MPL* and *CALR* mutations, again indicating that genetic factors play a role in the susceptibility to develop ET. Tapper and coworkers¹³ also identified an additional two single-nucleotide polymorphisms (SNPs), rs12339666 within *JAK2* and rs2201862, 153 kb downstream of the DS1 and EVI1 complex locus protein EVI1 (*MECOM*), which were associated with *JAK2V617F*-negative MPNs. Two additional SNPs, rs2736100 in telomerase reverse transcriptase (*TERT*) and rs9376092 between *HBS1L* and *MYB*, were associated with *JAK2V617F*-positive MPNs. The SNP between *HBS1L* and *MYB*, rs9376092, however, had a stronger effect on MPNs associated with *CALR* and/or *MPL* mutations, whereas in *JAK2V617F*-positive cases rs9376092 was associated with ET rather than PV. These investigators demonstrated that the candidate risk allele at rs9376092, which had a strong association with ET, was associated with reduced *MYB*. Prior functional analyses had shown that mice expressing low levels of *MYB* develop a transplantable ET-like disease. These findings indicate that multiple germ-line variants predispose to the development of each of the MPNs and link constitutional differences in *MYB* expression, in particular to ET.

ET has rarely been reported in the pediatric age group. The incidence of ET in childhood has been reported to be approximately 1 per 10^7 population, which is 60-times less than that in adults. Approximately 30% of children with this disorder experience thrombotic or hemorrhagic complications at diagnosis or later in their course, and 50% have splenomegaly. Mutations in one of the established MPN driver genes *JAK2*, *CALR*, or *MPL* were present in a lower percentage of pediatric cases (34%) compared with adult MPN patients (90%). The subgroup of patients without a detectable driver mutation tended to have higher platelet counts compared with patients with mutations.

Several families with multiple members having ET have been described. The prevalence of the *JAK2V617F* mutation in familial cases of MPN has been analyzed in 72 families, including 174 patients (68 with ET). The *JAK2* mutation was found in half of patients with ET, and a similar proportion as observed in sporadic, nonfamilial cases. Among 46 families with at least two cases of PV, ET, or PMF, the *JAK2* mutation was absent in six families, heterogeneously distributed in 18, and present in all patients with MPN in 22. Thus, the *JAK2* mutation does not seem to be required for the development of ET or other MPNs, and this familial clustering cannot be accounted for by the prevalence of the *JAK2* 46/1 haplotype. In familial MPNs, *CALR* mutations can also be somatically acquired and are associated with an ET or PMF phenotype.

PATHOBIOLOGY

ET is a clonal hematological malignancy originating at the level of the hematopoietic stem cell. The thrombocytosis that characterizes ET is caused by increased platelet production by megakaryocytes. Effective platelet production is increased as much as 10-fold and is associated with an increase in megakaryocyte clustering, volume, nuclear lobe number, and nuclear ploidy.

ET is typically a clonal hematopoietic disorder originating at the level of the pluripotent hematopoietic stem cell. A significant

proportion of nonclonally derived leukocytes exist in addition to the clonally derived population of leukocytes in patients with ET. In one study of 42 patients with ET, 31 patients exhibited clonality of at least one hematopoietic lineage, but the remaining 11 patients had polyclonal origin of all lineages studied. The biogenesis of polyclonal ET remains ill defined. It is possible that small numbers of normal hematopoietic stem cells account for this admixture of nonclonal populations. It has been reported by several groups that ET patients with polyclonal hematopoiesis have fewer thrombotic complications. Interestingly, in some patients, monoclonality of hematopoiesis is restricted to platelets despite the polyclonal origin of the other lineages. Other studies, however, have indicated a common origin of granulocytes, platelets, and B lymphocytes in this disorder. Such studies raise the possibility that the malignant transformation leading to ET occurs at a number of cellular stages along the hematopoietic cellular hierarchy.

Increased numbers of megakaryocyte progenitor cells are present in the BM and the peripheral blood of patients with ET. These data support the concept that the principal abnormality is an expansion of the progenitor cell pool. In addition, progenitor cells were noted to either be hypersensitive or independent of the addition of exogenous cytokines, including interleukin (IL)-3, IL-6, and thrombopoietin. A second subpopulation of colony-forming unit–megakaryocyte (CFU-MK) assayed from patients with ET remained dependent on the addition of exogenous cytokines.

This hypersensitivity of ET progenitor cells to a variety of cytokines is due to the clonal acquisition of driver mutations (*JAK2*, *MPL*, or *CALR*) that activate the JAK-STAT signaling pathway, allowing hematopoiesis to occur in the absence of exogenous cytokines. The *JAK2V617F* mutation occurs in 50–60% of ET patients while recurrent *CALR* mutations occur in 25% of patients and 3–5% have *MPL* mutations. The patients with ET who lack such driver mutations are said to be “triple negative”.

JAK2 is a cytoplasmic tyrosine kinase that plays a key role in mediating intracellular signaling from a variety of growth factors, including IL-3, erythropoietin, granulocyte-macrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), and thrombopoietin. Coexpression of *JAK2V617F* with a homodimeric type 1 cytokine receptor (including erythropoietin, thrombopoietin, or G-CSF) is necessary for hormone activation of JAK-STAT (signal transducer and activator of transcription) signaling pathways and for hematopoietic cell proliferation to become growth factor independent. The *JAK2V617F* mutation is present in ET patients with both clonal and polyclonal hematopoiesis. Patients with clonal hematopoiesis have a higher *JAK2V617F* allele burden (26%) than patients with polyclonal hematopoiesis (16%). The relative size of the *JAK2V617F* clone is often small and remains stable over time in patients with both clonal and polyclonal hematopoiesis. Although an allele burden higher than 50% indicating the presence of granulocytes homozygous for *JAK2V617F* has been found in 70% of PV patients, it has been observed less frequently in ET patients. All PV patients have assayable erythroid colonies that are homozygous for *JAK2V617F*, even in PV patients with a low burden of *JAK2V617F*. By contrast, hematopoietic colonies cloned from ET patients are only occasionally *JAK2V617F* homozygous, unlike the case of PV. The transition from *JAK2* heterozygous to homozygous progenitors is a consequence of homologous recombination. These studies suggest that such an event is characteristic of PV but rarely occurs in ET. If such an event occurred in ET, it would likely lead to a transition from an ET phenotype to a PV phenotype.

STATs are activated downstream to *JAK2V617F*. STAT3 is a pivotal regulator of megakaryocytopoiesis, which might provide an explanation for its exclusive upregulation in ET. To further examine the differences between hematopoiesis in *JAK2V617F* ET and PV, the gene expression changes in *JAK2V617F*-heterozygous erythroid colonies have been examined. Erythroblasts from ET patients were characterized by enhanced expression of genes associated with interferon (IFN) signaling and phospho-STAT1 compared with PV erythroblasts.⁵ STAT1 is essential for IFN- γ signaling. Increased STAT1 in normal CD34⁺ cells has been shown to favor megakaryocytic but

reduce erythroid differentiation, creating a differentiation pattern that resembles ET. Furthermore, inhibition of STAT1 signaling in ET hematopoietic progenitor cells led to enhanced erythropoiesis and reduced megakaryocytopoiesis. These studies suggest that in ET, *JAK2V617F* induces simultaneous activation of STAT5 and STAT1 pathways, but in PV, the relative reduced levels of phospho-STAT1 reduces a brake, favoring more profound erythropoiesis.

Thrombopoietin is the primary physiologic regulator of thrombopoiesis. This growth factor acts by binding to its cell surface receptor, MPL. MPL is expressed by CD34⁺ hematopoietic stem and progenitor cells, MKs, and platelets. Normal or slightly elevated thrombopoietin levels have been observed in patients with ET. Furthermore, expression of the thrombopoietin receptor and its mRNA has been shown to be dramatically reduced in the platelets of patients with ET. Thrombopoietin serum levels are controlled by platelet mass through MPL-mediated thrombopoietin uptake and degradation. The reduced platelet MPL expression occurs not only in ET but also in PV and PMF, and has been shown to be a downstream event of *JAK2V617F*, which promotes the proteasomal degradation of MPL. The reduced MPL likely results in the decreased capacity of platelets to absorb thrombopoietin, contributing to the increased megakaryocyte mass and thrombocytosis. The mutations in thrombopoietin receptor, *MPLW515L* and *MPL515K*, are present in approximately 3–5% of patients with ET. About 60% of patients with *MPL* mutations have the *W515L* mutation and 40% the *W515K* mutation. The mutant allele burden is greater than 50% in 50% of *W515K* patients compared with 17% of *W515L* patients. The most prevalent *MPL* mutations in ET occur on tryptophan 515, an amino acid that maintains MPL in an inactive form in the absence of cytokines. Rarely in ET patients another *MPL* mutation, *S505N*, located in the exon 10 domain that encodes the transmembrane domain of MPL and induces dimerization of the transmembrane helix in an active confirmation, serves as a driver mutation. The *MPL* mutations occurring in ET trigger conformational changes in the receptor, bringing in close proximity two molecules of bound JAK2 for transphosphorylation and activation of the JAK-STAT signaling cascade. The loss of tryptophan but not the acquisition of a particular residue induces the constitutive activation of MPL. More than 50% of patients with *MPL* mutant alleles are also *JAK2V617F* positive. In ET, both *JAK2V617F* and *MPL* mutations arise preferentially on a specific constitutional *JAK2* 46/1 haplotype. Two hypotheses have been proposed to account for this predilection: 46/1 is inherently genetically more unstable (hypermutable hypothesis) or 46/1 confers a growth advantage that favors the predominance of *JAK2V617F* hematopoiesis (fertile ground hypothesis). The association of *MPL* mutations with the *JAK2* 46/1 haplotype strongly favors the hypermutability hypothesis rather than the fertile ground hypothesis. The presence of *MPLW515K* mutations in ET patients are associated with lower hemoglobin levels and higher platelet counts, as well as preferential expansion of the numbers of megakaryocytes at the expense of erythroid precursors, as observed in BM biopsy specimens.

Mutations in the *CALR* gene occur in 25% of ET patients and rarely occur together with mutations of *JAK2* or *MPL*. *CALR* mutations have been observed exclusively in ET and MF patients but not PV. The wild-type *CALR* gene encodes for an evolutionarily conserved, multifunctional protein involved in multiple cellular processes ranging from calcium homeostasis and protein folding in the endoplasmic reticulum, to apoptotic cell death clearance and cellular adhesion. The *CALR* mutations identified in MPN mainly consist of deletions (i.e., type I) or insertions (i.e., type II) occurring within the exon 9, which create a novel epitope in the C-terminal domain of the protein. Despite the heterogeneity of these mutations, the new C-terminus sequence is identical and results in the loss of the KDEL domain, which is critical for *CALR* retention in the endoplasmic reticulum and its ability to regulate calcium homeostasis. The original studies describing *CALR* mutations in MPN indicated that such a uniform defect may confer a proliferative advantage to the malignant cells via activation of the JAK-STAT pathway. Mutations of *CALR* are found almost exclusively in patients with MF and ET, the two MPN entities in which MK hyperplasia is a hallmark of the disease.

Fig. 69.1 SCHEMATIC REPRESENTATION OF THE POTENTIAL MECHANISM OF ACTION OF MUTATED CALRETICULIN. Deletions (type I mutations) or insertions (type II mutations) occurring in the exon 9 of *CALR* gene (1) result in a novel epitope in the C-terminus of the protein which lacks the ER-retention signal (KDEL) and is positively charged compared with the negatively charged wild-type protein (2). The mutated *CALR* is capable of binding MPL (3), which, in turn, activates the JAK-STAT signaling pathway (4), thus providing proliferative advantage of the malignant clone (5). *CALR*, Calreticulin; *ER*, endoplasmic reticulum; *JAK-STAT*, Janus-activated kinase–signal transducer and activator of transcription; *MPL*, thrombopoietin receptor. (From Stanley RF, Steidl U: *Cancer Disc* 6:344, 2016.)

Intriguingly, the expression of both wild-type and mutated *CALR* is restricted to MK lineage, implying a role for *CALR* in normal MK biology. By corroborating these observations, a series of subsequent reports have shed light into the mechanisms responsible for the mutated *CALR* ability to induce MK hyperplasia and thrombocytosis in MPN. Thus, four independent laboratories have demonstrated that the oncogenic activity of mutated *CALR* is mediated by MPL, which is critical for both HSC and MK lineage development. Thus, mutant *CALR* expressed by hematopoietic cells *in vitro* or *in vivo* in mouse models binds and activates MPL, but not other type I hematopoietic cytokine receptors. This, in turn, leads to JAK-STAT pathway activation, resulting in the development of thrombocytosis and an ET-like phenotype. Interestingly, *in vivo* overexpression of either of the mutation variants (type I, deletion; or type II, insertion) induces thrombocytosis and constitutively activates MPL and JAK-STAT signaling. Yet, while type II mutations favor MK proliferation, type I mutations confer clonal dominance of HSC, resulting in splenomegaly, BM hypocellularity, and fibrosis, a phenotype reminiscent of “post-ET” MF. These findings mirror the clinical observations in which type I mutations are prevalent in MF patients while type II mutations are frequent in ET patients. Moreover, CD34⁺ hematopoietic progenitors from ET patients harboring the type II *CALR* mutation are capable of forming spontaneous CFU-MK, validating the initial suggestions that mutated *CALR* confers cytokine-independent cell growth.

Elegant molecular and biochemical studies dissecting the interaction between mutant *CALR* and *MPL* and its downstream consequences revealed that the N-glycosylation sites of the *MPL* extracellular

domain are required for its activation by mutated *CALR* and is independent of thrombopoietin binding site. Furthermore, mutated *CALR* translocates to the cell surface and acts in an autocrine manner in binding and activating MPL. Although the exact mechanisms by which the mutated *CALR* binds MPL remain under investigation, preliminary evidence suggests that the oncogenic properties of the mutated *CALR* can be attributed to the positive electrostatic charge of the novel peptide, which may be responsible not only for the physical interaction with MPL, but also for other cellular functions involving the normally negatively charged portion of the protein (Fig. 69.1).

The clinical phenotype of patients with *JAK2*-mutated and *CALR*-mutated ET differ. The presence of mutated *CALR*, which occurs in 25% of patients with ET and is mutually exclusive of mutations in *JAK2* and *MPL*, is associated with a younger age, male predominance, higher platelet count, lower hemoglobin level, and a lower risk of thrombotic complications. Investigators have recently demonstrated that the lower thrombotic rate in *CALR*+ ET may in part be due to reduced leukocyte activation compared with *JAK2V617F*-positive counterparts.

Occasional cases of ET are associated with loss-of-function *Lnk* (SH2B3) mutations. In mouse models, the inhibitory adaptor protein *Lnk* has been shown to be associated with downmodulation of erythropoietin and thrombopoietin signaling. *Lnk* can bind to wild-type *JAK2*, *JAK2V617F*, wild-type *MPL*, and *MPLW515L*. *Lnk* levels are upregulated and correlate with an increase in the *JAK2V617F* allele burden in MPN patients. In *JAK2V617F*-positive ET, *Lnk* mRNA expression is upregulated and serves to modulate

JAK2V617F-mediated cell regulation. Thrombopoietin-mediated signaling regulates *Lnk* expression at both the mRNA and protein levels. Furthermore, acquired *Lnk* mutations have been observed in less than 1% of ET. The inactivating *Lnk* mutations in ET patients result in JAK-STAT activation, leading to high levels of STAT3 and STAT5 activation.

Recently, Cabagnio and coworkers used whole-exome sequencing and next-generation sequencing targeting *JAK2* and *MPL* with the intent of detecting additional mutations in triple-negative ET patients. They found several signaling mutations including *JAK2V617F* at very low allele frequency, as well as additional mutations such as: *LNK* mutation, *MPL-S505N*, *MPL-W515R*, and *MPL-S204P*. *MPL-S204P* and *MPL-Y591N* were shown to be weak gain-of-function mutants increasing *MPL* signaling and conferring either thrombopoietin hypersensitivity or independence to expressing cells, but with a low efficiency. These data demonstrate that some clonal, noncanonical *MPL* gain-of-function mutations are associated with triple-negative cases of ET. In the triple-negative patients in whom these mutations were not detected, a number had clonal while the others had polyclonal hematopoiesis, suggesting that certain patients with triple-negative ET cannot be classified as having an MPN and should be evaluated for inherited forms of thrombocytosis that will be discussed later.

With the development of whole-exome sequencing, mutations in epigenetic regulators (such as *TET2*, *DNMT3A*, *ASXL1*, *EZH2*, and isocitrate dehydrogenase [*IDH1/IDH2*]) and in spliceosome components (such as *SRSF2*, *U2AF1*, and *SF3B1*) have been shown to be present in MPN patients with *JAK2/MPL/CALR* mutations. Other mutations were also directly associated with leukemic progression, such as *p53*, *RUNX1*, *CBL*, and deletion in *IKAROS*. Several of these mutations can occur in the same patient, and most frequently *SRSF2* can occur with *TET2*, *ASXL1* or *IDH* mutations. In contrast to MPN driver mutations, which are rare in other myeloid malignancies, these additional mutations are not specific to MPNs and are found with a higher frequency in patients with MDS and in MDS/MPN overlap syndromes, such as chronic myelomonocytic leukemia as well as AML. Biologic studies and mouse models have shown that these additional mutations may cooperate with the MPN driver mutations to favor clonal dominance (*TET2* or *DNMT3A*), to modify disease phenotype, or to promote either progression to MF or leukemic transformation (*ASXL1*, *IDH1/2*, *EZH2*, and *TP53*).

The ten–eleven translocation (*TET2*) gene encodes for a hydroxylase that is able to hydroxylate methylated cytosine. These mutations result in loss of function, leading to increased DNA methylation and a reduction in hydroxymethyl cytosine. *TET2* mutations occur in 11% of ET patients. Mutations in *TET2* can occur either before or after mutations of *JAK2V617F* or *MPL*. Mutations in the gene for *IDH* occur in 0.9% of ET patients and can functionally lead to similar effects as *TET2* mutations on DNA methylation. Furthermore, disrupting mutations of *ASXL*, which occur in 36% of PMF patients, are infrequent in ET, as are mutations of *CBL* or *EZH2*.

Furthermore, the transcription factor NF-E2 has been shown to be overexpressed in the cells of patients with MPNs independent of the presence or absence of *JAK2V617F*. NF-E2 acts as an epigenetic transcriptional regulator and chromatin modifier. Genetically engineered mice that overexpress NF-E2 have been created and are characterized by extreme thrombocytosis and leukocytosis, normal hemoglobin levels, and BM hypercellularity, a clinical picture similar to that observed in ET patients.

The cause of the increased risk of developing hemorrhagic and thrombotic events associated with ET remains the subject of investigation. Thrombotic complications occur most frequently in patients older than age 60 years; patients with a history of a thrombotic event; and individuals with cardiovascular risk factors, including tobacco use, hypertension, or diabetes mellitus, but hemorrhagic events occur almost exclusively in individuals with extremely high platelet counts ($>1000 \times 10^9/L$).⁴ In addition, leukocytosis ($>11,000/L$) and *JAK2V617F* positivity have been associated with the development of arterial thrombosis. Platelet counts in excess of $1000 \times 10^9/L$ are associated with a lower risk of developing arterial thromboses.

The incidence of thrombotic events in ET patients ranges from 1.5% to 6.6% per patient-year. The thrombotic events in ET are largely arterial, but venous thromboses also occur not infrequently. *JAK2V617F*-positive ET patients compared with patients with patients with a *CALR* mutation or those who are triple negative have a higher risk of developing thrombotic events, but a dose-dependent correlation between allele burden and the development of clinical symptoms has not been demonstrated. The age-related differences in the frequency of these events have been attributed to the coexistence of vascular disease in older patients. Many investigators have struggled to identify ET patients who are at the greatest risk of developing thrombotic episodes. Recently, a new thrombotic scoring system has been developed by investigators on both sides of the Atlantic.¹ In the latest iteration of this risk stratification schema four categories were delineated: very low risk (no thrombosis history, age ≤ 60 years, and *JAK2* unmutated); low risk (no thrombosis history, age ≤ 60 years, and *JAK2* mutated); intermediate risk (no thrombosis history, age >60 years, and *JAK2* unmutated) and high risk (thrombosis history, age >60 years, and *JAK2* mutation). How to personalize therapy based upon such a schema remains problematic and to date untested.²

Some progress has been made in defining the relationship between platelet numbers and the risks for thrombotic and hemorrhagic events in ET. In a randomized trial of patients at a high risk of developing a thrombotic event (>60 years of age, a history of a thrombotic episode, or both), the reduction of platelet numbers was highly effective in preventing additional thrombotic events (Fig. 69.2).⁵ Furthermore, the incidence of thrombotic events has been shown to be closely correlated with the duration of thrombocytosis in a case–control study. Unfortunately, there has been difficulty in defining what particular target platelet count should serve as an endpoint for myelosuppressive therapies to maximally reduce the degree of thrombotic risk. Many investigators have provided data that indicate that interactions between platelets and activated leukocytes participate in the thrombotic risk of ET patients, suggesting to some that normalization of leukocyte numbers should also be a therapeutic endpoint.

Several groups have now confirmed that the degree and duration of bleeding in ET patients is correlated with platelet numbers. The clinical spectrum of bleeding in ET patients closely resembles that observed in von Willebrand disease. Several groups have now shown that high platelet counts ($>1000 \times 10^9/L$) are associated with an acquired form of von Willebrand syndrome, and that reduction of platelet numbers is associated with correction of the von Willebrand syndrome-like abnormalities and cessation of bleeding episodes. The mean platelet count in patients with ET and acquired von Willebrand disease is $2050 \pm 1107 \times 10^9/L$. An increase in the number of

Fig. 69.2 PROBABILITY OF THROMBOSIS-FREE SURVIVAL IN 114 PATIENTS WITH ESSENTIAL THROMBOCYTHEMIA TREATED WITH HYDROXYUREA OR LEFT UNTREATED. (From Cortelazzo S, Finazzi G, Ruggeri M, et al: Hydroxyurea for patients with essential thrombocythemia and a high risk of thrombosis. *N Engl J Med* 332:1132, 1995.)

circulating platelets appears to favor the adsorption of larger von Willebrand multimers onto platelet membranes, resulting in their removal from the circulation and their subsequent degradation.

Platelets in patients with ET have been known for a considerable time to be qualitatively abnormal. Although both increased and decreased platelet reactivity has been described, these findings have not been definitively associated with thrombohemorrhagic complications with two noteworthy exceptions—erythromelalgia, in which the prompt relief of symptoms by cyclooxygenase inhibitors provides direct evidence that prostaglandins play a role in the development of vascular occlusion, and acquired von Willebrand syndrome, which is a major cause of bleeding in patients with ET.

Abnormal platelet aggregation has been reported in 35–100% of patients with ET. The majority of such studies have used conventional platelet aggregation studies performed on platelet-rich plasma. The simultaneous measurement of platelet aggregation and adenosine triphosphate–dense granule release by whole-blood platelet lumiaggregometry has been used to study platelet function in ET patients with the hope of identifying patients at a risk of developing thrombosis. A prospective analysis of large cohorts of patients has not been performed to confirm the utility of such assays. Platelets derived from patients with ET and PV have been shown to contain a large proportion of immature platelets that have been recently released from the BM. Such immature platelets have increased hemostatic activity, as demonstrated by a heightened response to thrombin and greater expression of P-selectin. Hydroxyurea has been shown to be capable of reducing the number of immature platelets in ET, which might partly be responsible for the reduced thrombotic risk associated with its use.

Abnormal aggregation studies have not been successful in predicting the incidence of episodes of hemorrhage or thrombosis. In ET, platelet aggregation is classically defective in response to epinephrine, adenosine diphosphate (ADP), and collagen but is usually normal with arachidonic acid and ristocetin. Characteristically, in ET, the first wave of aggregation is diminished, and the second wave of aggregation is absent in response to epinephrine. Interestingly, preincubation of ET platelets with thrombopoietin partly corrects the impaired aggregation in response to epinephrine, ADP, and collagen. An acquired form of platelet storage pool disease occurs frequently in ET. Platelet α -granule content and the release of the content of granules are abnormal, resulting in elevated plasma levels of platelet factor-4 and β -thromboglobulin.

Numerous individual functional platelet abnormalities have been demonstrated. A defect in the metabolism of arachidonic acid by lipoygenase has been documented, as have decreased numbers of platelet receptors for prostaglandin D₂ and adrenergic receptors for epinephrine. Platelets from patients with thrombotic episodes have been found to be capable of increased generation of thromboxanes and to have an increased affinity for fibrinogen. Elevations in β -thromboglobulin and serum thromboxane levels in ET patients are validated indices of enhanced in vivo platelet activation and possibly thrombin generation. Such abnormalities are not present in patients with secondary thrombocytosis and may provide some explanation for the high incidence of thrombosis associated with ET. The anti-thrombotic activity of aspirin has been attributed to its ability to permanently and selectively inactivate platelet cyclooxygenase-1 (COX-1), thereby blocking thromboxane biosynthesis. This action has served as the rationale for the widespread use of aspirin in ET patients for thrombosis prophylaxis in the absence of valid controlled clinical trials. COX-2 has been shown to be overexpressed by the megakaryocytes and platelets of ET patients; COX-2 can also contribute to the enhanced biosynthesis of thromboxanes in ET. Low-dose aspirin can only partially correct this enhanced thromboxane synthesis, likely because of the increased COX-2 activity associated with the increased rate of platelet generation associated with ET, providing the rationale for the use of more aggressive aspirin scheduling or the addition of thromboxane receptor A₂ antagonists to reduce the incidence of thrombotic events. Although laboratory data indicate a rationale for twice-daily dosing of aspirin, prospective clinical data for this approach are lacking.

The platelet activation observed in ET has also been linked to Src, which is a nonreceptor tyrosine kinase particularly abundant in platelets. In thrombin-stimulated platelets, Src kinase is required for platelet aggregation. This preactivation of Src that is characteristic of ET and the related platelet hyperactivity is likely to account for the hypercoagulable state that is emblematic of ET. Recent in vitro studies also implicate *JAK2V617F*-driven heparinase overexpression in ET as a novel thrombotic mechanism. Heparinase has previously been shown to complex and enhance the activity of tissue factor, resulting in activation of the coagulation cascade.

Microvascular thrombosis causing digital or central nervous system ischemia leads to a variety of clinical syndromes closely associated with ET. The survival of platelets in ET patients with erythromelalgia and thrombosis has been shown to be reduced. Thrombosis in this setting is associated with an increased platelet turnover. Treatment of erythromelalgia with aspirin increased mean platelet survival from 4.0 ± 0.3 days to 6.9 ± 0.4 days and was associated with a significant elevation of platelet numbers. These findings suggest that erythromelalgia results from platelet-mediated thrombosis of the arterial microvasculature of the extremities. Complete correction of this ischemic circulatory defect is associated with the use of platelet cyclooxygenase inhibitors, such as aspirin and indomethacin. Agents that do not inhibit platelet cyclooxygenase, such as coumadin, sodium salicylate, dipyridamole, sulfinpyrazone, and ticlopidine, are not active in the treatment of this disorder.

One intriguing explanation for the increased risk of thrombosis in patients with ET has been the observation that the total amount of thrombin generated on the platelet surfaces of patients with ET is markedly greater than that generated on the platelet surfaces of normal control participants or patients with reactive thrombocytosis. The molecular basis of this abnormality has not been defined. Increased numbers of platelet microparticles, as well as increased platelet–neutrophil and platelet–monocyte complexes, have been observed in patients with ET. Platelet microparticles support thrombin generation and leukocyte activation. Increased numbers of platelet microparticles have been associated with the development of vascular thrombosis.

Recently, in vivo leukocyte activation has been shown to occur in ET and to be associated with signs of activation of both the coagulation cascade and endothelial cells. Such platelet and leukocyte activation may play a role in the generation of the prethrombotic state that characterizes ET. Interestingly, the presence of the *JAK2* mutation is associated with a greater degree of platelet and leukocyte activation. Activated neutrophils are able to bind platelets, which triggers the expression of tissue factor, as well as endothelial cell activation and damage. From a clinical point of view, several studies have demonstrated that an increased leukocyte count ($>11,000 \times 10^9$) in patients with ET is an independent risk factor for developing arterial thrombosis, especially myocardial infarction, and is associated with an inferior survival rate. Therefore, an important role for leukocytes in the pathogenesis of thrombosis in ET is becoming more evident. Direct involvement of endothelial cells of MPN patients by *JAK2V617F* has been reported by several groups, which might lead to endothelial dysfunction in subsets of MPN patients, further enhancing the thrombotic predisposition to the development of splanchnic vein thromboses.

CLINICAL MANIFESTATIONS

The presenting symptoms of patients with ET are quite variable. Many patients (12–67%) reach medical attention fortuitously as a result of the extreme degree of thrombocytosis detected when obtaining a routine blood cell count. Most patients present with symptoms related to small- or large-vessel thrombosis, or minor bleeding. The thrombotic events at diagnosis and during follow-up occurred at rates of 10–29% and 8–31%, respectively. In general, arterial events predominate over venous events. Presentation with a major bleeding episode is unusual. Neurologic complications are common. [Table 69.1](#) lists representative neurologic complaints, of which headache

TABLE 69.1 Frequency of Neurologic Complaints Associated With Essential Thrombocythemia

Manifestations	Patients (n)
Headache	13
Paresthesias	10
Posterior cerebral circulatory ischemia	9
Anterior cerebral circulatory ischemia	6
Visual disturbances	6
Epileptic seizures	2
Total number of patients	33

Data from Jabaily J, Iland HJ, Laszlo J, et al: Neurologic manifestations of essential thrombocythemia. *Ann Intern Med* 99:513, 1983.

was the most common, with paresthesias of the extremities a close second. There was an extremely high incidence of transient ischemic attacks involving both the anterior and posterior cerebral circulation. These attacks have a sudden onset, last for a few moments, and are frequently associated with a pulsatile headache. The various symptoms occur sequentially rather than simultaneously and can be preceded or followed by erythromelalgia. Transient neurologic symptoms include unsteadiness, dysarthria, dysphoria, motor hemiparesis, scintillating scotomas, amaurosis fugax, vertigo, dizziness, migraine-like symptoms, syncope, and seizures. The syndrome is caused by platelet-mediated ischemia and thrombosis in end-arterial microvasculature. It is not unusual for these symptoms to eventually progress to definitive cerebral infarcts.

Microvascular circulatory insufficiency involving the toes and fingers is frequent. Such events can lead to digital pain, enhanced by warmth; distal-extremity gangrene; and classic erythromelalgia. The term *erythromelalgia* refers to a syndrome of redness and burning pain in the extremities. Erythromelalgia, which is characterized by a burning pain and a dusky congestion of swollen extremities, is usually preceded by paresthesias. Cold provides relief to these symptoms, and heat intensifies the symptoms. Patients prefer to wear shoes or slippers without socks and elevate their feet. These symptoms may progress in intensity and lead to peeling of the skin in affected appendages or affected toes or fingers, which then may become cold and ischemic with a dark purplish tinge. Erythromelalgia symptoms are asymmetric in the majority of cases. Symptoms related to coronary artery disease or transient ischemic attacks may precede or accompany the onset of erythromelalgia. Occasionally, hemorrhagic episodes may occur in patients experiencing erythromelalgia. Platelet counts in patients with erythromelalgia are frequently below $1000 \times 10^9/L$. The relief of such pain for several days after a single dose of aspirin is diagnostic of erythromelalgia. The specific microvascular syndrome of erythromelalgia is readily explained by platelet-mediated arteriolar inflammation and occlusive thrombosis leading to acrocyanosis and even gangrene. Skin biopsies from affected sites reveal arteriolar lesions without involvement of venules, capillaries, or nerves. The arteriolar endothelial cells are swollen and the vessel walls thickened by cellular swelling and deposition of intracellular material. Compared with atherosclerotic circulatory obstruction, arterial pulses in patients with erythromelalgia remain normal. Other patients develop platelet-mediated acral inflammation and arterial thrombosis, which can progress to ischemic acrocyanosis or necrosis of fingers, toes, and, rarely, the tip of the nose (Fig. 69.3).

Although thrombosis of the microvasculature is generally more frequent, thrombosis of large veins and arteries in patients with ET still occurs commonly. Patient symptoms frequently occur related to large-vessel thrombosis, mostly in the arteries of the legs, the coronary arteries, and the renal arteries. Involvement of the carotid, mesenteric, and subclavian arteries is frequent, and patients characteristically have venous thromboses involving the splenic vein, hepatic veins, or veins of the legs and pelvis. Unexplained thrombosis of the hepatic veins leads to Budd-Chiari syndrome, and thrombosis of the renal vein can

Fig. 69.3 GANGRENE OF THE TOE IN A PATIENT WITH ESSENTIAL THROMBOCYTHEMIA.

result in the development of nephrotic syndrome. Splanchnic vein thromboses occur predominantly in young women with ET. Patients with this complication are at a high risk of having a poor survival because of hepatic failure or transformation to MF or acute leukemia. It is worth noting that a fraction of patients with idiopathic splanchnic vein thrombosis may present with normal or near-normal blood counts but have an occult MPN based on genetic or histopathologic abnormalities. In a review of more than 800 patients with splanchnic vein thrombosis without a diagnosis of an MPN, a mean of 32.7% of patients were *JAK2V617F* positive. More than 50% of these patients were subsequently diagnosed with an MPN. In addition, 2.6% of patients with a cerebral sinus and vein thrombosis were also shown to be *JAK2V617F* positive. These studies suggest that all cases of splanchnic vein thrombosis and likely cerebral sinus and vein thrombosis should be tested for *JAK2V617F* to identify patients with an occult MPN. Occasional patients with idiopathic splanchnic vein thromboses with *CALR* mutations have been reported. In those patients who are *JAK2V617F* negative it is prudent to also search for *CALR* mutations. Priapism is a rare complication of ET, presumably caused by platelet sludging in the corpus cavernosum. In addition, myocardial ischemia and infarction associated with normal coronary angiograms has been reported in patients with ET, as has a high incidence of anginal symptoms. Acute renal failure has been observed after thrombosis of renal arteries and veins in patients with ET. Pulmonary hypertension secondary to alveolar capillary plugging by platelets and megakaryocytes has also been reported in patients with ET.

Hemorrhagic events occur in 3–11% of patients with ET; the primary site of bleeding is the gastrointestinal tract. Other sites of bleeding may be the skin, eyes, urinary tract, gums, tooth sockets (after extraction), joints, or brain. A high incidence of bleeding episodes during the immediate postoperative period is likely caused by postsurgical thrombocytosis and the development of acquired von Willebrand syndrome or the use of antithrombotic prophylaxis therapy. Bleeding is closely correlated with a significant increase in platelet counts in excess of $1500 \times 10^9/L$ and is associated with pseudohyperkalemia. It is important to emphasize that individual patients can experience both thrombotic and hemorrhagic episodes.

Appreciation of the risk of developing thrombohemorrhagic events in asymptomatic patients with ET who are younger than 40 years of age is imprecise at best. Such patients are thought to be at a low risk of developing thrombotic episodes unless they have experienced a prior thrombotic episode or have associated cardiovascular risk factors. The most common thrombotic complications include migraine headaches in 20% and erythromelalgia in 5% of the patients. Life-threatening hemorrhagic episodes are rare. The degree of leukocytosis has been suggested by some investigators to be useful in discriminating between young patients with a low or high risk to develop a thrombotic episode.

TABLE 69.2 Risk Stratification in Essential Thrombocythemia Based on Thrombotic Risk^a

Risk Category	Age >60 Years or History of Thrombosis	Cardiovascular Risk Factors
Low	No	No
Intermediate	No	Yes
High	Yes	Yes

^aCardiovascular risk factors: hypertension, hypercholesterolemia, diabetes, smoking, and congestive heart failure. Extreme thrombocytosis (platelet count $>1500 \times 10^9/L$) is a risk factor for bleeding. Its role as a risk factor for thrombosis in essential thrombocythemia is uncertain.

Data from Finazzi G, Barbui T: Risk-adapted therapy in essential thrombocythemia and polycythemia vera. *Blood Rev* 19:243, 2005.

A meta-analysis has revealed that the *JAK2V617* mutation is associated with a twofold higher risk of developing either a venous or arterial thrombosis but does not influence the risk of suffering from a hemorrhagic event. Regardless, it is conceivable that the significantly more advanced age and elevated hematocrit and leukocyte levels in mutation-positive patients might contribute to the apparent association between *JAK2V617F* and thrombosis reported in some studies.

Patients with ET who are older than 60 years of age who have had a prior thrombotic event have a greater risk of developing additional thrombotic events (Table 69.2). By contrast, the incidence of thrombotic and hemorrhagic complications in asymptomatic patients with ET who are younger than 60 years of age who have platelet counts of less than $1500 \times 10^9/L$ has been shown to be comparable to a normal control population. Gender, hypertension, diabetes mellitus, hypercholesterolemia, and smoking have been shown to be independent risk factors for developing arterial thrombotic complications in ET (see Table 69.2). Screening of patients for other acquired and inherited thrombophilic states may identify patients at an even higher risk for both arterial and venous thrombotic events.

Pregnancy is not contraindicated in patients with ET. The outcome of pregnancy in patients with ET has been the subject of intense investigation. The rate of having a successful pregnancy is 61% compared with an 85–90% rate in normal women. The rate of spontaneous abortions ranges from 39–44% compared with the miscarriage rate of 10–15% in normal pregnancies. Placental infarction is often responsible for intrauterine fetal growth retardation (5%). Abruptio placenta has been reported in 3.6% of cases, a rate that is higher than that observed in the general population (1%). Major thrombotic episodes occur in 3% of these pregnancies while major bleeding episodes occur in 2% of cases. These rates are higher than that observed in the overall population of pregnant women. Baseline platelet count is not predictive of pregnancy outcome. ET patients with the *JAK2V617F* mutation have been reported to be at a higher risk of developing complications with pregnancy. In the postpartum period, the platelet counts return to their earlier levels, and rebound thrombocytosis may occur in some patients. This is thought to increase the probability of vascular complications during this period to a level similar to that observed in other conditions of thrombophilia.

In the large majority of cases, the fetal losses in pregnant ET women occur during the first trimester. A previous history of spontaneous abortion may be the greatest risk factor for the development of subsequent spontaneous abortions.

Physical examination findings are relatively unremarkable in patients with ET. Most patients are not severely ill at diagnosis, with a median Karnofsky score of 90% being reported in one series. Splenomegaly is detectable in 40–50% of patients, and approximately 20% have hepatomegaly. During the course of the disorder, a further increase in the degree of hepatosplenomegaly may be observed in patients who are developing post-ET MF. Recently, skin manifestations of the MPN have been reported to be relatively common, ranging from paraneoplastic lesions, including vascular, neutrophilic

plaques, and unexplained dermatoses. Rarely, vascular changes result in microcirculatory flow abnormalities, leading to a vasculitis resulting in classic purpura that may progress to skin necrosis. This should be distinguished from leg ulcers that occur in patients being treated with hydroxyurea. Occasionally, patients also develop pyoderma gangrenosum or Sweet syndrome.

LABORATORY MANIFESTATIONS

The hallmark of ET is a sustained and unexplained elevation of the platelet count ($\geq 450 \times 10^9/L$). Accompanying leukocytosis is a common finding. A leukoerythroblastic blood picture, as well as teardrop-shaped RBCs are not features of ET but are suggestive of an early form of MF. Mild eosinophilia ($>400/mm^3$) and basophilia ($>100/mm^3$) have been reported in more than one-third of patients.

The most common morphologic abnormalities are variations in RBC size and shape and the presence of megathrombocytes (Fig. 69.3). The BM is usually normocellular or slightly hypercellular without a significant increase in granulopoiesis or erythropoiesis. Increased numbers of enlarged megakaryocytes with hyperlobulated or deeply folded nuclei that cluster in small groups along sinuses are the hallmarks of ET (see Fig. 69.4). Reticulin fibrosis is not significantly evident. A great deal of controversy currently surrounds distinguishing “true ET” from an early prefibrotic form of MF (prePMF) in which the BM is characteristically hypercellular with pronounced proliferation of granulocytes and reduced erythroid precursors. The megakaryocytes are increased in number but are loosely clustered or located along the endosteal bone surface. The megakaryocytes contain hyperchromatic, hypolobulated bulbous, or irregularly folded nuclei with an abnormal nuclear-to-cytoplasmic ratio. The histopathologic criteria for this form of prePMF have been combined with clinical criteria (minor criteria) by the World Health Organization (WHO). The 2016 criteria for the diagnosis of ET and prePMF are particularly useful (Table 69.3). These new criteria are heavily dependent on mutational analyses. The *JAK2V617F* mutation occurs in 50–60% of ET patients, while recurrent mutations in *CALR* mutations occur in 25% of patients and 3–5% have *MPL* mutations. Approximately 25% of patients harbor mutated *CALR* as either a type I (52-bp del) or type II (5-bp insertion).

The patients with ET who lack such driver mutations are said to be “triple negative” (Table 69.3). Based on the 2016 WHO Diagnostic Criteria, the presence of modest BM reticulin fibrosis does not exclude the diagnosis of ET. Although select hematopathologists can reproducibly distinguish ET from prePMF, it remains uncertain whether this distinction is broadly applicable. In 70–80% of ET patients, iron stores were present in the BM, albeit at reduced levels. Almost all patients have normal serum ferritin levels. The absence of iron stores in 30% of patients may merely be an epiphenomenon of a chronic MPN and not truly reflective of an iron deficiency state. Platelet aggregation study results are frequently abnormal, most often demonstrate an impaired aggregation response to epinephrine, ADP, and collagen but not to arachidonic acid and ristocetin. Spontaneous platelet aggregation has been reported to occur frequently in such patients, but this has not been a universal finding.

Approximately 25% of patients with ET have been reported to have elevated uric acid levels at diagnosis. The average value of the serum potassium at diagnosis is usually within the normal range, although 23% of patients have been reported to have pseudohyperkalemia, caused by the degranulation of platelets when in vitro clotting releases potassium. Both excessive numbers of RBCs and leukocytes can also be associated with these phenomena. The pseudohyperkalemia can be documented by measuring plasma instead of serum potassium levels and the lack of electrocardiographic findings associated with true hyperkalemia. Pseudohypoxemia has also been observed in ET patients with extreme degrees of thrombocytosis. Acquired von Willebrand syndrome is associated almost uniformly with a platelet count greater than $1500 \times 10^9/L$, a prolonged bleeding time, normal factor VIII coagulant activity, and a normal von Willebrand antigen level

Fig. 69.4 ESSENTIAL THROMBOCYTHEMIA: PERIPHERAL BLOOD SMEAR AND BONE MARROW BIOPSY. The peripheral blood smear in essential thrombocythemia (ET) shows a marked thrombocytosis with anisocytosis (varying sizes) of the platelets (A). The bone marrow (B) is hypercellular and exhibits a marked proliferation of large and giant megakaryocytes in loose clusters with other hematopoietic elements in the background. The large megakaryocytes (C) tend to be extensively lobulated.

but decreased von Willebrand factor–ristocetin cofactor activity and collagen binding activity, as well as a decrease or absence of large von Willebrand factor multimers simulating a type II von Willebrand disorder. The serum vitamin B₁₂ level can be increased in 25% of cases.

In ET, BM karyotypes are characteristically normal. The absence of the Philadelphia chromosome and the *BCR-ABL* rearrangement excludes the diagnosis of CML, which is important to consider when evaluating a new case of thrombocytosis. Rare patients share two molecular markers of MPNs (*JAK2V617F* and *BCR/ABL*). Aneuploidy is seen in the minority of cases at diagnosis. In fact, ET is associated with a definite chromosomal abnormality in only 7.8% of cases, but with disease progression there is an increased risk of aneuploidy. Specific chromosome abnormalities associated with ET have not been described, but abnormalities observed in PV and PMF, as well as in myelodysplastic syndrome (MDS), such as trisomy 1q, deletions of 5q, 13q, and 20q, trisomy 8, as well as monosomal karyotypes, have been reported. Many nonspecific chromosomal rearrangements have also been observed such as a complex karyotype, presence of a marker chromosome, and unusual translocations. Molecular cytogenetic studies in ET have not been performed extensively. In one reported study, addition of fluorescence in situ hybridization increased detection of chromosomally abnormal clones by 15%. However, in 21 patients studied with oligoarray comparative genomic hybridization, one additional patient with deletion 13q was identified compared with conventional cytogenetics. Leukemic transformation of ET is characterized by the development of an abnormal karyotype in 60–100% of patients. Consistent chromosomal abnormalities associated with ET progression in *JAK2V617F*-positive patients are der(1)t(1;9) and der(1;7)(q10;p10). Of the eight reported ET patients with der(1;7), five received previous chemotherapy (chlorambucil, hydroxyurea, pipobroman, melphalan, cytosine arabinoside, anthracycline), and six transformed to acute leukemia. Although der(1)t(1;9) is a consistent nonrandom rearrangement associated with de novo PV and with PV progression, four ET patients had der(1)t(1;9) with different breakpoints (p13;p13) and (q10;p10). In ET, similar to PV, PMF, and other myeloid disorders, formation of trisomy 1q alone or subsequent formation of jumping +1q translocations should be considered as a clonal marker associated with disease progression or transformation to AML. As has been previously mentioned, approximately 50% of ET patients are *JAK2V617F* positive, with only 4% having a high allele burden. Approximately 3–5% of patients have activating *MPL* mutations. Approximately 25% of patients harbor mutated *CALR* as either a type I (52-bp deletion) or type II (5-bp insertion).

DIFFERENTIAL DIAGNOSIS

There are numerous causes of primary, secondary, and spurious forms of thrombocytosis. A listing of the conditions that can lead to thrombocytosis is provided in Table 69.4. Primary thrombocytosis includes both acquired and hereditary forms. In acquired forms of primary thrombocytosis, the genetic abnormalities are present exclusively in hematopoietic cells, but in the hereditary forms, these underlying defects can be detected in both somatic and germ-line cells, and are inherited. The discovery of *JAK2*, *MPL*, and *CALR* mutations has provided definitive diagnostic tools with which to diagnose the MPNs, including ET. These mutations, however, can be found only in approximately 75% of ET patients. Hence, it is reasonable to consider *JAK2V617F* analysis and search for a mutation in *CALR* or *MPL* when evaluating patients with otherwise unexplained thrombocytosis. A positive test result indicates an underlying MPN. However, further investigations, including a BM biopsy (see Table 69.3) as well as cytogenetic analyses, are still required to differentiate ET from the other chronic MPNs, as well as from MDS presenting with thrombocytosis, such as the 5q syndrome and refractory anemia with ring sideroblasts and thrombocytosis (RARS-T; see Table 69.3) and prePMF.

For those patients who present with thrombocytosis who are triple negative for driver mutations, the first step in determining the cause of thrombocytosis is to exclude reactive forms of thrombocytosis. The causes of secondary or reactive forms of thrombocytosis are numerous, but the most common causes are infection, inflammation, hemolysis, severe exercise, malignancy, hyposplenism, and other causes of an acute-phase response (see Table 69.4). In a hospital population, patients with extreme thrombocytosis ($>1000 \times 10^9/L$) are not particularly rare in adult or pediatric patient populations. Examination of the blood smear is important to avoid confusion with so-called *pseudothrombocytosis*. This occurs in a number of conditions in which platelet-sized particles of red or white blood cell fragments (CLL, TTP, hemoglobin H disease), schistocytes, microspherocytosis, and cryoglobulinemia are erroneously enumerated as platelets by automatic particle counters. Confirmation of increased numbers of platelets by examination of the peripheral smear will avoid misdiagnosis and unnecessary clinical evaluation.

Whereas reactive thrombocytosis accounts for more than 88–97% of cases, thrombocytosis caused by an MPN accounts for only a minority of cases. Reactive thrombocytosis is more common in all age groups, except those in the eighth decade and older. Thrombotic and hemorrhagic events infrequently occur in patients with reactive thrombocytosis. These findings are in contrast to the enhanced risk

TABLE
69.3
2016 Revised World Health Organization Criteria for the Diagnosis of Essential Thrombocythemia, Pre-fibrotic Form of Primary Myelofibrosis, and Overt Primary Myelofibrosis, and British Committee for Standards in Hematology Criteria for Diagnosis of Essential Thrombocythemia
WHO ET Criteria**Major Criteria**

1. Platelet count $\geq 450 \times 10^9/L$
2. BM biopsy showing proliferation mainly of the megakaryocyte lineage with increased numbers of enlarged, mature megakaryocytes with hyperlobulated nuclei. No significant increase or left shift in neutrophil granulopoiesis or erythropoiesis and very rarely minor (grade 1) increase in reticulin fibers
3. Not meeting WHO criteria for *BCR-ABL1*⁺ CML, PV, PMF, myelodysplastic syndromes, or other myeloid neoplasms
4. Presence of *JAK2*, *CALR*, or *MPL* mutation

Minor Criteria

Presence of a clonal marker or absence of evidence for reactive thrombocytosis

Diagnosis of ET requires meeting all four major criteria or the first three major criteria and the minor criterion

WHO Criteria for Pre-Fibrotic Form of Primary Myelofibrosis**WHO prePMF Criteria****Major Criteria**

1. Megakaryocytic proliferation and atypia, without reticulin fibrosis >grade 1^a, accompanied by increased age-adjusted BM cellularity, granulocytic proliferation, and often decreased erythropoiesis
2. Not meeting the WHO criteria for *BCR-ABL1*⁺ CML, PV, ET, myelodysplastic syndromes, or other myeloid neoplasms
3. Presence of *JAK2*, *CALR*, or *MPL* mutation, or in the absence of these mutations, presence of another clonal marker,^b or absence of minor reactive BM reticulin fibrosis^c

Minor Criteria

Presence of at least one of the following, confirmed in two consecutive determinations:

- a. Anemia not attributed to a comorbid condition
- b. Leukocytosis $\geq 11 \times 10^9/L$
- c. Palpable splenomegaly
- d. LDH increased to above upper normal limit of institutional reference range

Diagnosis of prePMF requires meeting all three major criteria, and at least one minor criterion

- ^aSee Table 69.8.
- ^bIn the absence of any of the three major clonal mutations, the search for the most frequent accompanying mutations (e.g., *ASXL1*, *EZH2*, *TET2*, *IDH1/IDH2*, *SRSF2*, *SF3B1*) are of help in determining the clonal nature of the disease.
- ^cMinor (grade 1) reticulin fibrosis secondary to infection, autoimmune disorder or other chronic inflammatory conditions, hairy cell leukemia or other lymphoid neoplasm, metastatic malignancy, or toxic (chronic) myelopathies.

WHO Criteria for Overt PMF**WHO Overt PMF Criteria****Major Criteria**

1. Presence of megakaryocytic proliferation and atypia, accompanied by either reticulin and/or collagen fibrosis grades 2 or 3^a
2. Not meeting WHO criteria for ET, PV, *BCR-ABL1*⁺ CML, myelodysplastic syndromes, or other myeloid neoplasms
3. Presence of *JAK2*, *CALR*, or *MPL* mutation or in the absence of these mutations, presence of another clonal marker,^b or absence of reactive myelofibrosis^c

Minor Criteria

Presence of at least one of the following, confirmed in two consecutive determinations:

- a. Anemia not attributed to a comorbid condition
- b. Leukocytosis $\geq 11 \times 10^9/L$
- c. Palpable splenomegaly
- d. LDH increased to above upper normal limit of institutional reference range
- e. Leukoerythroblastosis

Diagnosis of overt PMF requires meeting all three major criteria, and at least one minor criterion

- ^aSee Table 69.8.
- ^bIn the absence of any of the three major clonal mutations, the search for the most frequent accompanying mutations (e.g., *ASXL1*, *EZH2*, *TET2*, *IDH1/IDH2*, *SRSF2*, *SF3B1*) are of help in determining the clonal nature of the disease.
- BM fibrosis secondary to infection, autoimmune disorder, or other chronic inflammatory conditions, hairy cell leukemia or other lymphoid neoplasm, metastatic malignancy, or toxic (chronic) myelopathies.

British Committee for Standards in Hematology Criteria for Diagnosis of Essential Thrombocythemia

Requires A1–A3 or A1 + A3–A5

- A1: Sustained platelet count $>450 \times 10^9/L$
- A2: Presence of an acquired pathogenic mutation (e.g., in *JAK2* or *MPL*)
- A3: No other myeloid malignancy, especially PV, PMF, CML, or MDS
- A4: No reactive cause for thrombocytosis and normal iron stores
- A5: BM aspirate and trephine biopsy showing increased megakaryocyte numbers displaying a spectrum of morphology with predominant large megakaryocytes with hyperlobated nuclei and abundant cytoplasm

BM, Bone marrow; CML, chronic myeloid leukemia; JAK2, Janus kinase 2; MDS, myelodysplastic syndrome; MPL, thrombopoietin receptor; PMF, primary myelofibrosis; PV, polycythemia vera.

From Harrison et al: *Br. J Haematol* 149:352, 2010.

of these two complications in patients with ET. This relatively high frequency of extreme thrombocytosis in an acute-care hospital emphasizes the need for caution in making a diagnosis of ET (Table 69.5). A number of groups have shown that reactive thrombocytosis may be a consequence of the elaboration of known cytokines in response to the underlying inflammatory or neoplastic disorder, and are accompanied by an elevated erythrocyte sedimentation rate or a high C-reactive protein (CRP). Elevated levels of IL-1, IL-6, GM-CSF, G-CSF, and thrombopoietin have been detected in such patient populations and frequently in individuals with thrombocytosis caused by an underlying MPN. Elevation of thrombopoietin levels has not only been found in patients with reactive thrombocytosis but also in patients with ET. IL-6–induced thrombocytosis is mediated

in part by secondary thrombopoietin production by the liver in inflammatory disorders and malignant diseases. CRP is an acute-phase reactant, the hepatic synthesis of which is mediated by IL-6. CRP levels are high in patients with high levels of IL-6. In one series, whereas 81% of patients with reactive thrombocytosis had elevated IL-6 or CRP levels, patients with uncomplicated thrombocytosis secondary to an MPN had undetectable IL-6 levels. Low levels of both IL-6 and CRP are strongly indicative of the thrombocytosis being the consequence of an underlying MPN.

Both familial forms of thrombocytosis and thrombocytosis that accompanies hematologic malignancies are examples of primary thrombocytoses. The MPNs are characterized by clonal hematopoiesis, but in the familial forms of thrombocytosis, hematopoiesis

TABLE 69.4 Conditions Associated With Thrombocytosis

Primary Thrombocytosis		
Malignancies		
	Essential thrombocythemia	
	Polycythemia vera	
	Primary myelofibrosis	
	Chronic myeloid leukemia	
	Refractory anemia with ringed sideroblasts and thrombocytosis	
	Chronic myelomonocytic leukemia	
	MDS/MPN overlap	
Familial thrombocythemia (inherited mutations in thrombopoietin or thrombopoietin receptor)		
Secondary (Reactive) Thrombocytosis		
Blood loss or iron deficiency		
Infection		
Inflammation		
Disseminated malignancy		
Hemolysis		
Drug therapy		
Hyposplenism		
Cytokine administration		
Spurious Thrombocytosis		
Schistocytes		
Cytoplasmic fragmentation of neoplastic cells		
Cryoglobulinemia		
Bacteria		
MDS, Myelodysplastic syndrome; MPN, myeloproliferative neoplasm.

BM, Bone marrow; ET, essential thrombocythemia; RT, reactive thrombocytosis. Modified from Tefferi A, Hoagland HC: Issues in the diagnosis and management of primary thrombocythemia. *Mayo Clin Proc* 69:651, 1994.

is polyclonal. An abnormality of thrombopoietin production or of the thrombopoietin receptor has been documented to be the basis of these inherited disorders leading to thrombocytosis. Because the median age of diagnosis of patients with these familial forms of thrombocytosis is 17 years, these disorders should be carefully considered in all *JAK2V617F*-, *MPLW515L*-, and *MPL515K*-negative children with multiple family members with thrombocytosis.

Several different mutations have been reported in families in which excessive thrombocytosis has been attributed to increased thrombopoietin production.⁸ A Dutch family with 11 family members and a Japanese family with eight family members were reported with a hereditary form of thrombocytosis that was inherited as an

autosomal dominant. The thrombopoietin receptor in the Dutch family was normal, yet there was a G-to-C transversion in the splice donor site of intron 3 of the thrombopoietin gene. All of the affected members of the Dutch family were shown to have elevated thrombopoietin levels. In this family, a point mutation in the thrombopoietin gene was believed to lead to systemic overproduction of thrombopoietin, leading to a familial form of thrombocytosis. This was the first example of a human disease caused by increased efficiency of mRNA production. Actually, the translation of full-length thrombopoietin is almost completely inhibited by the presence in the 5' untranslated region of seven AUG codons, which create seven upstream open reading frames (uORFs). These uORFs are potent inhibitors of translation, and mutations in this area cause thrombocytosis by eliminating the normal physiological inhibition of thrombopoietin mRNA translation. Additional families with thrombocytosis caused by a similar genetic mechanism have been identified.

Hereditary mutations of *MPL* can either result in loss of function and thrombocytopenia, or in gain of function and thrombocythemia, and are important models to analyze the mechanism of c-Mpl activity. Familial thrombocytosis has been attributed to germ-line mutations of *MPL* (*MPL-S505N*, *MPL-K39N*, and *MPL-P106L*). *MPL-S505N* was first described in a Japanese pedigree of familial thrombocytosis that is inherited in an autosomal dominant fashion. This disorder has been attributed to a dominant-positive activating mutation of the cellular receptor of *MPL*. Eight additional Italian families with thrombocytosis and *MPL-S505N* have been identified. In these individuals hematopoiesis is polyclonal. Etheridge and coworkers recently described a novel, autosomal dominant germ-line mutation that causes familial ET resulting from a single-nucleotide substitution, generating the mutant kinase *JAK2R564Q*. Their data indicate that this mutation leads to isolated thrombocytosis. Mild thrombocytosis was observed as well as polyclonal hematopoiesis. Furthermore, increased activation of *JAK2* was confirmed in the platelets of *JAK2R564Q*-positive family members compared with those without the mutation.

A polymorphism of the thrombopoietin receptor (*MPL* Baltimore, *MPL-K39N*) that is accompanied by thrombocytosis has also been described. This germ-line polymorphism is caused by a single-nucleotide substitution that results in a lysine-to-asparagine (K39N) substitution in the ligand-binding domain of *MPL*. The polymorphism occurs exclusively in African-Americans and appears to have an autosomal dominant pattern of inheritance with incomplete penetrance because some heterozygotes have normal platelet counts while others have thrombocytosis. Approximately 7% of African-Americans are heterozygous for *MPLK39N*. The mutation in the homozygous state is associated with extreme thrombocytosis with a reduced expression of platelet *MPL*, which has been proposed to affect the receptor's ability to bind thrombopoietin, resulting in its reduced clearance and increased stimulation of megakaryocytopoiesis. *MPL-P106L* is another germ-line mutation associated with thrombocytosis that has been found in 3.3% of Arabs. It leads to severe thrombocytosis in homozygotes and occasionally to mild thrombocytosis in heterozygotes. In the families described with this germ-line mutation, extreme thrombocytosis was associated with homozygosity and the mode of inheritance is regarded as being autosomal recessive with possible mild manifestations occurring in heterozygotes.

Subjects with familial forms of thrombocytosis are characteristically diagnosed at earlier ages than patients with ET, and appear to have similar risks for thrombotic and hemorrhagic complications. These disorders were initially considered to be associated with a benign clinical course, but follow-up of such families for longer periods of time has corrected this misperception. Overall, 23 members of a Dutch and a Polish family with a form of thrombocytosis attributed to excessive thrombopoietin production were shown to have similar thrombotic and hemorrhagic complications as individuals with ET. Also, these family members experienced vasomotor symptoms, including erythromelalgia and Raynaud phenomena, which responded to aspirin therapy but not hydroxyurea therapy. Furthermore, many of these patients developed splenomegaly as well as BM histopathologic findings that resemble an MPN, including BM hypercellularity,

clustering of megakaryocytes, and a mild increase in BM fibrosis. Surprisingly, more prolonged follow-up of members of the Dutch family due to overproduction of thrombopoietin have revealed progression to symptomatic MF in one individual and progression to acute leukemia in a second family member. The patient with acute leukemia had not received any chemotherapeutic agents, and evaluation of the strength of the relationship between this high thrombopoietin condition and the development of acute leukemia requires further investigation of these families. Similarly, patients with an activating mutation of *MPL*, *MPL-S505N*, also have a high incidence of major thrombotic events, including stroke, myocardial infarction, and Budd-Chiari syndrome. In adult patients, overt BM reticulin and collagen fibrosis associated with mild reductions in hemoglobin levels have been observed, but differences in platelet counts, incidence in thrombotic episodes, or splenomegaly have not been observed when one compares these individuals with ET patients. In women with *MPL-S505N*, hematopoiesis was polyclonal, and the mutation was observed not only in hematopoietic tissues but also other somatic tissues. Family members who are affected by this mutation appear to have a significantly shorter survival time than nonaffected family members who did not have thrombocytosis, with affected individuals dying most frequently of thrombotic events or complications of MF. By contrast, individuals with either *MPL-K39N* or *MPL-P106L*, which both involve the extracellular domain of *MPL*, affecting its ability to bind thrombopoietin, were not observed to have an increased risk for thrombosis, splenomegaly, or BM fibrosis.

Table 69.3 outlines the 2016 WHO criteria for the diagnosis of ET that incorporates *JAK2V617F*, *CALR* and *MPL* mutational analyses. RBC mass and plasma volume studies, if available, are sometimes helpful in differentiating between *JAK2V617F*-positive ET with borderline elevated hematocrits from patients with PV, but such patients likely represent a continuum of evolution of a *JAK2V617F*-positive hematologic malignancy. BM karyotypic analysis or studies of the *BCR-ABL* fusion gene are imperative in every patient to exclude the diagnosis of CML or to detect another clonal hematologic malignancy. This step is necessary because the natural history of these disorders is very different, and early therapeutic intervention with specific medical therapy for CML, such as a BCR-ABL tyrosine kinase inhibitor is essential.

Occasionally, ET may be distinguished from RARS-T. These patients present with thrombocytosis that is associated with a moderate-to-severe anemia and frequently splenomegaly. Their BMs are characterized by the morphologic features of ET and the presence of more than 15% ringed sideroblasts. This entity likely represents a heterogeneous, poorly defined disorder that includes a spectrum of conditions sharing features of an MPN and a myelodysplastic disorder. This entity is associated with *JAK2V617F* in 58% of reported patients, *MPLW515* mutation in 7% of reported patients, and *CALR* mutation in <5% of patients. Occasional patients with thrombocytosis and increased ringed sideroblasts but without anemia have also been described. Patients with RARS-T have a similar prognosis as ET patients. RARS-T has been recently shown to be associated with somatic mutations of *SF3B1*, a gene encoding a core component of the RNA splicing machinery. RARS-T therefore likely results from a combination of *SF3B1* and *JAK2* or *MPL* mutations. About 25% of patients with RARS-T have wild-type *SF3B1*, suggesting that other molecular defects can be associated with RARS-T.

Because patients with preMF frequently present with thrombocytosis, this form of PMF can frequently be difficult to distinguish from ET. This early form of PMF was previously referred to as a *prefibrotic form of PMF*. In prePMF, nucleated RBCs, teardrop-shaped RBCs, immature myeloid cells, and megathrombocytes are observed in the peripheral blood. In the BM biopsy, the megakaryocytes are markedly abnormal, a morphologic finding that is helpful in distinguishing this entity from ET. In prePMF, the megakaryocytes often appear in clusters adjacent to the sinusoids; deviations in the nuclear cytoplasmic ratio in the megakaryocytes are observed with abnormal patterns of chromatin clumping, and plump clouds similar to a balloon-shaped lobulation of the nuclei are observed associated with minimal fibrosis or even absent reticulin fibrosis during this stage of PMF.

The presence of clonal hematopoiesis, at least in one lineage, quickly establishes the diagnosis of ET. Unfortunately, techniques to study clonality are currently not widely available and are restricted to the evaluation of female patients. Such studies may be particularly useful in young female patients with thrombocytosis. Probes for a variety of genes on the X chromosome can be informative for clonal analysis of blood cell production in more than 72% of female Americans. In such patients, analysis of restriction fragment length polymorphisms can be used to establish a pattern of clonal hematopoiesis, which is indicative of a hematologic malignancy and established the diagnosis of ET in a young female patient with thrombocytosis who was lacking a driver mutation. Polyclonal hematopoiesis is found in all cases of reactive and familial thrombocytosis. Polyclonal hematopoiesis, however, does not exclude the diagnosis of ET because in several series almost one-third of patients who met the clinical criteria for ET had polyclonal hematopoiesis in all studied lineages. The biogenesis of this polyclonal form of ET is poorly understood. Initial studies, however, have suggested that women with polyclonal hematopoiesis may have fewer thrombotic complications than those with clonal hematopoiesis.

At times, it is impossible to define the cause of an individual patient's thrombocytosis. In an asymptomatic patient, follow-up to determine whether the degree of thrombocytosis increases is warranted. If additional clues to the cause of the thrombocytosis are subsequently revealed, a diagnosis will become apparent. Some reassurance is provided by reports of larger cohorts of patients, each with platelet counts of greater than $1000 \times 10^9/L$, which have been followed for years. Virtually none of the patients with reactive thrombocytosis developed a cerebrovascular accident, thrombophlebitis, or a peripheral arterial thrombosis.

PROGNOSIS

The probability that a patient with ET will survive 10 years ranges from 64% to 80%. In a large study from Spain with extensive follow-up, there was no substantial difference between the probability of survival of patients with ET and that of a control population. However, a study of 322 consecutive patients seen at the Mayo Clinic and followed for a median follow-up of 13.6 years showed a different pattern. Survival of patients with ET was similar to that of the control population during the first decade of disease, but the survival became significantly worse thereafter. Multivariable analysis identified an age at diagnosis of 60 years or older, leukocytosis ($>15,000/\mu l$), previous venous thrombosis, tobacco use, and diabetes mellitus as independent predictors of poor survival. The risk of developing leukemia or MF was low in the first 10 years (1.4% and 3.8%, respectively) but increased substantially in the second (8.1% and 19.9%, respectively) and third (24.0% and 28.9%, respectively) decades of the disease. The presence of the *JAK2V617F* mutation did not influence either survival or the rate of leukemic transformation in this analysis. The rate of leukemic transformation was higher in patients with platelet counts above $1000 \times 10^9/L$ and abnormal hemoglobin levels. The development of MF was heralded by the appearance of immature myeloid precursors and dacryocytes in the blood smear, and increased serum lactate dehydrogenase levels followed by a reduction in platelet numbers and progressive splenomegaly. The presence of *CALR*, which occurs in 15–25% of patients with ET and is mutually exclusive with mutations in *JAK2* and *MPL*, is associated with younger age, male sex and higher platelet counts, lower hemoglobin levels, and a lower risk of thrombotic complications.

The International Prognostic Score for Essential Thrombocythemia (IPSET) was developed from the retrospective review of clinical outcome of 891 patients with ET diagnosed by WHO criteria in which age ≥ 60 years, leukocyte count $\geq 11 \times 10^9/L$, and history of thrombosis were determined to have prognostic significance for survival, with weighted values of 2, 1, and 1 points, respectively. The IPSET categories of low (no points), intermediate (1–2 points), or high (3–4 points) had corresponding median survivals of not yet reached, 24.5 years, and 13.8 years, respectively. Analysis of this

Fig. 69.5 Overall (A) and leukemia-free (B) survival of patients with true ET versus early or PMF. ET, Essential thrombocythemia; PMF, prefibrotic primary myelofibrosis. (Data from Barbui T, Thiele J, Passamonti F, et al: Survival and disease progression in essential thrombocythemia are significantly influenced by accurate morphologic diagnosis: An international study. *J Clin Oncol* 29:3179, 2011.)

cohort for thrombotic risk determined age >60 years (1 point), history of thrombosis (2 points), presence of cardiovascular risk factors (1 point; diabetes, hypertension, smoking) and the presence of mutated *JAK2* (2 points) as independent risk factors. Low-risk (0–1 points), intermediate-risk (2 points), and high-risk (3+) categories were associated with 1.03%, 2.35% and 3.56%/year risk of thrombosis, respectively.⁹

A major determinant of the prognosis of a patient with a presumptive diagnosis of ET depends on the discrimination of whether such patients actually have true ET or an early form of MF based on histopathologic and clinical criteria adopted by the WHO (see Table 69.3).¹⁴ In a group of 891 patients with a prior diagnosis of ET with BM biopsies evaluated retrospectively histopathologically, 16% were reclassified as having prePMF. Thrombosis rates and *JAK2V617F* positivity were similar in the two groups. However, patients with prePMF had higher leukocyte counts, lower hemoglobin levels, higher platelet counts, higher lactic dehydrogenase levels, greater numbers of circulating CD34⁺ cells, and a greater incidence of palpable splenomegaly than patients with true ET. Survival was reported to be significantly inferior for those patients with pre PMF compared with patients with histopathologically validated ET (Fig. 69.5). In one series with a median follow-up of approximately 7 years, the median survival of patients with ET ranged from 16 to 21 years, and the survival of the patients with the preMF ranged from 10.8 to 14.4 years, with the majority of deaths being attributed to progression to overt PMF and acute leukemia. Although the patients with ET enjoyed a more favorable outcome, the 15-year cumulative incidences of overt MF and acute leukemia were still 9.3% and 2.1%, respectively, emphasizing the seriousness of this diagnosis, especially in younger patients.

Death of ET patients predominantly results from thrombotic complications, but transformation to AML is an important cause of mortality. The phenotype of the blast cell can be myeloid, myelomonocytic, megakaryocytic, of mixed lineage, or even lymphoblastic. According to the data mentioned earlier, the risk of patients with ET transforming into acute leukemia is greater than that of normal individuals. This is a phenomenon shared with the other MPN. The risk of developing acute leukemia after treatment with hydroxyurea alone has been reported to increase only slightly (3–4%), but the sequential use of hydroxyurea with other cytotoxic agents, such as busulfan or pipobroman, significantly increases the risk of developing a secondary leukemia.

The development of acute leukemia is often associated with a deletion of the short arm of chromosome 17, which is most frequently deleted in hydroxyurea-treated patients, but a trisomy of the long arm of chromosome 1 and monosomy 7q has been observed in patients treated with pipobroman. These cytogenetic abnormalities are believed to be induced by the use of these chemotherapeutic agents.

TABLE 69.6 Risk Factors for Thrombosis in 100 Patients With Essential Thrombocythemia

Risk Factor	Incidence of Thrombosis (% Patient-Year)	Relative Risk (95% CI)	p
Age (years)

Data from Finazzi G, Barbui T: Risk-adapted therapy in essential thrombocythemia and polycythemia vera. *Blood Rev* 19:243, 2005.

The median survival after the development of myelodysplasia or leukemic transformation is 4 months. Acute leukemia, which develops after ET, is frequently refractory to standard induction chemotherapy but has been recently reported to be responsive to hypomethylating agents, including 5-azacytidine and decitabine. Because allogeneic stem cell transplantation can be curative, rapid referral to a transplant center is recommended if the patient has an appropriate performance status and an allogeneic stem cell donor is available.

Therapy

The goal in treating patients with ET is to prevent additional thrombotic and hemorrhagic events without increasing the risk of transformation to post-ET MF, MDS, or AML. Both age (>60 years of age) and history of a prior thrombosis are widely accepted predictors of a patient developing additional thrombotic events during follow-up (Table 69.6). Other predictors of cardiovascular morbidity include a history of smoking, hypertension, obesity, diabetes mellitus, and congestive heart failure, and a white blood cell count greater than 11 × 10⁹/L. Ironically, patients with platelet counts greater than 1000 × 10⁹/L have a lower risk of developing an arterial thrombosis and a higher risk of bleeding. These parameters have been widely used by clinicians to stratify ET patients according to their risk for developing additional thrombotic events. Such stratification strategies have been used to make treatment decisions to reduce the platelet count. It is important to emphasize that such risk factors have been

identified based on retrospective analyses of registries of ET patients that have largely not been created using modern molecular and histopathologic diagnostic tools. Using such patient-stratification strategies, patients have been placed into high-, intermediate-, or low-risk groups based on their predicted risk of developing an additional life-threatening thrombotic event. This strategy is uniformly implemented throughout Europe and North America. The benefit of this strategy is based on a single clinical trial that indicated that the reduction of platelet numbers to less than $600 \times 10^9/L$ with hydroxyurea therapy was associated with a reduction of developing additional thrombotic events compared with a control group (see Fig. 69.2). This study involved a total of 114 patients, and the median follow-up period was only 27 months. Greater degrees of platelet suppression have not been shown to be associated with further reduction in the possibility of developing a thrombotic episode, which in hydroxyurea-treated high-risk patients has been reported to be 1.66% patients per year. Although the implementation of such a strategy is widely accepted, it is important to be aware that this approach is not based on robust data that one associates with modern-day evidence-based medicine. In fact, in several studies, an elevated leukocyte count of above $11 \times 10^9/L$ has been more closely associated with the risk of developing additional thromboses than the degree of elevation of the platelet count. These conflicting reports in the literature among experts in this field make it increasingly more difficult to be dogmatic about who to treat with platelet-lowering agents and what the target platelet count should be. The risk stratification of patients should not be ignored, and patients with a life-threatening thrombosis or disabling symptoms because of microcirculatory problems should receive drugs that lower the platelet count. If a patient of any age has excessive thrombocytosis and a thrombotic or hemorrhagic event, that patient must be treated. However, for asymptomatic ET patients in so-called *high-risk categories*, the decision to embark upon a strategy including platelet-lowering agents is in reality a murky one that is more based on personal treatment decisions rather than volumes of data.

The treatment of asymptomatic low-risk patients with ET is controversial and remains largely problematic, yet greater insight into the management of such patients has recently been gained. Management of ET patients with life-threatening hemorrhagic or thrombotic episodes is more straightforward. Life-threatening thrombotic events require platelet pheresis in combination with the institution of myelosuppressive therapy. In this situation, immediate physical removal of large numbers of platelets is preferred because chemotherapeutic agents generally require 18–20 days before platelet counts can be reduced to normal levels. It is recommended to reduce the platelet count to $500,000/mm^3$ by each platelet pheresis and suggested that achievement of such a goal requires the passage of two blood volumes over a 3–4-hour period.

Such a therapeutic approach has been used to treat acutely ill patients with problems such as cerebrovascular accidents, myocardial infarction, transient ischemic attacks, or life-threatening gastrointestinal hemorrhage. Long-term platelet pheresis is an ineffective means of controlling thrombocytosis, presumably because of the rapid rate of production of platelets. Therefore, most clinicians begin by administering a chemotherapeutic agent that has a rapid onset of action, such as hydroxyurea at doses of 2–4 g/day, simultaneously with the institution of platelet pheresis. The dose of hydroxyurea requires close monitoring with appropriate reduction of dose to avoid excessive myelosuppression.

In patients found to have ET and who are clearly symptomatic and fall into the high-risk group, little controversy exists as to the need for lowering platelet numbers. The large number of thrombotic complications that occur in patients with ET who smoke points to the urgent need for smoking cessation. Most investigators try to normalize the platelet count or reach a platelet count at which the symptoms of the high-risk patient resolve. Although major bleeding episodes requiring hospitalizations are rare, patients with extreme thrombocytosis ($>1500 \times 10^9/L$), acquired von Willebrand syndrome, and history of hemorrhagic episode are clearly at risk for developing additional bleeding complications. These patients require reduction

of the increased platelet numbers to the normal range with use of a variety of agents, including hydroxyurea, anagrelide, or IFN- α . According to some authors, such patients should avoid exposure to aspirin even if they have hemorrhagic complications and thrombotic episodes simultaneously.

Another situation that requires treatment is discomfort caused by erythromelalgia or progression of erythromelalgia to frank gangrene. Such patients respond within days to low-dose aspirin therapy or platelet-reduction therapy.

During the 1980s and 1990s, hydroxyurea became the drug of choice for the treatment of ET. The impetus for this practice was based on the knowledge that agents such as ^{32}P and alkylating agents such as melphalan and busulfan were leukemogenic. The popularity of the ribonucleoside reductase inhibitor, hydroxyurea, for the management of ET was due to the belief in the early 1970s that it was nonleukemogenic. Hydroxyurea can be administered at a dose of 15 mg/kg initially, with adjustment of the dose to maintain a platelet count (at the least) below $600 \times 10^9/L$ without inducing significant neutropenia. After the agent is started, frequent monitoring of blood counts is mandatory to avoid the development of neutropenia until the maintenance dose is determined. The use of this drug in a high-risk group of patients with reduction of platelet numbers to less than $600 \times 10^9/L$ has resulted in reduction of thrombotic events compared with a control population. The reduction of platelet numbers to this level did not entirely eliminate the occurrence of additional thrombotic episodes.

Hydroxyurea use is associated with some toxicity, including dose-related neutropenia, fever, nausea, stomatitis, hair loss, nail discoloration, and lower extremity and oral ulcerations, as well as increased risk of developing squamous cell carcinoma of the skin. Many of these problems resolve with withdrawal of the drug or dose reduction, but leg ulcers can be persistent, sometimes requiring skin grafting. These ulcers typically heal within 1–9 months of cessation of therapy. Such leg ulcers have been reported to occur in 9% of patients treated with hydroxyurea and are an indication for immediate discontinuation of therapy and elimination of any rechallenge with the drug. Hydroxyurea is also not universally successful in controlling the thrombocytosis; resistance to hydroxyurea has been reported in 11–17% of cases. The criteria for defining resistance or intolerance to hydroxyurea have been established by an International Working Group. They include a platelet count greater than $600 \times 10^9/L$ after 3 months of at least 2 g/day of hydroxyurea (2.5 g/day in patients with a body weight >80 kg); platelet count greater than $400 \times 10^9/L$ and WBC less than $2500/mm^3$ or hemoglobin less than 10 g/dL at any dose of hydroxyurea; presence of leg ulcers or other unacceptable mucocutaneous manifestations at any dose of hydroxyurea; and hydroxyurea-related fever. In such situations, hydroxyurea can be substituted for (or combined with) other platelet-lowering agents. These criteria for hydroxyurea resistance are imperfect because they do not include the development of a thrombotic event while on therapy, which is the central goal of therapy. Whether such patients who develop a new thrombosis would benefit from use of another therapeutic agent has not been explored.

The risk of evolving to acute leukemia is extremely low in untreated ET patients. More recent prospective studies both in ET and PV have confirmed that hydroxyurea therapy is associated with a low incidence of leukemic transformation when used alone ($<5\%$) and with long-term follow-up (≤ 14 years). However, the leukemic risk increased significantly when the drug is used before or after treatment with alkylating agents, particularly busulfan. One can conclude from these studies that hydroxyurea therapy alone is less leukemogenic than alkylating agents or ^{32}P alone, but a small increased risk for the development of leukemia secondary to its use cannot be completely excluded. Of concern is the observation that a high proportion of AML and MDS occurring in ET patients treated with hydroxyurea alone have morphologic, cytogenetic, and molecular characteristics of the 17p deletion syndrome. These patients are reported to have a typical form of dysgranulopoiesis characterized by hypolobulated polymorphonuclear leukocytes with small vacuoles in neutrophils and *p53* mutations.

An alternative to hydroxyurea is therapy with anagrelide. Data on the use of anagrelide in ET suggest that it is nonleukemogenic. When considering the risk-to-benefit ratio, one can conclude that hydroxyurea therapy is a first-line therapy for ET patients at a high risk of developing an additional thrombosis, including those older than 60 years of age or with a history of a thrombotic episode or with significant other cardiovascular risk factors. Such nonleukemogenic drugs as IFN- α , anagrelide, or pegylated IFN appear to be good choices in symptomatic patients younger than 40 years of age.

Anagrelide is a member of the imidazo(2,1-b)quinazolin-2-1 series of compounds. When studied in humans, it was noted that anagrelide in small doses produced thrombocytopenia. The drug acts primarily by reducing megakaryocyte size and ploidy, and decreasing megakaryocyte proliferation. Anagrelide therefore appears to lower platelet counts, primarily by interfering with the development of megakaryocytes. Anagrelide suppresses megakaryocytopoiesis by selectively reducing the expression levels of GATA-1, FLI-1, NFE-2, and FOG-1 in cells belonging to the megakaryocytic lineage. The effects of anagrelide do not involve thrombopoietin-mediated signal transduction events. GATA-1 and FOG-1 play critical roles in megakaryocytic differentiation. Anagrelide in low doses is effective in lowering the platelet count in 93% of patients. Most importantly, it is effective despite resistance to prior therapies. Resistance to anagrelide therapy has not been documented, but occasionally patients have been observed to require extraordinarily high doses to control the excessive thrombocytosis. The recommended initial dose is 0.5 mg orally two to four times a day. The dose should be increased by 0.5 mg/week to control thrombocythemia. The dose of anagrelide should not exceed 10 mg/day or a 2-mg/dose. Excessive use will result in predictable thrombocytopenia and increase the likelihood of side effects. The median maintenance dose in patients with ET is 2 mg/day administered in divided doses. Data on more than 3000 patients with a variety of MPNs complicated by extreme thrombocytosis are available. In addition, follow-up of more than 500 patients for more than 5 years had been reported. Anagrelide has been shown to be an effective drug in the treatment of ET, resulting in a median time to response of 2.5–4 weeks. An effect on platelet numbers is usually noted in 6–10 days. Anagrelide leads to a reduction in hematocrit in 25–36% of patients, but it has no effect on white blood cell numbers, systemic symptoms, or the degree of splenomegaly. Anagrelide use in 1700 patients reduced the incidence of thrombohemorrhagic episodes related to thrombocytosis associated with MPNs from 0.66 symptoms per patient before therapy to 0.07 symptoms per patient after 28–30 months of therapy.

The most common side effects of anagrelide resulted from its vasodilatory and positive inotropic actions. These effects resulted in complaints of headache, dizziness, fluid retention, palpitations, and high-output cardiac failure. The vasodilatory effect leads to reduced renal blood flow, resulting in fluid retention. In addition, gastrointestinal complications, such as nausea, abdominal pain, and diarrhea, are prominent. These side effects usually develop within 2 weeks of initiation of therapy and frequently diminish in severity or resolve within 2 weeks of continued therapy. Because of its ability to promote fluid retention and the development of tachyarrhythmias, anagrelide therapy should be used with caution in patients with cardiac disease and should be administered carefully to elderly patients. If congestive heart failure or arrhythmias other than tachycardia develop, anagrelide therapy should be discontinued. Prolonged anagrelide therapy may be associated with a potentially irreversible drug-induced cardiomyopathy that is reminiscent of tachycardia-induced cardiomyopathy. Dose reduction can be used to lessen the degree of tachycardia or fluid retention. Before the institution of anagrelide, it is recommended that a basic cardiac evaluation be performed, including an assessment of cardiac risk factors, a careful cardiac history, and an electrocardiogram, which can be used as a baseline if the patient develops rhythm disturbances. Although most adverse effects are mild or moderate, in one series, therapy was discontinued in 16% of patients because of intolerable side effects, especially headache, nausea, fluid retention, and, rarely, frank congestive heart failure. Anagrelide has no mutagenic activity, but its use is not currently

Fig. 69.6 EVENT-FREE SURVIVAL IN A HYDROXYUREA-TREATED GROUP COMPARED WITH AN ANAGRELIDE-TREATED GROUP. Primary end points were arterial or venous thrombosis, serious hemorrhage, or death from any of these causes. (From Harrison CN, Campbell PJ, Buck G, et al: Hydroxyurea compared with anagrelide in high-risk essential thrombocythemia. *N Engl J Med* 353:33, 2005.)

advised during pregnancy. Because of its small molecular weight, it is believed to be capable of crossing the placenta and thus may lead to fetal thrombocytopenia. Anagrelide appears to be a suitable drug for the treatment of young, symptomatic patients with ET and for those who are resistant or refractory to front-line treatment with hydroxyurea.

Hydroxyurea and anagrelide have been compared in a large randomized trial of 809 “high-risk” patients with ET in combination with low-dose aspirin (75–100 mg/day).⁷ The dose of each cytoreductive agent was titrated to achieve a platelet count $<400 \times 10^9/L$ and long-term control was attained in each treatment arm. Overall, patients randomized to anagrelide (and aspirin) were more likely to reach the composite primary endpoint of major thrombosis (arterial or venous), major hemorrhage, or death from vascular causes ($p = .03$; Fig. 69.6). When individual endpoints were assessed, arterial thrombosis, major hemorrhage, and the development of MF were all significantly more frequent in patients treated with anagrelide (7% vs. 2%; $p = .004$, .008, and .01, respectively). Anagrelide and aspirin seemed to offer at least partial protection from thrombosis because the prevalence of thrombotic events (8% at 2 years) was significantly less than that observed in the control arm of a previous study (28%). Intriguingly, the number of venous thromboses was less frequent in patients treated with anagrelide ($p = .006$). In addition, patients with *JAK2V617F*-positive ET were more sensitive to therapy with hydroxyurea but not anagrelide. Recent analyses of anagrelide-treated ET patients indicate responsiveness irrespective of driver mutation status. In long-term follow-up of 67 patients with ET treated with anagrelide, therapy-related anemia was more frequent in *CALR*-mutated patients without differences in thrombotic rates among the four molecular subtypes. Also, the incidence of discontinuation of anagrelide therapy because of drug-related adverse events was significantly greater than that observed with patients receiving hydroxyurea. Based on this large randomized study, hydroxyurea is presently considered first-line therapy for patients with high-risk ET (Table 69.7). Although equivalent control of the platelet count was achieved with both agents, hydroxyurea proved superior, perhaps because of its ability to reduce not only platelet numbers but also leukocyte numbers, which have been associated with thrombosis in ET patients. In addition, the combination of anagrelide and low-dose aspirin was associated with a higher incidence of bleeding episodes, suggesting

TABLE 69.7 Choice of Drugs for Treatment of Patients With High-Risk Essential Thrombocythemia

Age (years)	Treatment of Choice	Second Line
<50	Interferon	Anagrelide Hydroxyurea
50–75	Hydroxyurea	Interferon Anagrelide
>75	Hydroxyurea	Anagrelide Busulfan

that aspirin therapy might be best avoided in patients being treated with anagrelide.

The ANAHYDRET study was a prospective, randomized, non-inferiority study comparing hydroxyurea to anagrelide treatment in 259 patients with treatment-naïve, high-risk ET (WHO diagnosis confirmed).⁶ Anagrelide was determined to be noninferior to hydroxyurea based on equivalent rates of thrombotic (arterial and venous) and hemorrhagic (major and minor) complications. A criticism of this study was the low rate of aspirin use in this study of approximately 28% in both arms and the lack of data indicating relative rates of transformation to MF.

IFN- α has been used to treat the MPN associated thrombocytosis since the 1990s. IFN- α acts by directly inhibiting megakaryocyte colony formation and secondarily by inhibiting the expression of thrombopoietic-stimulating cytokines, such as GM-CSF, G-CSF, IL-3, and IL-11 and by stimulating the production of negative regulators of megakaryocytopoiesis, such as IL-1ra (receptor agonist) and macrophage inflammatory protein 1 (MIP-1a). IFN- α inhibits thrombopoiesis by suppressing thrombopoietin-induced phosphorylation of the *JAK2* substrates, MPL and STAT5. Furthermore, IFN- α also induces the production of suppressor of cytokine signalling-1, which inhibits thrombopoietin-mediated cell proliferation. In a total of 212 patients treated with IFN- α in a total of 11 different clinical trials, a response rate of approximately 90% was reported. Therapy was administered to outpatients, most frequently at an initial dose of 3 million units daily, and usually produced a rapid decrease in platelets within 2 months. The mean time to complete response with a daily dose of 3 million units daily was about 3 months. IFN- α was effective in patients who had received other chemotherapeutic agents and in patients resistant to conventional cytotoxic drugs. In the majority of patients, the IFN dose required to maintain a normal platelet count during maintenance therapy was lower than the induction dose. In one study, 61% of patients required 3 million units three times a week, 15% once a week, and 24% daily. In addition, sustained remissions that persisted for 3–36 months were achieved with IFN- α therapy in 9–16% of patients. IFN- α is reported to be nonmutagenic and does not cross the placenta, making it a useful drug for the treatment of the symptomatic pregnant patient with ET. Reduction in platelet numbers with IFN results in a marked improvement in clinical symptoms. Toxicity, especially in older patients, the need for parenteral administration, and cost limit the usefulness of IFN- α . Side effects include flu-like symptoms during induction therapy, such as fever, bone and muscle pain, fatigue, lethargy, and depression. Symptoms are frequently controlled with acetaminophen. Long-term administration of IFN- α can result in mild weight loss; alopecia; retinal abnormalities; rarely, a reversible form of sarcoidosis and a reversible form of left-sided heart failure; and the development of autoimmune conditions, including thyroiditis leading to hypothyroidism and autoimmune hemolytic anemia. Patients may develop neutralizing antibodies to recombinant IFN, leading to a concomitant rise in platelet numbers. Approximately 25% of IFN therapy-treated ET patients discontinued therapy due to poor compliance or limiting side effects.

A semisynthetic protein polymer conjugate of IFN- α 2b, pegylated IFN (peg-IFN α -2b), was anticipated to be superior to unmodified IFN as related to its adverse event profile and efficacy when used to

treat ET patients. This formulation of IFN provides prolonged activity that permits once-weekly dosing. Normalization of blood counts occurred after a median time of 2–3 months; 12% of patients discontinued therapy because of inability to tolerate the drug, and 17% did not achieve normalization of their platelet counts. The majority of side effects were WHO grade 1 or 2, although some encountered grade 3 toxicity, primarily fatigue and flu-like symptoms. More importantly, no thromboembolic or hemorrhagic complications occurred during the period of treatment, although 12 thrombotic events occurred in 42 patients (24%) in the 24 months before the institution of therapy. This form of IFN, however, appears to lead to a similar frequency and severity of side effects during long-term use as experienced with conventional IFN. Interestingly, the use of another pegylated form of IFN (peg-IFN α -2a) in patients with PV was able to decrease the percentage of mutated *JAK2* allele in 24 out of 27 treated patients from a mean of 49% to a mean of 27%.¹⁰ The use of this form of IFN appeared to be associated with fewer side effects than standard forms of IFN or peg-IFN α -2b. This form of pegylated IFN has been used to treat approximately 40 patients with ET, with more than 75% of patients achieving a complete hematologic remission. Almost 40% of patients with *JAK2V617F*-positive ET had a reduction in their *JAK2V617F* allele burden, with occasional patients no longer having detectable *JAK2V617F*, leading to their being classified as having achieved a complete molecular remission. Although hematologic remissions were frequently achieved after 3 months of therapy, the effects on *JAK2V617F* were observed after 6 months of treatment. Most patients were successfully treated with 45–90 μ g/weekly, and 22% of patients ceased therapy because of toxicity. Surprisingly, the hematologic and molecular responses persist for a number of months after discontinuation of therapy, suggesting that intermittent therapy may be an acceptable means of chronically administering this drug. More recently, molecular responses in a cohort of 31 CALR+ ET patients treated with peg-IFN α -2b were reported with a baseline allelic frequency of 41% reduced to 26% and two complete responses. Patients with additional subclonal mutations (*TET2*, *ASXL1*, *IDH2*, and *TP53*) were less likely to achieve molecular responses. This is consistent with the finding that patients harboring concurrent mutated *JAK2* and *TET2* can still have evidence of persistent *TET2*, despite complete response of *JAK2V617F* after peg-IFN α -2b therapy.

No data indicating whether IFN therapy delays or prevents the evolution to MF are available. To gain a more comprehensive assessment of the clinical usefulness of IFN- α , a prospective clinical trial comparing IFN- α with hydroxyurea in patients with ET is underway at numerous sites in North America and Europe. Until the results of this trial are available, IFN- α or anagrelide should be considered as reasonable alternatives to hydroxyurea in a patient younger than 40 years of age who has had a previous thrombotic episode (see Table 69.7), but which drug is the standard of care in so-called *high-risk patients* will require data emanating from the randomized trial. A number of small-molecule inhibitors of *JAK2* have been evaluated for the treatment of ET patients. These agents reproducibly lower platelet counts, but the definition of the appropriate role of such agents in the treatment of ET patients will require their careful evaluation in well-controlled clinical trials.

The use of platelet antiaggregating agents remains an important area of investigation. Patients with ET have an increased predisposition to hemorrhage, which is likely potentiated by the use of drugs that affect platelet function. Transient ischemic attacks and erythromelalgia associated with ET respond rapidly to aspirin alone. In erythromelalgia, symptoms disappear for 2–4 days after administration of a single dose of aspirin. Although these agents surely have a role in the treatment of these specific complications, their use should be pursued with extreme caution because of the increased risk of hemorrhage. Low-dose aspirin therapy has been uniformly recommended for virtually all patients with ET independent of their risk of developing a thrombotic event. These recommendations are somewhat surprising because they are based on two clinical trials of the effects of low-dose aspirin therapy in PV patients, and such a trial with aspirin has never been performed with a population of ET

TABLE 69.8 Outcome in Patients With Low-Risk Essential Thrombocythemia Followed With Careful Observation or Treated With Antiplatelet Therapy

	Observation (848 Person-Years)		Antiplatelet Therapy (802 Person-Years)		<i>p</i>
	Events (<i>n</i>)	Incidence Rate (95% CI)	Events (<i>n</i>)	Incidence Rate (95% CI)	
Thrombosis (arterial and venous)	15	17.7 (10.7–29.3)	17	21.2 (13.2–34.1)	.6
Arterial thrombosis	8	9.4 (4.7–18.9)	13	16.2 (9.4–27.9)	.2
Venous thrombosis	7	8.2 (3.9–17.3)	4	4.9 (1.9–13.3)	.4
Bleeding	5	6.0 (2.5–14.5)	10	12.6 (6.8–23.4)	.09

From Alvarez-Larrán A, Cervantes F, Pereira A, et al: Observation versus antiplatelet therapy as primary prophylaxis for thrombosis in low-risk essential thrombocythemia. *Blood* 116:1205, 2010.

patients. An independent analysis of the data from these two trials by the Cochrane Collaboration indicated that the use of low-dose aspirin therapy was associated with a statistically nonsignificant reduction in the risk of fatal thrombotic events and was not associated with an increased risk of bleeding episodes. Furthermore, after a retrospective study of 198 patients with low-risk ET, Alvarez-Larrán et al concluded that antiplatelet therapy did not reduce the incidence of thrombotic events and might increase the bleeding risk if platelet counts are greater than $1000 \times 10^9/L$ or aspirin is used in patients with a bleeding history (Table 69.8). Most recently, a retrospective study of 433 patients (*CALR*=271, *JAK2V617F*=162) with low-risk ET receiving aspirin demonstrated no significant reduction in thrombotic complications, but rather an increase in hemorrhagic complications in the *CALR*-mutated cohort (12.9 vs. 1.8×1000 patient-years, *p* = .03). Interestingly, the presence of *JAK2V617F* and cardiovascular risk factors were associated with higher risk of thrombosis, which was reduced with administration of aspirin, and time to cytoreductive therapy was shorter in the *CALR*-mutated cohort compared with the *JAK2V617F* cohort of ET patients.

Aspirin should be used with caution in patients with peptic ulcer disease. Such patients who require aspirin benefit from the concurrent use of a proton pump inhibitor such as omeprazole rather than switching them to clopidogrel. This more critical evaluation of the evidence supporting the indiscriminate use of aspirin therapy in ET patients requires serious reconsideration of this practice. In patients who absolutely require aspirin therapy, one should avoid the simultaneous administration of aspirin with a nonsteroidal antiinflammatory drug (NSAID) such as ibuprofen or naproxen, because such NSAIDs are known to compete with aspirin for a common binding site on COX-1 that prevents aspirin from gaining access to and acetylating its target serine. Low-dose aspirin therapy must be restricted to patients with platelet counts of less than $1500 \times 10^9/L$ and not be used in patients receiving anagrelide therapy unless they have experienced an arterial thrombotic event. The diagnosis of acquired von Willebrand syndrome should be excluded before aspirin use and considered a contraindication to the use of aspirin. Whether all patients with low-risk ET should be uniformly treated with aspirin remains speculative because prospective randomized clinical trials including appropriate numbers of patients so as to assure the resolution of this dilemma have not been completed to date.

A continuing clinical controversy revolves around the question of whether any treatment is indicated in patients with ET in whom the platelet count elevation is initially detected fortuitously and who remain largely asymptomatic. In a retrospective study of 99 consecutive low-risk ET patients (age <60 years) who presented with extreme thrombocytosis (platelet count $>1000 \times 10^9/L$) but without a previous history of thrombohemorrhagic complications, the incidence of major thrombosis and hemorrhagic events was shown to be similar during follow-up to those who were treated with prophylactic cytoreductive therapy and those who did not receive such therapy. If the clinician feels compelled to use some therapeutic intervention in young, asymptomatic patients, low-dose aspirin (81 mg/day) appears to be effective in the treatment of microvascular complications, and its use is associated with limited toxicity. Still, it seems reasonable to withhold therapy in younger, asymptomatic patients until the

development of a clinically significant thrombotic or hemorrhagic event. Patients older than 60 years of age with other significant risk factors for cardiovascular complications are probably best served by immediate institution of therapy.
